A vibrant, abstract painting serves as the background for the book cover. It features a variety of colors including orange, yellow, blue, purple, and red, applied in thick, textured brushstrokes. The composition is dynamic, with overlapping and contrasting colors creating a sense of depth and movement.

*This page intentionally left blank*

The *Oxford Library of Psychology*, a landmark series of handbooks, is published by Oxford University Press, one of the world's oldest and most highly respected publishers, with a tradition of publishing significant books in psychology. The ambitious goal of the *Oxford Library of Psychology* is nothing less than to span a vibrant, wide-ranging field and, in so doing, to fill a clear market need.

Encompassing a comprehensive set of handbooks, organized hierarchically, the *Library* incorporates volumes at different levels, each designed to meet a distinct need. At one level is a set of handbooks designed broadly to survey the major sub-fields of psychology; at another are numerous handbooks that cover important current focal research and scholarly areas of psychology in depth and detail. Planned as a reflection of the dynamism of psychology, the *Library* will grow and expand as psychology itself develops, thereby highlighting significant new research that will have an impact on the field. Adding to its accessibility and ease of use, the *Library* will be published in print and, later on, electronically.

The *Library* surveys psychology's principal subfields with a set of handbooks that capture the current status and future prospects of those major sub-disciplines. This initial set includes handbooks of social and personality psychology, clinical psychology, counseling psychology, school psychology, educational psychology, industrial and organizational psychology, cognitive psychology, cognitive neuroscience, methods and measurements, history, neuropsychology, personality assessment, developmental psychology, and more. Each handbook undertakes to review one of psychology's major sub-disciplines with breadth, comprehensiveness, and exemplary scholarship. In addition to these broadly-conceived volumes, the *Library* also includes a large number of handbooks designed to explore in depth more-specialized areas of scholarship and research, such as stress, health, and coping; anxiety and related disorders; cognitive development; or child and adolescent assessment. In contrast to the broad coverage of the subfield handbooks, each of these latter volumes focuses on an especially productive, more highly focused line of scholarship and research. Whether at the broadest or most specific level, however, all of the *Library* handbooks offer synthetic coverage that reviews and evaluates the relevant past and present research and anticipates research in the future. Each handbook in the *Library* includes introductory and concluding chapters written by its editor to provide a roadmap to the handbook's table of contents and to offer informed anticipations of significant future developments in that field.

An undertaking of this scope calls for handbook editors and chapter authors who are established scholars in the areas about which they write. Many of the nation's and world's most productive and best-respected psychologists have agreed to edit *Library* handbooks or write authoritative chapters in their areas of expertise.

For whom has the *Oxford Library of Psychology* been written? Because of its breadth, depth, and accessibility, the *Library* serves a diverse audience, including graduate students in psychology and their faculty mentors, scholars, researchers, and practitioners in psychology and related fields. Each will find in the *Library* the information they seek on the subfield or focal area of psychology in which they work or are interested.

Befitting its commitment to accessibility, each handbook includes a comprehensive index, as well as extensive references to help guide research. And because the *Library* was designed from its inception as an online as well as a print resource, its structure and contents will be readily and rationally searchable online. Furthermore, once the *Library* is released online, the handbooks will be regularly and thoroughly updated.

In summary, the *Oxford Library of Psychology* will grow organically to provide a thoroughly informed perspective on the field of psychology, one that reflects both psychology's dynamism and its increasing interdisciplinarity. Once it is published electronically, the *Library* is also destined to become a uniquely valuable interactive tool, with extended search and browsing capabilities. As you begin to consult this handbook, we sincerely hope you will share our enthusiasm for the more than 500-year tradition of Oxford University Press for excellence, innovation, and quality, as exemplified by the *Oxford Library of Psychology*.

## ABOUT THE EDITORS

### **Donald H. Saklofske**

Don Saklofske is a Professor, Department of Psychology, University of Western Ontario. He is editor of the Journal of Psychoeducational Assessment and Canadian Journal of School Psychology, Associate Editor of Personality and Individual Differences, and editor of the Springer Series on Human Exceptionality. Don is the current president of the International Society for the Study of Individual Differences.

### **Cecil R. Reynolds**

A Distinguished Research Scholar at Texas A & M University, Dr. Reynolds is a Professor of Educational Psychology and a Professor of Neuroscience. He is well known for his work in psychological testing and assessment, and is the author or editor of more than 30 books, including The Handbook of School Psychology, the Encyclopedia of Special Education, and the Handbook of Psychological and Educational Assessment of Children. He also authored the widely used Test of Memory and Learning (TOMAL) and the Revised Children's Manifest Anxiety Scale. He has published a total of more than 300 scholarly works

### **Vicki L. Schwean**

Vicki is currently Professor and Dean of Education, University of Western Ontario.

*Rune J. Simeonsson and Andrea Lee*
11. Responsible Use of Psychological Tests: Ethical and Professional Practice Concerns 222  
*Jonathan W. Gould, David A. Martindale, and James R. Flens*

## **Part Two • Models of Assessment**

12. Cognitive Assessment: Progress in Psychometric Theories of Intelligence, the Structure of Cognitive Ability Tests, and Interpretive Approaches to Cognitive Test Performance 239  
*Dawn P. Flanagan, Vincent C. Alfonso, Samuel O. Ortiz, and Agnieszka M. Dynda*
13. Principles of Assessment of Aptitude and Achievement 286  
*W. Joel Schneider*
14. Principles of Neuropsychological Assessment in Children and Adolescents 331  
*Cynthia A. Riccio and Cecil R. Reynolds*
15. Models for the Personality Assessment of Children and Adolescents 348  
*Donald H. Saklofske, Diana K. Joyce, Michael L. Sulkowski, and Emma A. Climie*
16. Principles of Behavioral Assessment 366  
*Tanya L. Eckert and Benjamin J. Lovett*
17. Therapeutic Assessment with Adolescents and Their Parents: A Comprehensive Model 385  
*Deborah J. Tharinger, Lauren B. Gentry, and Stephen E. Finn*

## **Part Three • The Practice of Psychological Assessment**

18. History Taking, Clinical Interviewing, and the Mental Status Examination in Child Assessment 423  
*Mauricio A. Garcia-Barrera and William R. Moore*
19. Psychological Testing by Models of Cognitive Ability 445  
*A. Lynne Beal, John O. Willis, and Ron Dumont*
20. Methods of Neuropsychological Assessment 474  
*Susan Homack*
21. Memory Assessment 494  
*Wayne Adams*
22. Formal Methods in Assessing Child and Adolescent Personality and Affect 526  
*Patricia A. Lowe, Erik L. Fister, Susan M. Unruh, Jennifer M. Raad, Justin P. Allen, Tiffany L. Arrington, Skylar A. Bellinger, Liesl J. Edwards, Belinda N. Kathurima, Jeaveen M. Neaderhiser, Christopher R. Niileksela, Jessica Oeth Schuttler, Matthew J. Grumbein, and Stephen W. Loke*
23. Methods of Assessing Academic Achievement 562  
*Michelle A. Drefs, Tanya Beran, and Meghann Fior*
24. Methods of Assessing Learning and Study Strategies 586  
*Kathy C. Stroud*
25. Models and Methods of Assessing Creativity 614  
*James C. Kaufman, Christina M. Russell, and Jonathan A. Plucker*
26. Methods of Assessing Behavior: Observations and Rating Scales 623  
*Erin Dowdy, Jennifer Twyford, and Jill D. Sharkey*

27. Models and Methods of Assessing Adaptive Behavior 651  
*Jason Hangauer, Jonathan Worcester, and Kathleen Hague Armstrong*

**Part Four • Special and Emergent Topics in Child and Adolescent Assessment**

28. The Authentic Alternative for Assessment in Early Childhood Intervention 671  
*Marisa Macy and Stephen J. Bagnato*
29. Assessing Mild Intellectual Disability: Issues and Best Practices 683  
*Daniel J. Reschly*
30. Toward a Synthesis of Cognitive-Psychological, Medical/Neurobiological, and Educational Models for the Diagnosis and Management of Dyslexia 698  
*Nancy Mather, Bennett A. Shaywitz, and Sally E. Shaywitz*
31. Testing Accommodations for Children with Disabilities 722  
*Brian C. McKeitt, Stephen N. Elliott, and Ryan J. Kettler*
32. Special Issues in Forensic Assessment of Children and Adolescents 735  
*Kathryn Kuehnle, Steven N. Sparta, H. D. Kirkpatrick, and Monica Epstein*
33. Assessing Non-Cognitive Constructs in Education: A Review of Traditional and Innovative Approaches 750  
*Anastasiya A. Lipnevich, Carolyn MacCann, and Richard D. Roberts*
34. Assessment of Subjective Well-Being in Children and Adolescents 773  
*E. Scott Huebner and Kimberly J. Hills*
35. Assessment of Parenting Behaviors and Style, Parenting Relationships, and Other Parent Variables in Child Assessment 788  
*Laura G. McKee, Deborah J. Jones, Rex Forehand, and Jessica Cuellar*
36. Linking Children and Adolescent Assessment to Effective Instruction: An Evidence-based Perspective from the Experimental Literature 822  
*H. Lee Swanson*

## PREFACE

Psychological assessment has paralleled the growth of psychology and its specialties since the appearance of the famous Galton tests, the founding of psychology beginning with establishment of Wundt's laboratory, and the successful application of Binet's ability tests. Whether measuring a specific sensory process (e.g., auditory discrimination), broader psychological constructs such as personality (e.g., Big 5), or an observable behavior (e.g., frequency of motor tics) or a latent trait such as intelligence, psychologists have always espoused the importance of measuring the constructs and variables that are the domain of psychological science and using the resulting information as part of the data that can facilitate and enhance decision making in psychological practice. It is not overstating to say that measurement and assessment are the cornerstones of psychology providing the tools and techniques for gathering information to inform our understanding of human behavior.

Precision in every sense of the word is key in psychological assessment. This begins with a description and operational definition of the trait or behavior under examination derived from the theory and research necessary to add empirical support. Following from this foundation is the development of scales that may include various tests (e.g., objective, self report, performance) as well as observation and interview methods to accurately measure (i.e., reliability, validity) the defined behaviors or traits. Standardizing these measures allows for even greater precision in administration, scoring, and interpretation. Data are gathered not only when the test is first published but in follow-up research that further allows for various comparisons of the individual's responses or test scores to normative and criterion interpretations, including change scores whether due to maturation or 'treatment'. Thus psychological measurement addresses the fundamental questions of "how much" and within the context of assessment, contributes to the additional questions of "what and why". Measures are extensions of theory- and research- based findings such that tests developed to measure intelligence are derived from various theories that have received empirical support. In turn, the findings can be used for a variety of 'applied' purposes - to explain, predict and change behavior.

A well used phrase in the measurement/assessment area is, "the more information and the better it is, the better the decision that will be made". Psychologists have created thousands of 'tests' over the past 100 years tapping such key cognitive constructs as intelligence and memory, personality factors such as extraversion and neuroticism, and conative measures including motivation and self efficacy. As psychological knowledge expands, so does the very need to measure and assess these 'new' variables. With the emergence of contemporary models such as emotional intelligence and theory of mind, new measures have quickly followed. Of course it is both theory but also the development of new data analysis techniques

such as structural equation modeling that has allowed us to determine how psychological constructs interact and even moderate or mediate the impact of particular factors on outcomes measures. In turn, this has enhanced the use of 'test batteries' to aid in the psychological assessment of a myriad of human 'conditions' ranging from depression and psychopathy, to learning disabilities and Attention Deficit-Hyperactivity Disorder. 'Clinical' assessment and diagnosis, necessary for determining the selection and application of the most appropriate evidence-based interventions, is grounded in the interface between a complex of key factors (both endogenous and exogenous) that can be obtained from our psychological tests and measures.

Although measurement and assessment are central to psychology, and all science-based disciplines and their resulting practices, psychological tests have been heavily criticized over the years. These criticisms not only come from other disciplines and the general public but also from psychologists themselves. For example, psychological test use has been challenged in the courts and the Response to Intervention (RTI) perspective that has gained momentum in education argues against a reliance on psychological tests for psychological and educational diagnosis. These are but two recent examples of the variability of opinion on assessment. But whether the attack comes from humanistic psychologists or radical behaviorists who might challenge the need for employing tests at all, the fact is that all psychologists engage in "assessment" through the gathering and analysis of data to aid decision making. Counseling psychologists rely heavily on 'talk' to determine a person's needs and issues whereas behaviorists are diligent in observing and measuring overt behaviors (without recourse to proposing underlying hypothetical factors) which can then be used to identify the antecedents and consequences relevant to the behavior in question. Psychoanalytically oriented psychologists may make greater use of projective techniques and free association as the 'data' for guiding their diagnosis and therapy decisions but still are engaged in the assessment process at all stages of their work with clients. These differences 'within' psychology show that assessment is not a static action but an ongoing process that starts with efforts to identify the 'issues' and continues as one observes changes related to everything from life events to therapy outcomes, including the need to reevaluate as new information comes to the fore.

The decisions that need to be made by psychologists can vary from traditional placement, selection and classification to program evaluation, early identification screening, and outcome prediction. Indeed, psychologists engage in a rather amazing array of assessments for many purposes. Psychological assessments and the measurement of various states, traits, and attributes have become valuable because in so many instances they reduce the error rates involved in predictions and decision-making. In fact, psychological assessment and the measurement process are useful only to the extent they can reduce error relative to reliance on other techniques. Determining the correct diagnosis to understand the presenting problems of a client (including the determination that there may be no pathology present), predicting who will be successful in a sales job, who will 'make it' academically in college, or whether medication has been effective in changing behavior, all require a most detailed and comprehensive assessment. In the forensic context, the extent of

functional impairment in a brain injury following a motor vehicle collision, which parent a child of divorce should reside within a custody agreement, and in capital murder cases in some USA states, who is eligible for the death penalty (defendants with intellectual disability cannot be executed) are a few examples of the many predictions and decisions to which psychological test data contribute in meaningful ways.

Another traditional view is that “tests are neutral; it is what we do with them that makes them useful-useless, informative-misleading, ‘good-bad’, or the like. These viewpoints clearly place psychological assessment in context. Psychological tests that assess the complexities of human behavior just don’t appear from nowhere, nor does their use and application automatically follow from simply administering and scoring a test. Assessment employs multimethod-multimodal techniques that rely on scientific knowledge derived from research, theoretical constructs or latent traits and models of human behavior (normal development of social behavior to models of psychiatric classification such as the DSM series). Whatever the ‘methods’ of assessment, there must be a demonstration of their reliability and validity. This required psychometric support is necessary to weave assessment findings into our psychological knowledge of human behavior that then may lead to prevention and intervention techniques (primary, secondary, tertiary) intended to reduce psychological challenges and promote psychological health and wellness. This process requires a high degree of clinical knowledge and professional competency regardless of one’s psychological orientation. Coupled with this is an adherence to the highest professional standards and ethical guidelines.

The editors of this volume are committed to ‘best practices in psychological assessment’ and while psychological assessment knowledge, techniques, and applications continues to ‘improve, we are reassured by a position paper published by Meyer et al (2001) *American Psychologist* (2001, 56, 128–165) that summarized the literature on psychological assessment. Based on an extensive review of the published literature, it was concluded that: “psychological test validity is strong and compelling, psychological test validity is comparable to medical test validity, distinct assessment methods provide unique sources of information . . .”. It is further stated that: “. . . a multimethod assessment battery provides a structured means for skilled clinicians to maximize the validity of individualized assessment” and that future investigations should “focus on the role of psychologists who use tests”.

A very large literature has addressed the myriad of topics of relevance to psychological assessment. There are a number of journals devoted specifically to this topic including *Psychological Assessment* edited by Cecil Reynolds and the *Journal of Psychoeducational Assessment* edited by Don Saklofske. However, the continued growth and new developments in the assessment literature requires an ongoing examination of the ‘principles and practices’ of central importance to psychological assessment. In particular, the psychological assessment of children and youth has undergone some of the greatest developments, and those developments are the primary focus of this book.

This volume on assessment has been organized primarily, but not exclusively, around clinical and psychoeducational assessment issues. To ensure we are on solid

ground, the foundations that underlie current psychological assessment practices are revisited. For example, the mobility of people has led to major changes in the demographics of countries making cultural issues a major focus in assessment. Linked with these foundations are chapters addressing some of the fundamental principles of child assessment that particularly focus on ability, achievement, behavior and personality. Techniques and specific methods of practice can change rapidly, and we have paired such chapters where possible with the chapters (or sections within a chapter in some cases) from the two previous sections. Theory provides us with guidance in practice when techniques change, new methods are introduced, and new data are presented, as well as when we encounter new presenting issues and circumstances with patients or when asked new questions by referral sources as raised with some specific examples in the fourth section of this volume. A volume on methods that does not also focus on theory is a short-lived work. Here we hope to see theory integrated with research and practice that will enable you to read the chapters in this book, as well as future publications, not just more profitably but critically as well.

We are especially grateful to all of our authors who wrote the informed and insightful chapters for this volume. Each is an expert who has contributed extensively to psychological assessment research and practice with children and youth and who individually and collectively have made this a book rich in content. While a number of people at Oxford University Press have had a role in this book, we are indebted to Chad Zimmerman, Sarah Harrington, and Anne Dellinger who have provided the necessary guidance and advice that has supported this book from proposal to publication. We also wish to extend our appreciation to Anitha Chellamuthu for guiding this book through the editing phases to publication.

# The Role of Theory in Psychological Assessment

Darielle Greenberg, Elizabeth O. Lichtenberger, and Alan S. Kaufman

## Abstract

This chapter reviews the role of theory in cognitive and neuropsychological assessment from a historical perspective. Theory has been applied to both test development and test interpretation, and it provides a strong framework for valid psychological assessments. Theory-based tests of the twenty-first century such as the Kaufman Assessment Battery for Children—Second Edition (KABC-II), Stanford-Binet Intelligence Test—Fifth Edition (SB-V), Das-Naglieri Cognitive Assessment System (CAS), Woodcock Johnson Test of Cognitive Abilities—Third Edition (WJ-III), and Differential Ability Scales—Second Edition (DAS-II) are highlighted as valid and reliable testing tools. Contemporary methods of test interpretation, including the Cross Battery Assessment approach and the Planning, Attention-Arousal, Simultaneous, and Success (PASS) model of processing, are presented as valid methods of interpretation based on theory. As noted from the chapter's historical perspective, incorporating theory in an assessment helps clinicians synthesize information that is gathered from the evaluation's multiple sources, and ultimately results in more accurate interpretations and interventions.

**Key Words:** theory, psychological assessment, cognitive, neuropsychological, testing, Cross Battery Assessment, PASS model

For centuries, professionals have been fascinated with the functions of the human body and brain. Attempts to measure brain function, specifically cognitive abilities, date back to 2200 B.C. in China. It is believed that the emperor gave formalized tests to his officers as a way to test for fitness of duty (Kaufman, 2009). With technological advances, significant strides have been made in the area of cognitive abilities and human intelligence. However, controversy regarding the components of these abilities and how to assess them still exists (see, e.g., Flanagan & Harrison, 2012).

The purpose of this chapter is to discuss the role of theory in psychological assessment from a historical perspective. The history is rich and has had an impact on contemporary test development and interpretation. What is meant by “psychological

assessment”? Psychological assessment involves a synthesis of the information gathered from several sources, including psychological tests, family history, behavioral observations, and so forth, to understand or make statements regarding an individual's diagnosis, level of functioning, and treatment. Simply administering a test, such as the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV; Wechsler, 2003) or even a theory-based test like the Woodcock-Johnson III (WJ III; Woodcock, McGrew, & Mather, 2001b; Woodcock, McGrew, Schrank, & Mather, 2007) or Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004a), would be considered psychological testing, and the data collected from multiple other sources in addition to this one test would round

out a complete assessment. Theory has played a significant role in cognitive and neuropsychological assessments, and it is these types of assessments that are the focus of this chapter. Although we acknowledge the usefulness of theory in the development of other types of tools, such as group-administered tests, personality tests, or non-cognitive tests, our particular discussion will center around the role of theory in developing and interpreting tests of cognitive ability. The role of theory in psychological cognitive and

neuropsychological assessment is two-pronged. The first prong is the development of tests from theory, and the second is the interpretation of tests from theory.

### Historical roots and landmarks

Before describing the modern role of theory in test interpretation and development, a historical review of the period from 1500 to 1970 is warranted. A timeline of historical landmarks in psychological assessment appears in Table 1.1.

**Table 1.1 Timeline of Select Historical Landmarks in Psychological Assessment**

2200 B.C.	Chinese emperors gave formalized tests to their officials as part of a standardized civil service testing program.
A.D. 1575	Juan Huarte published <i>Examen de Ingenios</i> (The Tryal of Wits) in which he tried to demonstrate the connection between physiology and psychology.
1799	Jean-Marc Itard worked to rehabilitate “Victor,” a young wild boy found in the woods. Itard assessed differences between normal and abnormal cognitive functioning.
1644	Thomas Willis, an English physician, detailed the anatomy of the brain.
1800	Franz Gall created <i>phrenology</i> , or the idea that the prominent bumps on a person’s skull determined his personality and intelligence.
1861	Pierre Broca discovered that the speech-production center of the brain was located in the ventro-posterior region of the frontal lobes (now known as “Broca’s area”).
1874	Carl Wernicke found that damage to the left posterior, superior temporal gyrus resulted in deficits in language comprehension. This region is now referred to as “Wernicke’s area.”
1837	Edouard Seguin established the first successful school for children with mental retardation.
1838	Jean Esquirol proposed that mental retardation was distinct from mental illness. He suggested that mental disabilities could be categorized into different levels.
1879	William Wundt founded the first psychological laboratory in Germany.
1884	Francis Galton theorized that intelligence was based on sensory keenness and reaction time. He set up a laboratory that used tests to measure these physical and mental abilities.
1888	James McKeen Cattell opened a testing laboratory at the University of Pennsylvania, and his work helped establish mental measurement in the United States.
1904	Charles Spearman proposed a two-factor theory of intelligence that included a general factor (g) and specific (s) factors.
1905	Albert Binet and Theodore Simon developed an intelligence test for screening school-age children.
1909	E. L. Thorndike proposed that intelligence was a cluster of three mental abilities: social, concrete, and abstract.
1917	Robert Yerkes and Lewis Terman developed the Army Alpha and Army Beta, group-administered intelligence tests.
1933	Louis Thurstone used a factor-analytic approach to study human intelligence.

(continued)

**Table 1.1 (Continued)**

1935	Ward Halstead established the first laboratory in America devoted to the study of brain–behavior relationships.
1939	David Wechsler published the Wechsler-Bellevue Intelligence Scale.
1949/1955	David Wechsler published the Wechsler Intelligence Scale for Children (WISC) and the Wechsler Adult Intelligence Scale (WAIS).
1959	J. P. Guilford proposed a Structure of Intellect model of intelligence.
1963	Raymond Cattell and John Horn proposed a theory of crystallized and fluid intelligence, expanding on Cattell's work in 1941.
1979	Alan Kaufman published “Intelligent Testing with the WISC-R,” which launched the assessment field into merging theory into test interpretation.
1983	Alan and Nadeen Kaufman published the Kaufman Assessment Battery for Children (K-ABC).
1985	John Horn expanded the <i>Gf-Gc</i> model to include ten abilities.
1986	Robert L. Thorndike et al. published the Stanford-Binet—Fourth Edition, which was designed to conform to <i>Gf-Gc</i> theory.
1989	Richard Woodcock revised the 1977 Woodcock-Johnson Psych-Educational Battery (WJ), which was not based on theory, to develop the WJ-R, founded on 7 Broad Abilities posited by Horn's <i>Gf-Gc</i> theory.
1990	Colin Elliott published the Differential Ability Scale (DAS), which was based on <i>g</i> theory.
1993	John Carroll proposed a three-stratum theory of cognitive abilities, including general ability (level III), broad abilities (level II), and narrow abilities (level I).
1994	J. P. Das, Jack Naglieri, and John Kirby propose the Planning, Attention, Simultaneous, Successive (PASS) theory of intelligence.
1997	Kevin McGrew proposed an integrated Cattell-Horn and Carroll model of cognitive abilities, which was refined by Dawn Flanagan, Kevin McGrew, and Samuel Ortiz in 2000.
1997	Jack Naglieri and J. P. Das published the Cognitive Assessment System (CAS), which is based on the PASS theory of intelligence.
2000	Dawn Flanagan and colleagues developed the Cross-Battery approach to test interpretation.
2001	Woodcock-Johnson—3rd ed. was published, which was based on a CHC theoretical model.
2003	Stanford-Binet—5th ed. was published, which was based on a CHC theoretical model; WISC-IV was published, based on cognitive neuroscience research and theory
2004	Kaufman Assessment Battery for Children—2nd ed. was published, which was based on a dual (CHC and Luria) theoretical model.
2007	Colin Elliott published the Differential Ability Scale—Second Edition (DAS-II), which was based on CHC theory.
2008/2012	Pearson published the latest versions of Wechsler's scales, the WAIS-IV (2008) and WPPSI-IV (2012); all of Wechsler's fourth editions are based on cognitive neuroscience research and theory, especially concerning fluid reasoning, working memory, and processing speed.

## ***Historical Antecedents Before the Nineteenth Century—Juan Huarte, Jean-Marc Itard, and Thomas Willis***

Psychological assessment has its roots mainly in the nineteenth century. However, before the 1800s, there were the influential works of men such as Juan Huarte de San Juan and Jean-Marc Gaspard Itard. The sixteenth century was the beginning of the modern era, which brought about economic, political, social, and religious changes. Scientific innovations were booming. In 1575, Juan Huarte, a Spanish physician, published *Examen de Ingenios* (The Tryal of Wits) in which he tried to demonstrate the connection between physiology and psychology. This publication was considered the best-known medical treaty of its time (Ortega, 2005). Huarte believed: 1) Cognitive functions were located in the brain; 2) cognitive functions were innate; 3) human understanding was generative; 4) qualitative differences existed between humans and animals; and 5) language was a universal structure. He also theorized that language was an index of human intelligence and suggested the idea of testing to understand intelligence. Huarte's ideas greatly influenced modern psycholinguistics, organizational psychology, and psychological assessment (Ortega, 2005). Needless to say, his beliefs were revolutionary for his time.

Over two decades later, during the eighteenth century, philosophers and scholars began to question the laws, beliefs, and ideas of the aristocracy. In 1799, the work of Jean-Marc Itard drew public attention for his work with a feral young boy, "Victor," who was found in the woods. Physicians who examined Victor described him as "deaf," "retarded," "a mental defective," and "hopelessly insane and unteachable" (Ansoll, 1971; Lane, 1986; Lieberman, 1982). Itard disagreed and believed that Victor's deficiencies were not the result of mental deficiency, but rather due to a lack of interaction with others. For five years, he attempted to "rehabilitate" Victor using an intense education program at the Institute of Deaf Mutes. Itard's aims were to increase his socialization, stimulation, and education. Although Itard was not successful in making Victor "normal," Victor was able to speak and read a few words and follow simple directions. Itard's program was perhaps the first of what we call today an Individualized Educational Program or Plan (IEP).

During these times, physicians were not only responsible for medically examining people like Victor, but they were also in charge of studying and explaining the relationship between brain function and behavior (known today as *neuropsychology*)

(Boake, 2008). Although not a physician, René Descartes, one of the greatest philosophers, was the first to note that the brain was the most vital organ in mediating behavior. He struggled with understanding and explaining the mind–body connection. After seeing an animated statue of St. Germaine, he theorized that the "flow of animal spirits" through nerves caused the body to move, which led to behaviors (Hatfield, 2007). This theory is known today as the *mechanistic* view of behavior. Descartes believed that although the body and mind interacted, they were, indeed, separate entities.

In 1664, an English physician by the name of Thomas Willis was the first to detail the anatomy of the brain. He is considered to be one of the greatest neuroanatomists of all time and the founder of clinical neuroscience (Molnar, 2004). After studying many patients and dissecting their brains, he described two types of tissue in the brain: gray and white matter. Agreeing with Descartes, he theorized that the white matter was made up of channels that dispersed the "spirits" produced by the gray matter. Willis was also convinced that the brain structures themselves influenced behavior.

## ***Nineteenth-Century Contributions from Brain Research—Franz Gall and Pierre Paul Broca***

Around the 1800s, in Austria, physician Franz Gall introduced the idea that the brain was made up of separate organs that were responsible for certain traits, such as memory and aggressiveness. He created *phrenology* or the idea that one could examine the prominent bumps on a person's skull and determine his or her personality and intelligence; a larger brain meant greater intelligence.

Although incorrect about the connection between bumps and intelligence, Gall sparked interest in the area of brain localization (or the idea that specific areas of the brain were responsible for specific functions). As advances in medicine took place, modest progress in understanding human anatomy was made. Prior beliefs had inaccurately attributed behavior to "spirits," while Gall's theories were dismissed as absurd. However, "the field was not ready for behavioral localization" (Maruish & Moses, 1997, p. 34).

After attending a conference, Pierre Paul Broca, a French physician, focused on understanding how brain damage affected people. While working in a hospital, Broca came into contact with a patient who had lost his use of speech, although he could still comprehend language. Because the

patient could only say and repeat the word “tan,” he became known as Tan. After Tan died in 1861, Broca performed an autopsy and found a lesion on the left side of the brain’s frontal cortex. Other patients like Tan were found to have the same damaged area. From these patients, Broca postulated that the brain’s left side of the frontal cortex was responsible for processing language. This region of the brain would later become known as *Broca’s area*. Broca’s lesion-method, which involved localization of brain function by studying the anatomy of the brain lesion, became an accepted tool for understanding the brain–behavior relationship.

Several years later, German physician Carl Wernicke suggested that not all the functions of language processing were in the area Broca described. During his work on the wards of the Allerheiligen Hospital, he found that patients who sustained damage to or had lesions on the superior posterior portion of the left hemisphere also experienced problems with language comprehension. This area was later named *Wernicke’s area*. In 1874, Wernicke published a model of language organization, describing three types of language centers: 1) motor language (damage to this center produced the speech production problems described by Broca); 2) sensory language (damage to this area produced comprehension deficits); and 3) a pathway between these two centers (damage resulted in impairments in repetition) (Mariush & Moses, 1997).

### ***Nineteenth Century Contributions from Research on Mental Deficiency—Jean Esquirol and Edouard Séguin***

Along with attention to brain function localization, interest in criminals, mental illness, and mental disabilities (and the differences between them) arose. Thanks to the works of Jean-Etienne Dominique Esquirol and Edouard Séguin, mental disability was no longer associated with insanity (Aiken, 2004). Esquirol theorized that persons with mental illness actually lost their cognitive abilities. In contrast, he determined that those who were called “idiots” never developed their intellectual abilities, and he proposed several levels of mental disability (i.e., morons, idiots, etc). He also believed them to be incurable. Eduardo Séguin was a student of Itard and Esquirol. Séguin disagreed with Esquirol and believed that mental deficiencies were caused by sensory isolation or deprivation and could be mitigated with motor and tactile stimulation (Winzer, 1993). Agreeing with Itard that children with mental disabilities could learn, Séguin

expanded Itard’s work into three main components: 1) motor and sensory training; 2) intellectual training; and 3) moral training. During the French Revolution, Séguin fled to the United States. He continued his work and established several schools devoted entirely to teaching children with mental retardation. Along with promoting understanding of those who had mental deficiencies, Esquirol and Séguin’s work fostered a continued curiosity about intelligence and intelligence testing.

### ***The Birth of IQ Tests in the Late 1800s—Francis Galton and James McKeen Cattell***

Western society experienced many changes in culture and technology in the late 1800s. Compulsory-education laws in the United States and Europe and the rise of psychology as a quantitative science were precursors to the introduction and measurement of intelligence (Thorndike, 1997). Before the compulsory-education law, only children whose families came from higher social strata (or who were interested) attended school. The curriculum was set to meet the standards and needs of *these* students. As one can imagine, not everyone was educated. The majority of American society included people and parents who were uneducated or who were unable to speak English (due to the large number of immigrants). Giving access to public education was a way to improve literacy and assimilate immigrants. Thus, the new laws resulted in heterogeneity in the student body and a dramatic increase in student failure rates (Thorndike, 1997). Due to the astonishing failure rates, leaders believed education should not be wasted on those who would not benefit, so they devised plans to “weed out” the children who were most likely to fail—intelligence testing was one method.

Along with the educational changes came the rise of psychology as a quantitative science. Gustav Fechner, Herman Ebbinghaus, Sir Francis Galton, and James McKeen Cattell were among the early forerunners who believed mental abilities could be measured (Sattler, 2008; Wasserman, 2012). While Fechner believed he had discovered “the physics of the mind,” Ebbinghaus developed a way to empirically study memory and mental fatigue. In England, Sir Francis Galton believed that people were born with a blank slate and that they learned through their senses. He theorized that intelligence was based on sensory keenness and reaction time; so, people who had more acute senses were more intelligent. He developed tests to measure these physical and mental abilities and set up a laboratory in 1884,

which was open to the public. In the announcement of his lab, called the Anthropometric Laboratory, he stated that one of its purposes was to serve “those who desire to be accurately measured in many ways, either to obtain timely warning of remediable faults in development, or to learn their powers” (Sattler, 2008, p. 216). However, the idea of such a laboratory was not a novel one. William Wundt is credited with the establishment of the first psychological laboratory, in Germany in 1879. Galton, with the help of his friend the mathematician Karl Pearson, was also formidable in originating the concepts of *standard deviation*, *regression to the mean*, and *correlation*. Unfortunately, his assumptions and the results of his tests were often not supported by the statistics he developed. Because of his contributions, nevertheless, Galton is often called “the father of the testing movement” (Ittenbach, Esters, & Wainer, 1997).

Galton’s assistant, James McKeen Cattell, is responsible for coining the term *mental test* and for bringing Galton’s ideas to the United States (Boake, 2002; Ittenbach et al., 1997; Wasserman, 2012). Cattell was interested in studying individual differences in behavior. He believed in the importance of measurement and experimentation and established his own laboratory in Pennsylvania. He developed 50 different measures to assess sensory and motor abilities, although these measures did not differ significantly from Galton’s tasks. Important to the history of assessment, Cattell realized the usefulness of tests as a way to select people for training and diagnostic evaluations. As such, he attempted to bring together a battery of tests. Cattell provided us with a standard way to measure human intellectual ability rather than keeping the field of psychology as an abstract discipline (Thorndike, 1997).

### ***The Dawn of the Twentieth Century and the Dynamic Contributions of Alfred Binet***

At the end of the nineteenth century, after being publicly embarrassed for his failed work in the area of hypnosis, Frenchman Alfred Binet turned his attention to the study of intelligence. With his two daughters as his subjects, he created and played a series of short games with them. From these encounters, he theorized that intelligence involved more complex mental abilities than just the senses. Binet believed that intelligence was equated with common sense, and called intelligence “judgment...good sense...the faculty of adapting one’s self to circumstances” (American Psychological Association (APA), 2004, p. 1). Binet believed that

intelligence was multifaceted and could be measured in three ways: 1) The medical method (anatomical, physiological, and pathological signs of inferior intelligence); 2) the pedagogical method (school-acquired knowledge); and 3) the psychological method (direct observations and measurements of intelligent behavior) (Foschi & Ciciola, 2006). In 1894, he devoted much of his time to researching the mental and physical differences among schoolchildren and became the director of Laboratory of Physiological Psychology in France.

By 1904, Binet was associated with a group of parents and professionals called the Free Society for the Psychological Study of the Child. This group was concerned with school failure rates. The compulsory-education laws in France impacted the government’s ability (and private institutions) to provide education to all children. The result was a national system of screening exams for secondary and university education students (Schneider, 1992). The exams did not create a problem for those who advanced, but did for those considered “abnormal” due to their inability to be educated. Children who failed were deemed to belong to one of two categories: 1) Those who could not learn, and 2) those who could learn but would not do so. Those who could not learn were labeled “stupid,” while the latter were referred to as “malicious.” Binet’s involvement with this organization led to his appointment to the French Ministry of Public Instruction, a committee created to identify “abnormal” children. With his main objective to differentiate “normal” children from the “retarded” ones, he created the “metric scale of intelligence” (Schneider, 1992, p. 114). This new approach was *not* to measure sensory or motor reaction times, but rather to measure a child’s response to questions. He organized questions based on a series of increasing complexity and assumed that those who answered the more complex questions displayed higher intellectual levels. His original scale, *Measuring Scale of Intelligence*, was introduced in 1905 with the help of Victor Henri and Theodore Simon. The scale comprised 30 items measuring what he believed encompassed intelligence, such as visual coordination, naming objects in a picture, repeating a series of numbers presented orally, constructing a sentence using three given words, giving distinctions between abstract terms, etc. His test was used exclusively to determine whether children needed specialized classes. According to Binet, children who demonstrated intellectual retardation for at least two years were candidates for the classes. Along with the first

IQ test, Binet introduced the important notation of error. He realized that measuring intelligence was not completely accurate and that his tests provided only a sample of an individual's behavior. Binet's original scale and its revisions that followed (1908, 1911, and 1916) "served as both a model of form and source of content for later intelligence tests" (Boake, 2002). The Stanford-Binet Scale (1916) and its 1937 and 1960 revisions became the dominant measures of intelligence in the United States for a half-century.

### ***The Dawn of the Twentieth Century and Charles Spearman's Theory of General Intelligence (g)***

The contributions of English psychologist Charles Spearman cannot be overlooked. As a student of Wundt and influenced by Galton, Spearman was intrigued with the concept of human intelligence. While doing his research, he noted that all mental abilities were correlated to each other in some way. He concluded that scores on a mental ability test were similar—a person who performed well on one test would perform well on another (Deary, Lawn, & Bartholomew, 2008). He concluded that intelligence was a general ability that could be measured and expressed as a numerical value. Spearman believed that intelligence was made up of *general ability* or *g*, plus one or more *specific* or *s* factors, and proposed a general-factor or *g* theory. He stated:

G means a particular quantity derived from statistical operations. Under certain conditions the score of a person at a mental test can be divided into two factors, one of which is always the same in all tests, whereas the other varies from one test to another; the former is called the general factor or G, while the other is called the specific factor. This then is what the G term means, a score-factor and nothing more.... And so the discovery has been made that G is dominant in such operations as reasoning, or learning Latin; whereas it plays a very small part indeed in such operation [sic] as distinguishing one tone from another... G is in the normal course of events determined innately; a person can no more be trained to have it in higher degree than he can be trained to be taller. (Deary et al., 2008, p. 126)

This theory was revolutionary and considered to be the first of many. In 1927, Spearman noted positive correlations (or positive manifold) among cognitive tests explained by psychometric *g* (Reynolds, 2012). When he compared children with normal ability to those with low ability, he observed that

correlations were stronger in low ability groups compared to high ability groups. Spearman theorized "as a general rule the effects of psychometric *g* on test scores decrease as *g* increases, likening it to the law of diminishing returns from economics" (Reynolds, 2012, p. 3). This phenomenon has become known as Spearman's law of diminishing returns (SLODR). Along with these theories, Spearman refined the use of correlation statistics. Using factor analysis, he improved test reliability by using a correction formula to deal with the errors in his observations that obscured the "common intellectual factor" (von Mayrhauser, 1992). Although his theory was criticized, Spearman's use of statistical factor analysis remains an important part of contemporary research and test development.

### ***The Growth of the Binet and Nonverbal Tests in America in the Early Twentieth Century***

Along with Binet, other individuals were studying and pursuing the measurement of intelligence. Two men, in particular, were influential pioneers—Henry Goddard and Lewis Terman. Henry Goddard is often considered the first "school psychologist" (Thorndike, 1997). In 1905, he was the director of the Vineland Training School for retarded children and was interested in their unique abilities. Although he wanted to measure the abilities of his students, no measure was available. His search led him to France, where he met Binet. Although he was skeptical, he translated the Binet-Simon scale from French to English and successfully used the scale on his students. In 1908, he introduced an adapted version of the scale, making minor revisions and incorporating standardization (2,000 American children were used). His version was used specifically to evaluate those with mental retardation. While Goddard translated and promoted the Binet-Simon scale, Lewis Terman expanded, standardized, and revised the scale. Terman was responsible for the tentative revision of the Binet-Simon scale in 1912 and the Stanford Revision and Extension of the Binet-Simon Scale in 1916. Terman is also known for renaming the *mental quotient* that Stern developed in 1914. The idea behind this *intelligence quotient* was that the use of a ratio provided a better measurement of mental retardation than the difference between two ages, because the difference did not mean the same thing at different ages (Sattler, 1992).

The beginning of World War I (WWI) initiated the need to evaluate millions of potential American soldiers for "fitness for duty." This seemed an impossible

task, given the number of recruits (some of whom were immigrants) and the fact that the only measures of abilities were based on an individual administration. In 1917, Robert Yerkes and Lewis Terman led a team that developed the group-administered intelligence tests known as Army Alpha and Army Beta (Thorndike, 1997). The Army Alpha was given to the “literate” group, which covered mostly verbal abilities. Army Beta, which involved mostly nonverbal skills, was administered to the “illiterate” group or the group that performed badly on the Army Alpha. The Beta group (composed of mostly immigrants) had more difficulty performing well on the test, resulting in their rejection by the Army to serve as soldiers in WWI.

After the war, a heated debate ensued regarding the validity of the Army testing and the Stanford-Binet. Those involved were outraged about the prejudicial statements of the results of the Army testing, which claimed that individuals from different regions (North vs. South) and of ethnic minorities were inferior (Goddard was largely responsible for questionable interpretation of the test data that led to the racist claims). At the core of the debate was the nature of intelligence, a familiar controversy that began years earlier.

### **Twentieth-Century Opponents of Spearman's *g* Theory**

Shortly after Spearman's theory was introduced, a debate regarding the nature of intelligence began. Critics believed that Spearman's theory was too simplistic. Thus, in 1909, Edward Lee Thorndike and his colleagues (Lay and Dean) tested the *g* hypothesis and concluded from their analysis, that they were almost tempted to replace Spearman's *g* theory by the equally extravagant theory that “there is nothing whatever common to all mental functions, or to any half of them” (R. M. Thorndike, 1997, p. 11). E. L. Thorndike believed that intelligence was a cluster of three mental abilities: 1) social (people skills); 2) concrete (dealing with things); and 3) abstract (verbal and mathematical skills) (Shepard, Fasko, & Osborne, 1999). While critics like Thorndike continued to question and denounce Spearman's theory, Spearman endlessly sparred with his critics, maintaining that his theory was sound. Although never resolved, this heated debate continued for almost 20 years.

By 1936, the Stanford-Binet was widely accepted in the United States as the standard for measuring intelligence (Roid & Barram, 2004). Finally, Spearman had “proven” his theory. But, much to his

chagrin, E. L. Thorndike disagreed again. Thorndike criticized tests similar to Stanford-Binet for measuring only one aspect of intelligence; he continued to insist that intelligence was not a single construct, but much more complex.

Between 1918 and 1938, additional tests (such as Kohs' Block Design Test and the Bender Visual Motor Gestalt Test) were developed and published in response to the debate, but only a few theories (e.g., Thurstone's multiple factor analytic approach) were introduced (Thorndike, 1997). Challenging Spearman's theory, Louis Thurstone (1938) believed that intelligence was not a unitary trait and assumed that intelligence was systematically organized. Using factor analysis, he identified factors including verbal fluency, perceptual speed, inductive reasoning, numeracy, rote memory, deductive reasoning, word fluency, and space or visualization skills. He believed that each factor had equal weight in defining intelligence and labeled these factors *primary mental abilities*.

### **David Wechsler's Innovations in the 1930s**

While many individuals were debating the Army testing issue, David Wechsler was preparing to “reinvent the wheel.” Wechsler's contributions to the field of psychological assessment are unmistakable. While waiting to serve in the Army, Wechsler came in to contact with Robert Yerkes. Later, he was the assigned psychologist who administered the Army Alpha and Army Beta to recruits. As he gave the tests, he began to observe the weaknesses of these tools and was determined to use his strong clinical skills and statistical training to develop a new and improved test. Wechsler attributed the misdiagnosis of civilians as having low mental abilities to the heavy emphasis on verbal skills. He hypothesized that if civilians were evaluated on other levels, their abilities would be judged “normal.” He believed:

Intelligence is an aspect of behavior; it has to do primarily with the appropriateness, effectiveness, and the worthwhileness of what human beings do or want to do... it is a many-faceted entity, a complex of diverse and numerous components.... Intelligent behavior... is not itself an aspect of cognition.... What intelligence tests measure, what we hope they measure, is something much more important: the capacity of an individual to understand the world about him and his resourcefulness to cope with its challenges.  
(Wechsler, 1975, p. 135)

When he became chief psychologist at Bellevue Psychiatric Hospital in 1932, he needed a test that could be applied to his population. He stated that the Stanford-Binet scales helped in determining whether an individual had any special abilities or disabilities, but that its application was geared more toward children and adolescents than adults and that the profile interpretation was complicated and unstandardized (Boake, 2002). Creating a standardized measure, statistical in nature, for use with adults was his mission.

In 1939, after a seven-year project, Wechsler introduced his first scale—the Wechsler-Bellevue. He included many tasks from other tests, including the Army Alpha, Army Beta, Army Individual Performance Scale, and Stanford-Binet. He deemphasized previous heavy reliance on verbal skills by introducing nonverbal tasks along with verbal tasks. His selection and development of tasks was based on his belief that intelligence was part of a person's personality and comprised "qualitatively different abilities" (Sattler, 1992, p. 44). "[Wechsler's] aim was not to produce a set of brand new tests but to select, from whatever source available, such a combination of them as would best meet the requirements of an effective adult scale" (Boake, 2002, p. 397). His standardization sample included individuals ranging from seven to 59 years of age who lived in the New York area. By the 1940s, Wechsler's test had gained credibility and was widely used. Wechsler refined and revised his scales until his death in 1981. The scales continue to be modified, even today (as seen by the Wechsler Intelligence Scale for Children—Fourth Edition [WISC-IV], the Wechsler Adult Intelligence Scale—Fourth Edition [WAIS-IV]), and the Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition [WPPSI-IV], although they still remain tied—to some extent—to their original scales. Unlike earlier editions of Wechsler's scales, the fourth editions are based on cognitive neuroscience research and theory, especially within the domains of fluid reasoning, working memory, and processing speed. Furthermore, Wechsler's impact on the contemporary field of assessment remains profound, particularly in transforming the field of intelligence testing psychometric measurement to clinical assessment (Kaufman, in press; Wasserman, 2012).

### ***Mid-Twentieth-Century Contributions from Neuropsychology***

While some individuals were emphasizing the concept of intelligence and how it was to be

measured, others were interested in the relationship between the brain and behavior. Until the 1930s or so, the field of neuropsychology had been dominated by physicians (Boake, 2008). In 1935, Ward Halstead established the first laboratory in America devoted to the study of the brain–behavior relationship in humans. He was interested in understanding how brain damage affected cognitive, perceptual, and sensorimotor functioning. Because intelligence tests did not help quantify these deficits, he observed the daily activities of several patients and determined that their deficits were varied. Most notable were the loss of adaptive functioning and loss of flexibility of thought. Based on these observations, he compiled a battery of tests to administer in order to understand and examine the deficits. Several years later, Halstead collaborated with his former student Ralph Reitan to develop the Halstead-Reitan Battery. Reitan was responsible for researching and ultimately revising the battery. From his results, he developed indices of brain damage.

In Russia, Alexander Luria worked from a different angle. Luria developed a model of brain organization in which he theorized that brain–behavior relationship could be broken down into components he called *functional systems* (Sbordone & Saul, 2000). He believed that each area of the brain played a specific role in behavior. His theory "was acknowledged as brilliant and insightful, but was seen as forbiddingly complex and impractical for the average clinician" (Hebben & Milberg, 2009, p. 19).

### ***Mid-Twentieth-Century Contributions from Raymond Cattell, John Horn, and J. P. Guilford***

The revisions of the Wechsler-Bellevue Scale gave way to the development of additional tests and theories of intelligence between the 1940s and the 1970s. In 1941, Raymond Cattell introduced a dichotomous theory of cognitive abilities. He theorized that there were two types of intelligence—*crystallized* and *fluid* (Horn & Noll, 1997). Crystallized intelligence, *Gc*, involved acquired skills and knowledge based on the influences of a person's culture. In contrast, fluid intelligence, or *Gf*, referred to nonverbal abilities not influenced by culture.

For two decades, Cattell's theory, and theories in general, were largely overlooked. However, John Horn, a student of Cattell, was responsible for the resurgence and expansion of Cattell's theory, in 1965. Working together and utilizing Thurstone's work, Horn and Cattell theorized that crystallized and fluid intelligence also involved abilities such as

visual processing ( $G_v$ ), short-term memory ( $G_{sm}$ ), long-term memory ( $G_{lr}$ ), and processing speed ( $G_s$ ). In 1968, Horn added auditory processing ( $G_a$ ) and refined the descriptions of other abilities (Flanagan, Ortiz, & Alfonso, 2007). The theory remains in use today as a framework for test developers and approaches to test interpretation (which is discussed later).

In 1967, J. P. Guilford's Structure of Intellect (SOI) became one of the major theories used in the field of intellectual assessment (Kaufman, 2009). Rejecting Spearman's view, Guilford believed that intelligence was composed of multiple dimensions: *operations* (general intellectual processes, such as the ability to understand, encode, and retrieve information), *contents* (how the information is perceived, such as auditory or visual) and *products* (how the information is organized, such as units and classes). This theory was innovative as it implied that there were more types of intelligence (120) than just the  $g$  described by Spearman. Today, the theory is utilized in the field of learning disabilities and gifted assessments. Linda Silverman, a leading expert in the field of gifted assessment, stated:

Guilford's model was well received by educators, particularly those who decried the narrowness of some of the older conceptions of intelligence. The concept of a number of intelligences left room for everyone to be gifted in some way. But the model and the methodology have met with severe criticism within the field of psychology.... These researchers claim that there is not enough evidence to support the existence of the independent abilities Guilford has described. (Silverman, personal communication, July 8, 2008)

## Theory-based tests in the twenty-first century

With an understanding of the historical landmarks, we now turn our attention to the role of theory in test development. Over the past many centuries, our fascination with human cognitive abilities has led to many dramatic developments in the measurement of, and theories related to, intellectual abilities. The links between brain and human behavior and subsequent developments linking neurological pathways and cognitive thought processes have expanded our knowledge of how best to measure human abilities. Physicians, psychologists, researchers, and legislators alike have had a role in shaping psychological assessment. Following this historical path from 2200 B.C. through the end of

the twentieth century, we have learned that the field of intellectual assessment is continually evolving. We have highlighted some of the earlier theories related to the assessment of cognitive abilities, and we will now turn to the more modern theories that have shaped both test development and interpretation into the twenty-first century.

To date, the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004a), the Stanford Binet, Fifth Edition (SB5; Roid, 2003b), the Cognitive Assessment System (CAS; Naglieri & Das, 1997a), the Woodcock Johnson—Third Edition (WJ-III; Woodcock et al., 2001b; 2007), and the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007a) are all testing tools that have been based on theory.

## KAUFMAN ASSESSMENT BATTERY FOR CHILDREN—SECOND EDITION (KABC-II)

Drs. Alan and Nadeen Kaufman first introduced their Kaufman Assessment Battery for Children (K-ABC) in 1983. Their philosophy on theory and assessment was innovative and empirically based. The original K-ABC, a measure of intelligence and achievement for children aged 2½ to 12½, significantly differed from traditional tests (including the Wechsler, Woodcock-Johnson, and Stanford-Binet scales) in that it was rooted in neuropsychological theory (i.e., Luria-Das). The scales were divided in two processes: *sequential* and *simultaneous*. Those children who used sequential processing were described as solving problems in a specific, linear order, regardless of content. In contrast, children using simultaneous processing were described as solving problems in a spatial, holistic manner. This aspect of testing had not emerged until the K-ABC, even though theories of intelligence had mentioned the role of the brain. Another essential aspect of the K-ABC was its use with minority children. Cultural bias in psychological assessment has been the subject of longstanding debate among practitioners and researchers. Research had indicated that African-American children performed 15 to 16 points lower on the Wechsler scales than Caucasian children. The K-ABC significantly reduced this difference (by half) and it was said to be "culturally fair."

The KABC-II (Kaufman & Kaufman, 2004a) is used to evaluate the processing and cognitive abilities of children and adolescents aged three to 18 in a clinical, psychoeducational, or neuropsychological setting. It can be also used in conjunction with other assessment tools to identify mental

retardation, intellectual giftedness, and learning disabilities. The KABC-II remains a culturally sensitive tool. Data show that Caucasians and African Americans continue to show reduced differences in global scores relative to other tests of intelligence (Kaufman et al., 2005).

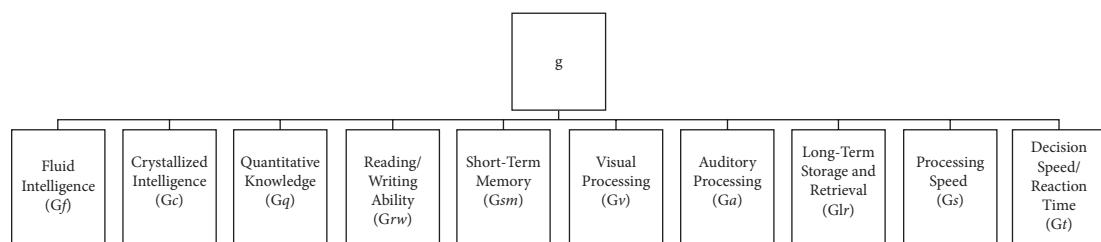

The KABC-II is based on Luria's neuropsychological theory, and also uses the Cattell-Horn-Carroll (CHC) theory. The KABC-II was drastically revised from the original K-ABC. Along with sub-test changes and its foundation in a dual theoretical model, the KABC-II gives the examiner the freedom to choose which of two global scores (one based on Luria theory and one based on CHC theory) is the most appropriate one for each person tested—an option that is not afforded by any other assessment tools (Kaufman, Lichtenberger, Fletcher-Janzen, & Kaufman, 2005). The choice is based on what is best suited to the child's background and reason for referral. For example, if the child is from a bilingual background, the Kaufmans suggest using the Luria Model or MPI (Mental Processing Index). In addition, if the child has or may have a learning disability in reading, they suggest using the CHC Model, which yields the Fluid Crystallized Index (FCI).

A brief review of these two theories is important to the understanding of the theory-based scales (i.e., MPI and FCI). The FCI is the global scale based on the CHC theory and measures general cognitive ability (Kaufman et al., 2005). The CHC theory is a combination of Horn-Cattell's (1968) *Gf/Gc* theory and Carroll's (1993) three-stratum theory (Flanagan, 2000; Schneider & McGrew, 2012). As previously mentioned, Cattell theorized that intelligence was divided into two abilities: fluid and crystallized. Crystallized intelligence or *Gc* involved abilities that were acquired through formal education and culture. In contrast, fluid intelligence or *Gf* consisted of inductive and deductive reasoning abilities that were influenced by biological and neurological factors. This theory was quite different

from the verbal–performance dichotomy used by the Wechsler tests. In 1965, Horn elaborated on the *Gf/Gc* theory to include the following additional cognitive abilities: visual processing (*Gv*), short-term memory (*Gsm*), long-term memory (*Glr*), and processing speed (*Gs*). In later years, he refined *Gv*, *Gs*, and *Glr* and added auditory processing (*Ga*), quantitative knowledge (*Gq*) and reading and writing (*Grw*). Horn believed that intelligence was composed of these equally weighted abilities. Figure 1.1 depicts CHC Broad Abilities classifications.

John Carroll's (1993) three-stratum theory is an extension of the *Gf/Gc* theory and other theories. From the results of numerous hierarchical factor-analyses based on correlational data, he theorized that intelligence or cognitive abilities have multiple levels or strata—Stratum I (narrow abilities), Stratum II (broad abilities), and Stratum III (general ability) (Kamphaus, 2008). Stratum I includes specific abilities, such as quantitative reasoning (the ability to reason inductively and deductively), listening ability (the ability to listen and comprehend), and spelling ability (the ability to spell). Stratum II involves the combinations of narrow abilities that form broader abilities, such as crystallized intelligence, fluid intelligence, quantitative knowledge, and so forth. For example, the broad ability crystallized intelligence or *Gc* refers to the acquired knowledge based on formal education and culture. The narrow abilities of *Gc* include skills such as language development, lexical knowledge, listening ability, and general (verbal) information. Finally, Stratum III encompasses general ability, or what have been labeled “general intelligence.”

In contrast to the FCI, the MPI is a global scale based on Luria's model. This scale measures mental-processing ability (a child's ability to solve problems) and excludes language ability and word knowledge (Kaufman et al., 2005). As the name suggests, the Luria model is based on the work of Luria in the 1970s. Luria believed that the brain's basic functions are represented in three “blocks”—Block 1 being arousal and attention, and corresponds to

**Figure 1.1** CHC Broad Abilities (Stratum II).

the reticular activating system; Block 2 being analyzing, coding, and storing information, and corresponds to the occipital, parietal, and temporal lobes; and Block 3 being executive functions, planning, and programming behavior, and corresponds to the anterior portion of the frontal lobes. Luria also believed that these “blocks” must work together in order for new material to be learned effectively. After information enters the brain, Block 2 is responsible for sending that information to Block 3. Realizing the importance of these systems, the Kaufmans included subtests measuring auditory and visual synthesis (such as requiring a child to point to a series of pictures in the correct order, corresponding to a series of words given by the examiner), as well as subtests that measure simultaneous processing that require use of Block 2 and Block 3 (such as requiring a child to point to a picture that does not go with the others around it).

The KABC-II was standardized on a sample of 3,025 children, stratified according to 2001 U.S. Census data. Reliability and validity data provide support for the psychometric properties of the test. Current literature, along with the test manual, indicates that it is a stable tool (Kaufman & Kaufman, 2004a; Kaufman et al., 2005). Internal consistency coefficients range from .69 to .97, test-retest coefficients range from .74 to .95, and validity coefficients range from .15 to .91. Like the K-ABC, the KABC-II is useful for evaluating minority children. The structure of the tool includes 18 subtests (such as copying the examiner’s exact sequence of taps on the table with fist, palm, or side of the hand; assembling several blue and yellow triangles to match a picture of an abstract design; etc.) and yields one to five scales, depending on the child’s age and interpretive approach used. For example, at age levels 7 to 18, ten core tasks are administered, yielding either MPI or FCI, either four scales (MPI) or five scales (FCI), and the Planning/Gf scale.

Fletcher-Janzen and Lichtenberger (2005) commented on the KABC-II’s strengths and weaknesses in the areas of test development, administration and scoring, and test interpretation. In terms of test development, the KABC-II has several strengths and weaknesses. Its strengths include the following:

- (1) It is based on dual theoretical models (Luria and CHC);
- (2) It allows evaluators to choose the theoretical model;
- (3) It evaluates a wide range of children and adolescents (ages 3–18);

(4) It allows evaluators to understand cognitive abilities in the context of academics, as it is normed with Kaufman Test of Educational Assessment—Second Edition (KTEA-II; Kaufman & Kaufman, 2004b);

(5) Its norms reflect a sample of ethnic minority responses (approximately 66%);

(6) It has ample floors and ceilings on nearly all subtests;

(7) It permits an evaluator to accept a correct response, regardless of the mode of communication (signing, writing, Spanish, etc.);

(8) The materials are well organized, sturdy, and novel; and

(9) It gives out-of-level norms for evaluating young children who might meet floors and ceilings too soon (Fletcher-Janzen & Lichtenberger, 2005).

In contrast, the KABC-II has several weaknesses in the area of test development, including the following: 1) Does not measure auditory processing (Ga) and processing speed (Gs); 2) record forms are complex; and 3) bonus points are used on three subtests, which confounds the measures (Fletcher-Janzen & Lichtenberger, 2005).

In terms of strengths of administration and scoring, the KABC-II:

(1) contains sample and teaching items that can be given in the child’s native language,

(2) allows the examiner to explain items in child-specific language if the child does not understand,

(3) has short, simple instructions,

(4) has limited subjective scoring items,

(5) contains subtests that are presented in both visual and auditory forms, and

(6) has a supplemental computer scoring and interpretation software.

Weaknesses include the following: 1) Scoring on some subtests requires special attention to avoid clerical errors; 2) discontinue rules are not consistent from subtest to subtest; and 3) some children may have difficulty understanding the grammar items on Rebus (Fletcher-Janzen & Lichtenberger, 2005).

For the KABC-II, interpretation strengths are as follows:

(1) Luria and CHC models are the foundation;

(2) Use of the CHC model works well for cross-battery assessment;

(3) Interpretation is dependent on global scales and scale indexes;

- (4) The interpretation system provides the evaluator with a continuous prompt to check hypotheses with other evidence;
- (5) The manual provides mean MPI and FCI, scale index, and subtest scores for ethnic minority groups;
- (6) Record form provides room to note basic analysis and strengths and weaknesses;
- (7) Out-of-level norms are available for gifted and lower functioning children;
- (8) Allows assessment of immediate and delayed memory;
- (9) Allows assessment of learning and crystallized knowledge;
- (10) A nonverbal index can be calculated and interpreted for children who have difficulty with oral communication (Fletcher-Janzen & Lichtenberger, 2005).

Interpretation weaknesses include: 1) the Knowledge/G<sub>c</sub> subtests do not allow evaluators to assess expressive language, and 2) some comparisons cannot be made because of age limits on some subtests, namely "Story Completion" and "Rover" (Fletcher-Janzen & Lichtenberger, 2005).

In one study that investigated the KABC-II's consistency with the CHC theory, Matthew Reynolds and his colleagues used the standardized sample (ages 3–18) as their participant pool (Reynolds, Keith, Fine, Fisher, & Low, 2007). Multiple-sample analyses were performed. Results showed the KABC-II measures the same construct across all ages. In addition, for school-age children, the test generally matches the five CHC broad abilities it is proposed to measure. The test provides a "robust measure of *g* and strong measures of *Gc*, *Gv*, *Glr*, and *Gsm*, and both *g* and the broad abilities are important to explaining variability in subtest scores" (Reynolds et al., 2007, p. 537). However, some inconsistencies were found in Gestalt Closure, Pattern Reasoning, and Hand Movements. The subtest Gestalt Closure appeared to measure crystallized intelligence (*Gc*) in addition to, or perhaps instead of, visual processing (*Gv*). The subtest Pattern Reasoning appeared to measure visual processing (*Gv*) in addition to fluid reasoning (*Gf*). Finally, the subtest Hand Movements measures fluid reasoning (*Gf*) in addition to short-term memory (*Gsm*). In terms of clinical applications, Fletcher-Janzen and Lichtenberger (2005) report that the KABC-II is effective for individuals who are deaf or hard of hearing, autistic, have speech and language disorders, mental retardation, ADHD, and learning differences.

Sex differences in cognitive abilities in children ages 6 to 18 have been found for the KABC-II (Reynolds, Keith, Ridley, Patel, 2008). In this study, multi-group higher-order analysis of mean and covariance structures (MG-MACS) and multiple indicator-multiple cause (MIMIC) models were used on the standardization sample. Results indicated that boys showed a mean advantage in latent visual-spatial ability (*Gv*) at all ages and in latent crystallized ability (*Gc*) at ages 6 to 16. In contrast, girls scored higher on the latent, high-order *g* factor, at all ages, but these results were statistically significant at only ages 6 to 7 and 15 to 16.

Researchers have investigated the application of other theories as they relate to the structure of KABC-II (Reynolds, Keith, & Beretvas, 2010; Reynolds & Keith, 2007). For example, in one study, Reynolds and Keith (2007) used the standardization sample for ages 6 to 18 to confirm the presence of SLODR. Confirmatory factor analysis was performed. Results indicated that SLODR was present, and "its presence was not dependent on the hierarchical model of intelligence. Moreover, [the] findings suggest that SLODR acts on *g* and not on the broad abilities" (Reynolds & Keith, 2007, p. 267). In another study by Reynolds et al. (2010), a factor mixture model was performed on the standardization sample to eliminate the previous division of participants into separate groups. The results also offered support for SLODR, "most notably the *g* factor variance was less in high *g* mean classes" (Reynolds et al., 2010, p. 231). Reynolds (2012) stated that although the presence of SLODR has been detected in several batteries, its effects on "the measurement of intelligence and interpretation of test scores is less well-understood." (p. 4).

For the most up-to-date research summaries of the KABC-II, consult Reynolds et al. (2010) and Singer, Lichtenberger, Kaufman, Kaufman, and Kaufman (2012).

#### THE STANFORD BINET, FIFTH EDITION (SB5)

Along with the KABC-II, the Stanford Binet is another theory-based assessment tool. Its history is long, dating back to Binet and Simon in 1905. The Stanford Binet–Fifth Edition (SB5; Roid, 2003b) is based on a five-factor hierarchical cognitive model, a combination of theories developed by Carroll, Cattell, and Horn now known as the CHC model (Roid & Barram, 2004). Roid retained the theory that *g* comprises verbal and nonverbal abilities. The SB5 is the first intellectual battery to cover five cognitive factors: fluid reasoning, knowledge,

quantitative reasoning, visual-spatial reasoning, and working memory, in both domains (verbal and nonverbal). Therefore, the SB5 yields a Full Scale IQ, Verbal IQ, Nonverbal IQ, plus the five factor indexes on each domain (Roid & Barram, 2004).

The SB5 is designed to assess an individual's general intellectual ability between the ages of three and 85 and above. It was standardized and stratified on a large sample (N = 4,800; ages 2–96) based on the 2001 U.S. Census data. Reliability and validity data provide support for the psychometric properties of the test (Roid & Barram, 2004). For example, internal consistency coefficients range from .90 to .98.

As the SB5 is a fairly new instrument, researchers need more time to explore it. However, strengths and weaknesses have emerged in terms of test development and standardization, administration and scoring, and test interpretation and application (Roid & Barram, 2004). In terms of test development and standardization, the SB5 has the following strengths: 1) Large norm sample; 2) large age range; 3) in-depth field testing and fairness reviews; 4) content-validity studies of CHC aligned factors; 5) use of item response theory; and 6) linkage with Woodcock-Johnson III Tests of Achievement (Roid & Barram, 2004). In contrast, weaknesses include: 1) it does not assess all CHC model factors; 2) it does not include many clinical and/or special group data; and 3) it correlates with only the WJ-III Achievement (Roid & Barram, 2004).

The SB5 has many strengths and weaknesses in terms of administration and scoring. Its strengths include the following:

- (1) Levels are tailored to the examinee's ability;
- (2) Scoring metrics are similar to other batteries;
- (3) It is a child-friendly test;
- (4) New Change-Sensitive Scores are used;
- (5) IQ score levels have been extended on both extremes (10 to 40 and 160 to 225);
- (6) Record forms are well-designed;
- (7) Helpful examiner pages are included in item books; and
- (8) There is an optional computer-scoring program that is easy to use (Roid & Barram, 2004).

In contrast, administration and scoring weaknesses involve the following: 1) levels may be confusing to evaluators; 2) shifting between subtests may be difficult for evaluators; 3) extended IQs are only available for Full Scale IQ; 4) nonverbal subtests do not have pure pantomime administration; 5) computer-scoring program is not included

with the kit; and 6) nonverbal knowledge may need expressive language skills (Roid & Barram, 2004).

In terms of interpretation and application, the SB5 has strengths including the following:

- (1) The assessment of working memory improves diagnoses,
- (2) The contrast between verbal and nonverbal subtests is useful,
- (3) A comprehensive interpretive manual is included,
- (4) Progress can be noted by using Change-Sensitive Scores,
- (5) Early prediction of learning disabilities can be made by using Working Memory, Knowledge, and Quantitative Reasoning scores, and
- (6) Extended IQs are used for assessment of giftedness and mental retardation (Roid & Barram, 2004).

The weaknesses in this area are: 1) nonverbal subtests require receptive and expressive language skills and 2) more studies of classroom application are needed (Roid & Barram, 2004).

Canivez (2008) investigated the SB5's link to theory by conducting orthogonal higher-order factor structure of the test. His participants included the three youngest age groups from the original standardization sample (N = 1,400 2–5-year-olds; 1,000 6–10-year-olds; and 1,200 11–16-year-olds). The results of the study indicated that the SB5 "fundamentally measures general, global intelligence (Stratum III; Carroll, 1993). When examining the 10 SB5 subtest correlation matrices for the three youngest age groups, there was no evidence to suggest the presence of more than one factor as proposed by Roid....No evidence of a five factor model was found" (Canivez, 2008, pp. 538–539).

Investigators have also looked into the effectiveness of the SB5 in assessing giftedness, autism spectrum disorders, preschool children, attention-deficit/hyperactivity disorder, autism, and working memory (e.g., Canivez, 2008; Coolican, Bryson, Zwaigenbau, 2008; Leffard, Miller, Bernstein, DeMann, Mangis, & McCoy, 2006; Lichtenberger, 2005; Minton & Pratt, 2006; Newton, McIntosh, Dixon, Williams, & Youman, 2008). Coolican and colleagues (2008) investigated the utility of the SB5 on children with autism spectrum disorders. Their participants included 63 children (12 girls, 51 boys) with a diagnosis of autism, Asperger's syndrome, and pervasive developmental disorder not otherwise specified (PDDNOS). Ninety percent of the children completed the SB5. Their results revealed a broad range of functioning;

individuals earned Full Scale IQs (FSIQs) ranging from 40 to 141. In addition, a higher percentage of children had stronger nonverbal skills than verbal skills. Minton and Pratt (2006) tested 37 students in grades two through six in Idaho. They concluded that elementary school students who were gifted or highly gifted scored significantly lower on the SB5 than on the WISC-III. This result suggests that using the two or three standard deviations from the mean as a cutoff for giftedness vs. nongiftedness was too high.

For the most up-to-date research summaries of the SB5, consult Roid and Pomplin (2012).

#### THE WOODCOCK JOHNSON—THIRD EDITION (WJ-III)

Although the original Woodcock Johnson was not theory-based, the Woodcock-Johnson Psycho-Educational Battery-Revised (WJ-R, Woodcock & Johnson, 1989) was grounded in Horn-Cattell theory. The latest revision, the Woodcock-Johnson III Tests of Cognitive Abilities (WJ III COG; Woodcock, Johnson, & Mather, 2001b; Woodcock et al., 2007), is based on Cattell-Horn-Carroll (CHC) theory and is designed to measure intellectual abilities of individuals from age five to 95. All three levels (stratum I, II, and III) of the CHC theory are represented on the WJ III, although the primary purpose of the test is to accurately measure broad CHC factor scores (Stratum II) (Schrank, Flanagan, Woodcock, & Mascolo, 2002). Sanders, McIntosh, Dunham, Rothlisberg, and Finch (2007) noted, “Creating tests that measured the CHC abilities allowed for analysis of within-individual variability and provided additional ipsative interpretative information” (p. 120).

The WJ III COG is divided into two major components—the standard battery and the extended battery. For the standard battery, seven cognitive factors, including comprehension-knowledge, long-term retrieval, visual-spatial thinking, auditory processing, fluid reasoning, processing speed, and short-term memory, are assessed along with the general intellectual ability. Three additional cognitive performance cluster scores can be calculated, which include verbal ability, thinking ability, and cognitive efficiency. Not all 20 tests are administered, but rather those subtests that are relevant to information the examiner seeks, as well as to the referral question. For example, the first seven subtests are administered for general intellectual ability. However, if an evaluator is wondering about an individual’s short-term memory (*Gsm*), the two additional subtests can be administered (Schrank et al., 2002).

A useful aspect of the WJ III COG is that it has been normed with the WJ III Tests of Achievement (WJ III ACH; Woodcock, McGrew, & Mather, 2001a) so that examiners can compare cognitive and achievement abilities. The WJ III ACH consists of 22 subtests that evaluate five areas, including reading, oral language, mathematics, written language, and academic knowledge (such as science). Like the WJ III COG, the WJ III ACH is divided into a standard and extended battery. Administering nine subtests will allow for a Total Achievement score to be obtained for children age five or older. Both the WJ III COG and WJ III ACH were normatively updated in 2007, which involved a recalculation of norms for subtests and clusters (Schrank & Wendling, 2012).

The WJ III COG was standardized on a sample of 8,818 ranging from age two to 95+ and selected from more than 100 “geographically and economically diverse communities” (Schrank et al., 2002). The psychometric properties of the test indicate a stable tool (McGrew & Woodcock, 2001; Schrank et al., 2002). For the standard battery, individual test reliabilities range from .81 (Test 3: Spatial Relations) to .94 (Test 5: Concept Formation). For the extended battery, individual test reliabilities range from .74 (Test 19: Planning) to .97 (Test 18: Rapid Picture Naming). Median cluster reliability statistics range from .88 (Short-Term Memory) to .98 (General Intellectual Ability—Extended). Test-retest reliability coefficients range from .73 to .96. Convergent and discriminant validity coefficients range from .20 to .60.

The WJ III COG has several strengths and weaknesses. Its strengths include the following: 1) the battery is based on empirically strong theory of cognitive abilities; 2) interpretation of its results offers important information regarding cognitive strengths and weaknesses; 3) it is conformed with the WJ III Tests of Achievement and provides actual discrepancy norms; 4) the tool is technically stable; and 5) the materials are well made. In contrast, its weaknesses include complexity of administration and interpretation, lack of hand scoring abilities, and the need for additional research for the clinical clusters (Schrank et al., 2002).

One illustrative study that linked the WJ III COG to CHC theory was conducted by Taub and McGrew (2004), who performed confirmatory factor analysis of the battery and determined its cross-age invariance. The WJ III COG standardization sample served as the data for this study. Three sets of confirmatory factor analyses were

performed. Results of the analyses provide support for the factorial invariance of the WJ COG when the 14 tests contributing to the calculation of the examinee's GIA and CHC factors scores are administered. Support is provided for the WJ III COG theoretical factor structure across five age groups (ages 6 to 90+) (Taub & McGrew, 2004, p. 72). Researchers have also looked into the effectiveness of the WJ III COG in assessing learning disabilities and attention problems (Leffard, Miller, Bernstein, DeMann, Mangis, & McCoy, 2006; Schrank et al., 2002). Schrank and his colleagues (2002) delineate several WJ III discrepancy procedures to assist in identifying specific learning disabilities, including ability-achievement, predicted achievement/achievement discrepancy, general intellectual ability/achievement discrepancy, oral language ability/achievement discrepancy, intra-ability discrepancy, intracognitive discrepancy, intra-achievement discrepancy, and intra-individual discrepancy.

Using the Woodcock-Johnson and Kaufman tests, Scott Barry Kaufman and his colleagues (2012) investigated whether cognitive *g* and academic achievement *g* are the same as the conventional *g* (Kaufman, Reynolds, Liu, Kaufman, & McGrew, 2012). From previous research, we know that IQ-achievement correlations are moderate to high, but that 50 to 75 percent of the variance in achievement is unaccounted for by cognitive ability. Many factors have been found to impact academics. Some of the variance is measurement error, whereas other variance is accounted for by such factors as student characteristics, school environments, and curriculum. They used two large nationally representative data sets and two independent test batteries. Second-order latent factor models and multi-group confirmatory factor analysis were used. The results indicated that *COG-g* and *ACH-g* are not the same as *g*. They are distinct but highly related constructs. And, importantly, Kaufman et al. (2012) gave strong support to the CHC theory-based structure of both the KABC-II and KABC-II).

For the most up-to-date research summaries of the WJ III COG and its 2007 normative update, consult S. B. Kaufman et al. (2012), Schneider and McGrew (2012), and Schrank and Wendling (2012).

#### **THE DIFFERENTIAL ABILITY SCALES—2ND EDITION**

The Differential Ability Scales (DAS; Elliott, 1990a) was developed by Colin Elliott from their predecessor, the British Ability Scales (BAS; Elliott, 1983a, 1983b), to focus on "specific abilities rather

than on 'intelligence'" (Elliott, 1997, p. 183). The second revision of the Differential Ability Scales (DAS-II; Elliott, 2007a) was designed to "address processes that often underlie children's difficulties in learning and what scientists know about neurological structures underlying these abilities" (Dumont, Willis, & Elliott, 2009, p. 5). The theoretical underpinning of the tool is not based on a single theory, but it has been connected to various neuropsychological processing models and the Cattell-Horn-Carroll theory, which has already been described above (Stavrou & Hollander, 2007).

The DAS-II is designed to evaluate children from the ages of two to 17. The test consists of 20 subtests and is divided into two overlapping age-level batteries—the Early Years (2:6–6:11) and the School Years (5:0–17:11). The Early Years battery is even further divided into a lower (2:6–3:5) and upper level (3:6–6:11). The battery yields an overall composite score labeled General Conceptual Ability (GCA), as well as several additional cluster scores, including Verbal Ability, Nonverbal Reasoning, and Spatial Ability. The Verbal Ability Cluster is a measure of crystallized intelligence or *Gc*, the Nonverbal Reasoning Cluster is a measure of fluid intelligence or *Gf*, and the Spatial Ability Cluster is a measure of visual-spatial ability or *Gv*. These clusters make up the core subtests. Other subtests, known as the diagnostic subtests, measure memory skills, processing speed, and school readiness.

The DAS-II was standardized and normed on 3,480 children living in the United States based on the October 2002 census. The psychometric properties of this tool indicate that it is a stable tool (Dumont, Willis, & Elliott, 2009; Stavrou & Hollander, 2007). Average internal consistency reliabilities range from .77 to .95. Test-retest reliability coefficients range from .83 to .92. In addition, the DAS-II has satisfactory concurrent validity (Dumont, Willis, & Elliott, 2009; Stavrou & Hollander, 2007). Mean overall correlation was .80.

Regarding the strengths and weaknesses of the DAS-II, the strengths include but are not limited to the following:

- (1) The General Conceptual Ability Score;
- (2) the Special Nonverbal Composite;
- (3) ability to administer the nonverbal subtests in Spanish and American Sign Language;
- (4) evaluation of differential abilities;
- (5) use of Cattell-Horn-Carroll theory;
- (6) fairly easy administration and scoring;
- (7) child-centered;

- (8) diagnostic subtests and clusters; and
  - (9) ability to evaluate learning differences
- (Dumont, Willis, & Elliott, 2009).

In contrast, weaknesses include but are not limited to the following: 1) norming that only extends to 17 years, 11 months; 2) it is a test of cognitive ability, not an IQ test; 3) it is a complex test that requires training; and 4) additional testing is required to understand the expressive language skills for younger children (Dumont, Willis, & Elliott, 2009).

Timothy Keith and colleagues have conducted confirmatory factor analyses of the DAS-II across age levels, using standardization data for ages 4–17 years, to support the CHC theoretical basis for the DAS-II for the Early Years and School-Age batteries (Keith, Low, Reynolds, Patel, & Ridley, 2010). These results confirmed the “robustness of the structure across age levels” (Elliott, 2012, p. 347).

Sex differences in cognitive abilities in children ages 5–17 have been found for the DAS-II (Keith, Reynolds, Roberts, Winter, and Austin, 2011). In this study, multi-group mean and covariance structural equation modeling was used on the standardization sample. Girls showed advantages on processing speed ( $G_s$ ) across all ages (especially ages 8–13) and free-recall memory, a narrow ability of long term retrieval ( $G_{lr}$ ), for some age groups. In contrast, boys showed an advantage on visual-spatial ability ( $G_v$ ) for most ages, ranging from less than 1 point at ages 8–10 to almost 5 points at ages 14–15. Younger girls showed an advantage on short-term memory ( $G_{sm}$ ). Statistically significant sex differences were not found on latent comprehension-knowledge ( $G_c$ ) or the latent  $g$  factor.

Researchers have explored the application of other theories as they relate to DAS-II, such as SLODR (Reynolds, 2012; Reynolds, Hajovsky, Niileksela, & Keith, 2011). Recently, Reynolds (2012) provided a deeper understanding of how SLODR impacts the measurement of intelligence and interpretation of test scores. The purposes of his study were: (a) to determine whether the  $g$  loadings of the composite scores were linear, and (b) if they were nonlinear, to demonstrate how SLODR affects the interpretation of these loadings. Using the norming sample, he performed linear and nonlinear confirmatory factor analysis. Several important contributions were made, such as (a)  $G_f$  was unaffected by SLODR ( $G_c$ ,  $G_v$ ,  $G_{sm}$ , and  $G_s$  decreased as  $g$  increased), and (b) “ $g$  loadings should be viewed as  $g$  level dependent” (p. 23).

For the most up-to-date research summaries of the DAS-II, consult Reynolds et al. (2011) and Elliott (2012).

## The role of theory in contemporary test interpretation

With an understanding of the role of theory in test development, we can now shift our focus to the role of theory in contemporary test interpretation. Until recently, the importance of using theory in test interpretation had not been universally accepted or acknowledged. According to Randy Kamphaus and his colleagues (Kamphaus, Petoskey, & Morgan, 1997; Kamphaus, Winsor, Rowe, & Kim, 2012), theory was not applied to test interpretation until the late 1970s. Theory-based test interpretation has evolved significantly since the early days of Binet, who used a measuring approach. Four “waves” have been delineated in terms of the history of test interpretation: 1) Quantification of a general level; 2) clinical profile analysis; 3) psychometric profile analysis; and 4) applying theory to intelligence test interpretation (Kamphaus et al., 1997; Kamphaus et al., 2012).

### *The First Wave—Quantification of a General Level*

Until the 1900s, identification of mental abilities was strictly medical or physical, such as “idioty” or “imbecility.” The first wave (quantification of a general level) began with Alfred Binet. As described in the previous section, in response to compulsory-education laws and increased failure rates among schoolchildren, Binet was appointed to the French Ministry of Public Instruction. His job was to develop a way to differentiate normal children from retarded ones. His 1905 *Measuring Scale of Intelligence* was created for this purpose. The interpretation was not based on a theory, but rather on two categories—whether the child was “normal” or “retarded.”

By the 1920s, other descriptive terms and ranges were utilized: for example, those with IQ scores of 50 to 74 were classified as “Morons,” IQ scores of 95 to 104 were described as “Average,” and IQ Scores of 125 to 149 were classified as “Superior” (Levine & Marks, 1928).

Terman delineated a different classification system from Binet. His categories ranged from “Definite feeble-mindedness” to “Near genius or genius” (Davis, 1940). During World War II, Wechsler attempted to apply a description of intelligence based on statistical frequencies and distance from the mean (i.e., 50% of people who earned IQ scores of 91 to 110 were in the Average range of intelligence). Today, we continue to use a classification system, but we understand and recognize that

it is only the first step to a meaningful interpretation of test results.

### ***The Second Wave—Clinical Profile Analysis***

During the mid-1940s, the use of clinical profile analysis replaced the classification system. The contribution of psychoanalytic theory to this wave is instantly recognizable, with David Rapaport, Merton Gill, and Roy Schafer being the major contributors. In 1940, Rapaport was appointed head of the Psychology and Research Departments at the famous Menninger Clinic. His interest was in understanding schizophrenia, and he did not deny that these individuals had impairments in intellectual functioning. Although Rapaport criticized the field for the lack of theory application, he justified using psychological testing in psychiatric settings (Lerner, 2007). He used a battery of tests, including the Wechsler-Bellevue Scale, Rorschach, Thematic Apperception Test, etc., and applied psychoanalytic theory to interpretation the results of each test.

Rapaport eventually collaborated with Gill and Schafer to propose a new approach (*Diagnostic Psychological Testing*) to test interpretation (Sugarman & Kanner, 2000). They believed that an IQ level had almost no diagnostic significance in their clinical work (Wiggins, Behrends, & Trobst, 2003). So they emphasized the quantitative “interrelations” among subtest scores and the qualitative aspects of individual item responses in order “to demonstrate that different types of maladjustment tend to have different distinguishing and recognizable impairments of test performance” (Wiggins et al., 2003, p. 57). Their five principles were:

- (1) Every single subtest score and response was significant and representative;
- (2) A comparison of the successes and failures led to further understanding of the examinee;
- (3) Subtest scores were related to each other and were representative of the subject;
- (4) Both the Verbal score and the Performance score was significant to the examinee’s overall makeup;
- (5) The data must be considered in light of other data.

The importance of scatter analysis was also described. *Scatter analysis* referred to “the relationship of any two scores or any single score to the central tendency of all the scores” (Wiggins et al., 2003, p. 58). For Rapaport and his colleagues, the Vocabulary subtest served as baseline for subtest comparisons because of its centrality and stability.

They suggested that a profile could be indicative of diagnoses such as “simple schizophrenia” or “depressives” (psychotic and neurotic). They stated, “A large percentage of schizophrenics scored relatively low on the arithmetic subtest, while they scored high on digit span. This pattern is a reversal of what is the usual pattern in neurotics, depressives, and normals” (Schafer & Rapaport, 1944, p. 280). In addition, a significant discrepancy between Digit Span Forwards and Digit Span Backwards was indicative of a psychotic process (Wiggins et al., 2003).

### ***The Third Wave—Psychometric Profile Analysis***

Access to computers and statistical software launched the third wave—“psychometric profile analysis.” The major contributors of this wave included Jacob Cohen (1959), Alexander Bannatyne (1974), and Alan Kaufman (1979). Cohen (1957, 1959) conducted the first factor analyses of the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949) and the Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955). He used the standardization sample data reported in both manuals for his analyses. For the WAIS, Cohen (1957) identified *g* (general intellectual functioning) along with five Factors Scores, including Factor A (Verbal Comprehension), Factor B (Perceptual Organization), Factor C (Memory), Factor D (Picture Completion), and Factor E (Digit Symbol). His Factor Scores were obtained by averaging the subtests said to measure these abilities. Factor A was obtained by averaging scores from the Information, Comprehension, Similarities, and Vocabulary subtests. Factor B was obtained by averaging the Block Design and Object Assembly subtest scores. Finally, Factor C was obtained by averaging the Arithmetic and Digit Span subtests. Factor D and Factor E were considered “minor factors.” In 1959, he analyzed the data from the WISC. His results were closely related to those obtained for the WAIS. In addition to the Verbal, Performance, and Full Scale IQs, five Factors Scores were discovered: 1) Factor A (Verbal Comprehension I); 2) Factor B (Perceptual Organization); 3) Factor C (Freedom from Distractibility); 4) Factor D (Verbal Comprehension II); and 5) Factor E (an unlabeled quasi-specific factor). Cohen indicated that Factor A seemed to involve aspects of verbal knowledge acquired by formal education, including facts (Information), verbal categorization (Similarities), and manipulation of numbers (Arithmetic). He distinguished Factor A from Factor D. Factor B required tasks on

nonverbal skills, involving the interpretation and/or organization of stimuli presented visually against a time limit. These skills included Block Design, Object Assembly, Mazes, and Picture Arrangement. Factor C involved tasks that required attention and concentration, including Digit Span, Mazes, Picture Arrangement, Object Assembly, and Arithmetic. Finally, Factor D involved the use of judgment and included Comprehension, Picture Completion, Vocabulary, and Similarities. Along with obtaining Verbal, Performance, and Full Scale IQs, Cohen delineated other Factor Scores helpful in interpreting an individual's intelligence. He also noted that his studies of the WISC and WAIS provided "insight into the process of intellectual maturation via the comparative analysis of the factorial structures for the three age groups" (Cohen, 1959, p. 285).

Like Cohen, Bannatyne (1974) offered an alternative interpretive system for the Wechsler scales. His reorganization was created in response to attempts to understand the results of the learning disabled (LD) student. The traditional Verbal, Performance, and Full Scale method did not account for the poor performances on certain subtests (i.e., Information and Vocabulary) and adequate performance on the Digit Span subtest. Bannatyne suggested analyzing these students' performances based on Spatial (ability to recognize spatial relationships and manipulate objects in space), Conceptual (ability to use general verbal language), Sequential (ability to retain visual and auditory information), and Acquired Knowledge categories (Webster & Lafayette, 1980). He proposed that a child with dyslexia would obtain a good spatial score and a poor sequencing score (Henry & Wittman, 1981). Although these categories appeared to have high reliability, inconsistent results were found among researchers (Kaufman, 1981). Kaufman noted, "One should not conclude, however, that Bannatyne's recategorizations are irrelevant to LD assessment: that would be far from the truth. Although the groupings do not facilitate differential diagnosis, they still provide a convenient framework for understanding the LD child's assets and deficits" (Kaufman, 1981, p. 522).

From Cohen's work, Kaufman (1979) constructed a systematic method for using the first three factors to interpret the scales of the Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler, 1974). He believed:

The focus is the child, with interpretations of the WISC-R and communication of the results in the context of the child's particular background,

behaviors, and approach to the test items.... Global scores are deemphasized, flexibility and insight on the part of the examiner are demanded, and the test is perceived as a dynamic helping agent rather than as an instrument for placement, labeling.... (Kaufman, 1979)

Kaufman's approach to test interpretation was based on three premises: 1) The WISC-R subtests assess what the person has learned; 2) the subtests are examples of behavior and not comprehensive; and 3) WISC-R evaluates mental functioning under fixed experimental conditions (Kaufman, 1979). This new approach included starting with the most general and global score (Full Scale IQ) and working to the more specific levels (a single subtest) until all meaningful hypotheses about the individual were revealed. He provided case report examples as a way to illustrate his method. Kaufman was the first to merge research and theory with testing. He noted the importance of taking into consideration physical, cultural, and language factors.

### ***The Fourth Wave—Applying Theory to Intelligence Test Interpretation***

Kaufman's interpretation method launched the fourth wave of test interpretation—applying theory to intelligence testing. The best contemporary models of theoretical interpretation include the Cross-Battery Assessment approach (Flanagan, McGrew, & Ortiz, 2000) and the Planning, Attention-Arousal, Simultaneous, and Success model of processing (Naglieri & Das, 1997a). The remainder of this section will be devoted to describing these approaches.

### ***Theory-Based Approaches in the Twenty-first Century***

#### **CROSS-BATTERY ASSESSMENT APPROACH TO INTERPRETATION**

In the late 1990s, Dawn Flanagan, Kevin McGrew, and Vincent Ortiz introduced the Cross-Battery Assessment approach (XBA). They believed that the traditional "verbal" and "nonverbal" interpretative framework presented by Wechsler was ineffective in meeting the needs of contemporary theory and knowledge regarding intelligence and intelligence test batteries (Flanagan, McGrew, & Ortiz, 2000). Their review of volumes of theories and intelligence tests found that an integration of Horn-Cattell Gf-Gc theory (Horn, 1991, 1994) and the three-stratum level theory of cognitive abilities provided "the most comprehensive and empirically

supported model of the structure of intelligence currently available" (Flanagan & McGrew, 1997, p. 315). They also found that no single intelligence test battery successfully operationalized the *GfGc* theory or measured all major broad *GfGc* abilities. This integration of theories resulted in the XBA. Flanagan and her colleagues state that the XBA "narrows the gap between practice and cognitive science" (Flanagan & McGrew, 1997, p. 314) and provides assessment professionals with a more "valid and defensible way of deriving meaning from test scores than that provided by the traditional (and largely atheoretical) Wechsler Scale approach" (Flanagan, 2000, p. 295). Furthermore, the XBA is a method of systematically analyzing broad and narrow abilities as a "cluster" rather than by individual subtests, identifies cognitive strengths and weaknesses, aids in the understanding of the relationship between cognitive and academic constructs, and provides a framework to enhance communication between professionals. They also believe that until new test batteries are developed, it is essential that professionals utilize the XBA.

The XBA is based on three pillars—contemporary CHC theory, broad CHC ability classifications, and narrow CHC ability classifications. These pillars are utilized to increase the validity of intellectual assessment and interpretation. The first pillar uses the Cattell-Horn-Carroll theory, which is the most comprehensive and empirically supported model of cognitive abilities (Flanagan & McGrew, 1997). The CHC theory was previously described.

The second pillar of XBA is the CHC broad or Stratum II classifications of cognitive and achievement tests (e.g., *Gc* or crystallized intelligence). Flanagan and her colleagues analyzed all subtests from the major intelligence and achievement batteries and classified them according to particular CHC broad abilities or processes. Currently, there are over 500 broad and narrow abilities classifications (Flanagan, Ortiz, & Alfonso, 2007). Having knowledge of which tests measure what abilities helps the clinician "organize tests into...clusters that contain only the measures that are *relevant* to the construct of interest" (Flanagan, Ortiz, & Alfonso, 2007, p. 23). For example, measuring short-term memory/working memory (*Gsm-MW*) is assessed by subtests such as Wechsler's Arithmetic, the Kaufman Assessment Battery for Children's (KABC-II's) Word Order, and the Woodcock-Johnson Third Edition's (WJ-III's) Numbers Reversed (Flanagan et al., 2007).

The third pillar of XBA is the inclusion of the CHC narrow (Stratum I) classifications of cognitive

and achievement tests according to content, format, and task demand (e.g., language development, listening ability, etc.). Flanagan and her colleagues (2007) believed that this layer is necessary to further improve assessment and interpretation validity and to ensure that underlying constructs are represented. The authors provide examples of construct representation and construct underrepresentation. They believe that the latter occurs when the assessment is "too narrow and fails to include important dimensions or facets of a construct" (Flanagan, Ortiz, & Alfonso, 2007, p. 26). An example of construct underrepresentation is the Concept Formation subtest on the Woodcock-Johnson III Tests of Cognitive Abilities (WJ III) because it measures only one narrow ability of fluid intelligence (*Gf*). Therefore, according to Flanagan and her colleagues, at least one other measure of *Gf* is needed to ensure appropriate representation of the construct. A clinician would need to use the Analysis-Synthesis test in conjunction with the Concept Formation test. In contrast, an example of construct representation is the Verbal Comprehension Index (VCI) of the Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV; Wechsler, 2008), because this index includes Vocabulary, Similarities, and Information, all of which represent aspects of crystallized intelligence (*Gc*).

The guidelines, implementation, and stages of interpretation for this cross-battery approach are detailed and specific. The steps include the following:

- (1) Select a primary intelligence battery;
- (2) Identify the broad CHC abilities or processes measured by the primary battery;
- (3) Select tests to measure the narrow CHC abilities not measured by the primary battery;
- (4) Administer all tests;
- (5) Enter the data into the XBA computer program;
- (6) Follow the guidelines from the results of the program.

The Cross-Battery Assessment Data Management and Interpretive Assistant, a computer program, has been designed to assist the evaluator (Flanagan, Ortiz, & Alfonso, 2007). The latest resource on the clinical application of the XBA and on research studies conducted on the approach is an excellent chapter by Flanagan, Alfonso, and Ortiz (2012).

With any approach, there are strengths and weaknesses. Strengths of the cross-battery approach include its use of modern theory, improved

communication among professionals, is a way to evaluate children with specific learning disabilities and cultural language differences, gives professional flexibility, and has computer-programmed assistance. The XBA affords professional flexibility. The guidelines of the approach allow evaluators to glean different types of data specific to the purpose of the evaluation. In terms of modern theory, the XBA is based on “the most empirically supported and well-validated theory of the structure of cognitive abilities/processes, namely Cattell-Horn-Carroll (CHC) theory....By utilizing this theoretical paradigm, the XBA approach has the advantage of being current and in line with the best available scientific evidence on intelligence and cognitive abilities/ processes” (Flanagan, Ortiz, & Alfonso, 2007, p. 212). This modern theory, in turn, provides professionals with a classification system for clear, valid, and specific communication of an individual’s performance similar to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) for clinicians.

Along with professional flexibility, use of modern theory, and improved communication among professionals, the XBA offers a promising system to evaluate individuals with specific learning disabilities (SLD) and those who are culturally and linguistically different (CLD) (Flanagan, Ortiz, & Alfonso, 2007). The many different definitions, measures, and interpretation approaches to learning disabilities have led to difficulties in evaluating individuals with SLD. The authors of the XBA delineate four levels (with sublevels) that must be met for a definite diagnosis of SLD, as follows:

(1) At Level I-A, a normative deficit in academic functioning is required;

(2) Level I-B, confounding factors (such as insufficient instruction, emotional disturbance, medical conditions, etc.) are considered and determined not to be the primary cause of the academic deficit(s);

(3) Level II-A, a normative deficit in a cognitive ability/process is required;

(4) Level II-B, confounding factors (such as insufficient instruction, emotional disturbance, medical conditions, etc.) are considered and determined not to be the primary cause of either the academic or the cognitive deficit(s);

(5) Level III, underachievement is demonstrated by an empirical or logical relationship between the cognitive and academic deficit(s) and by evidence of otherwise normal functioning, such as mild mental retardation;

(6) Level IV, there must be evidence of deficits in activities of daily life that require the academic skill (Flanagan, Ortiz, & Alfonso, 2007).

In addition to its strengths, the XBA has potential weaknesses, including its norm sample, complexity, time-consuming aspect, and lack of a standardization framework. First, there is no internal norm group, making the validity of the approach questionable. The XBA authors reply to and address this issue in their book *Essentials of Cross Battery Assessment* (Flanagan, Ortiz, & Alfonso, 2007). They believe that the XBA did not need a norm group since the tools used in each battery are valid. In addition, the authors suggest that examiners use assessment tools that were normed within a few years of each other, which leads to greater chances of the norming samples’ being similar. A second weakness of the XBA is its complexity. This alleged weakness is seen as a strength by Flanagan and her colleagues. They believe that holding evaluators to a high standard of theory and interpretation is essential. In addition to norming issues and complexity, the XBA is seen as time-consuming. The approach requires more administration, scoring, and hypothesizing than traditional methods. Along with revisions to the approach, a computerized program has been developed to reduce the time required. Finally, when utilizing the XBA, subtests are given out of order or omitted, thus can be seen as violating standardized administration procedures.

Research on the XBA is less plentiful than the plethora of research studies on CHC theory. Researchers have been applying CHC approach to cognitive abilities for many years, and most notably, in relation to academic achievement, including reading, writing, and mathematics (e.g., Flanagan, 2000; Flanagan et al., 2012; Floyd, Keith, Taub, & McGrew, 2007; Floyd, McGrew, & Evans, 2008; Schneider & McGrew, 2012; Taub, Floyd, Keith, & McGrew, 2008). Floyd and his colleagues (2008) investigated the contributions of CHC cognitive abilities to explaining writing achievement. Their participants included the norming sample used for the WJ-III Tests of Cognitive Abilities (Woodcock, McGrew, Mather, 2001b). From a simultaneous multiple regression, the researchers were able to determine that comprehension-knowledge, processing speed, short-term memory, long-term memory, auditory processing and phonemic awareness, and fluid reasoning demonstrated moderate to strong effects on writing achievement (basic skills and written expression).

Flanagan (2000) investigated the validity of CHC approach with elementary school students. Her sample included 166 students from the Woodcock-Johnson Psycho-Educational Battery-Revised (WJ-R; Woodcock & Johnson, 1989) technical manual. These children were given the WJ-R Tests of Cognitive Ability (Extended battery) and Achievement, as well as the Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler, 1974). Structural equation modeling was used. Findings demonstrated that the *g* factor underlying the Wechsler-based CHC cross-battery model “accounted for substantially more variance in reading achievement (25%) than the *g* factor underlying the atheoretical Verbal Comprehension-Perceptual Organization-Freedom from Distractibility (VC-PO-FD) Wechsler model” (Flanagan, 2000, p. 295). Results indicated that a Wechsler-based CHC cross-battery approach is “an effective way of ensuring valid representation of multiple cognitive abilities, especially those that have been found to affect significantly the development of reading skills” (Flanagan, 2000, p. 296).

#### NAGLIERI-DAS PASS APPROACH

Another contemporary and sound theory in test interpretation is the Naglieri-Das PASS approach. In the late 1970s, J. P. Das linked Luria’s work to the field of intelligence by suggesting that intelligence be seen as a cognitive construct (Naglieri, 1997). According to Luria, cognitive processing occurred in three separate, but necessary units: 1) regulating of cortical tone and maintenance of attention; 2) receiving, processing, and storing of information; and 3) programming, regulating, and directing mental activity (Das, Naglieri, & Kirby, 1994). Das then described this relationship in terms of the information integration model (Das, Kirby, & Jarman, 1979). Later, Jack Naglieri and Das collaborated to develop the PASS (Planning, Attention, and Simultaneous and Successive processing) theory of cognitive processing. They believed in the importance of Luria’s theory, but “focused more on the cognitive processing components rather than their specific neurological locations” (Das, Kirby, & Jarman, 1979). According to this approach, intelligence has three processes—attentional (cognitive activity), informational (simultaneous and successive), and planning.

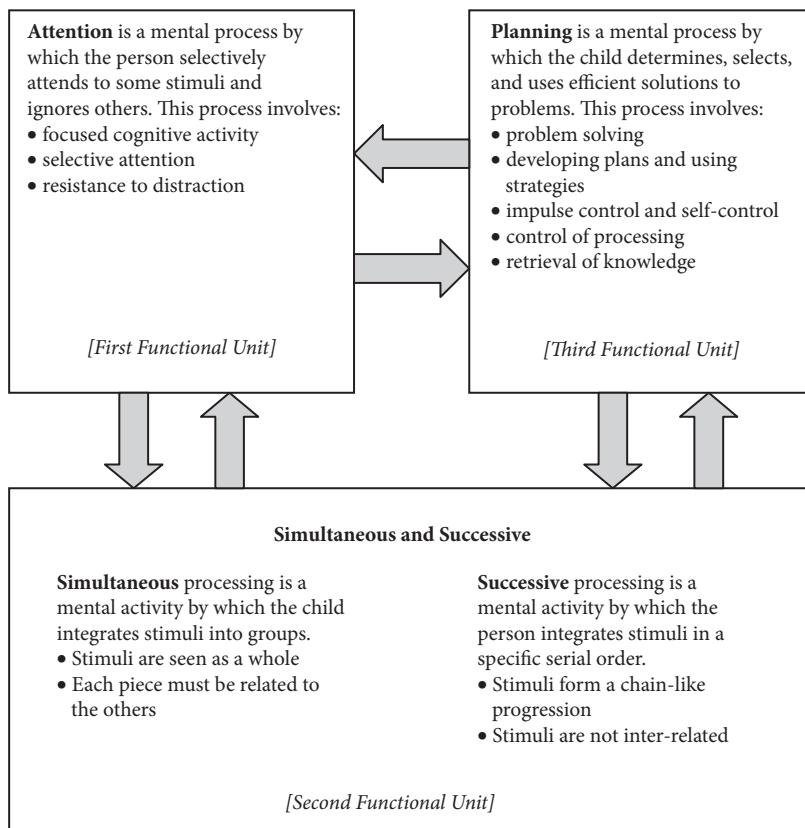

The first process examined by the theory is attention, which is located in the brainstem and lower cortex (Kirby & Das, 1990). This process allows a person to “respond to a particular stimulus and

inhibit responding to competing stimuli” (Naglieri, 1997, p. 249). The major forms of attention include arousal and selective attention. For Das and Naglieri, selective attention was of more interest than arousal, as arousal is assumed. According to the theory, *attention* refers to “specifically directed cognitive activity as well as resistance to the distraction of the competing stimuli” (Naglieri, 1997, p. 250) and is determined by both arousal and planning (Kirby & Das, 1990). Attention and arousal have been linked to task performance, which influences the informational and planning processes (Kirby & Das, 1990).

The information processes include simultaneous and successive processing, which typically operate collaboratively (Kirby & Das, 1990). The major difference is that simultaneous processing allows for “the integration of stimuli into groups where each component of the stimulus array must be interrelated to every other,” and successive planning allows for “the integration of stimuli that are serial-ordered and form a chainlike progression” (Naglieri, 1997, p. 250). In essence, with successive processing, the stimuli are not interrelated; rather, each stimulus is related only to the one it follows. Information that is processed simultaneously is said to be “surveyable,” because the stimuli are related and can be examined either during the activity (such as copying a design) or through recall (reproducing the design from memory) (Naglieri & Sloutsky, 1995). Simultaneous processing takes place when stimuli are perceived, remembered, or conceptualized and, thus, applied during both verbal and nonverbal tasks. Successive processing is tied to skilled movements, such as writing, because the specific skill requires a series of movements that are in a specific order (Naglieri, 1997; Naglieri & Sloutsky, 1995).

According to the theory, the planning processes use attention and information processes along with knowledge to help an individual identify and utilize the most effective solution(s) to a problem(s). This system is believed to be located in the prefrontal areas of the brain (Kirby & Das, 1990) and includes abilities such as developing a plan of action, evaluating the plan’s effectiveness, impulse control, regulation of voluntary actions, and speech (Naglieri, 1997). It is the *how* of the system; how to solve problems.

The PASS processes form a “functional system that has interrelated interdependent components that are closely related to the base of knowledge, and developmental in nature and influenced by the cultural experiences of the individual” (Naglieri &

**Figure 1.2 The Cognitive Processes of PASS Theory.** The PASS processes are dynamic in nature and form an interrelated, interdependent system (as noted by the arrows in the figure).

Sloutsky, 1995, p. 14). The system is interactive; all components work together to perform nearly all of our everyday life tasks. It provides an understanding of cognitive activities (i.e., how individuals learn, think, and/or solve problems). The figure below (Fig. 1.2) describes how the system functions.

Researchers have investigated the use of the PASS theory in evaluating learning disorders, attention deficit/hyperactivity disorder, and mental retardation (e.g., Das, 2002; Kirby & Das, 1990; Kroesbergen, Van Luit, & Naglieri, 2003; Naglieri, 1997, 2001; Naglieri, Das, & Goldstein, 2012; Naglieri & Otero, 2012; Naglieri, Salter, & Edwards, 2004). Naglieri and his colleagues (2004) assessed the PASS characteristics of children with attention and reading disabilities. One hundred and eleven children were administered the Cognitive Assessment System (CAS; Naglieri & Das, 1997a). Results indicated that the children with attention disabilities scored lower on the Planning scale than children in regular education. Children with reading disabilities scored lower on the Successive scale than children in regular education and children with

attention disabilities. These children also scored lower on the Simultaneous scale than children in regular education. Das (2002) linked dyslexia with successive-processing deficits. He found that individuals with this specific reading disability make “phonological errors while reading real or made-up words or are slow in reading them (i.e., are slow decoders), or are both slow and inaccurate.” (Das, 2002, pp. 31–32).

## Conclusions

Psychological assessment involves a synthesis of the information gathered from several resources to understand or make statements regarding an individual’s diagnosis, level of functioning or disability, and strategies for intervention or treatment. The history of assessment has its roots in many cultures, dating back to 2200 b.c. Each country focused on different aspects of understanding intelligence and developing measures to assess intelligence. Assessment abounds with many different theories, adaptations, and methods for interpretation that continue to change.

This chapter has explored the role of theory in psychological assessment, which is two-pronged—theory in test development and theory in test interpretation. Theoretically based test development and interpretation provides a strong framework for valid psychological assessments. In terms of test development, the KABC-II, SB5, CAS, WJ III COG, and DAS-II are all valid and reliable testing tools. We believe that the most valid and reliable contemporary methods of test interpretation include the Cross Battery Assessment approach (XBA; Flanagan et al., 1997; Flanagan et al., 2012) and the Planning, Attention-Arousal, Simultaneous, and Success (PASS) model of processing (Naglieri & Das, 1994; Naglieri et al., 2012). We encourage and challenge researchers and practitioners alike to continue developing tests and methods of interpretation based on theory, and to rely on the diverse theory-based instruments for the assessment of children, adolescents, and adults just as they continue to rely on Wechsler's scales (Flanagan & Kaufman, 2009; Lichtenberger & Kaufman, 2013).

# Testing: The Measurement and Assessment Link

Scott L. Decker

## Abstract

This chapter broadly reviews measurement theory, scale development, testing, and assessment. The chapter is divided into two broad areas to represent distinct phases of testing involving test development and test application. A model is provided to illustrate the integrated role of testing with measurement and assessment components. Theories of measurement are reviewed with the use of the Item Response Theory, not only for the purpose of objective measurement, but as a basic model to analyze how personal attributes interact with test stimuli. Interpretive phases of tests within an assessment process are described, which include decision-making, prescriptive action, and social outcomes.

**Key Words:** psychological testing, measurement, item response theory, decision-making

## Introduction

Measurement theory, scale development, testing, and assessment are all important contributors to test development and test application. Despite the detailed research in each of these areas, there are few models which focus on the integration and inter-relationship across these components. The model described in this chapter is used to illustrate the integrated role of testing with measurement and assessment components. Furthermore, measurement theories are discussed to illustrate the importance of objective in the analysis of how personal attributes interact with test stimuli. Extensions of the model to the interpretive phases of tests within an assessment process are also described.

The chapter is divided into two conceptual sections: (a) pre-application or development stage of testing, and (b) the application stage of testing. During the test development stage, theory and measurement are used for the purpose of understanding the test (i.e., developing construct validity). During the application stage, the test is used to understand the object it

was designed to measure. The purpose of dividing the chapter into these two sections is to provide a better integration of the numerous components in assessment, which include aspects of theory, measurement, measurement models, testing, decision-making, diagnosis, and prescriptive action. Additionally, these two sections coincide with contemporary categories of validity (Embretson, 1983). These concepts form a layer of interconnected concepts. For example, testing depends on measurement, which includes scaling, which in turn depends on the theoretical basis of a construct. *Assessment* is the integration of multiple sources of information for the purpose of making a judgement that leads to a prescriptive action. A *test*, or testing, is a device used to measure behavior which provides information in the assessment process. Measurement theory provides a critical foundation for constructing tests as measurement tools. Test interpretation is a part of a decision-making process in which some action, such as an intervention, is to be implemented. Interventions influence outcomes which are evaluated by social goals and values.

## Fundamental Issues in Testing

Psychology is replete with conceptual ideas of the inner workings of mental phenomena and postulated causes of behavior. Lacking, however, is the objective measurement of many of these theories and constructs. As a result, paradigms in psychology wax and wane. Often, the constructs of one theory rename the constructs of another theory. Few theories, however, provide objective measures by which to test the theoretical propositions of the theory. Stated differently, few objective measures exist to test the theoretical propositions of most psychological theories. As such, measurement has been described as the “Achilles’ heel” of psychological research (Pedhazur & Schmelkin, 1991).

Like in psychology in general, there is disagreement within the specific area of psychological measurement. Measurement models differ in Classical Test Theory from Item Response Theory (to be addressed later). Debate on the role of measurement scale of a test to permissible use of statistical procedures has raged for almost half a century (J. Stevens, 1996). As an additional confounding influence, different researchers use different terminology to describe similar aspects of testing. Terms such as “assessment instruments” are used, although some view assessment and testing as very different. Are “instruments” and “tests” equivalent? Similarly, the definition of “measurement model” and “measurement scale” are used interchangeably.

An additional difficulty in discussing testing, measurement, or assessment is that all of these topics are interrelated. This leads to an extraordinary complexity involved with each of these topics. As a possible consequence, these topics are often extensively written about, but in isolation and disconnected from the other topics. Similarly, many standard assessment textbooks provide adequate coverage on each of these topics but often do not provide an integration of the different components. Often, extensive psychometric evidence for the tests is provided, but applications of the test are dismissed and the test user is left to figure out how to appropriately apply the test, using “clinical judgement” (Kamphaus & Campbell, 2006; Sattler, 2001). Because the ultimate application for test usage has been left unspecified, this may have partially contributed to a growing dissatisfaction with the use of norm-referenced testing. As a result, context-based methods of testing that attempt to more directly link assessment from a specific context (e.g., functional behavior analysis, curriculum-based assessment, portfolio assessment) have grown in popularity,

although they have substantially less psychometric rigor.

## Foundations of Testing: Measurement

The foundation of testing is measurement. One important historical root of measurement in the behavioral sciences can be traced to Krantz, Luce, Suppes, and Tversky’s (1971) *Foundations of Measurement*. The three-volume set provided the basis for what has become known as the *representational theory of measurement* (Krantz, Luce, Suppes, & Tversky, 1971). In representational theory, measurement involves understanding an empirical observation that can be recoded in terms of mathematical structures (Luce & Suppes, 2001). Simplifying, “measurement” includes an object of measurement or the measurement of an object attribute. Object attributes, presumed to vary across different objects, can be coded, or represented, with different numerical values. The initial coding of empirical phenomena with numerals is qualitative. The abstraction of the phenomenon into numerals that are used as numbers in a number system that has quantitative properties is the basis of measurement. Significant debate in this fundamental step has long been a characteristic in the history of measurement. Using physical sciences as a model and reserving measurement for what we now would consider interval and ratio scales, Campbell (1920) insisted that all measurement must satisfy certain properties such as concatenation or additivity. Because psychological measurement rarely demonstrated such properties, Campbell concluded psychology could not be considered a science (Campbell, 1920).

This influenced the development of formal definitions of scaling. Stevens’s definition of measurement as “the assignment of numbers to aspects of objects or events according to one or another rule or convention” is perhaps the most popular definition of measurement (Stevens, 1968, p. 850). Stevens’s scaling is the assignment of numbers to a sample of behavior along a dimension characterized by some unit of metric. Stevens suggested four types of metrics that continue to be popular: *nominal*, *ordinal*, *interval*, and *ratio* (Stevens, 1946). Given their ubiquity in psychology, they will only be discussed briefly. *Nominal* amounts to naming or classify objects or persons into one or more categories. In nominal measurement of attributes, an attribute is either present or not. *Ordinal* involves the detection of an attribution and the rank ordering of the attribution. That is, object can be rank

ordered (high to low) by the number assignment to the attribute. *Interval* measurement entails not only rank ordering but the “amount” or quantity of difference, with constant or equal amounts between number assignments. Finally, *ratio* includes interval properties but also includes a true “zero” point for the absence of the attribute. Weight and height are two examples of ratio measures, and the widespread use of these measures and being ratio is not coincidental. For a more exhaustive review, see Pedhazur and Schmelkin, 1991.

Various aspects of these early conceptual models of measurement in behavioral science have continued to be debated for over half a century (Gaito, 1980; Guttman, 1977; Lord, 1946; Michell, 1986). However, Stevens's influence on the definition of measurement can clearly be seen in modern conceptualizations of measurement. Townsend and Ashby (1984) described measurement as a process of assigning numbers to objects in such a way that interesting qualitative empirical relations among the objects are reflected in the numbers as well as in the properties of the number system (Townsend & Ashby, 1984), or similarly to objects of measurement (Reynolds, 1986). Additionally, many modern approaches have sided with Stevens by including classification (nominal) and ranking (ordinal) as types of measurement (Pedhazur & Schmelkin, 1991).

Furthermore, various other methods of measurement have been described, but most capture concepts similar to those described in the Representational Theory of Measurement. For example, some have made a distinction between a *natural variable* and a *scaled variable* (Krantz et al., 1971). A natural variable is a variable that is defined by using the actual objects of interest that does not depend on abstract symbols such as numbers, on which scaled variables do depend (Reckase, 2000). Natural variables are directly observable from the objects of interest, whereas scaled variables are not. Natural variables can be conceptualized as detectable from direct observation and are discrete in that the observed event can be classified or be distinguished from other events or the absence of the event. For example, an observable event must be detected such that a determination of whether it is present/absent, or yes/no, can be made, or different gradations can be determined. Scaled variables are a conversion of these observable events into a metric of measurement by some rule. The scaled variable can be a raw score or a raw score corrected for a subject's developmental age.

## Applications of Psychometric Models in Measurement

Psychological theory describes the attributes of the object of measurement, the different values an attribute may have, and a causative explanation for differences in values across objects. Often in psychology the object of measurement is a person. The attributes that are of interest are behavior and mental processes that influence behavior. The attributes that are measured are dictated by theory. Similarly, the types of prompts or questions used in testing are dictated by theory. Different theories have different types of emphasis for different attributes. A *construct* is defined as the concept or characteristic that a test is designed to measure. Because constructs are unobservable, different lines of valid evidence are needed to provide information relevant to a specific interpretation of test scores. Furthermore, validity is generally the degree to which evidence and theory support the interpretation of test scores and is considered the most fundamental factor in evaluating a test (American Educational Research Association (AERA), American Psychological Association (APA), & National Council on Measurement in Education (NCME), 1999).

Measurement theory provides only an abstraction of attributes, whereas theory describes attributes in detail. Additionally, measurement describes the process of quantifying attribute values but does not describe what values should be quantified. The meaning of the number may differ by the type of number used to represent the attribute. For example, people share physical attributes (e.g., height, weight) but differ in the values of these attributes (100 lbs, 200 lbs).

*Scale* is a term used to describe the transformation of behavioral performance, typically in response to questions, into numbers and how to present the questions in order to get the best measurement. Formally, *scale* is the set of rules that are used to assign a number to an attribute (Thorndike, 2005). A familiar scale of measurement for the attribute of length in physical objects is the assignment of inches (the basic measurement unit) from a ruler or tape measure. Another common metric is temperature, which may use either Fahrenheit or Celsius measurement units.

Scaling in behavioral measurement is “messier” than in the physical sciences, or, one might say, it involves a larger degree of error. Scaling in psychology typically involves the assignment of numbers to behavioral responses. The behavioral responses are typically from predetermined stimuli with set rules for assigning numbers. Examples of such scaling are eliciting responses that can be scored as correct or incorrect, and adding the number of correct

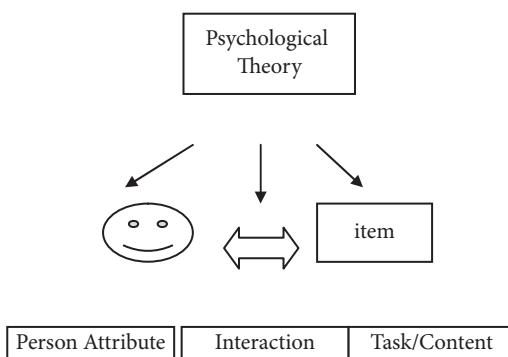

responses to get an overall score for a set of items. Scaling may also involve a set of rules to transform the raw score into another measurement scale, such as normative score (percentile, standard, or normalized).

In scaling behavioral measurements, there are different frames of references, or measurement models, that can be used. The two main paradigms are *random sampling theory* and *item response theory* (Suen, 1990), although this is sometimes referred to as *classical test theory* or *item response theory* (Embretson & Reise, 2000). Random sampling theory, which involves both classical test theory and generalizability theory, is based on a true score model. The premise is in any testing situation no person can be exposed to all the possible items within a construct domain. Therefore, the limited sample of items provides an *observed score*, which is viewed as an approximation to a *true score*. These psychometric models essentially address the problem of how to generalize from a sample to a larger population. Classical test theory has been the dominate paradigm until recently. Classic test theory has numerous limitations. Some of the most important involve estimating item difficulties, sample-dependent statistics, single reliability estimates, and problems in comparing scores across similar tests.

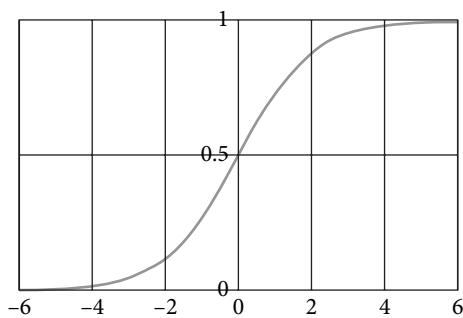

Due to these and other limitations in classical test theory, item response theory (IRT) has become the most frequently used psychometric paradigm, especially in test development. IRT is a type of latent trait model that presumes a unitary dimension to describe the attribute that is being measured. A benefit to IRT models is that the model scales behavioral responses based on the joint interaction of a person's ability with the item difficulty (Figure 2.1). The basic idea is that when a person's ability is greater than the item difficulty, then the person has a higher probability

of correctly answering the item. Conversely, when the item difficulty is greater than the person's ability, the person should incorrectly answer the item. When the item difficulty and the person's ability are equally matched, there is a 50/50 chance of getting the item correct. This basic relationship is modeled with a logistical curve (Figure 2.2).

Model-based measurement in IRT is fundamentally different from classical test theory. Similar to the measurement of physical objects, one does not need to invent a new "ruler" for every object investigated. Instead, the ruler or tape measure is used as an existing model. Item response models work on a similar premise. Although IRT models differ in the number of parameters used in the model, only the Rasch (one-parameter) model will be described here. There are also two- and three-parameter models that include parameters for item discrimination and guessing. These models are not presented, because they are extensions of the basic Rasch model, and some have argued the adding these additional parameters compromises aspects of objective measurement (Wright & Stone, 1979). The Rasch model describes the outcome of a person's ability interacting with a stimulus (item) with some difficulty that results in a binary outcome, such as pass/fail, correct/incorrect, etc. The underlying model is a logistics curve that models success and failure based on a person's ability and an item's difficulty. Unlike in classical test theory, the values for the item difficulties are not sample-dependent, just as the units of measurement do not change on a ruler based on the object being measured. The probabilistic outcome is a function of the difference in the person's ability (B) and the difficulty of the item (D). Rasch (1960) described the specific ordinal relationship to describe probabilities of a test simply as "a person having a greater ability than

**Figure 2.1** Schematic of theory in specifying person by task interaction.

**Figure 2.2** Logistical curve of ability with probability of response.

another person should have the greater probability of solving any item of the type in question (p. 117). Formally, when  $B = D$ , the probability of a correct response is 50/50. When  $B > D$ , the probability of a correct response increases from .5, and decreases when  $B < D$ . Formally, the probability of a correct answer is given in the following equation:

$$P(x = 1) = e^{(B-D)} / 1 + e^{(B-D)}$$

where  $e$  is the natural log function (2.7183) which is raised to the difference in the person's ability ( $B$ ) and the item difficulty ( $D$ ). The resulting units of measurement are described as *logits*, which are typically set to the arbitrary value of 0 as the mean. Suppose someone with a logit ability of 3 completed a spelling item that was calibrated to have a difficulty of 1. Using equation 1, the probability of correctly answering the item can be determined as:

$$P(1) = 2.7182^{(3-1)} / 1 + 2.7182^{(3-1)} = .88$$

Similarly, if a person with a logit ability of 3 interacted with an item calibrated with a difficulty of 4, obviously, the probability of success would be much less than in the previous example; and more specifically:

$$P(1) = 2.7182^{(3-4)} / 2.7182^{(3-4)} = .27$$

The relationship of different ability–difficulty differences can be viewed in Table 2.1. Object measurement is the repetition of a measuring unit and describes a constancy in measurement not dependent on the sample or measurement instrument. Notice from Table 2.1, the probability of success is the same for the same differences in measurement

**Table 2.1 Probability Outcomes Based on Person Ability and Item Difficulty**

B-D	P(x = 1)
3.0	.95
2.0	.88
1.0	.73
0.0	.50
-1.0	.27
-2.0	.12
-3.0	.05

regardless of the value of the measurement. For example, there is a probability of .73 regardless of whether the person's ability/item difference is 3-2, or 2-1, or -1-(-2).

Although conjoint measurement, which enables equal interval scaling (Stevens, 1946), technically includes Weak Order, Independence, Double Cancellation, Solvability, and Archimedean Condition (Kyngdon, 2008), the Rasch model's fulfillment of these properties, or approximate fulfillment, has led many to conclude it is the only measurement model in psychology that provides interval scaling (Andrich, 1988; Bond & Fox, 2001; Embretson, 1999; Embretson & Reise, 2000; Woodcock, McGrew, & Mather, 2001; Wright & Stone, 1979). Some disagree with these claims since there is still difficulty in verifying the equal interval nature of the actual underlying psychological or causal process of behavioral responses (Kyngdon, 2008). Additionally, some have argued IRT metrics are still arbitrary until observed scores, no matter the form, are mapped onto meaningful behaviors (Blanton & Jaccard, 2006). Regardless, such probabilistic features that are not sample-dependent represent a substantial improvement in psychometric measurement from that of its historic predecessor, classical test theory (Embretson, 2006).

This transformation of test values that provide indicators of behavior to a measurement scale is the quintessential distinction in testing as the “use of an instrument” from testing as “measurement.” The degree to which a test adequately “measures” a construct, rather than provides an arbitrary representation, is directly related to the degree to which valid inferences can be made on the change in amount of a construct. Thus, the issue of understanding the measured representation of psychological constructs is not just a technical issue relevant for quantitative psychologists, but is the foundation in which all concepts in psychology that involve constructs, which is the nearly the whole of psychology. In practice, items calibrated with the Rasch model are selected to have different difficulties that adequately cover the range of ability. The scale with selected items is then used for practical applications.

Psychological measurement, which involves both psychological theory and measurement, will continue to evolve. As demonstrated by measurement models, psychology will always involve the analysis of a person–item interaction, where the item may be an item or some other contextual variable identified or derived by psychological theory. Although far from perfect, the foundations of measurement

with representational theory of measurement and the application of measurement models as used in IRT probably represent the pinnacle, or near pinnacle, of measurement in the behavioral sciences. It is difficult to imagine what new purely measurement developments could occur that would fundamentally change psychological measurement beyond that provided by IRT models.

## Testing

Keeping the complex nature of measurement in mind, testing can now be more directly addressed. A *test* is an evaluative device used to sample an examinee's behavior in a specified domain that is scored using a standardized process (AERA et al., 1999). The objective of testing is to describe a characteristic of a subject as a numerical score to represent the quantity of the characteristic (Suen, 1990). Objects of measurement are psychological constructs. When used in assessment, tests are used to obtain information and reduce uncertainty (McFall & Townsend, 1998).

Although a test can be simply defined as a device for scoring behavior, the intricacies in this process are complex. A test is the assembly of stimuli that elicit behavioral responses from a test taker in which behavioral responses are numerically coded. The stimuli are typically calibrated, or ordered by difficulty, to form a scale that measures an attribute of an object (i.e., personal characteristic). The selection of the test stimuli or content is theoretically based. Additionally, a test provides information on the status of an attribute by recording some observable event or behavior. Linking recorded observations from the test to a measurement unit is an aspect of scaling.

Testing, as a component of psychological assessment, typically provides a measurement of a person's attribute (i.e., mental process). Multiple tests are used to measure different attributes to provide a comprehensive assessment to assist in the assessment decision-making process.

Behavioral responses are scaled by recording behaviors, usually with a predetermined response format, representative of the construct. Constructs have a dimension; that is, higher or lower amounts of a construct. The dimension represents the range of values to describe individual differences in attribute values across different objects. Objects are multidimensional (i.e., multi-characteristics) but are typically measured by unidimensional tests. Different attribute levels, as indicated by score values, are then examined or correlated with other attribute values

from different constructs as well as with important outcomes or events. For example, intelligence tests measure intelligence by combining multiple subtests measuring some theoretical attribute of intelligence. Scores are corrected for age-related variance and converted to a scale of a mean of 100 and a standard deviation of 15. The differences in levels of intelligence across different people result in a distribution, typically normal or Gaussian, across the measurement scale. Correlational methods can investigate the relationship of variations in intelligence with variations in other variables such as personality and academic achievement. The question as to whether intelligence can be represented by a single variable, and the nature of that single variable, is not an issue of measurement. Rather, this is an issue of theory and validity. Similarly, the accuracy and stability of assigning numbers to represent differences in attributes is an issue of reliability, which influences measurement but is not measurement.

## Testing in Assessment

At the time of writing this chapter, the Supreme Court of the United States made a decision in which testing was at the center of the lawsuit. In the *Ricci v. DeStefano* case (decision made in June, 2009), 20 firefighters sued the city of New Haven, Connecticut, alleging that they were discriminated against. Firefighters promotions were determined based on a test, but the test scores resulted in perceived disproportionate number of promotions of white firefighters. As a result, the test was declared invalid, and the results were discarded for fear of a lawsuit by the non-white firefighters. However, discarding the result of the test was also viewed as discrimination—against the white firefighters (and one Hispanic firefighter), and resulted in a lawsuit. Ultimately, the Supreme Court ruled that the city should not have thrown out the exam, arguing that by doing so, the city was using race as a criterion for promotion, which violated Title VII of Civil Rights Act of 1964, in which employment decisions cannot be made based on race.

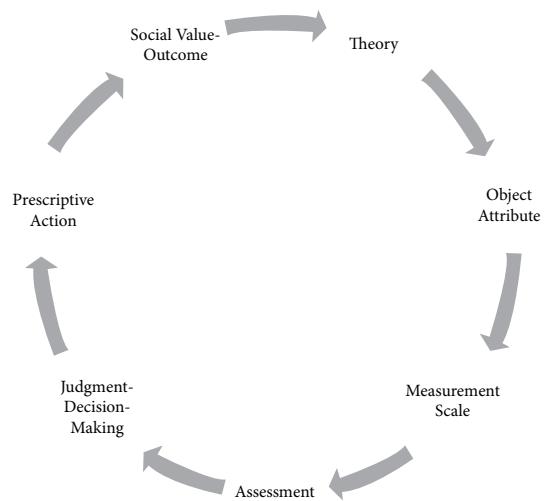

The point of mentioning this Supreme Court case is not to state an opinion on the verdict or address the issue of test bias (see Reynolds, Lowe, & Saenz, 1999, for more on test bias). The point here is to simply illustrate the complex and numerous layers of meaning involved in testing, which extends beyond just a device for measuring. Tests are always developed and administered for some purpose. The purpose is usually driven by some social need (e.g., promotion, intervention, or classification).

In each situation, judgement is required based on a decision-making process. The judgement then results in some action that satisfies the social need. Furthermore, social benefit, or perceptions of social benefit, may influence not just assessment but test development. In the New Haven firefighters' case, the city officials were required to make a judgement, first on test scores and then on the permissible use of test scores, which influenced social outcomes. As such, judgement and decision-making, as well as the resulting actions and the outcomes of those actions, are important components in assessment and provide an important link between theory, measurement, testing, assessment, and social outcomes.

Figure 2.3 depicts the integrative influence in the relationship between testing, measurement and assessment. As the role of theory, measurement, measurement scale, and assessment have been discussed previously in this chapter, the remainder of the chapter will cover *judgement*, *prescriptive action*, and *social outcome*. Although clinical judgement research is readily available, the process of translating a judgement into some action is not. Often, the action taken is more contextually derived and is difficult to determine in the abstract. Similarly, social outcomes are important but rely upon some action, which in turn relies upon judgement and assessment. In most treatment utility paradigms, assessment and decision-making are taken for granted and not represented in the models. Often such research demonstrates the utility of a behavioral intervention using a single-subject design and concludes that the change in baseline during the intervention did not require any sophisticated cognitive or personality tests. Not included, but important within an applied context, is "why," or the justification, an intervention was deemed to be needed and "why" the particular intervention was chosen. Such processes in behavioral research have remained covert mental processes of the experimenters.

Figure 2.3 represents a cyclical process that suggests that the major components of measurement, testing, and assessment are interrelated. Testing, in development or application, is interconnected to theory, measurement, and social values and consequences.

Not intended to be a unitary model of construct validity, the present model intended to (1) emphasize the sequential relationship of key stages in the application of tests in an assessment process, and (2) to emphasize the interrelatedness of these key stages. The Nomological Network (Messick, 1995) model consists of distributed but connected

**Figure 2.3** Sequential cycle of measurement, testing, and assessment.

nodes. Although this is accurate, it may not capture the sequential nature of the assessment process nor the sequential process of measurement or decision-making and how they are interconnected. Theory guides scale development, which influences what measures are used in a particular assessment. Similarly, judgements are the result of an assessment process and lead to an action that is "theoretically" believed to have a desirable social outcome; thus social value and theory are connected. Thus, the end of the chain of reasoning in testing loops back to the beginning in that it influences the actual design of the test. This is also partially idealized. For example, test development typically starts and ends with the accuracy in measuring a construct. As suggested by Figure 2.3, test development may also benefit by starting with (1) what is the social value of measuring a particular attribute, (2) what action or intervention can be taken based on information about an attribute, or (3) how can decisions be made based on a measurement of an attribute. Here, test development begins with the end in mind.

## Assessment

*Assessment* is a broader term than *testing* that involves the integration of test information with other sources of information (AERA et al., 1999). Assessment is a framework for constructing a unified meaning from various sources of information. Assessment goes beyond test scores and involves a multi-step and multidimensional evaluation of an individual.

Assessment marks the point at which a test, constructed via the methodology previously presented, is used as a tool of investigation rather than being the focus of the investigation. Assessment is:

concerned with the clinician who takes a variety of test scores, generally obtained from multiple test methods, and considers the data in the context of history, referral information, and observed behavior to understand the person being evaluated, to answer the referral questions, and then to communicate findings to the patient, his or her significant others, and referral sources. (Meyer et al., 2001, p. 143)

Because contextualized decision-making is required, assessment is not a completely objective process. As Matarazzo (1990) described in his APA presidential speech, assessment is “a highly complex operation that involves extracting diagnostic meaning from an individual’s personal history and objectively recorded tests scores...it is the activity of a licensed professional, an artisan familiar with the accumulated findings of his or her young science....” (p. 1000).

Assessment is often described in multiple stages. Sattler (2008) described assessment as an 11-step process that includes collecting data from multiple sources that include both formal testing procedures as well as observations, and clinical judgement. McFall and Townsend (1998) described assessment as consisting of eight layers that integrated various aspects involved in assessment. Layer 1 consisted of postulates, which were assumptions, beliefs, or values. Layer 2 was a formal theoretical model. Layer 3 was described as referents or observable instantiations, Layer 4 was instrument methods; followed by Layer 5 of measurement model; Layer 6, data reduction; Layer 7, data analysis; and Layer 8, interpretation and inference. A loop connects Layer 8 with Layer 2 to demonstrate the influence of inferences on the questions that gave rise to the assessment process (McFall & Townsend, 1998). According to McFall and Townsend (1998) the purpose of assessment was one of obtaining information and reducing uncertainty.

Most models of assessment generally describe the process of transforming test data into usable information as part of “test interpretation.” Sattler notes that test interpretation is the most challenging step in the assessment process, and it involves integrating assessment data, making judgements, and exploring implications (Sattler, 2008). Interpretation of test scores to provide meaningful information is central in the assessment process. Blanton and Jaccard

(2006) indicated meaning from test scores “must be established through research that links specific scores to the observable events that are relevant to the underlying psychological dimension of interest” (Blanton & Jaccard, 2006, p. 33). Similarly, scaled scores are believed to aid interpretation by indicating how a given score compares to those of other test takers (AERA et al., 1999). Procedural, objective, algorithmic methods for deriving “meaning” from test scores are generally not recommended because of the complexities involved with assessment, which include linking validity studies to a contextual purpose.

Interpretation of test scores is connected to the validity evidence for a test. According to the Standards, “Test scores ideally are interpreted in light of the available normative data, the psychometric properties of the test, the temporal stability of the constructs being measured, and the effect of moderator variables and demographic characteristics” (AERA et al., 1999, p. 121). Tests are valid to the degree in which evidence supports inferences from the test. The evidence to support inferences is based on validity evidence; thus test validity is central to test interpretation. *Validity* refers to the degree that evidence and theory support the interpretations of test scores (AERA et al., 1999).

Models of test validity have evolved over time to more accurately represent the nuances of process involved in the application of tests in assessment. Traditional validity research amounted to obtaining evidence that the test was measuring what it was suppose to measure (Campbell & Fiske, 1959). Here, construct validity was the central focus and obtained primarily by evidence of a test’s correlation with other tests with a similar label, and no, or lower, correlations with tests having a different label. Construct validity has been traditionally viewed as empirically established after the test was constructed (Cronbach & Meehl, 1955). The “meaning” of test scores was determined by their relation with other variables, which formed what was termed a “nomological network.” Similarly, the nomological network model of validity attempted to expand construct validity to incorporate other aspects of the assessment process (Cronbach & Meehl, 1955). This view was criticized at its inception as confusing “meaning” with “significance” (Bechtoldt, 1959). Over time, the validity concept has become “encrusted with additional meanings” and is likely to require revisions (Schwager, 1991).

Additionally, nomological networks have been difficult to define (Cronbach, 1988). Embretson (1985)

attempted to provide clarification by distinguishing construct representation from nomothetic span. *Construct representation* involves evidence to understand the processes, strategies, and knowledge that persons use to respond to test items and how these behaviors are represented by test scores. *Nomothetic span* is the evidence to support how individual differences as represented by test scores are related to external variables and the utility of those relationships. Different researchers promote different types of validity and use different terminology. For example, *nomological span* (Embretson, 1983) is synonymous with *external validity* (Cook & Campbell, 1979), which in turn is referred to as a *nomological network* (Messick, 1995), which creates additional problems for relating validity evidence to test interpretation.

Such criteria attempt to bridge the gap in assessment between using tests in data collection and making inferences leading to judgement with tests. Additionally, such criteria imply published validity on a test will make the connection for the clinician. Unfortunately, published research on most psychological tests does not provide such guidance.

In an attempt to focus less on the mechanical issues of construct validity, Messick (1980) has attempted to better address the connection between test "interpretation" and the social consequences of tests. Messick unification is described in the following diagram:

Other researchers have begun to de-emphasize construct validity, which has traditionally been viewed as the core pillar of assessment, and placed more emphasis on the social consequences aspect. The focus on social outcomes as the credentialing criteria of usefulness has been termed *treatment utility*. Treatment utility is "the degree to which assessment is shown to contribute to beneficial treatment outcome" (Hayes, Nelson, & Jarrett, 1987, p. 963). This functional approach would argue the only utility of testing is the degree to which it is associated with change in some valued social outcome. This

**Table 2.2 Messick's View of the Interaction of Test Interpretation with Prescriptive Action and Social Outcome Variables**

	Test Interpretation	Test Use
Evidential basis	Construct validity (CV)	CV + relevance/utility (R/U)
Consequential basis	CV + value implications (VI)	CV + R/U + VI + social consequences

Adapted from Messick, 1980.

approach places "treatment validity" at the core of validity (Fuchs, Fuchs, & Speece, 2002) and has led some to suggest norm-referenced tests should be discontinued due to a lack of treatment validity (Gresham, 2002; Reschly & Grimes, 2002).

Contemporary models of validity are therefore fragmentary. Integrating these different points of view has been difficult. The social consequences, such as treatment benefit, should be more highly weighted than in traditional models. However, sole focus on social outcomes creates numerous problems (Decker, 2008; Reynolds, 1986). As Messick (1980) states,

What matters is not only whether the social consequences of test interpretation and use are positive or negative, but how the consequences came about and what determined them. In particular, it is not that adverse social consequences of test use render the use invalid but, rather, that adverse social consequences should not be attributable to any source of test invalidity, such as construct under-representation or construct-irrelevant variance. (p. 748)

In Figure 2.3, processes are represented as beginning in assessment, judgement, prescriptive action, and social outcome. In support of treatment utility theories, much can be gained by first asking, "What is the benefit?" However, in support of construct theories, even social benefit involves "theory"; how the benefit came about is important, not just whether or not the benefit occurred, and some form of decision-making that informs prescriptive action is part of all interventions.

Attributes exist in individuals as finite, discrete properties but are measured as continuous variables labeled as constructs. Test interpretation involves numerous scores on continuous scales. However, the social value of assessment is one of deriving a discrete judgement. Thus, assessment requires the judgement of discrete probabilities from continuous scales to map to some prescriptive outcome. Currently, the categorical interpretation of test scores is arbitrarily given by dividing the normal distribution curve into ordinal categories (e.g., below average, average, above average). Indeed, qualitative outcomes appear to be the most informative to patients (depressed, not depressed) and may provide a linkage from test scores to real-world outcomes.

## Judgement and Decision-Making

The complexities of making judgements from assessment data are vast due not only to all the issues

in measurement theory, the theory of the construct being measured, and situational factors during testing, but also due to how these factors impact, or are impacted by, the contextual issues involved in applied assessment applications, which include social consequences. This gets to the interrelatedness of these different concepts. Unfortunately, the complexity increases as it is at this point that interpretation is defined by cognitive events of the clinician and thus a large number of new variables become influential. The role of clinical interpretation as part of the assessment process is perhaps the most important link in the chain (McFall & Townsend, 1998). However, it is also mostly described in qualitative terms such as “integrative,” “holistic,” “comprehensive,” and “synthesis.” Granted, this is due in part to the vast complexities involved that do not readily lend themselves to statistical modeling. Additionally, contemporary models of validity do not specify how clinicians should make evaluative decisions based on a certain context. Yet, evaluative clinical decisions are the primary mechanism that leads to prescriptive action and in turn to outcome. As a result, such processes are unaccounted for and remain implicit and ambiguous, or are determined to be irrelevant.

Perhaps part of the reason why “interpretation” and validity are often not specified or specified in multiple ways is because of the complexity and challenges involved. Part of the challenge is that validity research, often conducted under controlled conditions, may not always be relevant for the contextual issues in applied practice. Additionally, clinical decision-making is intimately a part of the assessment process, and different types of validity are prioritized based on the decision-making demands of researchers or clinicians (Kazdin, 2003). One validates, not a test, but an interpretation of data arising from a specified procedure (Cronbach, 1971). Recall that test validity is in part determined by evidence suggesting the test is measuring what it is “intended” to measure. However, “intentions” change based on contextual situations. A test can be perfectly valid and reliable but have no link or implication for real-world processes that are relevant to a clinical situation.

The primary confounding problem that has historically plagued assessment is the lack of integration between the different components involved in measurement and assessment within an applied context, such as treatment. Historically, psychological or cognitive measures have been developed to fit a particular theory, and evidence is provided to

validate a test as a measure of a theory. Traditionally, the outcome of testing was interpretation. The actual applications of how many practitioners would be using the instrument to make decisions has been of secondary value. True, test developers cannot anticipate all the possible uses for a particular test. However, these tests are then used by practitioners, and it is left up to the practitioner to know how to apply the test to assist him in making a decision in a specific context.

A review of research on clinical judgement is beyond the scope of this chapter (for a review see Garb, 1998; Garb & Schramke, 1996). In this chapter, two descriptions of cognitive phenomena in test interpretation will be discussed. Based on social-psychological research beginning with Solomon Asch in the 1940s, social psychologists have extensively researched how individuals develop overall impressions or judgements based on the accumulation of data (Lewicka, 1997). Lewicka (1988) distinguished between “diagnostic” and “prospective” processes, which have also been termed “categorical” versus “piecemeal” or top-down/bottom-up (Fiske & Pavelchak, 1986). Diagnostic inferences involve inferring a category membership based on specific features of an object (attribute→category); whereas prospective inference infers features of an object based on its category membership (category→attribute). Diagnostic inferences are bottom-up and data-driven; whereas prospective inferences are top-down and theory-driven. Essentially, observations are categorized to form concepts. Concepts in turn help us understand observations. In assessment, clinician judgement is influenced by the degree to which observations and concepts are used. When a concept is formed prior to data collection and not supported by data collection but maintained in prescriptive action, this is called *bias*.

During testing, clients are provided scores on various dimensions that represent attributes derived from theoretical constructs. In assessment, clinicians use scores on dimensions in supporting both diagnostic and prospective judgements that justify prescriptive actions in a social context. The whole foundation of clinician judgement resulting in social benefit rests on the mechanics of measurement, beginning with the assignment of a number to an attribute of a person.

It is important for clinicians to be aware of the type of decision that is required in an assessment process. This involves thinking through the referral question and clearly stating the problem,

determining possible outcomes of an assessment, and determining how outcomes will be prioritized based on assessment data. This provides an important connection between clinical judgement and prescriptive action that leads to social outcomes. Structuring assessment judgement outcomes is helpful in this process.

Although psychological assessments can be used for numerous goals (e.g., measure client attribute; determine disability, strengths, and weakness, etc.), we will limit the scope here to classification. Classification systems establish rules for placing individuals within a specific class and provide a means of investigating correlates of class membership, such as treatment outcomes (Sattler, 2001). In an assessment context where the clinician is asked to provide a diagnostic judgement, the judgement can be one of meter reading (Blanton & Jaccard, 2006), will be used to specify an interpretive statement made by the clinician that is a direct translation of a test score to another scaled frame of reference. For example, norm-referenced tests have charts indicating qualitative labels of, for example, “above average,” “average,” “below average.” “Inferred” interpretation is inferential. It involves direct interpretations of a test in which but goes beyond the test data. Diagnostic judgements—disability classification, for example—use numerous sources of data, none of which would directly lead to a clinical judgement.

As a simple example, suppose a clinician is asked to determine whether a person has a disorder or not (criterion classification), based on one data point that provides a positive or negative indicator. This interaction can be modeled in a classification matrix. Data can accurately classify individuals by suggesting

they have the condition, when they do, or they do not have the condition, when they do not. The other outcomes could be that the data incorrectly indicate the person either has or does not have the condition when the converse is true. Notice this example is simplistic in that psychological test data rarely provide a binary outcome of disorder/no disorder. Additionally, there are complexities involved in determining true criterion status. (Interested readers may consult the following sources for more detailed aspects of this process: Elwood, 1993; Franklin & Krueger, 2003; Gigerenzer, 2002.) However, the example is intentionally simplified for demonstration.

In such a scenario, a classification matrix describing the hypothetical outcomes of the test may be useful. Although such a matrix is frequently found in many assessment textbooks, such information is rarely reported for standardized commercial instruments used by psychologists (Elwood, 1993). There are several challenges to the use of such tables in practice. One problem, the *base rate problem*, has long been recognized and results from most of the clinical conditions’ having a low prevalence rate (Meehl & Rosen, 1955). In such conditions, positive predictive values almost always suggest classifying an individual as not having the disorder despite test data.

One means of overcoming this limitation is to use Bayesian methods (Franklin & Krueger, 2003). Bayes’s method is useful because it starts with the base rate probabilities of outcomes (disorder prevalence), then revises the probabilities based on new information.

As an example, Figure 2.4 shows the base rate probability for different diagnostic judgements that may be made when using assessments in schools. The overwhelmingly most likely categorical decision to be made from a random evaluation of any child in school is “normal.” Thus, any information suggesting a different category would have to be overwhelmingly informative to overcome this large base rate. Unfortunately, no such information exists. Fortunately, Bayes’s theorem provides a method to resolve this issue.

Bayes’s theory is a method of revising probabilities based on data. As a simple example, suppose the base rate of classifications for a group of disabilities frequently made in children are as shown in Figure 2.4. Furthermore, suppose the probability of classification for each of the disabilities is related to IQ differentially. For example, the probability of not having a clinical condition is linearly associated with IQ. Children with learning disabilities on average may have an average or slightly below-average IQ, as do children with ADHD. Children with mild mental

**Table 2.3 Decision-Making Matrix for Determining Judgement and Test Correspondence**

Criterion Classification		Test Results	
		+	-
+	A	B	
-	C	D	
		A + C	B + D

A = Sensitivity ( $A/A + C$ )

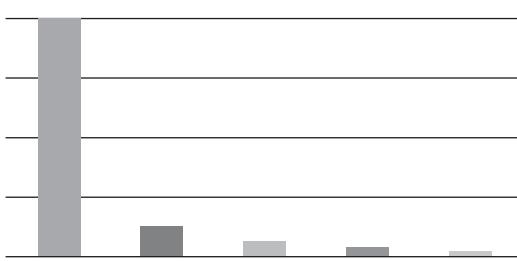

B = False positive

C = False negative

D = Specificity ( $D/B + D$ )

Positive predictive power =  $A/A + B$

Negative predictive power =  $D/C + D$

**Figure 2.4** Initial probability for categorical judgements based on base rates.

retardation (MMR) have lower IQs and by definition, typically two standard deviations. Children with pervasive developmental disorders like autism may have on average low IQs, but children within this classification may also have large standard deviations.

Suppose that, during the assessment process, an IQ score was obtained and resulted in a score of 75. Further suppose that the probability of being normal given an IQ of 73 was .20, and the probability of not being normal given an IQ of 73 was .80. That is, 80% of children with an IQ of 73 are found to have some clinical condition and are judged “not normal” or “developmentally atypical.” However, there is about a 20% chance of finding children who test this low on an IQ test but do not exhibit any atypical developmental features or any other impairment. What is the value in changing the probabilities of determining a child is normal based on this information?

Bayes’s theorem states that the probability of having a condition (C) given the data (D) is equal to the probability of the data given that the hypothesis is true (sensitivity), multiplied by the base rate, then divided by a normalizing factor that includes test specificity. Here the values are:

$$P(D|C) = .20 \text{ (probability of getting 73 given normal, sensitivity)}$$

$$P(C) = .20 \text{ (base rate of normal)}$$

$$P(D|-C) = .80 \text{ (probability of getting test score given NOT normal, specificity)}$$

$$P(C|D) = P(D|C)*P(C) / P(D|C) * P(C) + P(D| \text{ not } C)*(1-P(C))$$

If these numbers are entered into Bayesian formula, then the probability of being normal goes from .20 (base rate) to:

$$P(C|D) = .20 * .80 / .20 * .80 + .80 * (1 - .80)$$

$$P(C|D) = .50$$

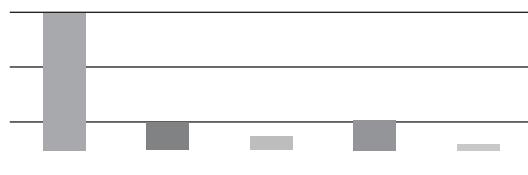

Suppose further that it was known that the probability of having MMR, given a test score of 73, was .80 and a specificity .20. That is, 80% of children with an IQ of 73 may also be shown to have low adaptive behavior, family history of MMR, very severe academic deficits that progressively drop by grade, etc. How would this information change the likelihood of MMR?

Using the same procedure as before, only changing the base rate to 3% (prevalence of MMR), the new probability is .11. Disregarding the effect of the other classification, the new graph revised where the probability of “normal” goes from .80 to .50 and the probability of MMR goes from .03 to .11 (Figure 2.5).

Now, additional information, such as “adaptive behavior,” which has its own sensitivity and specificity with normal and MMR, can be added to further change the likelihood of different categories. Similarly, background information such as gender, ethnicity, or age, could be added to influence the results (see Franklin & Krueger, 2003, for more complex examples using Bayesian networks). Eventually, multiple sources of information can be “integrated” to inform a categorical judgement. This procedure directly addresses the base rate problem as well as other problems that have plagued clinical inference (McFall & Treat, 1999). The base rate problem is overcome by the accumulation of highly sensitive and specific information. Additionally, it is proposed that this process “simulates” what good clinicians do when they “integrate” or “holistically” appraise test data within the assessment process. Additional implications will be discussed at the end of the chapter.

### Prescriptive Action

The purpose of clarifying classification decisions is not just to provide a better “label,” but rather to reduce the uncertainty of options in classification schemes, which in turn provides ready access to research on interventions (Kamphaus, Reynolds, & Imperato-McCormon, 1999). That is, classification or diagnosis supports prescriptive actions. Tests

**Figure 2.5** Probability revision given IQ scores.

are used in assessment to provide information that reduces uncertainty in decision-making, which leads to a judgement, which in turn leads to a prescriptive action.

The term *prescriptive action* is used here to represent the fact that assessment is not conducted for the purpose of getting scores on tests. Judgements and conclusions by themselves are useless unless such judgements guide future actions. The term *treatment* is not used but, rather, is considered a type of prescriptive action. Not all prescriptive actions must be physical acts; they can also be “states of knowledge.” A clinician may do an assessment and make a judgement that a patient’s memory is impaired, it has decreased over time, and this decline indicates dementia. In some cases the prescriptive action may be to inform client so the client can make necessary arrangements. In other cases it may be a referral for medication, assisted living, etc. As such, the term *prescriptive action* is used to indicate the actions that were taken, or belief states that were changed, as a result of the assessment judgement. Prescriptive action is a mediator between assessment and social outcome. Additionally, assessment for the purpose of writing reports that includes recommendations does not fully specify that recommendations are prescriptive actions, although often only indirectly related to assessment data. The results of assessment, and the interpretive process, should provide evidence to increase or decrease the probability of different hypotheses, which in turn lead to different prescriptive actions. As such, the pinnacle, or goal, of assessment is not test interpretation. The results of assessment, and the interpretive process, should test hypotheses that lead to different actions. The link between test interpretation, decision-making, prescriptive action, and outcome is rarely formulated as a unified model because often there is a high degree of contextual dependence in applied contexts. Neuropsychologists may conduct assessments to determine whether someone has suffered a brain injury, the nature of the injury, and the extent of functional loss. The type of judgement made depends on the prescriptive action, or purpose of the assessment. Suggesting a specialized intervention to remediate a cognitive processing weakness is of little value when the original purpose of the assessment was to determine whether the client is competent to stand trial! It is important that the prescribed action, judgement, and assessment process be in alignment. Although the contextual dependence of prescriptive action limits its specification because it may differ by context (and there are numerous contexts), it may still be specified in the abstract.

Figure 2.3 and the specification of judgement and prescriptive action as precursors to social outcome may help clarify some substantial problems in contemporary assessment literature. The problem is how to determine the utility of psychological assessment. Figure 2.3 also makes it clear that the utility of test in an assessment process cannot be directly determined by social outcome or benefit that results or does not result from the assessment. Assessment is several steps removed from beneficial client outcomes. Rather, the utility of tests depends on how they are used in a context to inform judgements that lead to different actions or outcomes.

Interventions are a type of prescriptive action that includes intentional manipulations to cause a change of some attribute or indicator in an intended direction. One difficulty in treatment is selecting an intervention from among numerous possible interventions. In school-based practice, numerous children having difficulty reading are prescribed phonological interventions, which are supported by research. Unfortunately, many of these children do not improve because they do not have problems in phonological processing, which a 10-minute test in phonological processing would have suggested. A child may do poorly in reading instruction, perhaps due to social-emotional problems like depression. Such a child may show improvement in reading skills as a result of reading intervention, although the underlying problem of depression remains and may affect future academic behavior. In such situations, what would be the value of administering a test that would have clarified the attributes of a child and would have in turn led to a better prescriptive action? Currently, there is no metric for determining this value. Similarly, there is no metric for reducing uncertainty in determining the underlying problem or selecting the appropriate intervention. Testing reduces the uncertainty in these possibilities. The use of testing to reduce the possibilities of error in defining the underlying problem of a child is not included in behavioral studies of treatment validity. Such studies often “assume” that a child’s status is known (e.g., depression, reading problems, etc.) and then asks how would giving a test reduce depression or improve reading (see Fletcher, Lyon, Fuchs, & Barnes, 2007, as an example in reading). Testing provides information about the attributes of an individual that contributes to decision-making within an assessment process, which in turn contributes to interventions that influence outcomes.

Other factors also impact decisions, as do the actual prescriptive actions taken that are more

causally related to treatment outcomes. The problem here is analogous to that of measurement. There is a construct with natural attributes, and one must assign labels to it in order to study it. Namely, the process involved in clinical decision-making, prescriptive action, and social outcome must be pre-specified and structured as data. Testing provides information when test results reduce the uncertainty in decision-making possibilities. Testing need not reduce the probability of one category to certainty ( $p = 1.0$ ) to be informative, but rather just change the distribution of possibilities (see previous example). Additionally, the process of “judgement” and “prescriptive action” need not be simply grouped under an umbrella of “interpretation” and assumed to be impenetrable to analysis. Measurement theory suggests a solution. Clarify the underlying attributes through theory, label them, and investigate.

## Social Outcome

Of course, like judgements, prescriptive actions are not selected in a vacuum but rather linked to social utility. That is, a prescriptive action is selected because it is judged or predicted to result in some benefit. Traditionally, this has been framed as *consequential validity*, but as a line of validity evidence rather than, as indicated here, as a more central element of assessment. The reason why such social goals or outcome variables need greater representation in test development is because such goals provide feedback on how to construct the decision-making model. The decision-making model informs the type of validity evidence needed for a test, which in turn influences how a test is constructed, as demonstrated in the previous example of maximizing information value for decision-making thresholds.

Demonstrating how psychological assessment services provide utility in psychological outcomes has been a defining characteristic of contemporary psychological practice. Influenced by managed health care, evidence-based practice has focused on “outcomes” by which to evaluate psychological services (Maruish, 1994). Effectiveness in providing services is determined by the degree to which specified outcomes are obtained. The influence of this philosophy is vast, and an outcomes orientation has influenced everything in psychology, from standards in training, to insurance reimbursement from third-party payments.

The use of psychological tests has not escaped this scrutiny. Interestingly, there are conflicting opinions on the utility of assessment in impacting treatment outcomes. Some have suggested that assessment is of little to no value (Hayes et al., 1987), which is

supported by many researchers with a behavioral orientation (Gresham & Witt, 1997; Reschly & Gresham, 1989). Similarly, some have suggested that outcomes should be the core aspect of test validity (Fuchs et al., 2002). Others have presented cogent arguments on the limitations of such an approach (Cone, 1989; Decker, 2008). Additionally, meta-analysis of more than 125 studies led to the conclusion that there is strong evidence for psychological test validity, that psychological test validity is comparable to that of many medical tests, assessment instruments provide unique information, and clinician decision-making is enhanced by the results of psychological tests (Meyer et al., 2001).

The misunderstanding inherent in approaches that dismiss the utility of psychological testing comes from a lack of specification in the application of psychological services. Namely, the role of decision-making is neglected. Administering Block Design from the Wechsler tests will not cause a desired outcome. However, results of such a test may provide information within the assessment process that requires clinician decisions to inform some course of action. Similarly, testing helps us record change as a result of intervention. Although traditional single-subject design methods are used, psychometric methods may also apply to interventions. The termed *intervention psychometrics* has been used to describe the application of psychometric theory to intervention methods (Decker, 2008).

Despite the inherent benefits in the focus on outcomes, there are some drawbacks. Perhaps the two most important are the two most general. First, the sole focus on any one thing inevitably leads to a neglect of other concepts. Second, singularity of focus often causes an oversimplification that creates a model unable to match the complexities of practical applications. Outcomes are important but perhaps no more so than methodologies determining service needs, adequate measurement representation of person-need, and adequate representation of the type of services matched to needs. Such measurement is needed if it can ever be determined that a particular configuration of matching needs to services through a diagnostic process creates a benefit beyond that which could be obtained through no diagnostic process or random matching.

An additional issue must be mentioned in the process of integrating data with social values. Similar to descriptions of assessment as top-down/bottom-up, or diagnostic/prescriptive, there are problems with describing assessment as driven by social values as a top-down process in assessment. Historic social

examples have shown the push of social values is not always just. The dichotomy of data as indicators of reality and social values as interpretive mechanisms has historically been a core theme to describe the relationship between science and religion. Science, as an attempt to describe the world as accurately as possible, and religion, as a prescriptive approach to how the world should be guided, have been at odds many times. Other examples can be given, but my guess is the reader gets the idea. Test validation, as such, may not be described as a methodical process involving reliability coefficients but may better been viewed as a “belief management” technique: that is, evidence is provided to support beliefs (i.e., clinical inferences), which in turn justify actions. *Validity* is a method of determining the degree of which beliefs concerning constructs can be “believed.” However, given the current status of validity research, there is yet a procedure in which the quantification of beliefs can be attained. How much, or how many lines, of validity evidence are needed before one’s action is selected over another? How are beliefs and actions to be connected? What if two contradictory belief systems are both supported by different lines of validity evidence? The Bayesian approach to hypothesis testing (previously presented) may serve as one technique to more explicitly represent clinician decision-making, which in turn helps make explicit the value of assessment. Currently, nothing in the current system of test validity exists to resolve these issues.

Figure 2.3 makes explicit judgement is linked to prescriptive action which is linked to social goals, which in turn are linked to theory. Table 2.4 provides different judgement, prescriptive action, and outcomes for different assessment contexts. Although it is difficult to define all possible values

for each stage, it is possible to provide broad indicators for each stage of assessment.

Here the emphasis is on pre-specification of possible events at each stage. The events listed for these stages in Table 2.4 are simplified to the point of being irrelevant for the listed assessment applications, but more specific and sophisticated classification schemes exist for each of the areas (see Wodrich & Schmitt, 2006, for an example of school-based classification). Such models provide direct linkage of assessment to actions that may be taken as a result of testing. For example, an educator may solely be interested in identifying children who are at risk for reading problems. This implies a binary decision-making outcome (“at –risk” or “not at –risk”). The test used to make such a decision need not be a comprehensive measure that measures the entire range of reading capability. Rather, such a test need only maximize information at the decision-making threshold for making a decision as to whether a child is at risk or not at risk.

## Conclusion

This chapter broadly reviewed measurement theory, scale development, testing, and assessment. The chapter was divided into two broad areas to represent distinct phases of testing involving test development and test application. The integrated role of testing with measurement and assessment components was demonstrated. Theories of measurement are reviewed with the use of the Item Response Theory, not only for the purpose of objective measurement but as a basic model to analyze how personal attributes interact with test stimuli. Interpretive phases of tests within an assessment process are described, which include decision-making, prescriptive action, and social outcomes. This

**Table 2.4 Linking assessment and outcomes through judgment and actions**

Assessment Purpose	Judgement	Prescriptive Action	Outcome
Disability	Disability present	Not eligible	Educational modification
	Disability absent	Eligible	
Forensic (competence to stand trial)	Competent	Stand trial	Social justice
	Incompetent	Do not stand trial	
Risk	At risk	Protect	Safety
	Not at risk	No protection	
Neuropsychological	Brain injury	Remediation/ accommodation	Life adjustment
Intervention	Determine problem	Intervene on problem	Improvement

extension is based on ambiguous concepts inherent in contemporary test theory. The interconnected “network” of concepts in testing contributes to the complexity of understanding testing, but nonetheless is necessary. Testing depends on measurement, which in turn depends on the theoretical basis of a construct. Assessment depends on testing, or typically, multiple tests for interpretation. Interpretation is a sub-part of a decision-making process in which some action, such as an intervention, is to be implemented. Interventions influence outcomes, which are evaluated by social goals and values.

Perhaps due to the complexities involved with testing, numerous misunderstandings have occurred that result not only in controversy in research but in misapplication of tests in society. Furthermore, the historic difficulties of not clarifying “interpretive” issues in testing have led to variations in the application of psychological testing, with some of the variability extending into the misapplication of practice. One need only look at the historic use of IQ measures as an example. Despite the fact the measures of intelligence are perhaps the greatest successful application of psychology, the negative connotations that surround lower IQ have created a negative impression on society, and it is doubtful that the term *IQ* will become vindicated. Additionally, the disconnection between how a test is developed and how it is used has led to criticisms involving the treatment utility of tests. This issue was indirectly addressed in this chapter by providing a clarification of why practitioners perceive the value of tests but that value is not captured in research studies. The value of assessment in treatment is not a result of assessments directly causing a change in functional status. Rather, tests used in assessment reduce uncertainty in the decision-making process, which leads to prescriptive action that causes change in social outcomes. This provides an explanation for why assessments have not been adequately tested within a treatment validity paradigm, but evidence is still required to demonstrate the decision-making utility of assessment for particular applications. A Bayesian model is reviewed as a demonstration of how this may be accomplished.

The purpose of reviewing the Rasch model in detail was to demonstrate how qualitative data can be quantified and converted to a unit of measurement. Similarly, most diagnostic classification schemes, although categorical, can be placed along a dimensional continuum (e.g., symptom severity, number of symptoms). Additionally, the value of social outcomes can be rank ordered. Most would

agree that full recovery or return to normal parameters of functioning is a more desired outcome for a client than simply being informed of the diagnosis, which in turn is more valuable than not knowing what the problem is at all. Providing a unitary metric of social outcomes to monitor treatment progress may be useful.

Messick, in a review of different perspectives of construct theory, concluded with:

The use of constructs to develop intuitive systems of meaning for observed relationships appears to be a fruitful heuristic if buttressed by convergent and discriminant evidence to validate the interpretation of test scores as measures of constructs and to validate observed relationships as reflective of meaningful connections in the nomological system (p. 587).

The model presented here for integrating testing with measurement and assessment may similarly be viewed as a “fruitful heuristic” in clarifying the utility of psychological assessment.

## Future Directions

There are several future implications for research and practice based on the model presented in this chapter. Test construction may benefit from more focus and clarification of the social outcomes specified by the theory that guides test development. Similarly, clarification of the information value of a test is needed, as well as increased focus on the theoretical analysis of the resulting decision-making. That is, what service is to be provided and what is its benefit.

Another implication is that the assessment field needs to develop better metrics of “information.” Such metrics exist but are not a part of mainstream psychometrics. The study of information was most formally begun by Claude Shannon (Shannon, 1948). The intended applications of the study of information were in the digital transmission of communication channels. Numerous attempts have been made to apply information theory to topics in psychology, with only a few successes (Luce, 2003). In contemporary research, its most important applications have come from statistics. For purposes of this chapter, the importance of information is that information can be formally measured. Central to its conceptualization is the statistical probability of an event to determine the likelihood of an actual event. Essentially, information theory quantifies statistically rare events as more informative. Entropy is maximized when a system of variables is completely random. As events become more orderly, entropy decreases.

Finally, another future implication of the model presented here is to provide “scale” value to prescriptive action and social outcomes. Just as measurement requires a representation of an attribute, unified models of assessment need better representations of judgement, prescriptive actions, and social outcomes. Representing attributes of these stages would enhance the investigation of how these processes are involved in assessment and would make clear how they contribute to social outcomes. Until such processes are made explicit, they will continually be viewed as a “black box” and either held in high esteem by some or disregarded by others.

## Future Directions

1. How could commercial test developers assist clinicians who would want to use Bayesian models of diagnostic decision-making?
2. Is it possible to develop an abstract clinician decision-making model that fits most situations in which psychological tests are used?
3. How could it be determined that a more context-specific decision-making model is better than a general, all-purpose decision-making model?
4. What are the different values that the variable “social benefit” may take?

## Acknowledgment

The author would like to thank Dr. Catherina Chang for reviewing this chapter.

# Measurement and Statistical Issues in Child Assessment Research

Matthew R. Reynolds and Timothy Z. Keith

## Abstract

This chapter focuses on measurement and statistical issues in child psychological assessment research. Topics with worked examples include multiple regression, confirmatory factor analysis, the Schmid-Leiman transformation, measurement invariance, and MIMIC models. Comparisons are made between simultaneous and sequential regression, higher-order and hierarchical factor models, and multiple-group mean and covariance structure analysis and MIMIC models. The chapter also discusses issues such as dealing with missing data, formative versus reflective measurement, and categorical versus continuous latent variables.

**Key Words:** hierarchical models, measurement invariance, higher-order confirmatory factor analysis, MIMIC models, multiple regression

## Introduction

Research in psychological assessment permeates the practice of psychology. Psychological assessment relies on psychological measurement research, which in turn relies on psychological theory. Psychological assessment research itself is a broad topic. Here we will skip statistical and measurement basics because these topics are well explicated elsewhere (e.g., McDonald, 1999). The chapter will begin with a discussion of multiple regression, an increasingly popular method that is not always well understood. Following multiple regression, a variety of topics such as dealing with missing data, confirmatory factor analysis, and measurement invariance will be reviewed. Worked examples will be provided for some of them.

Some of the issues discussed in this chapter may be considered advanced, though they have been around for a few decades. Modern computing, however, makes for easy implementation of these procedures. In fact, we believe some of these advances should be part of standard practice in psychological

assessment research. It is our intention to keep the presentation style as non-technical as possible with the goal of raising awareness; applied examples will demonstrate interesting and important questions that may be asked and answered using these methods. The references provide much more technical detail and should be consulted by readers who are interested in learning more. A theme of this chapter is that researchers should design research that is consistent with theory, and use methods to critically test those theories. To do so, it is essential to have good theories to draw from, and to have tools useful to test them. We believe the topics covered in this chapter include some of those tools.

## Multiple Regression

Most readers will be familiar with multiple regression, a popular analytical tool that allows researchers to answer questions about the effects of presumed causes on presumed effects. Two popular approaches, simultaneous and sequential regression, will be compared and contrasted in an example.

The two approaches are sometimes either treated as entirely different methodologies or are applied rigidly according to a cookbook set of rules. In the example it will be demonstrated that the statistical processes underlying the approaches are not different, and that the differences between the two are often found in interpretation only. Understanding the similarities and differences of the two approaches is useful so that the appropriate approach can be applied to specific research questions.

Data from the Early Childhood Longitudinal Study–Kindergarten (ECLS-K), a large-scale, publicly available dataset, were used in this example. Four variables were used to explain the science achievement of fifth-grade students: sex of the student (Sex, dummy coded so that boys = 0 and girls = 1), first-grade reading ability (Prior Reading), self-perceived competence in all academic areas (Perceived Competence), and teacher ratings of children's approach to learning (Learning Approach), which includes behavior such as attention and organization skills. The ECLS-K includes these variables among a multitude of others.<sup>1</sup> The sample for this example included 1,027 children.

There are three common approaches to multiple regression: simultaneous, sequential, and stepwise. Stepwise regression will not be illustrated here. The method is used only for predictive purposes, not explanatory (we will discuss these two purposes in more detail later on), and we do not encourage its use. There are numerous reasons that this atheoretical approach should be avoided, including the fact that it capitalizes on chance findings due to random sampling fluctuations and because it does not require a researcher to think (see Keith, 2006; Thompson, 1995).

### **Simultaneous Regression**

Simultaneous regression (also known as *standard multiple regression* or *forced-entry multiple regression*) is commonly used in explanatory research. Simultaneous regression produces estimates of the direct (unique) effect of the explanatory variables on the outcome variable. Specifically, correlations among the explanatory variables are accounted for so that the unique effects of the explanatory variables are estimated after the effects of the other variables have been removed. The method is useful for comparing the relative influences of variables on a single outcome variable of interest. All of the explanatory variables are entered or “forced” into the regression equation simultaneously. It is typical that  $R^2$  (i.e., the proportion of the outcome variance explained

by the optimal linear combination of predictors) and standardized ( $\beta$ ) and unstandardized regression ( $b$ ) coefficients are interpreted in simultaneous regression.

In this example, Science Achievement was regressed on Sex, Learning Approach, Prior Reading, and Perceived Competence. The linear combination of these variables explained 37% of the variation in Science Achievement ( $R^2 = .37$ ,  $F[4, 1022] = 149.03$ ,  $p < .01$ ). When the other variables were held constant, Sex ( $b = -3.98$ ,  $\beta = -.21$ ,  $p < .001$ ), Learning Approach ( $b = 2.47$ ,  $\beta = .17$ ,  $p < .001$ ), and Prior Reading ( $b = .54$ ,  $\beta = .52$ ,  $p < .001$ ) each had statistically significant effects on Science Achievement. The effect of Perceived Competence ( $b = .19$ ,  $\beta = .01$ ,  $p = .61$ ) was not statistically significant when the other variables were statistically controlled. A qualitative comparison of the standardized effects shows that Prior Reading ( $\beta = .52$ ) was the most important influence on subsequent Science Achievement.

### **Sequential Regression**

In sequential regression, the explanatory variables are not forced into the equation at once; rather, they are entered sequentially in what are often referred to as *blocks* (this type of regression is also often referred to as *hierarchical regression*). The order of entry has important interpretative implications and should be based on a researcher's knowledge or beliefs about causal order. In this example, Sex was entered in the first block, Prior Reading was entered in the second block, and Learning Approach and Perceived Competence were entered simultaneously in the third block.

Sex was entered in the first block because it has time precedence over the other explanatory variables. For example, reading ability in the first grade does not explain a child's sex, but a child's sex may have important implications for first-grade reading ability. Perhaps one could *predict* a child's sex by including first-grade reading in a prediction equation, but the interest here is in *explanation*. Moreover, the prediction of a child's sex based on reading ability is uninteresting and does not make sense.

In block two, Prior Reading was entered. Prior reading is likely to influence fifth-grade science achievement because students who are better at reading will read more and build their stored knowledge base. It may also affect perceived academic competence and learning approaches in fifth grade, which are developed from prior experiences. Learning Approach and Perceived Competence were entered

together in the third and final block, based on the belief that both of the variables combined add to the explanation of Science Achievement. They were entered last because lack of organizational skills and inattentiveness probably interfere with learning. Moreover, perceived academic competence is a general construct, most likely acquired over years of schooling, and thus this perceived competence should influence engagement and performance in specific academic areas like science.

Proper entry is critical in sequential regression, so it is worth considering further. It is plausible that how much a student knows in science influences teacher ratings of that student's approach to learning. If a student lacks knowledge in science, then that student may appear inattentive and unorganized in science class. The ratings are based on general academics, however, and not science, so the original order makes sense. The important point is that researchers must carefully consider order of entry and must also be prepared to defend their decisions (and defend them much more rigorously, within a theoretical framework, than we have done here).

Given this emphasis on the order of entry in sequential regression, our decision to enter Learning Approach and Perceived Competence together in one block may seem curious. Such a decision may suggest that the researchers are unsure of the proper causal sequence of the variables, or alternatively, that they believe that the variables assess related, overlapping constructs, and are interested in the effect of that overarching construct. Researchers should examine these kinds of decisions, or non-decisions, because they have important interpretative consequences. Finally, researchers should be prepared to defend their reasoning for including variables and omitting potential common causes in a regression. That is what solid research is about, and the omission of important common causes renders interpretation of the regression coefficients invalid.

For the sequential regression, Sex was entered into the equation first.  $\Delta R^2$  was used to determine if there was a statistically significant improvement in the proportion of variance explained in Science Achievement after Sex was included.  $\Delta R^2$  (.016) was statistically significant ( $F [1, 1025] = 17.09, p < .01$ ). Sex improves the explanation of Science Achievement above that of having no explanatory variables in the equation. Although  $\Delta R^2$  is most commonly interpreted in sequential regression, some researchers also interpret the coefficient associated with each variable as it is added to the equation. For the current example, these are  $b = -2.44$

and  $\beta = -.13$ , and the  $b$  suggests that, on average, girls score 2.44 points lower on the Science test than do boys (the negative coefficient means that girls, coded 1, score lower than boys, coded 0). If variables are entered in the proper order, these coefficients represent the *total* effect of Sex on Science Achievement, and this effect is different from the direct effect of Sex obtained from the simultaneous results. (We will return to this issue later.)

Second, Prior Reading was added to the equation, resulting in a statistically significant  $\Delta R^2 = .32$  ( $F [1, 1024] = 506.10, p < .01$ ). Explanation of Science Achievement was improved beyond the proportion of variance explained by Sex alone. The effect of Prior Reading ( $b = .60, \beta = .57$ ) was large. This effect represents the *total* effect of prior Reading on Fifth-Grade Science Achievement, both directly and possibly indirectly through the soon to be added variables Learning Approach and Perceived Competence. Someone unaware of what the regression coefficients in sequential regression represent might be confused by the coefficients related to Sex produced at this step. The coefficients for Sex have changed ( $b = -3.31, \beta = -.17$ ). Does this mean that Sex is more important than it was previously? We will address this issue in more detail below.

Last, Learning Approach and Perceived Competence were added as a block, resulting in a  $\Delta R^2 = .028$  ( $F [2, 1022] = 22.27, p < .01$ ) that was statistically significant. The addition of these two variables, in combination, improves the explanation of individual differences in Science Achievement. Regression coefficients estimated for Sex ( $b = -3.98, \beta = -.21, p < .001$ ), Prior Reading ( $b = .54, \beta = .52, p < .001$ ), Learning Approach ( $b = 2.47, \beta = .17, p < .001$ ), and Perceived Competence ( $b = .19, \beta = .01, p = .61$ ) in this step were identical to those obtained in the simultaneous regression. We now have several sets of coefficients that could be interpreted from the sequential regression. If we are interested in interpreting the effects, which are appropriate, and which should we interpret? Perhaps this interpretation is best explained by comparing the results with the results from the simultaneous regression.

### ***Simultaneous and Sequential Regression: A Comparison***

Path diagrams will be used to help compare simultaneous and sequential regression. A path model of the simultaneous regression is shown in Figure 3.1. In the diagram, the rectangles represent observed variables; the arrows, or paths,

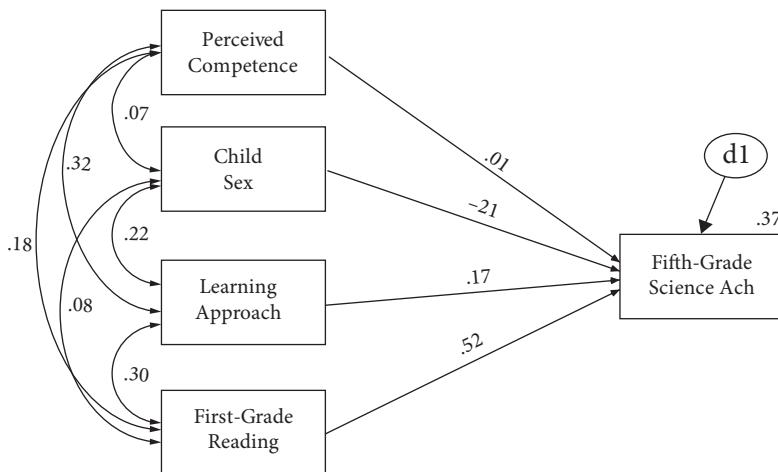

Figure 3.1 Simultaneous Regression in Path Form.

show a directed relation between the variables; the double-headed arrows represent a non-directive relation (i.e., correlation); and the oval represents a disturbance, commonly referred to as a *residual variance* in regression. In structural equation modeling, ovals typically represent latent, or unmeasured, variables. In this example, the oval represents all influences on the corresponding measured variables other than those shown in the model; these influences are not measured or modeled, and may include measurement error, nonlinear effects, random unknown influences, and all other unknown influences on the outcome (Arbuckle & Wothke, 1999; Bollen, 2002).

In the simultaneous regression shown in Figure 3.1, the explanatory variables correlate with each other, and each explanatory variable has a path connecting it directly to the outcome (Science Achievement), representing the presumed effect of these variables on science achievement. These effects are direct. Because the interrelations among the variables are controlled (by allowing them to correlate), these effects are also referred to as *unique effects*. Whatever is not explained by the linear effects of the explanatory variables is captured in the disturbance.

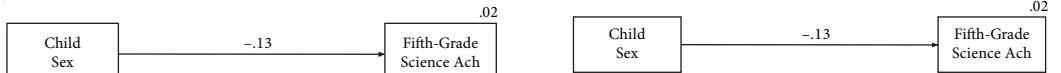

Compare this path model to the sequential regression path models shown in the left side of Figure 3.2. In the sequential regression there are three steps corresponding to what happened at each block of variable entry. Sex is entered first (Figure 3.2, Block 1), Prior Reading second (Figure 3.2, Block 2), and Learning Approach and Perceived Competence third (Figure 3.2, Block 3). An obvious difference between simultaneous (Figure 3.1) and sequential regression (on the left in Figure 3.2) is that some

of the non-directed arrows are now directed. The variables on the left side of Figure 3.2 show an order from left to right, and that ordering reflects the causal assumptions made in the sequential regression and justified, albeit rather weakly, earlier in this chapter.

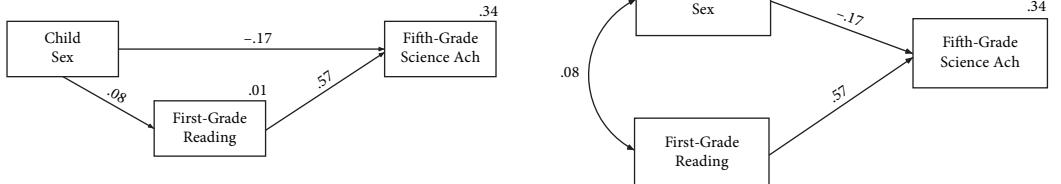

Figure 3.2 shows two types of path models, with the disturbances not included. The models on the left illustrate the causal reasoning underlying our sequential regression coefficients. The path models on the right demonstrate the coefficients associated with each step that are produced in the output. Although most analyses using sequential regression focus on  $R^2$  and  $\Delta R^2$  interpretations, we will focus on the interpretation of coefficients from the regression because these effects are often confused. Note, however, that the  $R^2$  values are the same regardless of whether the example on the left or right is used (these values are shown on the top right of the Science Achievement outcome variable in each Figure). It is instructive to uncover what is happening during a sequential regression, and this becomes clear with a focus on the coefficients estimated at each block.

Starting on the left in Figure 3.2, Block 1 shows Science Achievement regressed on Sex. The regression coefficient ( $\beta = -.13$ ) is interpreted as the total effect of Sex on Science Achievement (generally, we would interpret the unstandardized coefficient when focusing on a dummy variable, but the standardized coefficients are used in subsequent blocks, and so will be used in this first block. See Keith, 2006, for guidelines for interpreting standardized versus unstandardized coefficients, and Table 3.1 for the unstandardized coefficients).

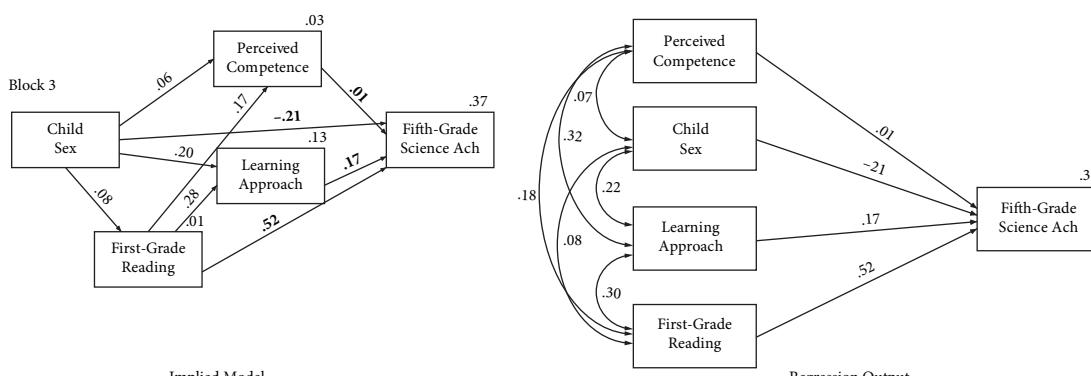

Block 1

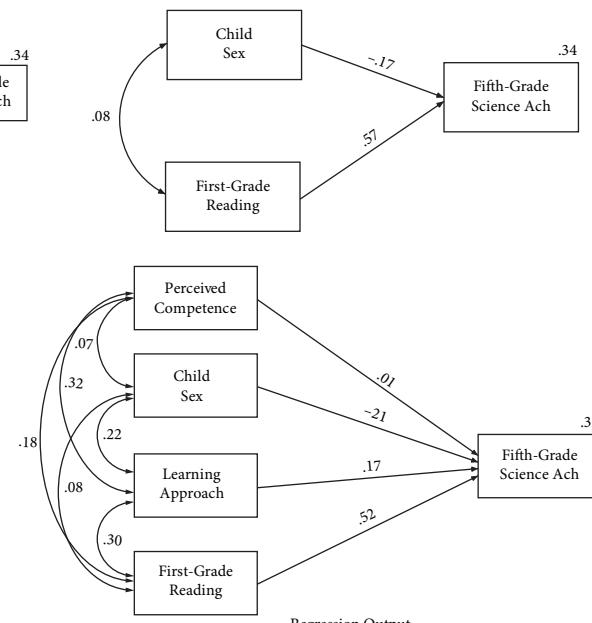

Block 2

Block 3

Implied Model

Regression Output

Figure 3.2 Sequential Regression Comparison in Path Forms.

In Block 2, Prior Reading was added. Shown in the second model on the left, Sex had a direct effect on Science Achievement and on Prior Reading, and thus through Prior Reading, an *indirect* effect on Science Achievement. On the right hand side of Figure 3.2 in Block 2 is the model that was *actually* run in Block 2, and the regression coefficients produced in the computer output. It may look like a simultaneous regression,

and indeed it is, but with only two predictors. The standardized effect ( $\beta = -.13$ ) associated with Sex in Block 1 was different from the standardized coefficient ( $\beta = -.17$ ) in Block 2. The total effect from Block 1 ( $\beta = -.13$ ) is now split into the direct effect ( $\beta = -.17$ ) and the indirect effect, with the indirect effect equalling the path from Sex to Prior Reading times the path from Prior Reading to Science Achievement ( $.08 \times .57 \sim -.04$ ). The indirect

Table 3.1 Comparison of Direct Effects from Simultaneous Regression and Total Effects from Sequential Regression

Variable	Direct effects obtained in simultaneous regression		Total effects obtained in sequential regression	
	$b(SE_b)$	$\beta$	$b(SE_b)$	$\beta$
Sex	-.398(.49)	-.21	-.244(.59) <sup>a</sup>	-.13
Prior Reading	.54(.03)	.52	.60(.03) <sup>b</sup>	.57
Learning Approach	2.47(.40)	.17	2.47(.40) <sup>c</sup>	.17
Perceived Competence	.19(.38)	.01	.19(.38) <sup>c</sup>	.01

Note: <sup>a</sup> From Block 1; <sup>b</sup> From Block 2; <sup>c</sup> From Block 3. Note that the effects for Learning Approach and Perceived Competence are the same across models because these variables were entered in the last block of the sequential regression.

effect is not calculated in the regression output, but this indirect effect is easily obtained by subtracting the direct effect ( $-.17$ ) in Block 2 from the total effect ( $-.13$ ) in Block 1 =  $.04$ . To answer the question posed earlier, the apparent effect of Sex does increase from the first to the second model because part of the *total* effect of Sex is explained by Prior Reading, and in this case, the indirect effect is positive, while the direct effect is negative. That is, girls have higher prior reading scores. The effect of Prior Reading on Science Achievement is also estimated (i.e.,  $\beta = .57$ ). If the causal order is correct, this effect represents the total effect of Prior Reading on Science Achievement. In Table 3.1, the direct effects interpreted in a simultaneous regression and total effects from the sequential regression are shown for comparison.

Last, Perceived Competence and Learning Approach were entered. On the left in Figure 3.2, Block 3, the estimates actually produced in the regression output in Block 3 are bolded. The estimates are identical to the direct effects obtained in a simultaneous regression. And of course a simultaneous regression is exactly what is shown on the right in Block 3. Calculations could be used to estimate the indirect effects. But if a researcher was really interested in all of these effects, this procedure can easily be performed in a structural equation modeling (SEM) program so that the direct, indirect, and total effects are all calculated (and statistical significance can be tested). The model in the SEM program would probably be specified to match the model in the left of Figure 3.2, Block 3.

We hope this illustration allowed the reader to make some mental connections between the two approaches. Why go through the trouble of illustrating these similarities and differences? First, many researchers are interested in the *unique* effects of variables on some outcome. That is, researchers are often interested in the effect of the explanatory variable of interest on the outcome, *controlling for other variables* in the model. They often use sequential regression and estimate the unique effect by adding the variable in the last block. It should be clear now, however, that these effects are easily captured in either simultaneous or sequential regression. The multiple blocks in a sequential regression are not required if this is the interest, even though sequential regression is often used by researchers for this purpose. Second, if researchers have a causal ordering in mind and they want to use sequential regression, it is important that they understand the nature of the coefficients they are

interpreting. In fact, drawing out a path diagram as shown on the left of Figure 3.2 would be beneficial so it is clear what types of effects are obtained. We urge both users and consumers of sequential regression research to routinely draw the models underlying their and others' regressions. Of course, if one is capable of drawing a model, it may be easier to simply analyze the model via a structural equation modeling program!

### **Summary of Multiple Regression**

Keith (2006) outlined additional similarities and differences between the two regression approaches, and a few will be mentioned here. There are many similarities, and even the differences are not necessarily true differences, but rather are differences in rigidly applied conventional interpretations. Note however that  $\Delta R^2$  is generally used as a test of statistical significance and interpreted in sequential regression.<sup>2</sup> It is common, however, to see regression coefficients also reported and interpreted in sequential regression.  $R^2$  and the statistical significance of the regression coefficients are generally interpreted in simultaneous regressions.  $R^2$  in simultaneous regression is identical to the  $R^2$  obtained in the final step in sequential regression when all of the explanatory variables are included. When coefficients are interpreted, however, it should be noted that sequential regression is focused on total effects, and simultaneous regression is focused on direct effects. Simultaneous regression also allows comparisons of the relative (direct) effects using standardized coefficients, and can typically be used to answer questions researchers use sequential regression to answer. And lastly, sequential regression might be considered when testing for moderators or for curves in the regression plane, but only if the researcher is interested in an overall test of an interaction effect or several interaction effects in a block. (This issue will be discussed more in the section on moderation.)

Simultaneous and sequential regression may be used for either explanation or prediction. In explanation, the regression coefficients represent the effects of the presumed causes on the outcome variable of interest, given the adequacy of the model. Prediction equations can also be obtained so that optimal linear combinations of variables can be used to predict an outcome. In our experience, most researchers are interested in explanation even though they may pretend that they are only interested in prediction. One typical scenario

(and we encourage the reader to do a quick literature search to find a multitude of examples) is for authors to discuss prediction in the introduction and results, and then switch to explanation when the findings are discussed. This is the research version of a bait and switch! The researcher may not even know that a switch has taken place, but any time a researcher makes a statement along the lines of “this research suggests that increases in variable x would lead to increases in variable y,” he or she has made an explanatory interpretation. Researchers should ask themselves whether the purpose of their research is *really* prediction or whether it is really explanation before they begin the process (Keith, 2006). To thine own self be true!

Lastly, although we have yet to note *explicitly* that researchers should use the method to match the purpose of their research, we are doing so here. *A priori* conceptual models are associated with structural equation modeling, but it should be obvious that such models are similarly important in regression. Therefore, researchers need to decide what type of regression, or combination of regressions, will be most consistent with their theoretical models.

## Mediation

There are plenty of excellent sources on mediation, so this introduction will be brief (Mackinnon, 2008; Shrout & Bulger, 2002; see also Kristopher Preacher’s website: [www.quantpsy.org](http://www.quantpsy.org)). Mediation occurs when a variable that is between the presumed cause and outcome partially or fully explains the effect of the presumed cause on the outcome. A test of mediation is generally considered a test of the indirect effect of one variable through another variable. Although sequential regression may be used to get an idea about or sometimes test mediation, tests of mediation are probably better off performed in structural equation modeling programs. The study of mediating variables is important because these variables provide an understanding of change mechanisms; for example, an understanding of how treatment effects arise. They are especially interesting because they help explain how outcomes come about.

## Moderation

Multiple regression may be used to test for interaction effects, or what is commonly referred to as *moderation*. Moderation is commonly tested via sequential regression. In child assessment research, moderation is often used to test predictive bias or

invariance. For example, do scores from a reading fluency measure predict reading comprehension equally well for boys and girls (see Kranzler, Miller, & Jordan, 1999)? That is, does sex moderate the relation between reading fluency and reading comprehension? To test for an interaction using multiple regression (i.e., moderated multiple regression), first, a new variable is created as the cross-product of the two variables of interest (e.g., sex multiplied reading fluency scores). Centering any continuous variables prior to creating the cross product is also often used to improve interpretation (Aiken & West, 1991; Keith, 2006), so for example the reading fluency scores would be centered. Next, the main effects (e.g., sex and reading fluency scores centered) are entered in the first block; the cross-product (sex times reading fluency scores centered) is entered in the second block. This cross-product, or interaction term, is added to determine if the interaction term adds unique information to the explanation of the outcome variable. If it adds to the explanation, then it may be said that the effect of one variable (reading fluency) on the outcome (reading comprehension) *depends* on or is moderated by the other variable (sex). Especially with a single cross-product, this analysis could also be performed in simultaneous regression, with the statistical significance of the unstandardized coefficient used as a test of significance for the cross product. The use of sequential regression, however, allows an omnibus test for multiple cross products or the calculation of an effect size (viz.,  $\Delta R^2$ ) for the interaction term (Turrisi & Jaccard, 2003, p. 86). See Keith (2006) for more examples of using regression to test for moderation.

## Missing Data

Missing data are a perennial concern for researchers. Advances in statistical theory in recent years, along with excellent and accessible reviews of missing data assumptions and techniques, have substantially improved our knowledge of how to handle missing data (e.g., Graham, 2009; Schafer & Graham, 2002; Wotheke, 2000). In fact, rather than just *dealing* with missing data, implementing planned “missingness” into research designs may be a cost-effective, efficient method of collecting data (McArdle, 1994). We will provide a brief explanation of missing data assumptions and techniques, but we encourage the reader to refer to some of the excellent sources for more in-depth and informed coverage (Enders, 2010; Graham, 2009; Schafer & Graham, 2002; Wotheke, 2000).

There are three general mechanisms assumed to underlie missing data: Missing Completely at Random (MCAR), Missing at Random (MAR), and Missing Not at Random (MNAR; Little & Rubin, 1987; Rubin, 1976). MCAR requires the assumption that missing data do not differ from those that are non-missing. Say a researcher was interested in studying the effects of IQ and motivation on achievement. After the data were collected, the researcher noticed that scores from the motivation variable were missing for several cases. If data were MCAR, then the missingness of motivation cases was unrelated to motivation scores themselves, as well as to the IQ and achievement scores. The MCAR assumption is required for researchers to use the common deletion methods of handling missing data (i.e., pairwise and listwise deletion). If the assumption is met, then the biggest concern about deleting cases should be a loss of statistical power. If the assumption is not met, then parameter estimates, such as means and regression coefficients, and standard errors of those coefficients, may be inaccurate.

MAR, the second assumption, implies data are missing at random. Indications of why data are missing, however, may be found in the other variables included in the dataset. For example, if motivation scores were missing, the missingness can at least be explained partially by IQ scores, achievement scores, or both. That is, it may be that higher-achieving individuals were more likely to answer the motivation questions. If data are MAR, modern methods such as maximum likelihood estimation and multiple imputation may be used to obtain unbiased estimates. When data are MAR, but the deletion methods are used in analysis, parameter estimates are likely to be biased in that they over- or underestimate the population values, and this bias will probably be difficult to detect.

The third possibility is that data are missing not at random, or MNAR. This type of missingness presents a problem. The missing values depend on something not measured in the dataset, and the reasons for their absence are unknown or unmeasured.

Knowledge of these three underlying mechanisms provides a framework from which a researcher can work. The good news is that it is typical for the mechanism to be at least somewhat understood. Moreover, when a researcher errs in making the assumption of MAR (when MNAR is really the case), the effects on the estimates in the model may be minimal (Graham, Hofer, Donaldson, MacKinnon, & Schafer, 1997).<sup>3</sup> Finally, even if

MCAR is assumed by the researcher, the methods discussed below are better to use than the outdated deletion and mean substitution methods because all of the cases can be used in the analysis.

### ***Outdated Methods***

Listwise deletion, pairwise deletion, and mean substitution are examples of commonly used, but outdated methods. Deletion methods are a simple way of handling missing data because cases are simply dropped from the analysis. Deletion, however, results in fewer participants and will result in biased estimates if the MCAR assumption is not met. Mean substitution, like it implies, involves substituting a mean for missing scores, and is a simple, outdated, and potentially hazardous approach to handling missing data. Although all cases are included in the analysis when mean substitution is used, this procedure should be avoided because it produces biased estimates. Because the same value (the mean) is substituted repeatedly for the missing values of that variable, the variance will be reduced, as will the relation of that variable with the other variables in the model (Wothke, 2000). Other outdated methods include regression-based and hot deck imputations, but these approaches also suffer from limitations. Rather than discussing these methods further, we recommend the application of modern methods and will focus on those (Schafer & Graham, 2002).

### ***Modern Methods***

There are a few modern model-based approaches to deal with missing data, including the expectation maximization algorithm (which uses a maximum likelihood approach) and multiple-group structural equation modeling, but here we will discuss two popular and relatively easy-to-implement methods: maximum likelihood (ML) and multiple imputation (MI). These model-based methods require the less stringent MAR assumption compared to the outdated methods that require MCAR.

ML is the first model-based method. Space precludes a detailed description of the procedure, but a few important points can be made (see Wothke, 2000). First, ML estimation does not impute individual values; rather, the parameter estimates are obtained from using all of the available information in the observed data. Second, in large-sample statistical theory it is well known that ML produces consistent estimates that reflect the population values when data are multivariate normal. Third, ML estimation (with missing data) is available in structural equation

modeling (SEM) software, and its implementation does not require additional work for the researcher. In fact, multiple regression models can be analyzed in SEM programs, making it easy to implement ML methods when data are missing. Last, and perhaps most important, ML results in similar or, more likely, more consistent and less-biased estimates than those obtained after performing deletion and mean imputation; these differences may be dramatic when the data are MAR (Wothke, 2000).

Multiple imputation (MI) is another model-based method. Like ML, the statistical theory of MI is established. In MI, rather than imputing one value for each missing value in the dataset, a set of values representing plausible values is imputed for each missing datum, creating several new datasets with different sets of these new plausible values. Analyses are conducted on each dataset, like they would be with a complete dataset, and the results are pooled. Valid statistical inferences can thus be made, as the results incorporate the uncertainty due to the missing data (Graham, 2009). Like ML, MI generally assumes multivariate normal data, although it seems to also handle multivariate non-normal data fairly well. Given a large sample size, the estimates from ML or MI should be similar. Many statistical programs now include programs for dealing with MI, making it fairly simple to implement.

Researchers should recognize that missing data are not something to be ignored, but something that should be dealt with thoughtfully. Trying to understand the mechanisms that underlie missingness can assist in a better understanding of the data that are available as well as those missing. MI and ML are two fairly simple ways to deal with missing data, even when large amounts of data are missing. Given the relative ease of implementation, these methods should be considered the standard since they outperform outdated procedures, allowing researchers to use all of their data.

## Factor Analysis

Factor analysis is an invaluable tool for understanding latent constructs and evaluating validity, and is commonly used to evaluate psychological assessment (measurement) instruments. The purpose of factor analysis is to uncover latent psychological attributes that account for correlations among observed variables. Quite simply, factor analysis is useful for understanding whether an instrument measures what it is supposed to measure. Although commonplace and useful in assessment research, factor analysis and other complex methods cannot make up for lack of relevant theory, common sense,

knowledge-base, and carefulness of a researcher. Factor analysis may be misused and abused, intentionally or unintentionally.

The two main types of factor analysis are confirmatory (CFA) and exploratory (EFA) factor analysis. We will focus on CFA in this chapter, with only a few comments on EFA. EFA is older, growing out of Spearman's early twentieth-century explorations of the nature of intelligence (Spearman, 1927). With EFA, researchers choose the method (e.g., principal factors, maximum likelihood), the criteria for selecting factors (e.g., eigenvalues greater than one, *a priori* knowledge), the criteria for meaningful loadings, and the rotation method, and then interpret the results. Each step requires judgement, and multiple factor solutions are often examined. If done well—by researchers who are careful in developing the measures, and who apply combinations of criteria, use good judgement, and have knowledge of the relevant literature—EFA can be an invaluable tool in uncovering latent variables that explain relations among observed variables. But, EFA may also be abused. It is not unusual to see researchers put little thought into the theory that guides measurement; gather data; use inflexible criteria for factor extraction and rotation; and interpret their findings as if they were revealed truth. The judgement required to be good at EFA is a feature, not a design flaw! For more information about EFA, readers should refer to other, excellent sources (e.g., Preacher & MacCallum, 2003; Wolfe, 1940).

One other topic worth mentioning concerning EFA is the distinction between factor analysis and principal components analysis (PCA). A component obtained in a PCA is different from a factor obtained in a factor analysis. A component is a composite variable. Factors are latent variables. Most psychological attributes are conceptualized as latent variables, not composites, and these attributes should be invariant across the different instruments designed to measure them. One of the long-standing critiques of PCA is that the components (i.e., composites) are not psychologically meaningful (Wolfe, 1940). Factor analysis is thus the appropriate tool to use in latent variable research, not PCA.

Second, the procedures are used for different purposes. PCA, a descriptive procedure, was developed for data reduction and to maximize the variance explained in observed variables. Factor analysis, a model-based procedure, was designed to uncover psychologically meaningful latent variables that explain the correlations among observed variables. Factor analysis thus analyzes the common variance,

separating it from the unique variance. Unique and common variances are not separated in PCA. These distinctions have not stopped researchers from substituting PCA for factor analysis. As some have noted, perhaps this is because even some popular statistical programs do not differentiate the two (see Borsboom, 2006, for a discussion). Although space precludes further discussion of this issue, there are other excellent treatments of the topic (e.g., Preacher & MacCallum, 2003; Widaman, 2007; Wolfe, 1940). For a demonstration of potential different findings related to the use of PCA—and outdated missing data methods—in applied research, see Keith, Reynolds, Patel, and Ridley (2008).

### **Confirmatory Factor Analysis**

CFA requires a researcher to specify the number of factors and the pattern of zero and free factor loadings *a priori*. CFA is commonly used in psychological assessment research to address questions related to the measurement of psychological constructs and construct validity. We will work through an example to demonstrate the usefulness of CFA in establishing construct validity in an individually administered intelligence test. Throughout the example, we will describe and deal with various issues that may arise when conducting CFA.

During the last 20 years there has been a shift in the development of intelligence measurement instruments; many developers now rely on underlying theory during the developmental phase. The shift represents a major advancement that has not only informed measurement, but has likewise informed research and theory (Keith & Reynolds, 2010). The most popular theory, or perhaps better described as a *taxonomy*, underlying the development of these instruments is the Cattell-Horn-Carroll (CHC) theory of intelligence (McGrew, 2009), a theory that combines Cattell-Horn's *Gf/Gc* theory (Horn & Noll, 1997) and John Carroll's three-stratum theory (Carroll, 1993).

The Kaufman Assessment Battery for Children-II (KABC-II; Kaufman & Kaufman, 2004) is an example of a popular measure of child and adolescent intelligence in which theory was used during the developmental phase. In fact, the KABC-II may be interpreted using either CHC theory or Luria's information processing theory. In our CFA examples, we will use the norming data from the KABC-II to evaluate the measurement structure of the test. The CFA models will be consistent with the scoring structure using the CHC theory interpretation only. The scoring structure for the KABC-II battery includes index scores for five CHC broad

abilities and a general ability referred to as the Fluid-Crystallized Index (FCI), as well as a few tests to supplement the broad ability indexes. The five broad CHC index scores include *Gc* (Knowledge), *Gv* (Visual Processing), *Gf* (Fluid Reasoning), *Glr* (Long-Term Retrieval), and *Gsm* (Short-Term Memory). *Gc* is measured with three subtests, *Gv* with four, *Gf* with two, *Glr* with four, and *Gsm* with three. We should note that the standard battery has fewer subtests, and some subtests were included as supplemental tests. The supplemental tests were used in our CFA to maximize the information available.

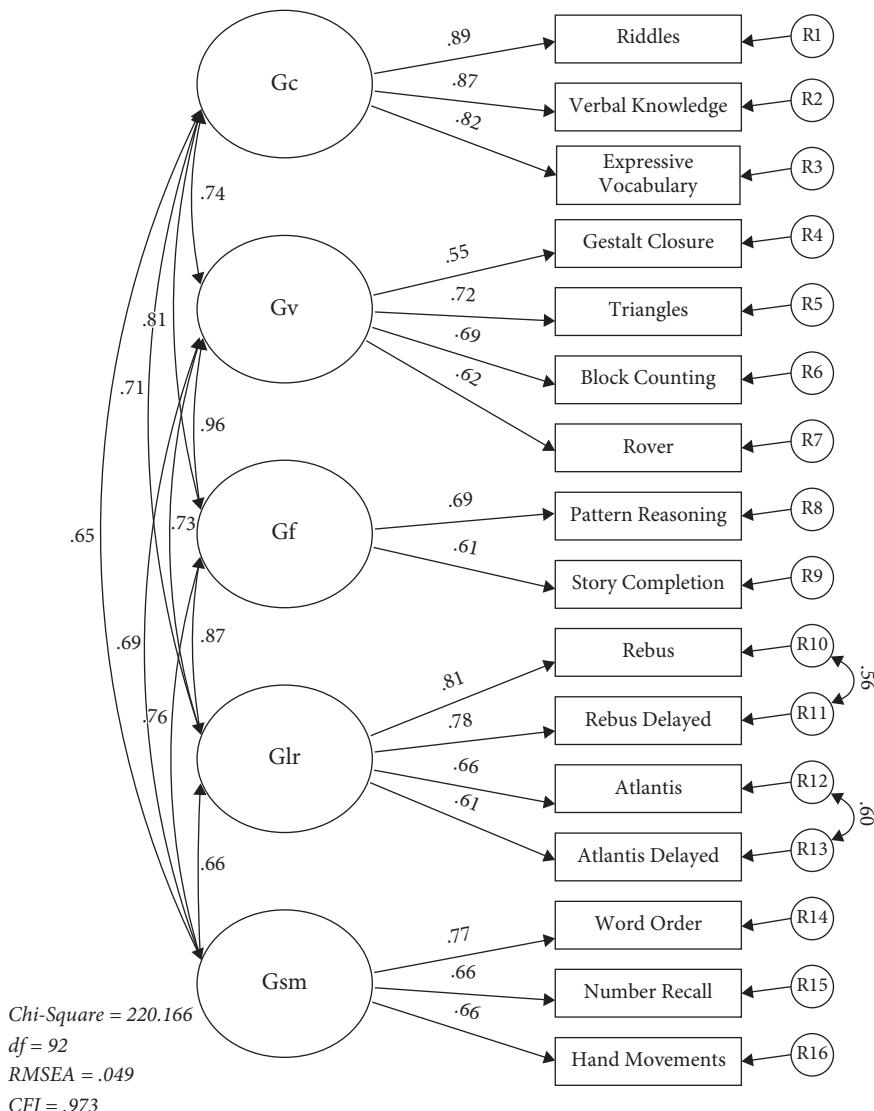

The data used in this example were age-standardized scores obtained from adolescents who ranged in age from 15 to 18. The sample included 578 participants. There were missing values for a few of the cases. The MCAR assumption was tenable. Rather than deleting cases, however, we chose to include *all* of the cases in the analyses using ML in Amos (Arbuckle, 2006) to handle missing data. Untimed scores were substituted for timed scores because in previous research the timed scoring procedure has been shown to introduce construct-irrelevant variance (Reynolds, Keith, Fine, Fisher, & Low, 2007). First-order and higher-order CFA models were estimated, and these are described below.

### **FIRST-ORDER MODELS**

#### *Specification*

A first-order CFA model with five factors representing the five broad-ability factor indexes is shown in Figure 3.3. Essentially, we are interested in answering this question: Does the hypothesized latent structure underlying the observed data match the KABC-II measurement (scoring) structure? We address this question empirically by explicitly matching our factor model to the five broad-ability indexes. In Figure 3.3, the ovals represent latent variables; rectangles represent the observed variables; directed arrows represent directed effects; and non-directed arrows represent correlations/covariances.

Each factor is indicated only by the specific subtests that make up that broad index (Figure 3.3). Relevant theory (Jensen, 1998) and the use of an overall test score would also suggest that the factors should be correlated; therefore, the first-order model allows for intercorrelations among the factors rather than specifying them as independent of each other. The *Glr* measurements each included a delayed recall version of the original test. The residual variances associated with the first measurement and corresponding delayed measurement were specified to correlate freely (e.g., *Rebus* with *Rebus*

**Figure 3.3** KABC-II First-Order Factor Structure with Standardized Loadings.

Delayed). These correlated specific factors represent overlap between the tests above and beyond what is explained by the  $G_{lr}$  factor. Although our input model is not presented, the residual variance paths and one loading per factor were fixed to one so that the scales were properly set and the model was properly identified.

#### Model Evaluation

Indexes have been developed to assist researchers in evaluating fit. (More detailed explanation of these indexes is given elsewhere [e.g., Marsh, Hau, & Grayson, 2005].) For this example, model fit was evaluated with the root mean square error of approximation (RMSEA; Steiger & Lind, 1980

and comparative fit index (CFI; Bentler, 1990), with values below .05 and above .95 indicating good fit, respectively. In addition, chi-squared ( $\chi^2$ ) was used to evaluate the fit of single models, and change in chi-squared ( $\Delta\chi^2$ ) was used to evaluate competing nested models (i.e., models that can be derived by constraining additional parameters in a model). Chi-squared demonstrates excessive power to detect model misfit in large sample sizes, but, in general, the lower the  $\chi^2$  value relative to  $df$ , the better.

#### Results

The fit indexes for this measurement model indicated model fit was acceptable:  $\chi^2 (92) = 220.17$ ,  $RMSEA = .05$ ,  $CFI = .97$ . The model with

standardized factor loadings is shown in Figure 3.3. The factor loadings were all substantial.<sup>4</sup> Like the directed paths in path analysis, one can interpret these loadings as regression coefficients. For example, the .88 standardized effect of  $G_c$  on Riddles suggests that a one standard deviation increase in latent  $G_c$  would result in a .88 standard deviation increase in a Riddles score.

The results support the interpretation of the broad-ability indexes on the KABC-II. It is not uncommon, however, for some subtests to measure more than one latent broad ability. Such subtests are often described as being *factorially complex* (McDonald, 1999). For example, to perform well on complex memory tasks requiring multiple steps, a person may employ a novel cognitive strategy to reduce the memory load, therefore reducing the memory requirement for successful performance. Novel problem-solving ability is associated with  $G_f$ , and working memory and  $G_f$  typically correlate strongly. The Hand Movements subtest on the KABC-II is an example of test that requires relatively complex memory; it is thus plausible that people high in  $G_f$  could reduce the memory load of the task via their novel problem-solving abilities. To test this hypothesis, we loosened the strict assumption that all subtests measure only one factor and allowed Hand Movements to indicate  $G_f$  and  $G_{sm}$ , or “cross-load.” This model fit the data well:  $\chi^2(91) = 180.81$ , RMSEA = .04, CFI = .98. Moreover, the improvement in model fit was statistically significant, as indicated by  $\Delta\chi^2(1) = 39.36$ ,  $p < .01$ . When allowed to load on both factors, Hand Movements had a standardized loading of .40 on the  $G_f$  factor and .30 on the  $G_{sm}$  factor.

There are a few salient points related to this finding. First, Hand Movements is a supplemental test and not part of the standard battery. Perhaps the authors were not confident enough that this indicator reflected  $G_{sm}$ , and it was not included in the standard battery for this reason. Therefore, the finding does not invalidate the measurement of  $G_{sm}$  using the broad index. Second, the finding provides some initial evidence that Hand Movements may measure more than  $G_{sm}$ , or that it is factorially complex. Third, when such *post hoc* modifications are made, there are always increased risks for sample-specific findings that may or may not be important.

Resolving what latent cognitive abilities Hand Movements measures will be left up to future research. One excellent method that could be used to investigate further what it measures is cross-battery factor analysis (CB-FA); that is, a factor analysis of Hand Movements with  $G_{sm}$  and  $G_f$  tests from other

intelligence batteries. Cross-battery factor analyses (and cross-battery confirmatory factor analysis, CB-CFA, in particular) across measurement instruments is an extremely useful method used to understand what tests measure (Keith & Reynolds, 2010, 2012). On a related note, it is not uncommon to see researchers factor analyze only the standard tests in a battery, even when both standard and supplemental tests are available; or, alternatively, to conduct two analyses, one including all tests and one including only those from the standard battery. We generally discourage this approach. Except under rare circumstances (e.g., a poorly designed or theoretically murky test), more measures will generally lead to a deeper understanding of the underlying constructs. In the present example, Hand Movements may be less desirable because it is factorially complex, but its inclusion, and its theoretically predictable cross-loading, also supports the validity of the underlying constructs. That is, Hand Movements can be understood as requiring novel reasoning as well as short-term memory. The fact that it shows substantial cross-loadings on two such factors supports those factors as indeed representing  $G_f$  and  $G_{sm}$ , respectively. The alternative, analyzing fewer measures, has the potential to mislead; when fewer tests are analyzed, factors are more likely to represent narrower abilities, and are more likely not to appear at all. When understanding the constructs underlying the test is the purpose, more is almost always better.

## HIGHER-ORDER MODELS

### Specification

In addition to the five CHC broad abilities, the KABC-II provides an index of a general mental ability, the FCI index. The next step is to match the analytic model (technically now a structural model because the covariance among the first-order factors were structured) with the overall scoring structure of the test. We consider the higher-order model, such as the one shown in Figure 3.4, the most appropriate. Typically, general intelligence ( $g$ ) is considered to influence performance on all measures of cognitive ability. The nature of  $g$  cannot be understood by surface characteristics of the items or tests designed to measure it, however, as tests that look completely different on the surface often have similar loadings on a  $g$  factor (Jensen, 1998). Instead,  $g$  is conceptualized at a higher level of abstraction than the broad abilities, which are typically defined by surface characteristics of the measurement instruments. Therefore, we believe that the higher-order model most accurately

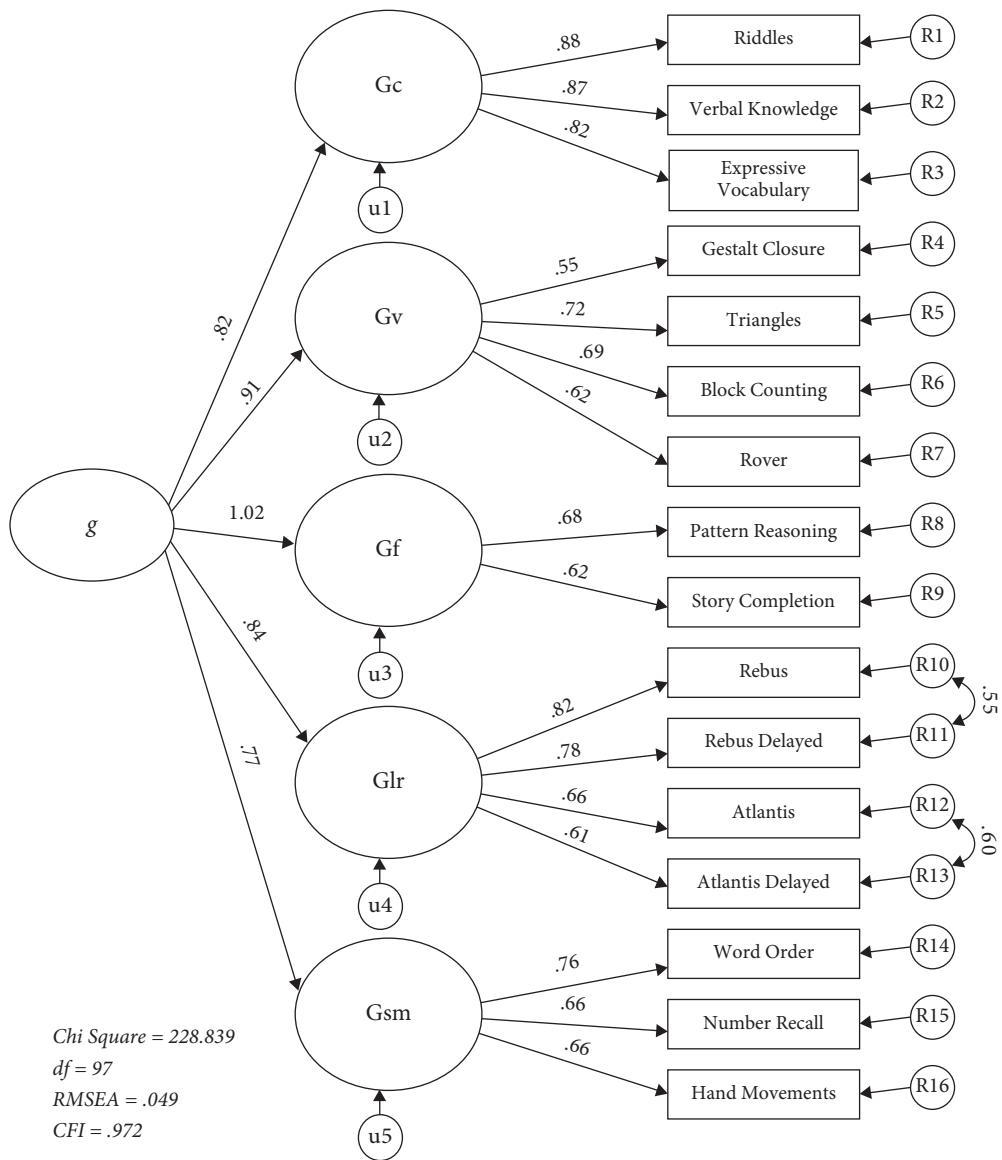

Figure 3.4 KABC-II Second-Order Factor Structure with Standardized Loadings.

mirrors current conceptions of human cognitive abilities (see Carroll, 1993; Jensen, 1998).

There are a few interesting things to note about the higher-order model shown in Figure 3.4. First, the second-order factor,  $g$ , in part, accounts for the covariance among the first-order factors. This conceptualization provides a more restricted and parsimonious account of the data than does the first-order model. In the higher-order model, there are five loadings on the  $g$  factor, while in the first-order model there were 10 correlations among the factors. Second, the  $g$  factor is indicated by the five latent variables and not the observed variables. It is a latent variable indicated by latent variables;  $g$  is at a higher order of

abstraction. In addition,  $g$  is considered to be more general than the broad abilities because it influences performance on all tests, albeit indirectly through those broad abilities. There are no “direct” effects of  $g$  on the subtests. The effect of  $g$  is completely mediated by the broad ability factors. Direct effects may be included,<sup>5</sup> but the representation in Figure 3.4 is both parsimonious and theoretically consistent with contemporary theory (Carroll, 1993; Jensen, 1998). Last, in Figure 3.4, notice the ovals, labeled with “u’s,” with arrows directed at the first-order factors. These uniquenesses, or disturbances, represent the variance left unexplained by  $g$ . These disturbances are interesting because they represent the unique aspects of the

broad abilities. That is, they represent unique variance only, not unique (or specific) and error variance, as do the residuals for the subtests. They reference the first-order factors, and the factors are perfectly reliable (cleansed of error), unlike the subtests.

### Results

The higher-order model fit well:  $\chi^2(97) = 228.83$ , RMSEA = .05, CFI = .97. The fit of the model along with relevant theory would indicate that the higher-order model was a plausible model for these data. However, there was also an oddity in the standardized factor loadings: The factor loading of  $G_f$  on  $g$  was 1.02 (Figure 3.4). How can a standardized loading be greater than one? It is possible, like in regression (Jöreskog, 1999), although such a result is almost always worth investigating further. Although not shown in Figure 3.4, in addition to the loading of 1.02, the unique variance ( $u_3$ ) for  $G_f$  was not statistically significantly different from zero. These two pieces of information suggest that  $G_f$  and  $g$  may not be statistically distinguishable, or that they are correlated perfectly. Interestingly, some have posited that  $G_f$  and  $g$  are identical (Gustafsson, 1984). An identical  $G_f$  and  $g$  is a theoretical question, however, because perfectly correlated variables need not be identical constructs. Nonetheless, by fixing the  $G_f$  unique variance ( $u_3$ ) to zero, rerunning the model, and then evaluating whether the model fit worse based on  $\Delta\chi^2$ , the *statistical* equivalence of the two variables in this sample could be tested. We ran such an analysis. The model with the  $u_3$  fixed to zero fit the data well:  $\chi^2(98) = 229.27$ , RMSEA = .05, CFI = .97. The  $\Delta\chi^2(1)$  was 0.44 ( $p = .51$ ), and was not statistically significant, suggesting that  $G_f$  and  $g$  are *statistically* equivalent, a finding not uncommon for higher-order analyses of intelligence data (Keith & Reynolds, 2012).

### Higher-Order Models and the Schmid-Leiman Transformation

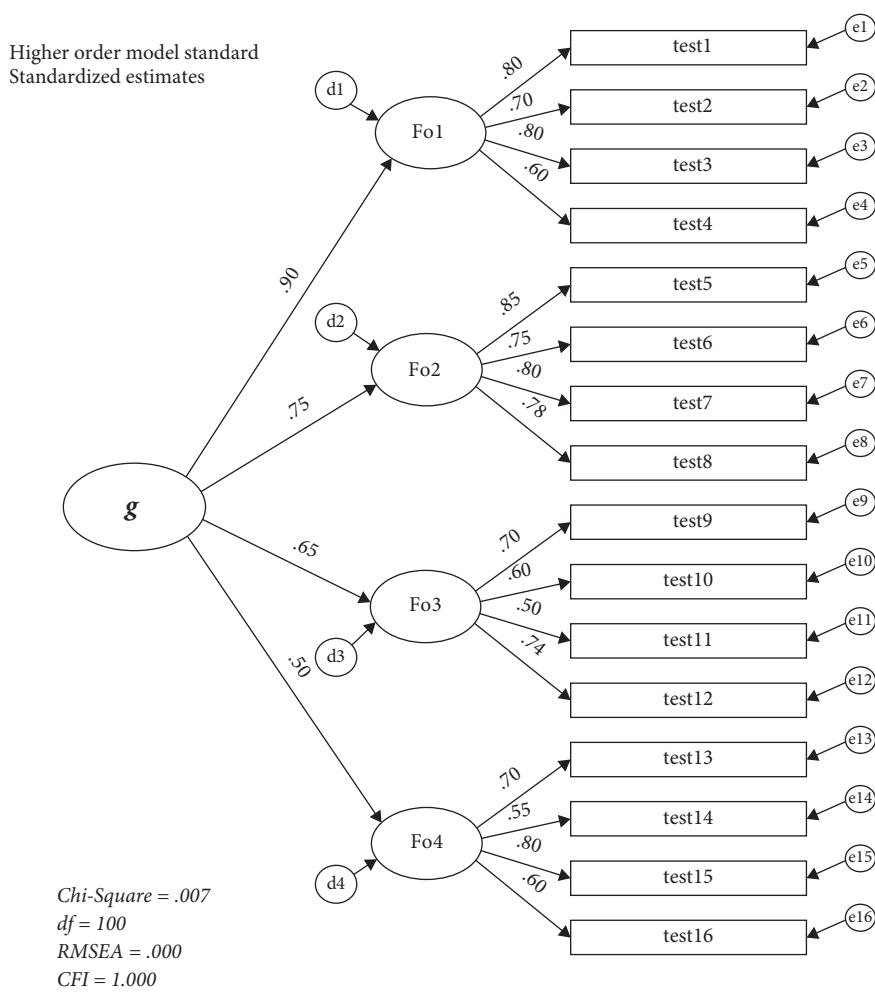

As already noted, in the higher-order model shown in Figure 3.4,  $g$  only affected the subtests indirectly, via the first-order factors. Said differently, the broad abilities completely mediate the effect of  $g$  on the subtests. Thus it is possible to calculate the total effect of  $g$  on each of the subtests in order to get some sense of the loading of each subtest (indirectly) on  $g$ . It would also be possible to compare this loading on  $g$  to the subtest's loadings on the broad abilities to get some sense of the relative effect of  $g$  versus the broad ability. The factor loadings of each subtest on its broad ability and on  $g$  are shown

**Table 3.2** KABC-II Loadings on the First-Order Factors (see Figure 3.4 for the First-Order Factor Names) and the Second-Order  $g$  Factor. The final column shows the residualized first-order factor loadings, with the effect of  $g$  removed.

Subtest	First-Order	$g$	Residualized First-Order
Riddles	.885	.728	.503
Verbal Knowledge	.868	.714	.494
Expressive Vocabulary	.824	.677	.469
Gestalt Closure	.555	.504	.232
Triangles	.724	.658	.303
Block Counting	.685	.622	.288
Rover	.617	.560	.258
Pattern Reasoning	.693	.693	.000
Story Completion	.627	.627	.000
Rebus	.817	.688	.440
Rebus Delayed	.783	.660	.421
Atlantis	.657	.554	.352
Atlantis Delayed	.610	.514	.328
Word Order	.764	.590	.486
Number Recall	.656	.507	.417
Hand Movements	.662	.511	.421

in Table 3.2. This may feel like cheating in some sense of the word, however, because for both loadings the effect of the broad abilities on the subtests is used. So, for example, the loading of Word Order on  $G_m$  is .76, whereas the loading of Word Order on  $g$  is  $.76 \times .77 = .59$ . Given that all of  $g$  loadings go through the first-order factors, these loadings are constrained by the loading of the first-order factor on  $g$ .

If the double use of the first-order loadings makes you feel uncomfortable, an alternative would be to ask: What is the residual effect of the broad abilities after  $g$  is taken into account? One way to calculate these residual effects is to square the  $g$  loadings (to obtain the variance accounted for by  $g$ ) and subtract these from the  $R^2$  for each subtest (a statistic available in any SEM program). The resulting value would represent the variance explained uniquely by the broad abilities, after accounting for the variance explained by  $g$ . The square root of that

**Figure 3.5** Higher-Order Model Results for the Simulated Data. The model fits nearly perfectly because the model shown was used to generate the data.

unique variance would then represent the unique loading of each subtest on the broad abilities after  $g$  is taken into account. These values are also shown in Table 3.2 in the last column on the right.

To further illustrate these and subsequent points, we will switch to simulated data. Figure 3.5 shows a straightforward factor model of 16 tests measuring four first-order factors and  $g$ , a higher-order factor. The model and the data are designed to be consistent with findings from analyses of intelligence test data. (The model fits these data perfectly, or nearly perfectly, because the model shown was used to simulate a matrix, which was then used in the analysis.) The first factor (Fo1) is most similar to  $g$ , and there is variability among the tests in how well they measure each broad ability. Figure 3.5 shows the loadings of each test on the broad abilities, and the first

column of numbers in Table 3.3 shows the loadings of each test on  $g$ . The second column of numbers in Table 3.3 shows the residualized loading of each test on the corresponding broad ability, or the unique effect of each broad ability on their subtest indicators, after accounting for  $g$ .

Discussion of the unique effect of the broad abilities suggests another way to calculate these effects. Figure 3.6 shows a slight variation of the higher-order model. In the initial figure, the disturbances of the first-order factors were scaled by constraining the path from the disturbance to the factor to 1.0 (what Kline, 2011, calls “unit loading identification” [ULI]). In Figure 3.6, an alternative method was used to scale the disturbances: The variances of the disturbances were set to 1, and the paths from the disturbances to the factors were estimated (unit variance identification, or UVI). With

Test 16	.300	.520	.520

*Note:* First-order loadings represent the first-order factor effect on the test, with effects of  $g$  removed and calculated with two different methods (see text for explanation).

in this specification, it is possible to calculate the indirect effects from the disturbances (the *unique variances* of the first-order factors) to the tests. So, for example, the effect of d4 on test 16 is  $.866 \times .600 = .5196$ , or .520. Again, this is the unique effect of the first-order factor, with the effect of  $g$  removed. These values are shown in the final column of Table 3.3; they are the same as those shown in the previous column.

This calculation of the unique, or residualized, effects of the first-order factors, after accounting for the second-order factor, is analogous to the common Schmid-Leiman procedure in exploratory factor analysis. Table 3.4 shows the Schmid-Leiman transformation for these same data. The solution is based on an exploratory principal factors analysis of the simulated data used for

Figures 3.5 and 3.6 (and Table 3.4), with extraction and promax rotation of four factors. As can be seen by comparing Table 3.4 with Table 3.3, the estimates from this exploratory analysis are quite close to those from the confirmatory analysis. (It should be noted that the ordering of factors was changed; that is, what is labeled as “Factor 1” in the table actually came out as “Factor 2” in the EFA). Again, the table comparisons show that residualizing the first-order factor loadings from a higher-order model is methodologically equivalent to a Schmid-Leiman transformation.

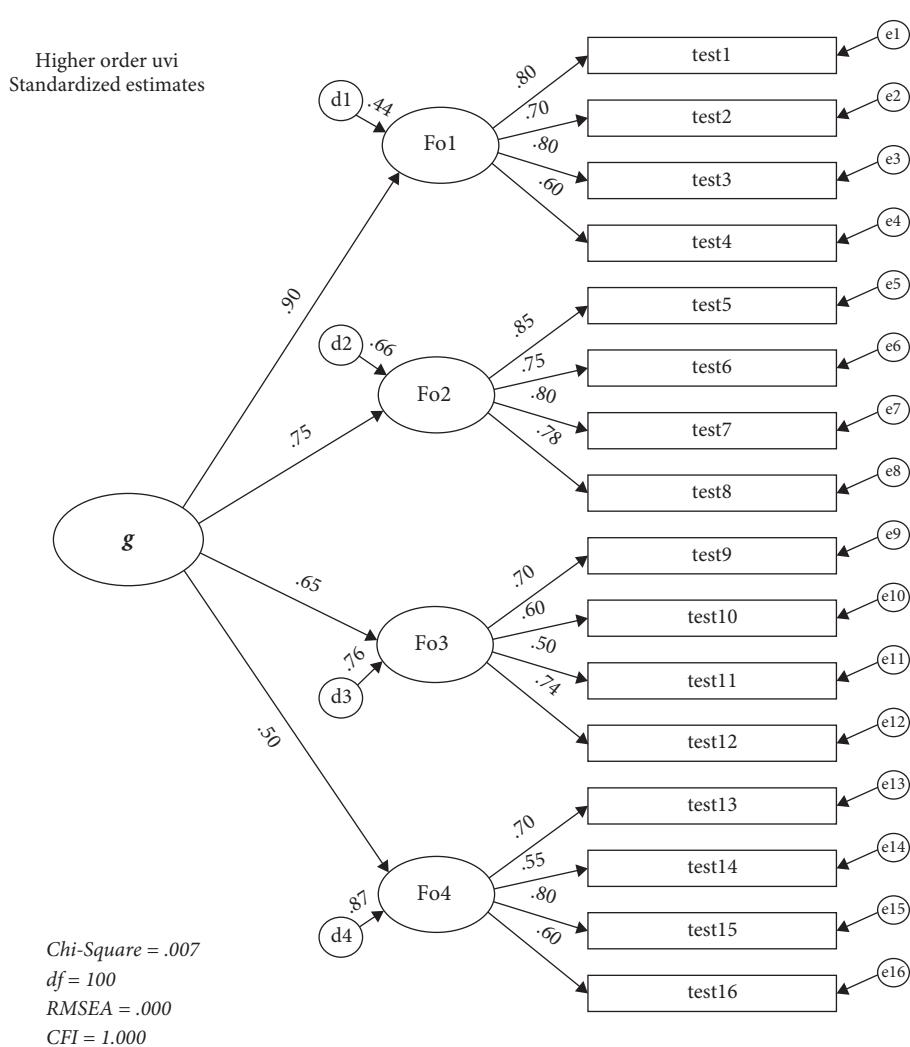

Several points are worth mentioning about these procedures. First, they go by a variety of names. Here we have referred to this as a *residualization of the first-order factor loadings*, accounting for the second. Others may refer to this as an *orthogonalization* (e.g., Watkins, Wilson, Kotz, Carbone, & Babula, 2006) because the first-order factors have been made *orthogonal* (uncorrelated with) the second-order factor. This concept is well illustrated in Figure 3.6, where the unique factors are uncorrelated with the second-order  $g$  factor. It would also be correct to refer to these loadings as the *g loadings* and the unique effects of the first-order factors. Some writers may simply refer to these as *first and second-order factor loadings*, apparently not recognizing that the first-order loadings are with  $g$  statistically controlled.

#### EFFECTS VERSUS PROPORTION OF EXPLAINED VARIANCE

Readers may wonder why we focused on factor loadings rather than variances. After all, one method used to calculate the factor loadings did so by converting the  $g$  loadings to variances. We believe the focus on factor loadings rather than variances is appropriate for several reasons. First, factor loadings are the original metric. They are readily interpretable as effects; that is, the effect of  $g$ , or the broad abilities, on the tests. Second, the focus on factor loadings also makes this procedure easily interpretable as a Schmid-Leiman transformation. Finally, because variances focus on the original metric squared, they provide misleading estimates of the relative importance of the factors (Darlington, 1990; Keith, 2006, Chap. 5).

#### TOTAL VERSUS UNIQUE EFFECTS

A final point concerning this residualization is the reminder that the tables show the loadings of  $g$ , and the loadings of the first-order factors *with g controlled*, or the total effect of  $g$  and the unique

**Figure 3.6** Higher-Order Model Estimated Using Unit Variance Identification. Note the standardized paths from the disturbances to the first-order factors.

effect of the first-order factors. As such, the technique gives interpretive predominance to  $g$ , essentially a tacit, Spearman-like notion that  $g$  is most important. There is nothing wrong with this interpretation as long as researchers and readers understand it. Readers who believe that first-order factors should be given interpretive predominance (a Thurstone-like notion) could reasonably argue for the opposite of this procedure: the interpretation of the first-order factor loadings versus the unique effect of  $g$ , *while controlling for the first-order factors*. Because the strict higher-order model has  $g$  affecting the subtests only through the broad abilities, for this approach the first-order factor loadings (i.e., the “First-Order” in Table 3.2) represent the effect of the broad abilities on the subtests, but the effect of  $g$  on the subtests would all be equal to zero

(because there are no direct effects of  $g$  on the broad abilities)! Thus we recommend reporting results of this transformation, but also reporting the original, un-residualized, first-order factor loadings.

### ***An Alternative to the Higher-Order Hierarchical Model***

The higher-order model is the most common method of estimating both broad (e.g.,  $G_f$ ,  $G_c$ ) and general ( $g$ ) abilities in the same model. Another type of hierarchical model is often referred to as the *nested-factors* or *bi-factor model*. In this type of hierarchical model, the general and broad factors are at the same level; an example using the simulated model is shown in Figure 3.7. Note that methodologists have used different names to refer to such models. The higher-order model is sometimes called

**Table 3.4 Schmid-Leiman Solution for the Simulated Data. The loadings are based on an exploratory principal factors analysis with promax rotation of four factors. The first-order loadings represent the effect of the first-order factor on the test, with the effects of  $g$  removed.**

a *hierarchical model* (e.g., Gustafsson & Balke, 1993; Mulaik & Quartetti, 1997), and the nested-factors model is often referred to as the *bi-factor*, or simply the *hierarchical*, model (McDonald, 1999). Here we refer to models such as those in Figures 3.5–3.6 as *higher-order models*, and those in Figure 3.7 as *hierarchical models*.

Conceptually, it may appear that this hierarchical approach provides a more direct approach to residualization than the Schmid-Leiman transformation shown in Tables 3.3 and 3.4. And this expectation appears confirmed by the values shown in Figure 3.7. The fit of the model is the same as it was for the higher-order model, and the loadings of the tests on  $g$  are identical to those shown in Table 3.3 (the symbol  $G$  is sometimes used to symbolize this factor because it is now a first-order, rather than a second-order, factor; Reynolds & Keith, 2007). Most importantly, the loadings of the tests on Fo1 through Fo4 are the same as the residualized

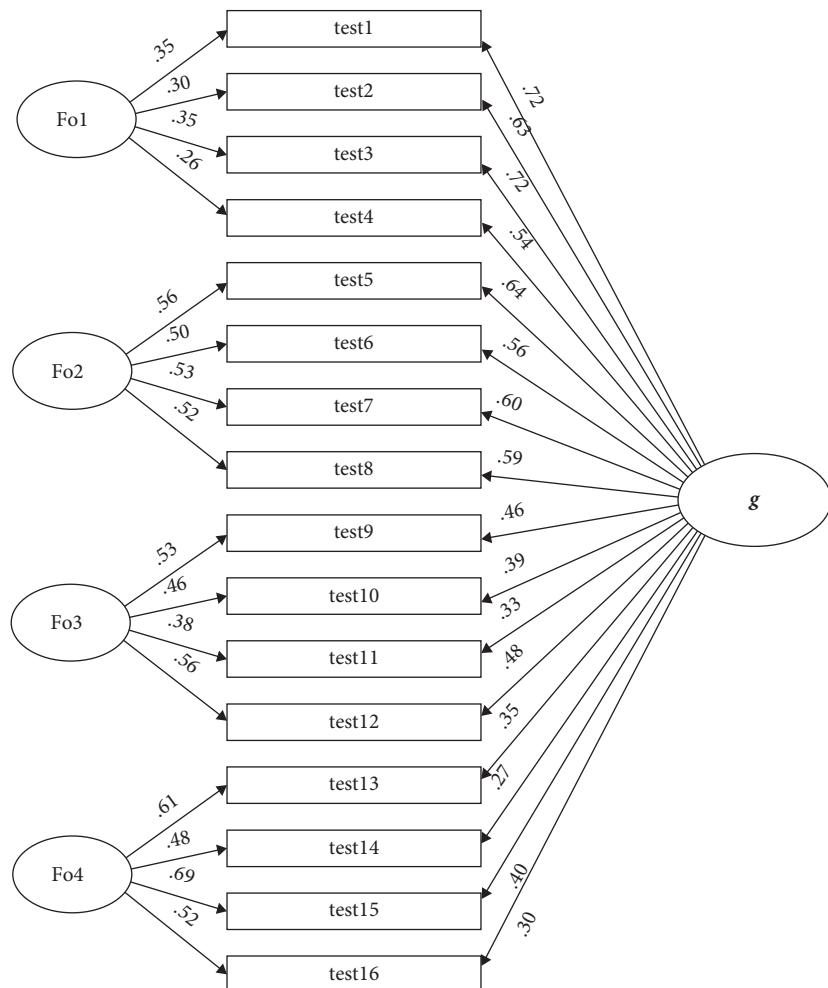

loadings for these factors in the higher-order model (Table 3.3).

It would seem, then, that a hierarchical model provides a simpler method for producing a Schmid-Leiman residualization. But this is not always the case. In fact, the only reason the two methods produced the same results is because a higher-order model was used to create the data in the first place. Note that, in Figure 3.5, the only way the second-order  $g$  factor can affect the tests is via the first-order factors. As a result, there are proportionality constraints on the residualized first-order factor loadings, by factor. So, for example, the first-order factor loading divided by the second-order factor loading is approximately .485 for the first four tests (which are on factor Fo1), .881 for tests 5–8 (on Factor Fo2), and so on.

Figure 3.8 shows a hierarchical model using a different set of simulated data. For this model, the hierarchical model shown was used to create the simulated data. Note that although the  $g$  loadings are similar to those shown for previous models, the loadings for Fo1 through Fo4 are different. More importantly, there are no proportionality constraints for this model.

Figure 3.9 and Table 3.5 show the results a higher-order solution for this same data. Note that, for this solution, there is no longer a nearly perfect fit of the model to the data. Note also the difference in factor loadings for the hierarchical solution versus the higher-order solution (Table 3.5). Finally, note the proportionality constraints for the first-order/ $g$  factor loadings for the higher-order solution, and the lack of those constraints for the hierarchical factor loadings. The higher-order model requires these constraints because the only way that  $g$  can affect the tests is indirectly, via the first-order factors.

What do these differences mean for the estimation of hierarchical models? Several points are worth noting. First, this comparison makes it obvious that the higher-order model is a more constrained version of the hierarchical model. Said differently, all higher-order models are hierarchical models, but not all hierarchical models are higher-order models. Relatedly, if a higher-order process created the data, a higher-order model and a hierarchical model will fit the data equally well. In contrast, if a hierarchical process (without proportionality constraints) created the data, then a hierarchical model will fit the data better than a higher-order model. Thus, in some sense, a comparison of a hierarchical model with a higher-order model is a test of which process created the data, and whether  $g$  affects first-order latent factors, or subtests directly.

Chi-Square = .007

CFI = 1.000

Hierarchical model 1

Standardized estimates

**Figure 3.7** A Hierarchical, or Nested Factors, Model Using the Same Simulated Data. The higher-order model is a more constrained version of this model.

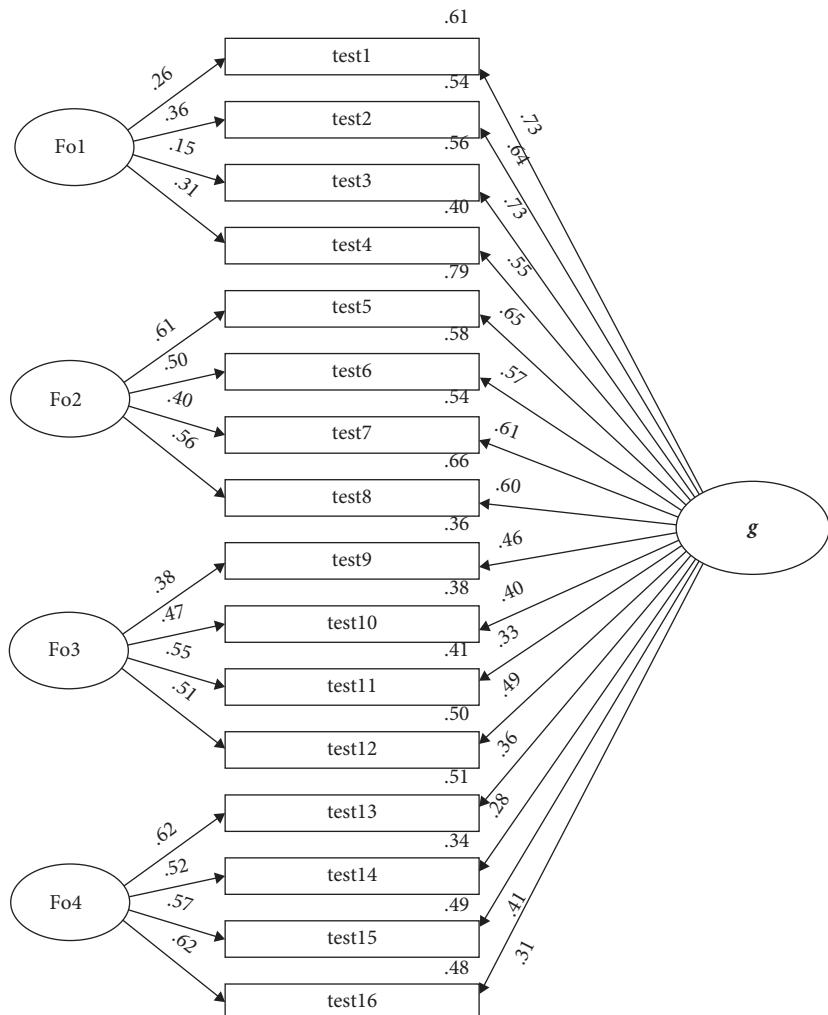

Another way of saying this is that a comparison of the models tests the proportionality constraints required by the higher-order model (for further discussion of these issues, see Mulaik & Quartetti, 1997; or Yung, Thissen, & McLeod, 1999).<sup>6</sup>

This discussion would seem to suggest that one should prefer hierarchical models to higher-order models. After all, they will fit the data at least as well, and often better. But the entire process of modeling involves placing theoretically derived constraints on data, so we should not simply choose one model because it will have a higher probability of fitting well. As preached repeatedly in this chapter, theory must drive modeling, and must drive analysis. In

the area of intelligence, we believe that higher-order models are theoretically more defensible, more consistent with relevant intelligence theory (e.g., Jensen, 1998), than are less constrained hierarchical models.

### Measurement Invariance

Psychological-assessment researchers often develop new instruments under the assumption that differences in the underlying psychological attributes produce individual differences in the observed test scores. It is typically implicitly assumed that the measurement of the latent attributes underlying those scores operate the same

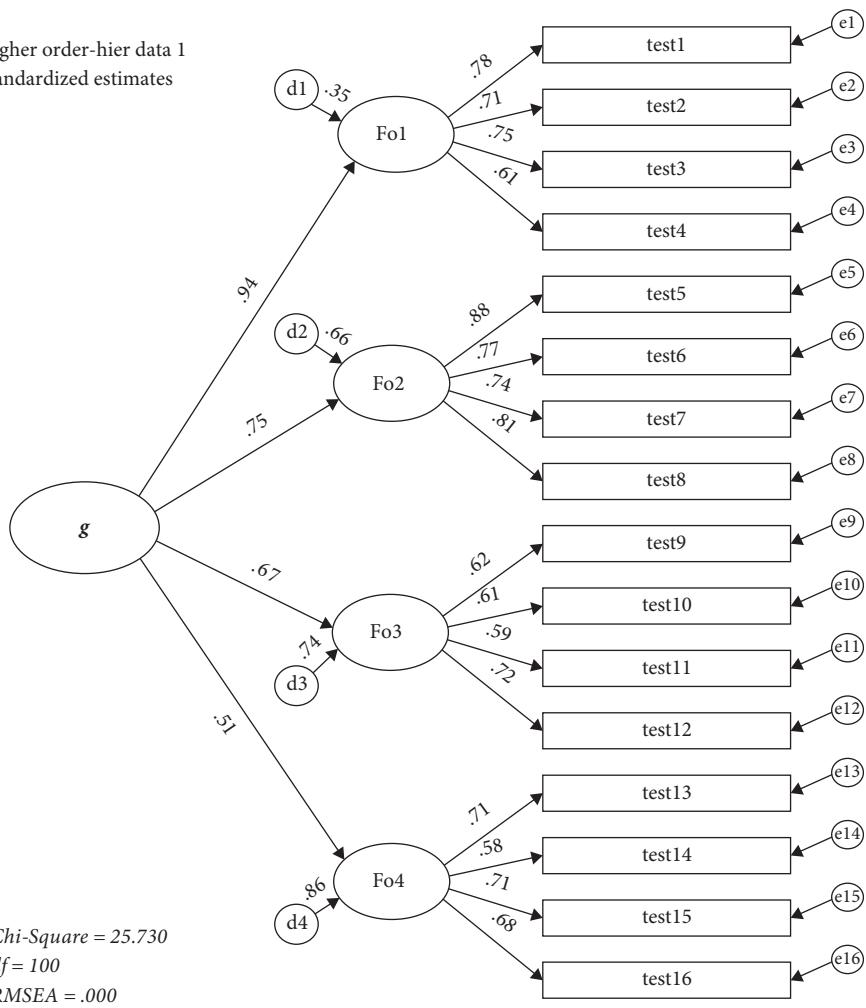

**Figure 3.8** A Hierarchical Model Using a Second Simulated Data Set. This model was used to generate the data.

way across different groups of people (e.g., males and females). Nonetheless, it is important that this assumption be explicit and tested empirically. One of the more important advancements in measurement, and one that is particularly germane to psychological-assessment research, is the development of a set of factor analytic procedures to assess for measurement invariance (Meredith, 1993). Here we will discuss the assessment of measurement invariance using factor analysis.

Measurement invariance is the assumption that observed scores should be identical in individuals who have identical values of a latent trait (Meredith, 1993). That is, a measurement is unbiased. For

example, if males and females are administered a measure of intelligence, their scores should depend only on their latent intellectual ability, not on their sex. Measurement invariance is extremely important in test development and in research involving group comparisons (e.g., sex, culture, treatment/control groups) of psychological attributes and test bias. We will discuss this concept in detail via a worked example of how to establish measurement invariance at the subtest level in an individually administered measure of intelligence. We will use multiple-group confirmatory factor analysis, or what is commonly referred to as *multiple-group, mean and covariance structure* analysis (MG-MACs).

Higher order-hier data 1  
Standardized estimates

**Figure 3.9** A Higher-Order Model for the Second Simulated Data Set. This model does not fit the data as well, because the model that created the data did not have the first-order and *g* factors proportionality constraints hidden within the higher-order model.

Age-standardized scores from the norming sample of the KABC-II (Kaufman & Kaufman, 2004) were used in the following example. Data from children and adolescents ages six to 18 were collapsed across the age range (1,189 females and 1,186 males). Previous research has demonstrated age invariance for the KABC-II, so collapsing across different age levels was deemed acceptable (Reynolds et al., 2007).

MG-MACS was used to test for measurement invariance across sex by adding parameter constraints sequentially in a set of multi-group models, moving from unconstrained to more constrained models. In multi-group models, factor models are estimated for more than one group (e.g., one for males and one for females). After the models are established, different sets of parameter constraints are added sequentially across groups, making the

overall model more restricted and parsimonious. For example, the factor loading of Word Order on the *Gsm* factor can be fixed to be the same for males and females. Including these various parameter constraints allows for tests of measurement invariance as well as substantive hypotheses relating to group differences in the latent attributes. The first-order factor model used in our CFA (Figure 3.3) example was used as our CFA model within each group in this example. Although a first-order model was used here, the MG-MACS approach can be extended to higher-order factor models to test various hypotheses about group differences in the second-order factor in addition to the first-order factors (see Reynolds, Keith, Ridley, & Patel, 2008 for examples with these same KABC-II data).

**Table 3.5 Comparison of a Hierarchical versus a Higher-Order Solution for the Second Simulated Data Set. These data were simulated via a hierarchical model.**

	Hierarchical Model		Higher-Order Model

Test 16	.306	.619	.343	.583

RMSEA, CFI, and  $\Delta\chi^2$  were used to evaluate fit. Changes in these values when constraints are added across models may indicate non-invariance, and that the hypothesis of the parameter equivalence across groups is not tenable.  $\Delta\text{CFI}$  has been recommended by some (Cheung & Rensvold, 2002), but also may be considered too liberal of a criterion by others. Here,  $\Delta\chi^2$  was used also to evaluate competing nested models, although some may consider this too conservative of a criterion. For the measurement invariance analyses, we used a more liberal cutoff of  $p < .001$  for  $\Delta\chi^2$  due to model complexity and the number of parameter constraints, but for tests of substantive hypotheses (typically involving fewer parameter constraints) a less conservative  $p$ -value was used. These are the types of decisions researchers may have to make during the course of a study. It is also possible, and likely best practice, to present the results of several criteria and discuss any discrepant findings.

### Factorial Invariance Models

Configural, factor loading (also known as *metric* or *weak factorial invariance*), measurement intercept (*scalar* or *strong factorial invariance*), and subtest residual (*strict factorial invariance*) invariance models were tested, in that order, to test for measurement invariance (Meredith, 1993). Strict factorial invariance is most consistent with the definition of measurement invariance. We also applied invariance constraints to factor variances and covariances, and compared latent factor means across sex: these are tests of differences in the nature of the latent cognitive abilities for males and females, and not related to measurement invariance.

The order of invariance models may differ depending on the preference of the researcher. Researchers may begin with the most constrained model and release constraints; other researchers may choose to test for invariance of the covariance structure before introducing the mean structure;

and others may have different preferences regarding model identification. Our experience suggests that the conclusions drawn from the analyses will generally be quite similar either way, provided the analysis was conducted thoughtfully. We started with less constrained models and moved sequentially to more constrained models; that is, more of the model parameter estimates were fixed to be equal across sex. As we moved to more constrained models, the invariance constraints applied in previous model remained, unless noted otherwise.

### CONFIGURAL INVARIANCE

The first step was to establish the factor structure for males and females, or configural invariance (with an example setup in Amos shown in Figure 3.10). The factor structure is identical to the CFA model used in our original KABC-II example.

In the configural model in Figure 3.10, the reference indicator for each factor has a fixed loading of one to properly scale the factors. The factor means are fixed to zero for each group, and the observed means of the subtests are estimated freely within each group. The number of factors and the pattern of factor loadings are the same for each group. All of the parameters estimated in a single group are estimated freely within each group in this configural model. This model is analogous to running independent confirmatory factor models for males and females, and then combining the information.

This multi-group model was estimated. The model fit information indicates acceptable fit ( $\chi^2 [184] = 654.00$ , CFI = .97; Corrected RMSEA = .05). Note that the  $df$  for this model is different from the previous first-order CFA example (184  $df$  versus 92  $df$ ). In a multi-group model, parameters unconstrained across groups are estimated within each group. The  $\chi^2$  value and  $df$  for this configural model are thus identical (within errors of rounding) to the values we would obtain for males and females if we ran CFAs separately for them, and subsequently summed the  $\chi^2$  and  $df$  from those two models (i.e., Males =  $\chi^2 [92] = 318.7$ , Females =  $\chi^2 [92] = 335.3$ ).

In many SEM programs, including Amos, the RMSEA needs to be corrected when using multi-group analysis. When the models were run independently, the RMSEA = .046 for Males and .047 for Females. If we ran a model on the full sample without differentiating male and female groups, the RMSEA = .047. Because the groups are considered independent, the RMSEA is expected to be similar to the RMSEA obtained in the full sample. In the configural model, however, the uncorrected RMSEA

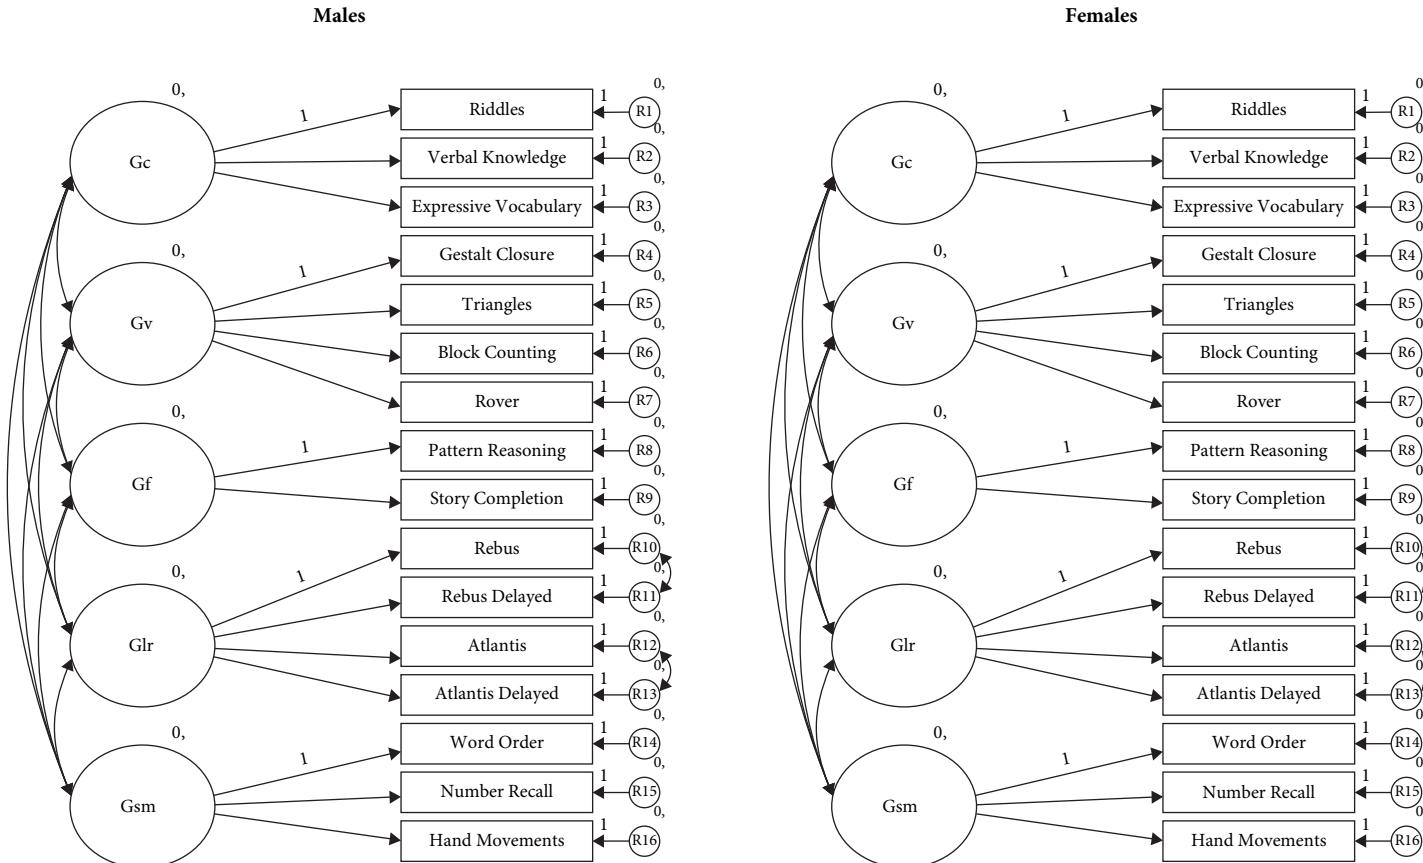

= .033. To account for multiple groups we applied a correction recommended by Steiger (1998): The RMSEA of .033 was multiplied by the square root of two (because there are two groups). The corrected RMSEA = .047 is what would be expected.

Based on the fit indexes and what is known about the KABC-II, the factor configuration across groups appeared acceptable, and thus we proceeded with invariance tests. Unacceptable results would pose some problems. The model would need to be reevaluated. An acceptable model for both groups should be established before proceeding to the following invariance steps.

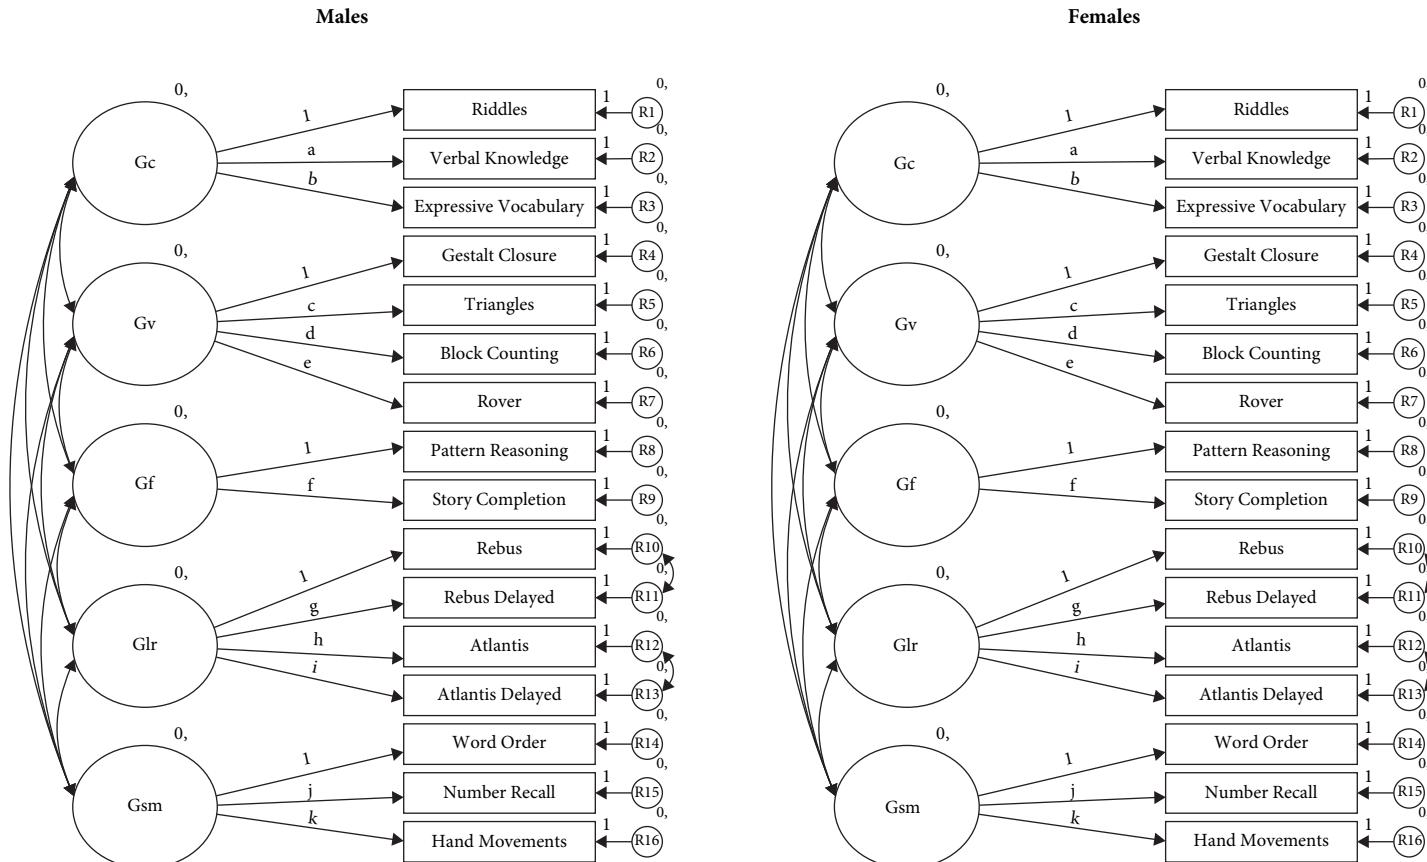

### FACTOR LOADING INVARIANCE

The step that typically follows configural invariance is invariance of the factor loadings, sometimes referred to as *metric* or *weak factorial invariance* (Meredith, 1993; Widaman & Reise, 1997). The factor loadings represent the link from theoretical to empirical worlds (Nesselroade & Thompson, 1995). And to test for invariance of the factor loadings, all of the corresponding (unstandardized) factor loadings were constrained to be equal across groups (see Figure 3.11). Factor loading invariance is a necessary but not sufficient condition for establishing measurement invariance (Meredith, 1993). As shown in Table 3.6 (“Factor Loadings”), the fit of the model is acceptable ( $\Delta\chi^2 [195] = 675.99$ ,  $p = .02$ ) when compared to the fit of the configural invariance model. The decrement in fit was not substantial, especially considering the large sample size and sensitivity of  $\chi^2$  to sample size. Using a  $p < .001$  criterion, the  $\Delta\chi^2$  did not fit significantly worse than the configural model ( $p = .02$ ). As a result, factor loading (or weak factorial) invariance is tenable.

If factor loading invariance is established, then group comparisons related to the first-order factor variances and covariances may be made. In a structural equation model, if factor loading invariance is established, one can then compare effects (paths from one latent variable to another) across groups. If the interest of the researcher is in comparing means in a CFA or SEM, however, then intercept invariance needs to be established as well. If factor loading invariance is not established, the subtests are not measuring the factors in the same way for males and females (although sometimes a researcher may establish partial invariance if only a few of the loadings were non-invariant). Without factor loading invariance, making comparisons between the groups based on the observed scores or the latent factors would be like comparing apples and oranges.

**Figure 3.10** Configural Invariance Setup in Amos for Males and Females.

**Figure 3.11** Factor Loading Invariance in Amos.

**Table 3.6 Tests of Factorial Invariance**

First-Order Model	$\chi^2$	df	$\Delta\chi^2$	$\Delta df$	p	CFI	RMSEA
Factorial Invariance

Factor Covariances	771.80	237	17.10	10	0.07	0.97	0.05

*Note:* Compare each model with previous model.

### INTERCEPT INVARIANCE

In this step, we explicitly tested the structure of the observed means as well by adding equality constraints on all of the corresponding measurement intercepts, in addition to the constraints from the previous model. This test, however, requires a few other adjustments to properly identify the model. In the configurational model, the latent factor means were fixed to be zero, identical across groups, while the observed means (intercepts) were freely estimated within each group.<sup>7</sup> In this intercept invariance model, the first-order factor means for females remained fixed to zero; the factor means for males, however, were freed. Because the measurement intercepts were constrained to be equal, the latent factor mean estimates for males now represent latent mean differences from females.

Many readers are familiar with modeling covariance structures (e.g., factor loadings, factor variances and covariances) when conducting factor analysis, but are not familiar with modeling the means. By constraining the intercepts to be equal, and only allowing for observed score mean differences to pass through the factor, we are testing whether differences in the factor means can account for the difference in the observed means of the subtests. That is, are the observed differences in means on the various subtests a result of differences in the latent means? Alternatively, if a subtest intercept differs between groups (when between-group differences are allowed in the factor means), then the factor cannot completely explain the mean difference on that subtest between groups. For example, if on the KABC-II we allowed males and females to differ in their latent means on the *Gsm* factor and found there was a significant intercept

difference in the Word Order subtest, we would conclude that any mean difference on the latent *Gsm* factor cannot account completely for the mean difference found on the Word Order subtest. The implication is that males and females scores do not differ on Word Order because of *Gsm* only (what the test is supposed to measure), but because of something else. For example, it might reflect a difference in something specifically related to that subtest or something else that is not being considered or measured. The consequences of such a difference would be that the Word Order subtest displays uniform bias (i.e., one group scores lower on the subtest for reasons other than the differences in the latent factor), and if factor or observed means are being compared, and Word Order scores are included, then mean differences in the factor may not reflect differences in *Gsm*. If there is an interest in comparing males and females on observed or factor means from the KABC-II, intercept (i.e., strong factorial) invariance must be established (Meredith, 1993). Of course, we do not know yet whether or not there are differences; this hypothesis needs to be tested formally within our model.

The results of the addition of the intercept constraints are shown in Table 3.6 (“Intercepts Model”). The change in the *df* between the factor loading and intercept model was 11 (16 subtest intercepts constrained equal, minus the 5 factor means freed for males). If a very strict interpretation were used (i.e.,  $\Delta\chi^2$ ), the addition of constraints resulted in a fit that differed significantly from zero. The other fit indexes did not indicate worse fit. Regardless, it is worth investigating further.

One might ask whether the degradation of fit was the result of a specific subtest or a combination of

several. It was due primarily to one: Block Counting was a source of local misfit. The observed score sex difference in Block Counting cannot be accounted for by the latent mean difference in  $Gv$ . Put differently, there is something specific about Block Counting that the  $Gv$  factor difference cannot account for. In this situation, we have a few other indicators of  $Gv$ , so we could free the constraint on the measurement intercepts for Block Counting and still make comparisons on the latent  $Gv$  mean. We will address this issue in more detail later in a brief discussion of partial invariance. For now, because this was not an example of gross non-invariance, we assume that intercept invariance was met to a satisfactory degree. Mean differences in the subtests can be accounted for by mean differences in the broad ability factors.

Reaching this level of strong factorial invariance is important because latent mean differences can now be compared. In addition, cross-group comparisons of composite (summed) test scores assume this level of invariance (intercepts and loadings are invariant).

#### RESIDUAL INVARIANCE

The last model used to test for measurement invariance was residual invariance; in addition to the previous constraints, the sixteen corresponding measurement residuals were also constrained to be equal across groups. If residual invariance (strict factorial invariance) is established, then group differences in the factor means and variances account fully for all group differences in subtest scores. If residual invariance is not met, the constraints for the specific residual variance may be removed, and factor means may still be compared. This type of invariance is consistent with measurement invariance because group differences in observed means and variances would only be attributed to group differences in the latent variables. Note though that group comparisons on factor or observed means may be made if either strong or strict factorial invariance is achieved.

The model fit did not degrade significantly (See Table 3.6, "Subtest Residuals"). Scores on the KABC-II test are unbiased when comparing males and females and strict factorial invariance is tenable. This means that researchers interested in group differences on the KABC-II may make defensible group comparisons of latent variables, and that practitioners may be confident that scores obtained for individuals when using the KABC-II do not depend on the sex of the child. This type of information is extremely important to applied psychologists, and from an applied-psychology perspective, the study could end here. Researchers,

however, may be interested in sex differences related to the five broad cognitive abilities.

#### Latent Broad-Ability Comparisons

Measurement invariance was established via tests of factorial invariance. When assessing for measurement invariance, the latent means, latent variances, and latent covariances are allowed to differ across groups. Questions related to group differences in these parameters are unrelated to measurement invariance. Although differences in the broad abilities should not be compared if invariance was not established (although partial invariance may be used), a researcher may still be interested in trying to explain why it could not be established. There may even be examples of situations where one would expect non-invariance; for example, if a researcher expected two groups to differ on one specific subtest because it included questions that only one group would be able to answer because the questions were specific to the culture of that group.

Here, however, because measurement invariance was established, we also investigated whether there were sex differences in the latent broad abilities. Latent mean differences were estimated in both the intercept and residual invariance models, and because strict factorial invariance was established, either model could be used to test for differences in the broad abilities, although the residual variances model is the more parsimonious model.

#### LATENT MEANS

Sex differences in latent means using MG-MACS are typically evaluated with two methods. One method is to constrain the latent means to be equal and refer to the  $\Delta\chi^2$  to determine whether the addition of the constraint resulted in a degradation of fit. If there is a significant degradation in fit, the groups demonstrate a mean difference on the latent broad ability(s). The second method is to locate the statistical significance tests for males' latent means in the output of either the measurement intercept or residual invariance model. The females' latent means were fixed to zero, so if the males' latent means were statistically significantly different from zero, they are significantly different from females. Negative means indicate higher means for females; positive means indicate higher means for males. The output from both intercept and residual variance invariance models indicated that five of the broad ability mean differences were statistically significant. Females showed an advantage in  $Gf$  (-.22),  $Glr$  (-.35), and  $Gsm$  (-.22). Males showed an advantage in  $Gv$  (.47)

and  $G_c$  (.25). The conclusions regarding the latent means were the same using either approach ( $\Delta\chi^2$  or significance tests). And although the magnitude of these latent mean differences may be unclear from an interpretative standpoint, they can be converted back to the original IQ score metric. See Reynolds et al. (2008) for further analysis in studying these differences when a higher-order general factor is included.

#### LATENT VARIANCES AND COVARIANCES

Researchers may also be interested in substantive questions about the variances and covariances across groups, although the interpretation of these differences is more ambiguous than those of the means. First, the corresponding factor variances were constrained to be equal. The degradation in model fit was not statistically significant ( $\Delta\chi^2$  [5] = 6.50,  $p = .31$ ). Males and females draw upon the same range of broad abilities. Because the factor variances were invariant, we next tested whether the covariances were significantly different. Applying these constraints did not result in a statistically significant degradation in fit ( $\Delta\chi^2$  [10] = 17.10,  $p = .07$ ). The broad abilities are equally related across sex. Note that if the variances of the broad abilities were significantly different across groups, we would have not tested for differences in the covariances. Note also that these findings also suggest invariance in loadings and unique variances for a higher-order model, since these would be estimated from the first-order variances and covariances.

#### **MIMIC Models**

Researchers may be familiar with a group of models referred to as *multiple-indicator multiple-cause* models (Jöreskog & Goldberger, 1975; Muthén, 1989). These are models in which latent variables, which are indicated by observed measures, also have variables (e.g., Sex) as causes. Like the MG-MACS models, these models may be used to test for group (mean) differences in latent factors and may also be used to test for intercept invariance. We will limit our discussion of MIMIC models to a comparison with MG-MACS models, and how to use this method to test for intercept invariance and group differences in the first-order factors. The first-order factor model from the KABC-II will be used.

One assumption of MIMIC models, which is tested with MG-MACS models, is that the variance-covariance matrix is invariant across groups (Kano, 2001), or even more explicitly, all of the model parameters related to the variance-covariance

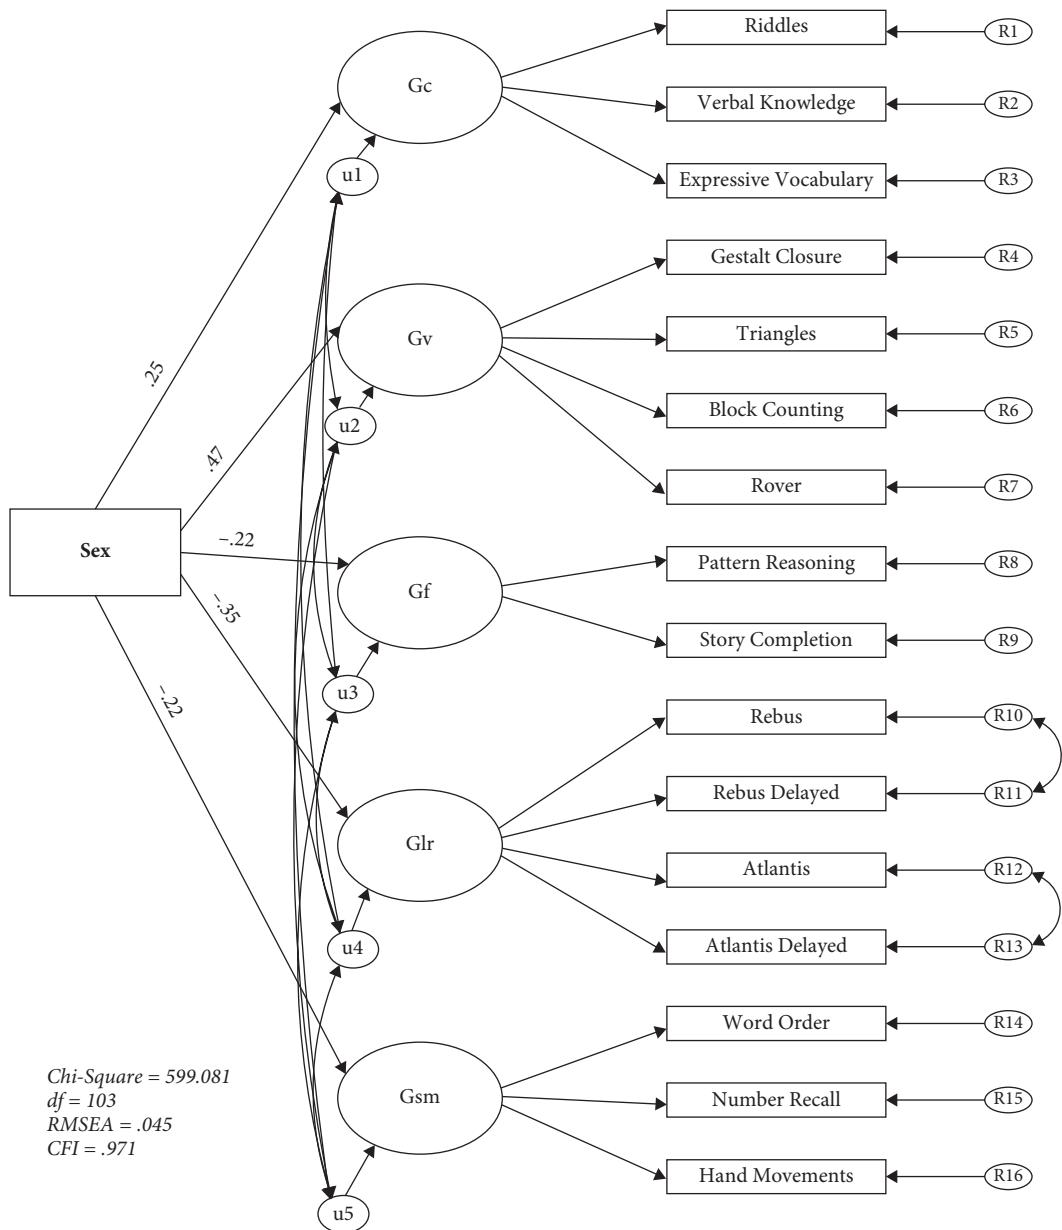

matrix are invariant across groups: factor loadings, residual variances, factor variances, and covariances. Hence, the observed KABC-II data for males and females would be assumed to arise from a common covariance matrix. Given that this assumption is met, MIMIC models may also be used to test for mean differences in the factors. The results we obtain should be the same as the latent mean differences found in the MG-MACS example.

See Figure 3.12 for a visual representation of the model. The common factors, which are regressed on Sex (dummy coded so females = 0 and males = 1), now have disturbances associated with them. These disturbance variables represented the variance in the factors not explained by Sex. The unstandardized estimates shown on the paths from Sex to the broad factors represent latent mean differences between males and females. Negative values are in favor of females, positive values in favor of males. These estimated values are identical to the latent mean differences obtained in the MG-MACS approach. Because the assumption of a common variance-covariance matrix was met (or more specifically, a common covariance structure as the latent variances, latent covariances, unstandardized factor loadings, and residual variances were equal in the MG-MACS tests), the results should be identical, and they were.

We hope we have highlighted some of the differences in assumptions related to MIMIC and MG-MACS models. Awareness of assumptions underlying the two approaches is always useful for gaining an appreciation and understanding of techniques. MG-MACS models are more flexible in that all of the assumptions may be tested explicitly. Some might consider MIMIC approaches easier to implement, especially for those who are more inclined to use regression-type methods. Nevertheless, assumptions must be met before groups are compared, and MG-MACs are more explicit in testing these assumptions. Lastly, it is also possible to combine the two types into hybrid models that allow for very interesting comparisons of latent variables (Keith et al., 2008; Lubke, Dolan, Kelderman, & Mellenbergh, 2003; Marsh, Tracey, & Craven, 2006).

#### **Partial Intercept Invariance with MIMIC and MG-MACS**

MIMIC models require the assumption that two groups share a common covariance matrix (Kano, 2001). If that assumption is met, MIMIC models may also be used to test for intercept invariance by including directs effect from the group (e.g., Sex) to

**Figure 3.12** MIMIC Model for Sex Differences in First-Order Factor Means in the KABC Latent Broad Abilities. Unstandardized estimates are shown with positive effects indicating a male advantage and negative effects indicating a female advantage.

the observed indicator. To illustrate, we return to the MG-MACS and MIMIC models with the KABC-II data. In the MG-MACS example, we could have concluded that sex differences in  $Gv$  could not account for observed mean differences in Block Counting (if a strict interpretation of  $\Delta\chi^2$  was used). Based on that conclusion, the invariance constraint on the measurement intercept associated with the Block Counting test could have been removed, and this model could have been used to test for latent

mean differences with partial measurement invariance for  $Gv$  (Byrne, Shavelson, & Muthén, 1989). Given that there are several indicators of  $Gv$ , this would be considered acceptable. Intercept invariance can also be tested using MIMIC models. In Figure 3.13, notice a direct effect from the Sex variable to the observed indicator Block Counting, in addition to the effects from Sex to the factors. The direct effect from Sex to Block Counting is statistically significant. Beyond the  $Gv$  factor difference,

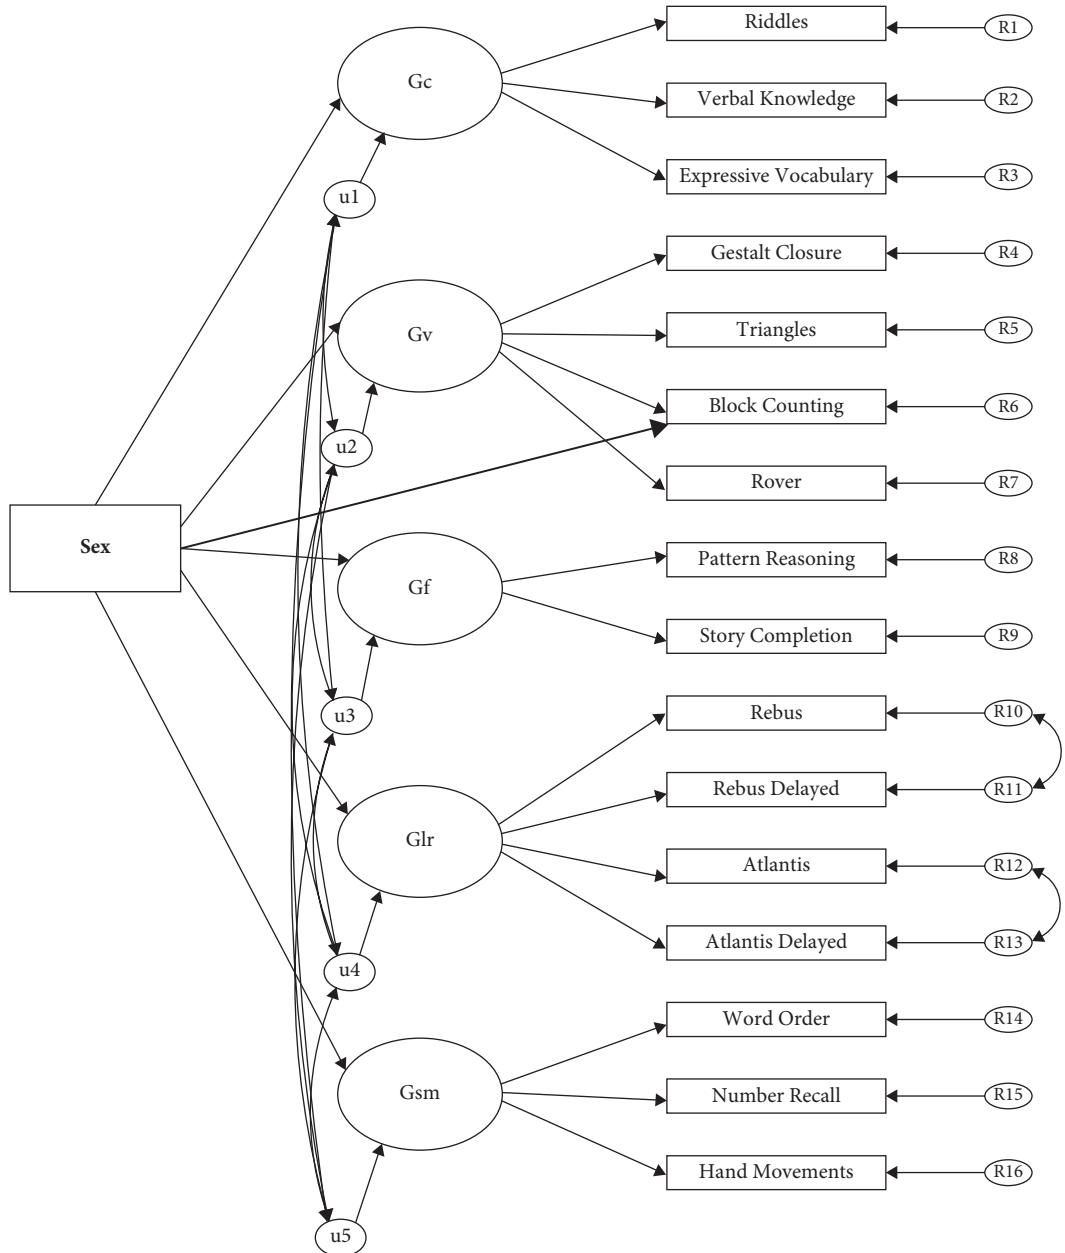

Figure 3.13 MIMIC Model with Direct Effect of Sex on Block Counting.

there is a sex difference between males and females on Block Counting. Again, the mean sex difference on this subtest cannot be accounted for fully by differences in the factor. Or, for those who are familiar with item response theory terminology, the Block Counting test acts differentially across sex (i.e., uniform bias). Allowing for the direct effect from Sex to Block Counting corresponds to freeing the equality constraints on the Block Counting intercept in the MG-MACS analysis.

This illustration should also bring something else to mind: mediation. *Mediation* refers to the effect of one variable explained via another. It should be clear from the MIMIC model diagram shown in Figure 3.13 that the *Gv* factor partially mediates sex differences in the observed *Gv* variables. The *Gsm*, *Glr*, *Gf*, and *Gc* factors, however, fully mediate the effects of sex on observed differences in the subtests. Or, to put it differently, with intercept invariance, differences in the latent factor means should *fully*

mediate differences in the observed scores related to that factor.

## Variables and Their Measurement

An essential part of solid assessment research is that researchers think critically about how their observed data arise. Fancy statistical techniques will not save one from sloppy thinking; even complex statistical analyses cannot make a silk purse from a sow's ear. This section introduces several additional important issues a researcher should think about before developing measurement instruments, and before analyzing and interpreting scores from those instruments. Attention to these issues should improve the quality of research because they force researchers to think carefully about what they are trying to measure, how the measurements come about, and which type of variable to include in an analysis.

### Categorical versus Continuous Latent Variables

Almost all variables in psychology are considered to be *latent* variables. For example, social anxiety is a construct that cannot be observed, but differences in latent social anxiety should produce differences in how individuals respond to questions designed to measure that latent construct. If social anxiety is hypothesized as a latent variable, then researchers might be interested in whether latent social anxiety is either a category (type) or a dimension (continuous). Those who believe that anxiety is a type or categorical latent variable would say that a person either has social anxiety or doesn't, whereas those who ascribe to a continuous definition would say that the severity of anxiety depends on where along the latent social anxiety dimension a person is located (see Meehl, 2006, for more discussion). This distinction has both practical implications for the design of measurement instruments and theoretical implications related to understanding important psychological phenomena. Moreover, the distinction is important because a researcher would then need to be clear whether the latent anxiety variable in their model is a categorical or a continuous latent variable. Briefly, we will discuss a few points related to distinctions between categorical (type) and continuous (dimensions) latent variables.

The first point is that observed scores do not inform the nature of the latent variable. That is, continuous or categorical observed variables do not inform us whether latent variables are continuous or categorical. For example, in one type of continuous

latent variable model, the common factor model, the latent variable may be indicated by continuous or categorical variables. Alternatively, in the latent class model (where a class is a latent categorical variable), the latent class variable is indicated by categorical observed variables; but in yet another categorical latent variable model, the latent profile model, the latent variable is indicated by continuous variables.

Second, it can be shown that a common factor model (continuous) is very difficult to distinguish from a latent profile (categorical) model (Bartholomew, 1987). And although some analytic techniques may assist us in distinguishing between categorical versus continuous latent variables empirically, the distinction is typically based on theory, not statistics. Researchers should therefore think carefully about whether the latent variable underlying the observed data is one of a continuum or category. From a measurement perspective, the measurement model designed for a continuous construct is used to develop scales where ultimately a score is obtained in an attempt to estimate the rank order of where a person is located along the latent dimension. Alternatively, a measurement model used with a latent categorical structure would be developed with the goal of classifying individuals in the appropriate group (e.g., anorexic versus non-anorexic). Latent class variables are variables used typically to represent *qualitatively* different groups of people.<sup>8</sup>

Finally, there are interesting developments in factor analysis and item response theory that allow for the use of both categorical and continuous latent variables (e.g., Lubke & Muthén, 2005). These models will provide opportunity for many interesting applications. Certainly it would also be exciting to see similar developments in psychological theory. Perhaps advances in these methods will provide researchers with more clarity for theory development, or more developed theories in some areas of psychological will continue to drive the development of new methods to test them.

### Reflective versus Formative Measurement

Issues related to reflective and formative measurement have been generating considerable interest recently (see Bollen, 2007; Edwards & Bagozzi, 2000; Howell, Breivik, & Wilcox, 2007). Assessment researchers should be aware of this distinction because it is important to the measurement of constructs in research. Perhaps the distinction between the two types is most easily demonstrated

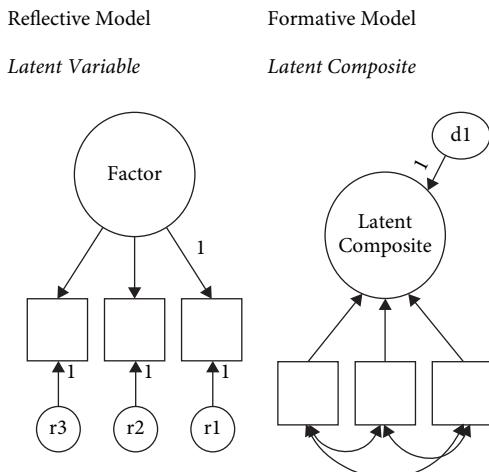

Figure 3.14 Reflective and Formative Latent Variable Measurement.

via the direction of path arrows. In reflective measurement, the causal direction flows from the latent variable to the indicators (effect indicators) (see Figure 3.14). In formative measurement, the causal direction flows from the indicators (causal indicators) to the latent composite variable.

Reflective models are most commonly used in psychology. Factor analysis and internal reliability estimates assume a reflective model (Bollen & Lennox, 1991). In reflective measurement, it is assumed that equally reliable indicators are interchangeable, which is not the case with formative indicators. Most, if not almost all, variables in psychology are conceptualized as latent variables measured via reflective or “effect” indicators. Nevertheless, a decision to use a reflective model should not be automatic; theoretical justification is required.

In reflective models, the latent variable is the common cause of the interrelations among the indicators (e.g., a confirmatory factor model). For example, visual-spatial ability affects performance on all tests that require some aspect of visual-spatial manipulation. Differences in visual spatial ability produce individual differences in the observed scores on visual-spatial tests. The factor model on the left of Figure 3.14 is a model representing reflective measurement. The unique and error variance are removed at the indicator level and captured in the residual variance. The latent variable causes, or is reflected in, the indicators. An increase in the level of the factor will correspond to higher scores on each of the indicators.

The model on the right of Figure 3.14 represents a formative latent variable, or a latent “composite.”

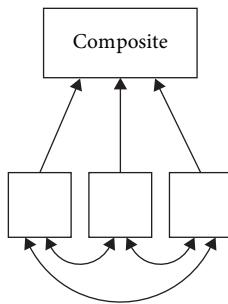

An example of such a formative variable might be overall time spent reading.<sup>9</sup> Someone might read magazines, books, articles online, or the backs of cereal boxes. If a person increases the time spent reading books, overall time spent reading increases, but it says nothing about time spent reading the backs of cereal boxes. That is, increased reading time does not imply that reading across the different areas will increase. In formative measurement, the constructs are caused or formed by the correlated measures. The disturbance variable captures whatever is not explained the indicators. In Figure 3.14, the model on the right is statistically under-identified, meaning that if the model were analyzed it would not converge, and unique estimates could not be obtained. These types of models typically need to be evaluated within a structural equation model where there is some type of external criteria. As a result, the interpretation of the latent composite also typically depends on other variable(s). The constructs or interpretations of these constructs will likely change depending on the indicators or dependent variables included in the model.

Our purpose here was to introduce these terms and reiterate the importance of clearly defining measurement prior to research. Most, if not all, psychological attributes will be measured reflectively; nevertheless, this is not a given, and researchers need to think critically about measurement. Interested readers should consult several additional, excellent sources on this topic (e.g., Bollen, 2007; Bollen & Lennox, 1991; Edwards & Bagozzi, 2000; Howell, Breivik, & Wilcox, 2007; MacCallum & Browne, 1993).

### Composite versus Latent Variables

Examples of reflective latent variables and formatively measured latent composites were discussed in the previous section. Here we discuss a related issue: the decision to study latent variables versus composite variables (e.g., variables used in our multiple regression analysis).

It is important to note that when we refer to “composite variables” here, we are not referring to “latent variables.” The diagram shown in Figure 3.15 will help clarify the distinction. The difference between this Figure 3.15 and the formatively measured latent variable (Figure 3.14, on the right) is that a disturbance term has been removed, and rather than use an oval to represent the variable, a rectangle was used. The composite variable, therefore, represents a linear composite of observed indicators. The model is similar to a principal component model

**Figure 3.15** Observed Linear Composite Variable.

where measurement error and unique variance are captured in the component itself. Earlier, PCA was discussed as an unacceptable method of studying latent variables, and here it should be clear that a principal component is a *composite* variable, a variable where error and other unique or unaccounted influences are not removed.

When analyzing data, researchers often study their variables of interest indirectly via the substitution of composite variables rather than studying them directly through latent variables. Composite variables are caused by their indicators, or measured formatively, analogous to the latent “composite” variables. Composites include measurement error and invalidity. Aggregated items, components from principal component analysis, and extracted factor scores that have been summed are all examples of composite variables. Composite variables are not latent variables. Composites may provide ideas about the latent variables the researcher are really interested in, but the composite itself is not equivalent to the latent variable (Bollen & Lennox, 1991). For example, multiple regression is performed with multiple composite variables used as explanatory variables and as an outcome variable, each providing hints of latent variables. Because composites are used, however, the estimates of coefficients obtained from multiple regression analysis are inconsistent, and a researcher does not know whether they are biased upward or downward, or even if they are biased at all (Bollen, 1989, pp. 166–167). Most assessment researchers are interested in studying and measuring latent variables. Well-conceived latent variables are consistent with the theoretical constructs, and thus measurement and analytical models should reflect theoretical models. Child-assessment research should therefore be focused on the study of latent variables, because latent variables underlie what is observed.

## Other Issues

There is a host of issues we did not discuss in this chapter. Psychometrics and statistics is a dynamic field, and this chapter could only deal with a limited number of issues, and even with those we encourage readers to refer to our sources for more detailed descriptions. A couple of other issues deserve at least a mention because they are so common.

### Test Bias

Test bias was addressed partially in the section on moderation and in the section on measurement invariance using MG-MACS and MIMIC models. Measurement invariance is extremely important in making sure differences in the latent traits are reflected in test scores, and not group membership. But there are other means used to evaluate bias, especially with regard to external criterion, often referred to as *prediction invariance*. It is likely that assessment researchers are more familiar with prediction invariance, as it has been used more often in applied assessment research and is of particular importance for selection into important programs. As discussed, prediction invariance (or bias) is often evaluated with moderated multiple regression models using one variable to predict a criterion across groups. The regression slope and intercepts should not differ across groups for prediction invariance to be tenable (or if tested in a multi-group path model in a SEM program, the residual variances may also be tested for equality across groups). Readers may wish to refer to other sources for a more detailed discussion on test bias (e.g., Reynolds & Lowe, 2009) and the seemingly surprising but common incompatibility of measurement invariance and predictive invariance (Borsboom, Romeijn, & Wicherts, 2008; Millsap, 2007).

### Regression to the Mean

Given that two variables (e.g., pretest–post-test scores; scores from two different measures) are not perfectly correlated, the rank order of individual's scores will differ across measurements, with extreme scores more likely to be closer to the mean. This regression to the mean is a statistical fact. Those who are rank ordered at the top or bottom will tend to be replaced, or scores that are furthest from the mean on one variable will tend not to be as extreme on the other variable. A correlation coefficient represents the amount of nonregression toward the mean: the closer to  $+/-1$ , the less regression toward the mean (Campbell & Kenny, 1999). The most important implication from regression to the mean is that

substantive meaning should not be given to these changes in rank ordering. Campbell and Kenny (1999) provided an excellent treatment on this topic: it should be required reading for anyone who is interested in treatment or program evaluation.

## Conclusion

We have covered a variety of measurement and statistical issues and examples in this chapter. Although some of our examples (e.g., higher-order models; MIMIC models) are considered structural equation models, we have not formally discussed structural equation modeling in this chapter. There are numerous resources available on structural equation modeling ranging from complex to simple (Bollen, 1989; Keith, 2006); obviously, with our focus on latent variables, we see structural equation modeling as vital tool in psychological assessment research. For example, complex structural equation modeling could be applied to better match various multi-method assessment approaches. We also believe one key to future research is that important measurement issues be worked out before structural equation modeling is used. As we stated in the beginning, psychological assessment is contingent on measurement, which is contingent on theoretically important psychological attributes. Psychological assessment research should involve each of these aspects.

## Acknowledgments

We are grateful to Alan Kaufman and Mark Daniel for access to the KABC-II data. We also thank Randy Floyd for providing assistance with the Schmid-Leiman section and Matthew Irvin for comments on an early version of this chapter. We are solely responsible for any errors or opinions expressed in this article.

## Notes

1. The ECLS-K also includes sampling weights and strata variables (geographic and public versus private schools), but these were not included in this analysis. For ease of exposition, we took a random sample consisting of 10% of the total cases and only included the cases with complete data. We will address better methods to deal with missing data later.

2. Semipartial (or part) correlations, equal to the square root of  $\Delta R^2$ , may also be used to test unique effects and may be a

better measure of the importance of an effect than is  $\Delta R^2$ . See Darlington (1990) and Keith (2006) for further discussion.

3. We make this statement cautiously and do not advocate that researchers just assume the MAR and run their analysis. Thinking critically about the data and running sensitivity analyses are recommended. See Graham and colleagues (1997) and Graham (2009) for a more detailed discussion.

4. Weak loadings do not necessarily indicate that anything is wrong with the model, because the goal is to explain the correlations among tests, not maximize the variance explained.

5. There is a limited number of direct effects that may be included. For each group of tests indicating a first-order factor, unless other model constraints are applied, one direct effect would need to be omitted, or fixed to zero, for proper model identification.

6. It is possible to have hybrid-type models, in which  $g$  affects tests both directly and via first-order factors; such models will quickly result in problems with identification, however. Hierarchical models are often difficult to estimate, and, in our experience, start values are often needed to make the models work. Note that the hierarchical models shown here have uncorrelated factors, a common constraint. Such constraints also require a minimum of three tests per factor, however, or empirical under-identification will result. Hence, it is not uncommon to find constraints on the hierarchical model that do not necessarily make sense theoretically.

7. Given that this step requires both the fixing and the freeing of parameter constraints, it may appear that this model is not nested with the previous model. That is not the case. We could have identified the original multi-group model by fixing each factor's reference variable intercept to be zero across groups and freeing the constraint that the latent factor means equal zero. The factor means would have represented the mean of the reference variable subtest (i.e., the mean of Riddles). These differences in model identification do not make a difference in the outcome, but this alternative method of model identification would have more clearly demonstrated the nested nature of these models.

8. Latent classes may also represent mixture components, where each class represents a distinct distribution which may not have psychological meaning. The discussion is outside of the scope of this chapter (see Dolan & van der Maas, 1998; and Lubke & Spies, 2007, for a discussion).

9. We will use the term *latent composite variable*. Some reserve the term *latent variable* for reflective measurement only (e.g., MacCallum & Browne, 1993). And of course, one could also argue that enjoyment of reading is an internal characteristic that affects the amount one reads across settings. In that case, Reading Time (or enjoyment) would be better modeled as a reflective, i.e., traditional, latent variable.

# Psychometric Versus Actuarial Interpretation of Intelligence and Related Aptitude Batteries

Gary L. Canivez

## Abstract

Interpretation of intelligence tests involves making various inferences about the individual based on their performance. Because there are many different scores within intelligence tests reflecting different levels (Full Scale, factors, subtests) and there are many different comparisons provided in test manuals and the extant literature, there is a multitude of possible inferences. This chapter is concerned with reviewing the various available scores and comparisons with suggested interpretations and a review of the empirical investigations of their psychometric fitness (reliability, validity, utility). Differentiation of psychometric interpretation versus actuarial interpretation methods is presented, as well as a review of research related to each. Most intelligence test interpretation methods are considered psychometric in nature, and most lack sufficient reliability, validity, or utility for individual clinical use; improvements in the clinical assessment of intelligence may result from greater development and use of actuarial approaches.

**Key Words:** intelligence test interpretation, reliability, validity, utility, actuarial decision-making, clinical decision-making

## Introduction

Interpretation of intelligence tests involves drawing inferences about an individual based on scores obtained on a particular test. Because contemporary intelligence tests provide many different types of scores, there is a variety of inferences that could be made about any individual. Furthermore, various intelligence tests are constructed to reflect different theories of intelligence or cognitive abilities, and interpretations may also be based on the particular theory upon which the test is based. While a test may be created to reflect a particular theory, clinicians may also apply alternate or competing theories in the interpretation of test scores. Legitimate inferences about an individual from various intelligence test scores or procedures, however, must *each* be supported by reliability, validity, and utility research on the various scores, comparisons, and their uses.

*Standards for Educational and Psychological Testing* (American Educational Research Association, American Psychological Association, and the National Council on Measurement in Education [AERA, APA, NCME], 1999) provides numerous guidelines for considering the reliability and validity of test scores that should be applied to intelligence test scores. Such guidelines apply to test authors and publishers, but ultimately it is the test user who must decide which test scores, comparisons, and procedures possess sufficient evidence of reliability and validity to report and interpret. Test scores that do not possess adequate reliability, validity, and utility will lead the test user to make inaccurate and inappropriate inferences about the individual when interpreting those test scores and comparisons. Such inaccurate and inappropriate inferences may well lead to recommendations for classification,

diagnosis, or treatment that may also be wrong. Weiner (1989) cogently noted that in order to practice in an ethical manner, psychologists must “(a) know what their tests can do and (b) act accordingly” (p. 829). Numerous ethical standards also concern the use of tests and measurement procedures in clinical practice (APA, 2010; National Association of School Psychologists [NASP], 2010).

Interpretation of intelligence tests may involve description of the individual's performance, prediction of the individual's performance in related areas such as classroom learning or performance on academic achievement tests, classification or diagnosis of the individual, and informing or recommending treatments. Each of these “interpretations” requires empirical support for appropriate use. With respect to individual test scores, it has been argued that if a score is to be used for individual decisions or clinical decision-making, reliability indices should meet or exceed .85 (Hills, 1981) or .90 (Aiken, 2000; Guilford & Fruchter, 1978; Nunnally & Bernstein, 1994; Ponterotto & Ruckdeschel, 2007; Salvia & Ysseldyke, 1988, 2001). Specific inferences about the individual are tied more to the various estimates of the validity of test scores and their diagnostic utility; however, scores that lack sufficient reliability cannot be valid or of diagnostic utility. It is within this framework that psychometric and actuarial intelligence test interpretations are examined.

## History of IQ Test Interpretations

Kamphaus, Winsor, Rowe, and Kim (2005) provided a useful description of the history of intelligence test interpretation. The earliest application of intelligence test interpretation was associated with a classification of the individual's test score (and thus the individual) according to descriptive terms based on the overall test score and prediction of school functioning. The earliest classification systems contained descriptive terms (viz., “idiots,” “imbeciles,” “morons”; Levine & Marks, 1928) that are considered pejorative by today's standards. Each intelligence test presently published also contains descriptive classifications for test score ranges, and these are frequently the first “interpretation” made. Kamphaus et al. also noted that present-day descriptive terms typically reflect some aspect of score deviation from the average range, but each test contains somewhat different descriptors and may include different score ranges. While the earliest intelligence tests provided one overall test score (i.e., IQ), present-day intelligence tests contain numerous

scores reflecting different levels of the test. Such scores include an overall, omnibus Full Scale score; several factor-based scores or indexes; subtest scores; ipsative or deviation scores derived from comparing subtest or factor scores to the individual's overall mean score; and theoretically or logically combined subtest composite scores.

Kamphaus et al. (2005, p. 26) referred to a “second wave” of test interpretation proposed by Rapaport, Gil, and Schafer (1945–1946) that ushered in an approach to intelligence test interpretation still in use by many today. The approach advocated by Rapaport et al. was that of going beyond the overall, omnibus Full Scale IQ and examining the shape of the subtest profile to provide a description of subtest highs and lows for the individual. These strengths and weaknesses were presumed to reflect some aspect of psychopathology as well as consideration for intervention. Wechsler's examination (1944) of differences between verbal and performance scales as well as subtest profile shape and deviations was also included in this second wave and reflected Wechsler's clinical approach to test interpretation. This is in contrast to Wechsler's note that subtests are merely different practical estimates for measuring general intelligence.

Criticism of these early interpretation methods on empirically based psychometric grounds led to what Kamphaus et al. (2005) referred to as the “third wave,” wherein application of psychological measurement methods was used to evaluate various intelligence test scores and interpretation methods. Cohen's investigation (1959) of the factor structure of the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949) was one of the first of its kind and provided an empirical means for identifying subtest association to factors or dimensions underlying the WISC. While Wechsler assigned WISC subtests to the verbal or performance scale based on subtest content, Cohen's factor analysis empirically assigned subtests to factors based on their shared variance, and resulted in the three-factor structure (Verbal Comprehension, Perceptual Organization, and Freedom from Distractability) of the WISC. Cohen was critical of WISC subtest scores based on the high levels of shared variance and low subtest specificity (non-error variance unique to the subtest). Subsequently, this three-factor structure was frequently replicated with other samples and Cohen's WISC factor names were retained in both the second (WISC-R; Wechsler, 1974) and third editions of the WISC (WISC-III; Wechsler, 1991). Kaufman (1979) provided a means for calculating

scores for the three factors to provide more factorially pure scores than the VIQ and PIQ.

Kaufman's significant influence on intelligence test interpretation is reflected in the hierarchical and sequential process of interpretation and subtest analyses (Kaufman, 1979, 1994; Kaufman & Lichtenberger, 2000, 2006) frequently taught in graduate programs and used by practitioners (Alfonso, Oakland, LaRocca, & Spanakos, 2000; Groth-Marnat, 1997; Kaufman, 1994; Pfeiffer, Reddy, Kletzel, Schmelzer, & Boyer, 2000). Levels of test interpretation were ordered from the most reliable and valid scores (Full Scale IQ and composite scores) to the least reliable and valid scores (single subtest scores). Kaufman's approach continued the clinical interpretation method of unique profile shape (subtest strengths and weaknesses) much like that of Rapaport et al. (1945–1946), but his profile interpretation method of comparing an individual's subtest scores to their own overall mean performance was through the identification of statistically significant strengths and weaknesses and consideration of base rates. This ipsative approach examines intraindividual differences and is an *ideographic* interpretation approach, in contrast to the *nomothetic* interpretation approach (normative comparisons) provided by the standard scores of intelligence tests. Sattler (1982, 1988, 1992, 2001, 2008) and Sattler and Ryan (2009) also provided for similar intelligence test interpretations based on a sequential order from the global score to subtest comparisons.

Reliability and validity research highlighting major problems with ipsative comparisons and profile interpretations (discussed in detail later in this chapter) led to what Kamphaus et al. (2005) referred to as the “fourth wave” where intelligence theory was applied to intelligence test construction and interpretations. The earliest intelligence tests were seemingly constructed from a pragmatic perspective and some would say atheoretical. Thorndike (1990, p. 226) noted Alfred Binet was “theoretically agnostic” with regard to the Binet-Simon scale. Zachary (1990) noted David Wechsler's minimal explication of theory in constructing the original Wechsler-Bellevue (WB) scales in 1939. However, as several have pointed out, when constructing and modifying his tests, Wechsler used Spearman's (1904, 1927) theory of general intelligence ( $g$ ) and was also influenced by other contemporary intelligence theories (Saklofske, 2008; Tulsky et al., 2003; Zhu & Weiss, 2005). Wechsler's definition of *intelligence* (i.e., “global capacity”; Wechsler, 1939, p. 229) also reflected Spearman's  $g$ .

Contemporary intelligence tests are now greatly influenced by theories of intelligence or models of intelligence measurement in their construction and interpretation. Presently, one of the most influential models of intellectual measurement is that of Carroll (1993, 1995, 1997a, 2003), which proposes that intelligence tests measure various intellectual abilities that are hierarchically ordered. Carroll's (1993, 2003) three-stratum theory of cognitive abilities proposes some 50–60 narrow abilities (Stratum I) at the bottom (subtests), 8–10 broad-ability factors (Stratum II) in the middle (first-order factors), and the general (“ $g$ ”) ability factor (Stratum III) at the top (second-order factor) and reflected by the overall FSIQ or global IQ. Many contemporary intelligence tests are constructed to reflect Carroll's model of intelligence measurement either explicitly or implicitly. The American Psychological Association task force study of intelligence (Neisser et al., 1996) noted that the hierarchical nature of intelligence measurement was the most widely accepted view, and this still appears to be true.

Another theoretical perspective of intelligence measurement closely related to, and preceding that of Carroll, is the *Gf-Gc* theory of Cattell and Horn (Cattell, 1943; Horn, 1988, 1991; Horn & Cattell, 1966; Horn & Noll, 1997). Cattell and Horn's *Gf-Gc* theory describes aspects of reasoning abilities that allow the individual to solve novel problems (*fluid intelligence* [ $Gf$ ]) and abilities acquired through the individual's exposure to aspects of their culture such as language and educational experiences (*crystallized intelligence* [ $Gc$ ]). Extension of *Gf-Gc* theory by Horn (1991) and Horn and Noll (1997) is similar to that of Carroll with some 8–9 or more broad dimensions but does not include higher-order  $g$ , arguing there was insufficient construct validity evidence for singular  $g$ .

Cattell-Horn-Carroll (CHC) theory is an approach wherein researchers melded the work of Cattell and Horn with that of Carroll (Evans, Floyd, McGrew, & Leforgee, 2001; Flanagan, 2000; McGrew, 2005), but this is an odd combination, given that Carroll provided evidence for higher-order  $g$  while Horn argued that singular  $g$  did not exist and was a statistical artifact. Carroll's model, Cattell and Horn's model, or the combined CHC model are often cited as theoretical foundations or influences in present versions of intelligence tests such as the Wechsler Intelligence Scale for Children–Fourth Edition (WISC-IV: Wechsler, 2003), Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV: Wechsler, 2008a), Stanford-Binet

Intelligence Scales–Fifth Edition (SB-5: Roid, 2003a), Differential Ability Scales–Second Edition (DAS-II: Elliott, 2007a), Wide Range Intelligence Test (WRIT: Glutting, Adams, & Sheslow, 2000a), Reynolds Intellectual Assessment Scales (RIAS: Reynolds & Kamphaus, 2003), Kaufman Adolescent and Adult Intelligence Test (KAIT: Kaufman & Kaufman, 1993), and Kaufman Assessment Battery for Children–Second Edition (KABC-II: Kaufman & Kaufman, 2004a).

Luria's neuropsychological theory was the foundation for the development of the Kaufman Assessment Battery for Children (K-ABC; Kaufman & Kaufman, 1983) and later, the development of the Planning, Attention, Simultaneous, Successive (PASS) theory (Das, Naglieri, & Kirby, 1994) which is the foundation for the Cognitive Assessment System (CAS: Naglieri & Das, 1997a). While the KABC-II is linked to and can be interpreted according to CHC theory, it is also linked to and can be interpreted according to Luria's theory through its dual theoretical foundation (Kaufman & Kaufman, 2004a). CAS interpretation follows the PASS theory and is related to Luria's three functional units of the brain (Naglieri, 1997; Naglieri & Das, 1990, 1997b).

Kamphaus et al. (2005) noted that, in practice, clinicians frequently interpret not only the overall Full Scale/Composite intelligence test score, which is an estimate of Spearman's *g* (Spearman 1904, 1927) and the apex of Carroll's hierarchy (1993), but also interpret factor-based scores and ability profiles produced from subtest strengths and weaknesses. These subtest profile-interpretation systems (Flanagan & Kaufman, 2004; Kaufman, 1994; Kaufman & Lichtenberger, 2000; Sattler, 2001, 2008; Sattler & Ryan, 2009) are exceedingly popular in psychology training and clinical practice (Alfonso et al., 2000; Groth-Marnat, 1997; Kaufman, 1994; Pfeiffer et al., 2000).

Despite their popularity, clinicians *must* confront the issue of whether there is sufficient empirical support for *all* these interpretation methods and the resulting inferences. While many test publishers, test authors, workshop presenters, and textbook authors present all the above methods for interpreting intelligence tests and argue for their utility, it is the test user who must decide which methods have adequate reliability, validity, and utility for clinical application and making inferences and decisions about the individual they assess. By interpreting all such scores, the clinician is adding (or replacing) interpretations beyond the overall Full Scale score

and thus, knowledge of such score interpretation improvement *beyond* the overall IQ score is imperative (Brody, 1985). Furthermore, interpretation of scores at every level of the test ignores the fact that scores at the subtest and factor level are themselves correlated and *not* independent, representing mixtures of *g* and subtest variance (Carroll, 1993). These and other critically important interpretation issues are further explicated throughout this chapter.

## Psychometric Interpretation Methods

Descriptions of intelligence test interpretation methods from stage one through stage four (Kamphaus et al., 2005) are ostensibly *psychometric* interpretation methods. Interpretations based on psychometric grounds are interpretations based on various scores provided by the intelligence test as well as derived scores or comparisons of different scores. These scores can be used in descriptive (level of performance), predictive (estimate of performance on related variable), and classificatory (assignment to diagnostic group) ways. Clinicians use test scores and analysis information as well as test session observations, background information, interview information, etc., and make a clinical decision, judgement, or inference regarding the individual. Such decisions might be considered *clinical* decisions rather than *actuarial* (statistical) decisions because it is the clinician's *judgement* of meaning of the score(s) that guides the interpretation (decision) rather than strict adherence to a statistically based (formula) interpretation (decision) (Meehl, 1954, 1957; Meehl & Rosen, 1955).

Intelligence test scores are (or can be) associated with a hierarchical model similar to Carroll's (1993, 2003) Stratum III (omnibus, Full Scale score), Stratum II (factor-based scores), or Stratum I (subtest scores). These scores are standardized scores and reflect comparison to the normative group appropriate for the individual. Interpretations from the standardized scores are nomothetic and allow for understanding how the individual performed relative to others their age in the population. Other derived scores such as ipsative factor score comparison, pairwise factor score comparisons, ipsative subtest comparisons, and pairwise subtest comparisons are rooted in the clinical intelligence test interpretation approaches articulated by Rapaport et al. (1945–1946), Kaufman (1979, 1994), Kaufman and Lichtenberger (2000, 2006), Sattler (1982, 1988, 1992, 2001, 2008), and Sattler and Ryan (2009) and are ideographic. These are comparisons of the individual to himself or herself. Another

means by which clinicians may interpret scores from intelligence tests is the combination of various subtest scores into composite scores based on some logical or theoretical connection (Kaufman, 1994; Kaufman and Lichtenberger, 2000, 2006; Sattler, 2001, 2008; Sattler & Ryan, 2009).

Finally, some have argued that no single intelligence test adequately measures all of Carroll's (1993, 2003) Stratum II dimensions, or Horn and Noll's (1997) *Gf*-*Ge* factors, and in order to better assess these broad intelligence dimensions, subtests from different intelligence tests should be combined in what is referred to as "cross-battery assessment" (Flanagan & McGrew, 1997; Flanagan & Ortiz, 2001; Flanagan, Ortiz, & Alfonso, 2008; McGrew & Flanagan, 1998). Cross-battery assessment is rooted in the aforementioned CHC theory. Such cross-battery assessment is proposed to better account for an individual's varied broad abilities (Stratum II) in cognitive assessment; which in turn is used to understand their educational difficulties, provide better differential diagnosis, and guide interventions. While the cross-battery assessment approach attempts to improve assessment of cognitive abilities and has intuitive appeal, there are numerous substantial psychometric problems cogently pointed out by Glutting, Watkins, and Youngstrom (2003), which have yet to be adequately empirically addressed. Other issues noted later in this chapter also have implications for such interpretations. Thus, individual clinical use of such cross-battery interpretation methods is not recommended.

Examination of psychometric interpretation methods proceeds in order of the hierarchy and structure of intelligence tests (Carroll, 1993, 1995; Neisser et al., 1996). This order also parallels the psychometric interpretation procedures recommended by Kaufman (Flannagan & Kaufman, 2004; Kaufman, 1994; Kaufman & Lichtenberger, 2002, 2006) and Sattler (Sattler, 2008; Sattler & Ryan, 2009) as well as contemporary intelligence test authors through their test technical and interpretation manuals.

### **Global IQ Score Interpretation/Stratum III**

The first level of intelligence test interpretation involves the reporting and description of the overall, omnibus, global, or Full Scale score; which is measured or estimated by two or more subtests within the scale. Full Scale scores represent an estimate of *g* or Spearman's general intelligence factor (Spearman, 1904, 1927), which is the apex of Carroll's (1993,

1995) hierarchical model. Substantial evidence for interpretation of global Full Scale scores (*g* estimates) exists (Gottfredson, 2002, 2008; Jensen, 1998; Kubiszyn et al., 2000; Lubinski, 2000; Lubinski & Humphreys, 1997; Neisser et al., 1996).

Interpretation of Full Scale scores typically begins with a presentation and description of the standard score, percentile rank, and confidence interval (obtained score or estimated true score) for the standard score to account for measurement error, consistent with *Standards for Educational and Psychological Testing* (AERA, APA, NCME, 1999). Classification of the Full Scale score within a descriptive category (or range of descriptive categories around the confidence interval) reflecting some deviation from average is also frequently made (i.e., average, above average, significantly below average). These normative descriptors are intended to provide an illustration of how the individual performed relative to others their age. This is necessary given the interval level measurement such standardized scores represent.

Another aspect of interpretation of the Full Scale score is an inference as to what to expect from the individual in regard to their acquisition of academic skills (i.e., academic achievement). The predictive validity of intelligence test Full Scale scores is well documented (Bracken & Walker, 1997; Brody, 2002; Brown, Reynolds, & Whitaker, 1999; Flanagan, Andrews & Genshaft, 1997; Gottfredson, 2008, Konold & Canivez, 2010; Naglieri & Bornstein, 2003) and intelligence is a construct that precedes and influences the development of academic achievement because as Jensen (1998) noted "school learning itself is *g*-demanding" (p. 279). Watkins, Lei, and Canivez (2007) also demonstrated that verbal and perceptual measures of intelligence (WISC-III) predicted future academic achievement in reading and mathematics but reading and mathematics did not predict future measured intelligence, thus supporting Jensen's position of the temporal precedence and influence of intelligence on academic achievement.

Full Scale scores are also used in making classification or diagnostic decisions regarding psychopathology, disability, and giftedness. Classification or diagnosis of mental retardation (MR)/intellectual disability (ID) requires by definition "significantly subaverage general intellectual functioning" (Public Law 108-446 [IDEIA]; U. S. Department of Education, 2006, p. 46756) or "significantly sub-average intellectual functioning" (APA, 2000, p. 49). It is generally agreed that a score 2 *SD* below

the population mean would satisfy this criterion. Historically, the operational definition for classifying specific learning disability (SLD), according to IDEIA prior to IDEIA 2004, involved first a severe discrepancy between predicted academic achievement given a certain level of intelligence and actual academic achievement. This criterion was concerned with the *unexpectedly* low achievement associated with the concept of learning disability (Reynolds, 1984). While federal law no longer mandates the use of the severe discrepancy criterion, states may allow local school districts to continue using this criterion in SLD classification (IDEIA 2004) and predicted (expected) achievement is based on a person's general intellectual ability. DSM-IV-TR (APA, 2000) specifies individually measured achievement from a standardized test that "is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education" (p. 53, p. 54, p. 56) for classification of its SLD type disorders (viz., Reading Disorder, Mathematics Disorder, Disorder of Written Expression, respectively). Assessment for intellectual giftedness also has implications for intelligence testing and it is generally thought that a Full Scale intelligence test score  $2SD$  above the population mean would satisfy the criterion of significantly above average intelligence.

#### **GLOBAL SCORE PSYCHOMETRIC SUPPORT**

Psychometric support for Full Scale IQ, or related omnibus scores, is strong and includes the highest internal consistency estimates, short-term temporal stability, long-term temporal stability, and predictive validity coefficients (Bracken & McCallum, 1998b; Canivez & Watkins, 1998; Elliott, 2007b; Glutting, Adams, & Sheslow, 2000b; Kaufman & Kaufman, 1983, 1993, 2004a, 2004b; Naglieri & Das, 1997b; The Psychological Corporation, 1999; Reynolds & Kamphaus, 2003; Roid, 2003b; Wechsler, 2002a, 2002b, 2003, 2008b; Wechsler & Naglieri, 2006; Woodcock, McGrew, & Mather, 2001). In studies of long-term temporal stability of WISC-III IQ scores, the Full Scale IQ possessed the highest stability coefficient of all scores available and this also held across a variety of demographic variables (sex, age, race/ethnicity, disability) (Canivez & Watkins, 1998, 1999, 2001). Similar results were also reported by Krohn and Lamp (1999) for the K-ABC and Stanford-Binet Intelligence Scale: Fourth Edition (SB:FE; Thorndike, Hagen, & Sattler, 1986). These are expected findings according to true score theory, and reflect the power of aggregate scores that contain less error variance. Assessing temporal stability

is important as it addresses one of the major sources of error variance in intelligence tests not addressed by the internal consistency estimate (Hanna, Bradley, & Holen, 1981). Hanna et al. also noted the importance of assessing intelligence test measurement error related to scoring and administration errors.

IQ tests have a rich history of accounting for meaningful levels of academic achievement variance (Brody, 2002; Naglieri & Bornstein, 2003), with average IQ-achievement correlations near .55 across age groups (Neisser et al., 1996; Brody, 2002). Thorndike (1986) also noted approximately 85% to 90% of predictable criterion variable variance is accounted for by a single general score. Among co-normed intelligence and achievement tests it is quite common to observe concurrent IQ-achievement correlations near .70. It is often said that the most important application of intelligence tests is their ability to forecast student achievement (Brown, Reynolds, & Whitaker, 1999; Weiss & Prifitera, 1995) and the prediction of school performance with intelligence tests has been a primary use since the creation of the first Binet-Simon Scale of Intelligence (Binet & Simon, 1905).

#### ***Broad Factor/Verbal-Nonverbal Score Interpretation/Stratum II***

##### **VERBAL VS. NONVERBAL ASSESSMENT**

Recognition of literacy issues affecting standardized intelligence testing was noted in the early 1900s and influenced the creation and use of the Army Alpha (verbal) and Army Beta (nonverbal) tests (Thorndike, 1997), with Yoakum and Yerkes (1920) noting the use of Army Beta for recruits who failed Army Alpha to prevent "injustice by reason of relative unfamiliarity with English" (p. 19). Wechsler (1939) also recognized the need to assess intellectual abilities through both verbal *and* nonverbal (performance) means. The selection and aggregation of subtests into composite scores were originally based on subtest task requirements, and, Wechsler noted, "the subtests are different measures of intelligence, not measures of different kinds of intelligence" (1958, p. 64). For Wechsler, verbal and performance measures were not different types of intelligence, but rather different ways to measure it. Verbal and performance measures relate to Carroll's (1993) Stratum II dimensions, which he referred to as "flavors" of *g*. Authors of contemporary *nonverbal* intelligence tests note that it is the method of assessment that is nonverbal rather than the cognitive process involved in solving the tasks (Bracken &

McCallum, 1998a, 1998b; Naglieri, 2003a, 2003b; Wechsler & Naglieri, 2006). Naglieri wrote, “the term *nonverbal* refers to the content of the test, not a type of ability” (2003a, p. 2). Thus, the content or demands of subtests and composites may differ but they still measure general intelligence. Spearman referred to this as the “indifference of the indicator” (1927, p. 197).

For individuals who have hearing impairments or are deaf, have receptive or expressive language deficits, or are from ethnic minority groups with limited English proficiency; nonverbal assessment of intellectual abilities is particularly useful (Bracken & McCallum, 1998b; Naglieri, 2003a). This is primarily because the verbal (English) methods would likely underestimate the intellectual abilities of such individuals. But there are other clinical groups for whom differences between verbal and nonverbal (performance) estimates have been reported or hypothesized. These include individuals with traumatic brain injury, bilingualism, autistic disorder, Asperger’s disorder, and delinquents or psychopaths. Most intelligence test technical manuals (i.e., WPPSI-III, WISC-IV, WAIS-IV, KAIT, UNIT, KABC-II, DAS-II) typically provide clinical group and matched normal group comparisons in test performance that sometimes illustrate similar verbal–nonverbal differences but frequently contain small samples that are intended to be only preliminary investigations.

#### **VERBAL–NONVERBAL (VIQ-PIQ/VCI-PRI) COMPARISONS**

Kaufman and Lichtenberger (2006) devoted two chapters to VIQ and PIQ differences as they related to neuropsychology (brain functioning or injury) and clinical research and use. Many of the studies were of adults and with WB or WAIS data, but some studies were with children and adolescents and WISC data. Their review of more than 50 studies and approximately 2,700 patients who had unilateral brain damage generally supported the PIQ > VIQ for left-hemisphere lesions and VIQ > PIQ for right-hemisphere lesions on the WB, WAIS, and WAIS-R, but there was greater consistency for the right-hemisphere lesion groups. Variables that appeared to have possible moderating effects included age, sex, race or ethnicity, and educational attainment. Group difference studies are not sufficient for individual diagnostic use of such signs, and Kaufman and Lichtenberger noted calls by Matarazzo and colleagues (Bornstein & Matarazzo, 1982, 1984; Matarazzo, 1972; Matarazzo &

Herman, 1984) for due caution for such individual use of VIQ-PIQ differences by attending to base rates in the population. Furthermore, it is one thing to assess an individual with known brain injury and lesion, observe VIQ-PIQ differences of a large magnitude, and infer the likely cause for the VIQ-PIQ difference to the brain damage; but in the absence of brain injury or lesion, to infer such from VIQ-PIQ differences is a much riskier proposition.

Such inferential problems from test scores or other “signs” in psychology have been pointed out at least as far back as 1955 (Meehl & Rosen, 1955) and are also articulated by others (Lilienfeld, Wood, & Garb, 2000; McFall 2005; Swets, Dawes, & Monahan, 2000; Watkins, 2009; Watkins, Glutting, & Youngstrom, 2005) as it relates to the Reverend Thomas Bayes’ (1702–1761) theorem of conditional probabilities and base rates. Leonard and Hsu (1999) and Nickerson (2004) provide excellent descriptions of Bayes’ theorem (Bayes, 1763) and its implications and applications. One feature of diagnostic tests often highlighted is *sensitivity*, which indicates the probability of obtaining a positive test result, given that the person has the target disorder. However, in diagnostic use of a test, a clinician is much more interested in *positive predictive power*, or the probability of a person’s having the target disorder, given a positive test result. A similar contrast is that of *specificity*, which indicates the probability of obtaining a negative test result, given that the person *does not* have the target disorder; and *negative predictive power*, the more important indicator of the probability of a person’s not having the target disorder, given a negative test result. With respect to low base rates, it is difficult for tests to improve accuracy in individual cases (Lilienfeld et al., 2006; McFall, 2005; Meehl, 2001; Meehl & Rosen, 1955).

In the case of VIQ-PIQ differences and inferences regarding brain injury and function, inverse probabilities suggest that there may well be a much greater proportion of individuals with brain injury and lesions who show VIQ-PIQ differences (sensitivity) than individuals with VIQ-PIQ differences who also have brain injury and lesions (positive predictive power). Neuropsychologists are also probably more likely to see patients referred for evaluations who have brain damage and observed VIQ-PIQ (VCI-PRI) discrepancies; and while those who have brain damage are more likely to show VIQ-PIQ (VCI-PRI) discrepancies, neuropsychologists may overestimate the value of these VIQ-PIQ (VCI-PRI) differences because they are not likely to

see those with VIQ-PIQ (VCI-PRI) discrepancies who do not have brain damage.

Review and summary of research provided by Kaufman and Lichtenberger (2006) regarding PIQ > VIQ for delinquents or “psychopaths” indicated that some distinct group difference studies found such differences as suggested by Wechsler (1944, 1958), but results overall were reportedly mixed. Kaufman and Lichtenberger noted that use of this PIQ > VIQ “sign” as recommended by Wechsler should not be used for individual diagnosis due to a lack of empirical support. Inconsistency of PIQ > VIQ findings for individuals with autistic disorder was also noted, in addition to small effect sizes, and thus determined to be of no diagnostic clinical use (Kaufman & Lichtenberger). More recently, a large Swedish study of individuals with Asperger’s disorder, autism, or pervasive developmental disorder—not otherwise specified (PDD-NOS), based on DSM-IV criteria (American Psychiatric Association, 1994), found profile level (overall IQ) differentiated Asperger’s from autism and PDD-NOS, but scatter and shape of profiles were small (Zander & Dahlgren, 2010). Within the autism group, a mean VCI-POI difference of 9 points ( $SD = 20.5$ ) in favor of POI was observed and represented a medium effect size, but Zander and Dahlgren also noted individual profiles were too variable for individual diagnostic use of the Swedish version of the WISC-III (Wechsler, 1999) in differentiating among PDD diagnoses.

Cronbach (1990), however, noted problems with interpreting difference scores due to their low reliability. VIQ-PIQ difference scores, for example, have been shown to have poor temporal stability (too low for individual clinical use) and thus likely of questionable utility (Canivez & Watkins, 1998, 1999, 2001; Cassidy, 1997). The inference from significant VIQ-PIQ differences is that the individual has stronger cognitive skills in one area than the other, as well as giving rise to speculation as to the implications of the difference. However, if the difference score is not sufficiently reliable, it cannot be valid or of diagnostic value. Also, what such an analysis and inference ignores is the fact that VIQ and PIQ scores are not independent and such inferences from them are obscured by shared variance.

While Canivez, Neitzel, and Martin (2005) did not examine VIQ-PIQ differences in their study on relationships between the WISC-III, KBIT, Adjustment Scales for Children and Adolescents (ASCA: McDermott, Marston, & Stott, 1993), and academic achievement; with a sample ( $N = 207$ ) of various students (non-disabled, learning disability,

mental retardation/intellectual disability, and emotional disability); additional VIQ-PIQ analyses of this dataset were conducted for this chapter. Correlations between VIQ-PIQ discrepancies and all ASCA syndromes (core and supplementary) and global adjustment scales ranged from  $-.004$  to  $.056$  ( $p > .05$ ) and ranged from  $-.003$  to  $.099$  ( $p > .05$ ) with measures of academic achievement. Furthermore, there were no significant differences in VIQ-PIQ discrepancies between the four diagnostic groups. Glutting, Youngstrom, Oakland, and Watkins (1996) also examined relations between WISC-III scores and ASCA (and other measures) and found low WISC-III IQ and index score correlations ranging from  $-.27$  to  $.18$  ( $M_r = -.04$ ) across all ASCA syndromes and global adjustment scales.

While some research may indicate distinct group differences with respect to VIQ > PIQ or PIQ > VIQ, this is necessary but not sufficient for individual diagnostic utility, and until such diagnostic utility is demonstrated in differentiating individuals within these groups, clinicians should not assume that a VIQ/VCI and PIQ/POI/PRI difference is an indicator, marker, or sign for that diagnostic group. Study of distinct clinical groups may well reflect the problem of inverse probabilities where members of a distinct group may likely demonstrate VIQ-PIQ “signs” (sensitivity), but those who demonstrate VIQ-PIQ “signs” may not necessarily be members of that distinct clinical group (positive predictive power). Kaufman and Lichtenberger (2006) noted that, “when evaluating V-P differences for individuals instead of groups, extreme caution must be exercised” (p. 316). In the absence of diagnostic utility research affirming the diagnostic utility of scores for individual diagnostic purposes (especially their positive predictive power), interpretation of those scores should probably be curtailed.

#### FACTOR/BROAD-ABILITY SCORE COMPARISONS

Beginning with the WISC-IV, revised Wechsler scales no longer provide VIQ and PIQ scores and now only report factor index scores as Stratum II abilities, as they are more factorially pure indexes of latent abilities. Like Full Scale scores, interpretation of factor or broad-ability scores typically first involves a presentation and description of the standard score, percentile rank, and confidence interval (obtained score or estimated true score) for each standard score to account for measurement error (AERA, APA, NCME, 1999). Classification of factor or broad-ability scores within a descriptive category (or range of descriptive categories around

the confidence interval) reflecting some deviation from average is also frequently made (i.e., “average,” “below average,” “significantly above average”). Like Full Scale scores, these normative descriptors are intended to provide an illustration of how the individual performed relative to others their age and are a function of the interval level measurement the standardized scores represent.

Because there are multiple factor or broad-ability scores, test authors and publishers provide in their respective manuals procedures for comparing these scores to each other. Tables of critical values of difference scores as well as base rates for differences are presented in test manuals and provide clinicians a convenient way to determine which factor or broad-ability scores differ and how rare such a difference was in the standardization sample. Like VIQ-PIQ differences, the inference from significant differences between factor or broad-ability scores is that the individual has stronger cognitive skills in one area than the other and there is speculation as to the implications of these strengths and weaknesses. Factor or broad difference scores that are not sufficiently reliable cannot be valid or of value. Like the VIQ and PIQ scores, factor or broad area scores are not independent and inferences from them are also obscured by shared variance.

### **FACTOR/BROAD-ABILITY PSYCHOMETRIC SUPPORT**

Psychometrically, factor scores or broad-ability scores typically have internal consistency estimates, short-term stability estimates, and predictive validity coefficients that are generally lower than the Full Scale score but higher than individual subtest scores (Bracken & McCallum, 1998b; Elliott, 2007b; Glutting, Adams, & Sheslow, 2000b; Kaufman & Kaufman, 1983, 1993, 2004a, 2004b; Naglieri & Das, 1997b; The Psychological Corporation, 1999; Reynolds & Kamphaus, 2003; Roid, 2003b; Wechsler, 1997, 2002a, 2002b, 2003, 2008b; Wechsler & Naglieri, 2006; Woodcock et al., 2001). This is expected, as true score theory predicts that scores with more items and subtests will have less error variance and thus greater reliability and true score variance. This also means that factor scores or broad-ability scores typically include more error variance than the Full Scale score. However, some factor scores or broad-ability scores have better reliability estimates than others, partly related to the number of subtests (and items) that comprise the factor-based score. In long-term stability studies of the WISC-III (Canivez & Watkins, 1998, 1999,

2001) for example, it was found that across the total sample and across age, sex, race or ethnicity, and disability groups that the VCI, POI, FDI, and PSI scores had lower stability coefficients than the FSIQ but more importantly, only the VCI and POI scores showed long-term temporal stability coefficients close to being high enough for individual interpretation or decision-making ( $r \geq .85$ ; Hills, 1981;  $r \geq .90$ ; Aiken, 2000; Guilford & Fruchter, 1978; Nunnally & Bernstein, 1994; Ponterotto & Ruckdeschel, 2007; Salvia & Ysseldyke, 1988, 2001). The FDI and PSI score stability coefficients were too low (too unstable) for individual clinical use. Similar results were also obtained by Krohn and Lamp (1999) for the K-ABC and SB:FE.

### **FACTORIAL/STRUCTURAL VALIDITY**

While some factor-based scores might possess acceptable reliability coefficients (internal consistency, short-term stability, long-term stability) and reliability is a foundation for possible score validity, validity is ultimately more important. Also, “validity is always *specific to some particular use or interpretation*” (Linn & Gronlund, 1995, p. 49). Investigations of the internal or structural validity of intelligence tests is often conducted via factor analyses (exploratory [EFA] and confirmatory [CFA]), but recently, some intelligence test authors and publishers (Elliott, 2007b; Roid, 2003b, Wechsler, 2008b; McGrew & Woodcock, 2001) opted to report only results from CFA. This is in contrast to previous practice (and some current practice) wherein both EFA and CFA results were both reported (Bracken & McCallum, 1998b; Elliott, 1990; Glutting et al., 2000b; Kaufman & Kaufman, 1993; Naglieri & Das, 1997b; Wechsler, 1991, 2002a, 2002b; Wechsler & Naglieri, 2006). Gorsuch (1983) noted the complimentary nature of EFA and CFA, suggesting that greater confidence in the internal structure of a test is obtained when EFA and CFA are in agreement. As noted by Frazier and Youngstrom (2007), there is good cause for concern regarding the disagreement between the number of latent factors reported in contemporary intelligence tests based only on CFA procedures (or the most liberal EFA factor-extraction criteria) and the number of factors suggested with EFA procedures using the most psychometrically sound methods for determining the correct number of factors to extract and retain. For example, DiStefano and Dombrowski (2006) and Canivez (2008) provided markedly different results for the SB-5 than the CFA results presented in its technical manual (Roid, 2003b).

Another EFA approach to investigate the internal structure of intelligence tests is the Schmid and Leiman (1957) procedure, which was recommended by Carroll (1993, 1995, 1997a, 2003); McClain (1996); Gustafsson and Snow (1997); Carretta and Ree (2001); Ree, Carretta, and Green (2003); and Thompson (2004). Because the narrow abilities (subtests) and broad abilities (factors) are themselves correlated, subtest performance on cognitive abilities tests reflect combinations or mixtures of both first-order *and* second-order factors. Carroll argued that variance from the second-order factor should be extracted first to residualize the first-order factors, leaving them orthogonal to each other and the second-order factor. Thus, variability associated with the higher-order factor is accounted for prior to interpreting variability in the lower-order factors. In this way, it is possible to see how the reliable test variance is partitioned to higher- and lower-order dimensions. However, almost no test manuals provide these analyses for practitioners to review.

When the Schmid and Leiman (1957) procedure has been used with contemporary intelligence tests, the higher-order factor ( $g$ ) accounted for the largest portion of variance, and considerably smaller portions of variance remained at the lower-order (factors) level (Bracken & McCallum, 1998b; Canivez, 2008, 2011; Canivez, Konold, Collins, & Wilson, 2009; Canivez & Watkins, 2010a, 2010b; Domrowski & Watkins, in press; Dombrowski, Watkins, & Brogan, 2009; Nelson & Canivez, 2012; Nelson, Canivez, Lindstrom, & Hatt, 2007; Watkins, 2006; Watkins, Wilson, Kotz, Carbone, & Babula, 2006). This is one reason the primary (if not exclusive) interpretation should be at the Full Scale score level. Clinicians *should be* provided such information about the portions of test variance captured at the different levels of the test in test manuals to facilitate decisions about the importance of the different dimensions and what should be interpreted. Unfortunately, this information is absent from most contemporary intelligence test technical manuals. However, decisions about the validity and interpretation of intelligence tests cannot be sufficiently answered or resolved using only structural validity or internal structure perspective (EFA or CFA) (Canivez et al., 2009; Carroll, 1997b; Kline, 1994; Lubinski & Dawis, 1992).

#### **FACTOR/BROAD-ABILITY INCREMENTAL VALIDITY**

When considering intelligence test validity and interpretation across multiple levels and scores from a test, it is critical to consider the *external* validity

investigations such as predictive validity and incremental validity of lower-level scores beyond that of higher-level scores (Haynes & Lench, 2003; Hunsley, 2003; Hunsley & Meyer, 2003). In this way the relative importance of factor scores versus the global Full Scale score may be assessed. However, *validity* should not be confused with *diagnostic utility* (Meehl, 1959; Mullins-Sweatt & Widiger, 2009; Wiggins, 1988), as the latter is concerned with the application of test score interpretation to the individual. It follows that construct validity and criterion-related validity, Cronbach and Meehl (1955) preferred construct validity, are a prerequisite without which utility is not possible.

A major aspect of intelligence test use is its utility in assisting in the diagnosis or classification of an individual (e.g., MR, SLD, GT). Examination of the diagnostic or predictive utility is also a prerequisite for the ethical use of test scores (Dawes, 2005). Ultimately, the greatest utility would be the ability of a test or set of variables to accurately determine the likelihood of treatment response under specified conditions (i.e., treatment validity). However, prediction is, in and of itself, important, regardless of treatment utility (Glutting, Watkins, & Youngstrom, 2003) and is frequently investigated.

The importance of incremental validity investigations in general, and in the case of multilevel intelligence test interpretation in particular, is based on an important scientific principle articulated by William of Ockham (alt. "Occam"): the law of parsimony (Occam's razor), which states "what can be explained by fewer principles is needlessly explained by more" Jones, 1952, p. 620). Thus, science favors a less complex explanation over a more complex explanation for phenomena. In the case of intelligence test interpretation, the Full Scale score, an estimate of  $g$ , is a more parsimonious index than the lower-level factor or broad-ability scores (and subtest scores) and satisfies the law of parsimony. Intelligence test Full Scale scores demonstrate substantial criterion-related validity (Neisser et al., 1996; Carroll, 1993; Gottfredson, 1997, 2008, 2009; Jensen, 1998; Lubinski, 2000; Lubinski & Humphreys, 1997), so in order for the factor scores to be relevant, they must demonstrate *meaningful* predictive validity *beyond* that afforded by the Full Scale score.

Besides describing performance on factor-based scores or broad-ability scores, clinicians are often instructed to consider predictive utility and explanation of performance in academic achievement areas reflecting the higher- and lower-order factor scores.

For example, if significant differences between factor scores exist, or if factor scores deviate from the individual's mean factor performance, that variability among factor scores suggests to some that the FSIQ is not interpretable and that the clinician must examine and interpret the examinee's unique pattern of performance on the factors or broad abilities (Flanagan & Kaufman, 2004; Hale & Fiorello, 2004; Kaufman, 1994; Kaufman & Lichtenberger, 2002, 2006; Lezak, 1995; Sattler, 2008; Sattler & Ryan, 2009; Weiss, Saklofske, & Prifitera, 2003; Wolber & Carne, 2002). Others (Gridley & Roid, 1998; Hale & Fiorello, 2004; Hildebrand & Ledbetter, 2001) have suggested that under these conditions the FSIQ would not be a valid predictor of the individual's academic achievement. Even when there are no differences among factor scores, interpretation of the factor scores may still be done. Those promoting the clinical approach to test interpretation of factor index variability often argue that, while the deviations might not be appropriate for diagnosis, the ability patterns (strengths and weaknesses) could be helpful for instructional strategies, interventions, or treatments or provide hypotheses about the individual (Flanagan & Kaufman, 2004; Kaufman, 1994; Kaufman & Lichtenberger, 2002, 2006; Sattler, 2008; Sattler & Ryan, 2009).

Whether or not such factor score differences provide useful indications for treatment, accommodations, or hypothesis-generation will, in part, be based upon their incremental validity. A primary use of intelligence tests is to predict or account for academic achievement, and if the index scores are to be of practical clinical utility, they must account for meaningful portions of achievement variance *beyond* that provided by the Full Scale score (Haynes & Lench, 2003; Hunsley & Meyer, 2003). This is a necessary, but not sufficient, condition for clinical utility and use with *individuals*. In considering incremental validity, there are two approaches that are often taken and are highly dependent upon the nature of the question being asked and the level of analysis.

In their innovative and highly influential article "Distinctions Without a Difference: . . .," Glutting, Watkins, Konold, and McDermott (2006) thoroughly examined the validity of observed scores *and* latent factors from the WISC-IV in estimating reading and mathematics performance on the WIAT-II using the WISC-IV—WIAT-II standardization linking sample. Both approaches are important and legitimate methods, but they answer different questions and use different statistical procedures. If one

is interested in testing theory and *explaining* latent achievement constructs from latent intelligence constructs, then the use of structural equation modeling (SEM) is an appropriate statistical method (Glutting et al., 2006). However, because the latent constructs are not directly observable, *and* latent construct scores are difficult to calculate and not readily available, there are no direct practical clinical applications (Oh, Glutting, Watkins, Youngstrom, & McDermott, 2004). If one is interested in clinical application of test scores in *predicting* academic achievement from intelligence test scores, hierarchical multiple regression analysis (HMRA) is an appropriate statistical method (Glutting et al. 2006) and may be the most common statistical method in incremental validity (McFall, 2005). HMRA techniques utilize the observed IQ and factor scores that psychologists have available to them. Unlike the perfectly reliable latent constructs in SEM, in clinical assessment and interpretation for individuals, psychologists *must* use observed scores from tests, and those scores contain measurement error.

Glutting et al. (2006) demonstrated that the WISC-IV FSIQ predicted substantial portions of variance in reading and mathematics scores on the WIAT-II, but the four factor index scores (VCI, PRI, WMI, PSI) did not contribute additional meaningful prediction beyond the FSIQ. Other studies of incremental predictive validity before and after Glutting et al. (2006) provided similar results (Canivez, 2011; Freberg, Vandiver, Watkins, & Canivez, 2008; Glutting, Youngstrom, Ward, Ward, & Hale, 1997; Kahana, Youngstrom, & Glutting, 2002; Ryan, Kreiner, & Burton, 2002; Watkins, Glutting, & Lei, 2007; Youngstrom, Kogos, & Glutting, 1999). Glutting et al. concluded that their results were very like "previous epidemiological studies from both the United States and Europe that showed specific cognitive abilities add little or nothing to prediction beyond the contribution made by *g* (Jencks et al., 1979; Ree, Earles, & Treachout, 1994; Salgado, Anderson, Moscoso, Bertua, & de Fruyt, 2003; Schmidt & Hunter, 1998; Thorndike, 1986)" (2006, p. 110).

Furthermore, in their SEM analyses, Glutting et al. (2006) found only the higher-order *g* and the VC latent construct offered significant *explanations* of reading and mathematics constructs (PR, WM, and PS constructs provided no increases in explanation). Similar SEM findings were also reportedly obtained with the Woodcock-Johnson Revised Tests of Achievement (WJ-R; Woodcock & Johnson, 1989) (Keith, 1999; McGrew, Keith, Flanagan,

& Vanderwood, 1997) and with the WISC-III (Wechsler, 1991; Oh et al., 2004). Kuusinen and Leskinen (1988) and Gustafsson and Balke (1993) reportedly reached similar conclusions with other measures of ability and achievement (Glutting et al., 2006).

Why the factor scores failed to add incremental predictive validity over and above the FSIQ may relate to the earlier discussion of hierarchical EFA where the lower-order factors accounted for substantially smaller portions of reliable variance (Canivez, 2008, 2011; Canivez & Watkins, 2010a, 2010b; Nelson & Canivez, 2012; Nelson et al., 2007; Watkins, 2006; Watkins et al., 2006). If test authors and publishers are interested in improving the incremental predictive validity of cognitive tests, it may be necessary to (a) increase the number of subtests estimating the factor scores to capture more variance, and/or (b) construct cognitive subtests that contain less  $g$  variance (and more Stratum II or broad-ability variance). However, at present, empirical results continue to corroborate the overwhelming majority of the reliable criterion variable variance is predicted by the single Full Scale intelligence test score (Thorndike, 1986).

Multiple regression analysis research with the WJ-III cognitive clusters predicting reading (Evans, Floyd, McGrew, & Leforgee, 2001) and writing (Floyd, McGrew, & Evans, 2008) found some clusters were more important than others. However, these were not *hierarchical* multiple regression analyses first accounting for  $g$  and then accounting for cluster score improvement in predicting academic achievement. Thus, the incremental validity of clusters beyond  $g$  was not investigated. Other recent WJ-III research used SEM procedures to examine direct vs. indirect *explanations* of  $g$  with direct vs. indirect *explanations* of broad-ability dimensions in areas of reading decoding (Floyd, Keith, Taub, & McGrew, 2007) and mathematics achievement (Taub, Floyd, Keith, & McGrew, 2008). Both studies noted the WJ-III influences of  $g$  were large but indirect through the broad-ability dimensions. However, as Floyd et al. noted, the WJ-III has a problem regarding possible criterion contamination that could inflate the predictive power of some broad-ability dimensions. Determining direct vs. indirect influences of general intelligence is further complicated and unresolved due to issues of singularity, multicollinearity, and reported Heywood cases in SEM of the J-III in the Floyd et al. study (i.e., Gf- $g$ , Glr- $g$ , Gsm- $g$  [three-stratum model] and Gf- $g$  [two-stratum model]; paths at 1.0). Another

important issue remains, despite these authors' arguments for practitioner use of SEM results in informing test interpretation. Glutting et al. (2006) pointed out,

We previously demonstrated the following: (a) The constructs from SEM rank children differently than observed scores, and children's relative position on factor-based constructs (e.g., VC) can be radically different than their standing on corresponding observed factor scores (the VCI); (b) construct scores are not readily available to psychologists; and (c) although it is possible to estimate construct scores, the calculations are difficult and laborious (cf. Oh et al., 2004, for an example). Therefore, one of the most important findings here is that psychologists cannot directly apply results from SEM. (p. 111)

Thus, SEM results provide theoretical *explanations* for relationships between the cognitive and achievement variables, but this does not mean that there is direct application in the prediction of achievement performance from the cognitive test scores. Thus, the incremental predictive validity of factor or broad-ability scores for clinical use is very much in doubt.

Perhaps the most extreme view regarding the clinical value of the FSIQ is that of Hale, Fiorello, and colleagues (Fiorello, Hale, Holdnack, Kavanagh, Terrell, & Long, 2007; Fiorello, Hale, McGrath, Ryan, & Quinn, 2001; Hale & Fiorello, 2004; Hale, Fiorello, Bertin, & Sherman, 2003; Hale, Fiorello, Kavanagh, Holdnack, & Aloe, 2007; Hale, Fiorello, Kavanagh, Hoeppner, & Gaither, 2001), who proclaimed the invalidity of the FSIQ in predicting academic achievement when significant intracognitive variability (factor or subtest scatter or variation) was observed. They argued that practitioners should "never interpret the global IQ score if there is significant scatter or score variability" (Hale & Fiorello, 2001, p. 132).

The approach that Hale, Fiorello, and colleagues used to render such a recommendation is that of regression commonality analysis of global and factor-index scores from the WISC-III (Wechsler, 1991), and achievement scores from the Wechsler Individual Achievement Test (WIAT; Wechsler, 1992). Another method (later deemed inappropriate) was their entering factor or broad-ability scores into the first block of hierarchical multiple regression and entering the Full Scale score in the second block to test how much incremental validity there is in the Full Scale score over and above the lower-order factor or broad-ability scores. This approach was

criticized by Glutting et al. (2006), who wrote that while it had “intuitive appeal,” and was “employed on occasion (Hale, Fiorello, Kavanagh, Hoeppner, & Gaither, 2001)” (p. 106), such use violates the law of parsimony such that psychologists would favor a more complex accounting for predictive validity rather than the less complex predictor ( $g$ ) when the many factors at best only account for marginally more achievement variance.

A special issue of the journal *Applied Neuropsychology* further addressed these issues and the merits and conclusions of the approach of Hale, Fiorello, and colleagues (Reynolds, 2007). Fiorello et al. (2007) applied regression commonality analysis to WISC-IV factor index scores obtained from the 228 participants previously diagnosed with learning disability (LD), attention deficit–hyperactivity disorder (ADHD) and traumatic brain injury (TBI) from the special-groups data reported in the WISC-IV Technical Manual (Wechsler, 2003b). However, they only included participants with FSIQ scores between 80 and 120 “to ensure extreme scores did not affect study results” (Fiorello et al., 2007, p. 5). Primary conclusions of their results were that the WISC-IV FSIQ is not appropriate for interpretation for these groups (those with intracognitive variability) due to small, shared variance of the four index scores; and individual idiographic interpretation is appropriate based on sizable unique variance components.

The manuscript of Fiorello et al. (2007) was provided to several statistics and psychological measurement experts for critique and comment who provided very different assessments and conclusions. Dana and Dawes (2007); Faust (2007); and Watkins, Glutting, and Lei (2007) pointed out numerous methodological errors as well as empirical evidence arguing against the Hale, Fiorello, et al. use of regression commonality analysis. Hale et al. (2007) provided a rejoinder to address the critiques but appeared to only restate their original position rather than rebut the critiques and data presented (Dana & Dawes, 2007; Faust, 2007; Watkins et al., 2007). Daniel (2007) also provided a critique of Fiorello et al. and used a simulation study to demonstrate that high levels of index-score scatter *did not* affect the FSIQ predictive validity. Schneider (2008), quite dissatisfied with the Hale et al. (2007) rejoinder indicating they did not recognize the flaws in their analyses, provided yet another critique of the Hale, Fiorello, and colleagues’ application of regression commonality analysis. Daniel (2009) also provided evidence that WISC-IV subtest or factor score

variability does not invalidate the FSIQ in predicting WIAT-II performance, as he showed in comparisons of high- and low-variability groups. In an investigation of the predictive validity of the DAS general conceptual ability index (GCA; Elliott, 1990) when significant and unusual scatter was observed, Kotz, Watkins, and McDermott (2008) found no significant differences in predicting academic achievement by the GCA across groups showing significant *and* clinically unusual differences between factors.

In summary, while factor or broad-ability scores may possess higher reliability estimates than subtest scores, and some have acceptable reliability estimates to support individual decision-making, the validity research does not provide strong enough support for their interpretations in many instances. Furthermore, this discussion was concerned with the issue of statistical incremental validity, not clinical incremental validity, which Lilienfeld, Wood, and Garb (2006) noted could negatively affect decisions based on the “dilution effect,” whereby “presenting participants with accurate but nondiagnostic information...often results in less accurate judgments” (p. 11), as reported by Nisbett, Zukier, and Lemley (1981). Unless stronger support is provided for their incremental validity, clinicians should restrain their clinical interpretations to the Full Scale score in most, if not all, instances.

### ***Subtest-Based Score Interpretation/ Stratum I***

Interpretation of intelligence test subtest scores is most frequently conducted through examination of subtest deviations from the individual’s average subtest performance through ipsative comparisons, an ideographic procedure. As noted by Rapaport et al. (1945–1946), the examination of subtest highs and lows (strengths and weaknesses) for an individual was to provide the clinician with valuable information about the individual that could assist in diagnosis and treatment. Zeidner (2001) recommended the use of cognitive strengths and weaknesses derived from the WISC-III as the basis for psychoeducational recommendations. As with other test scores, investigation of reliability and validity of subtest scores is a requirement for determining their utility and thus interpretability.

### **SUBTEST PSYCHOMETRIC SUPPORT**

While Full Scale scores (and some factor or broad-ability scores) demonstrate uniformly high estimates of reliability and validity, the same cannot be said for subtest scores. Great variability

exists within and between various intelligence tests as to the magnitude of their subtest reliability estimates. Invariably, intelligence test subtests typically have lower internal consistency estimates than composite scores (Bracken & McCallum, 1998b; Elliott, 2007b; Glutting et al., 2000b; Kaufman & Kaufman, 1983, 1993, 2004a, 2004b; Naglieri & Das, 1997b; Psychological Corporation, 1999; Reynolds & Kamphaus, 2003; Roid, 2003b; Wechsler, 2002, 2003, 2008b; Wechsler & Naglieri, 2006; Woodcock et al., 2001). Importantly, internal consistency estimates provide the highest estimates of intelligence subtest reliability because they do not consider important sources of error such as temporal stability, scoring errors, or administration errors (Hanna et al., 1981). In examining the long-term stability of WISC-III scores, Canivez and Watkins (1998) found the stability coefficients for subtests ranged from .55 to .75; thus, none showed acceptable stability for individual clinical decision-making. Considering more stringent criteria for reliability estimates for individual clinical interpretation (Aiken, 2000; Hills, 1981; Guilford & Fruchter, 1978; Nunnally & Bernstein, 1994; Ponterotto & Ruckdeschel, 2007; Salvia & Ysseldyke, 1988, 2001), many (most) intelligence test subtests are inadequate. For the subtests with reliability coefficients (internal consistency, short-term stability, long-term stability) that meet or exceed minimum standards, it is also necessary to know how much subtest specificity exists (reliable subtest variance *unique* to that subtest). More importantly, subtest score *validity*, particularly incremental validity, must be empirically supported, or their measurement may simply be redundant.

#### **IPSATIVE SUBTEST COMPARISONS**

While interpretation of individual subtest scores in isolation is not very common, the use of intricate subtest interpretation systems (Kaufman, 1994; Kaufman & Lichtenberger, 2000, 2006; Sattler, 2001, 2008; Sattler & Ryan, 2009) is very popular, both in psychology graduate training and in clinical practice (Alfonso et al., 2000; Groth-Marnat, 1997; Kaufman, 1994; Pfeiffer et al., 2000). The argument is that if there is substantial scatter or variability among the subtests, then an IQ score (or factor score) "represents a summary of diverse abilities and does not represent a unitary entity" (Kaufman & Lichtenberger, 2000, p. 424). The specific patterns of subtest scores presumably invalidate global intelligence indices (Groth-Marnat, 1997), and subtest scores and subtest composites become the principal

focus of test interpretation. Subtests that are significantly higher or lower than the child's own average (i.e., ipsative comparisons) are deemed strengths or weaknesses; and while some authors (Kaufman & Lichtenberger, 2000; Sattler, 2008; Sattler & Ryan, 2009) point out that such ipsative or subtest comparisons are not diagnostic, they simultaneously claim that such strengths and weaknesses allow the psychologist to formulate hypotheses concerning the underlying problems and implications for the individual. Such hypotheses are then to be examined with other data sources and used for recommending educational or psychological treatment.

If these hypotheses are to be of use, they must be based on scores or results that have acceptable reliability, otherwise one may be formulating hypotheses about characteristics or possible interventions with essentially random indicators. Furthermore, "Any long-term recommendations as to a strategy for teaching a student would need to be based on aptitudes that are likely to remain stable for months, if not years" (Cronbach & Snow, 1977, p. 161). If suggestions regarding differential teaching styles, curricular materials, interventions, and learning environments (Kaufman, 1994; Kaufman & Lichtenberger, 2000; Sattler, 2008; Sattler & Ryan, 2009) are made based on subtest interpretive methods, then investigation of the reliability and validity of such subtest interpretive methods is imperative.

#### **IPSATIVE SUBTEST COMPARISON PSYCHOMETRIC SUPPORT**

Watkins (2003) provided a comprehensive and thorough review of the literature regarding intelligence test subtest analyses and noted the overwhelming shortcomings and failures of subtest analyses to reliably and validly inform psychological practice. The temporal stability of WISC-R's (Wechsler, 1974) cognitive strengths and weaknesses was examined by McDermott, Fantuzzo, Glutting, Watkins, and Baggaley (1992), who found that classification stability of the relative cognitive strengths and weaknesses identified by subtest elevations and depressions was near chance levels. Livingston, Jennings, Reynolds, and Gray (2003) also found the multivariate stability of WISC-R subtest profiles across a three-year retest interval too low for clinical use. Watkins and Canivez (2004), in examining WISC-III subtest ipsative strengths and weaknesses and numerous subtest composites across a three-year retest interval, found agreement, on average, at chance levels. Furthermore, *none* of the 66 subtest composites reached the minimum level

of agreement necessary for clinical use (Cicchetti, 1994). Given the poor reliability of ipsative and subtest composite scores, that such scores or profiles would be valid and diagnostically useful is highly unlikely.

Review of the literature on subtest analysis validity and utility (Watkins, 2003; Watkins, Glutting, & Youngstrom, 2005) showed that subtest scores, patterns, and analyses were unable to adequately identify global neurocognitive or neuropsychological deficits presumably related to learning disability (Watkins, 1996), nor were they related to or valid for diagnosis of learning disabilities (Daley & Nagle, 1996; Glutting, McGrath, Kamphaus, & McDermott, 1992; Hale & Raymond, 1981; Hale & Saxe, 1983; Kahana et al., 2002; Kavale & Forness, 1984; Kline, Snyder, Guilmette, & Castellanos, 1992; Livingston et al., 2003; Maller & McDermott, 1997; Mayes, Calhoun, & Crowell, 1998; McDermott & Glutting, 1997; McDermott, Goldberg, Watkins, Stanley, & Glutting, 2006; McGrew & Knopik, 1996; Mueller, Dennis, & Short, 1986; Ree & Carretta, 1997; Smith & Watkins, 2004; Thorndike, 1986; Ward, Ward, Hatt, Young, & Mollner, 1995; Watkins, 1999, 2000, 2003, 2005; Watkins & Glutting, 2000; Watkins & Kush, 1994; Watkins, Kush, & Glutting, 1997a, 1997b; Watkins, Kush, & Schaefer, 2002; Watkins & Worrell, 2000). Furthermore, subtest analyses were not valid in the classification of behavioral, social, or emotional problems (Beebe, Pfiffner, & McBurnett, 2000; Campbell & McCord, 1996, 1999; Dumont, Farr, Willis, & Whelley, 1998; Glutting et al., 1992; Glutting et al., 1998; Lipsitz, Dworkin, & Erlenmeyer-Kimling, 1993; McDermott & Glutting, 1997; Piedmont, Sokolove, & Fleming, 1989; Reinecke, Beebe, & Stein, 1999; Riccio, Cohen, Hall, & Ross, 1997; Rispens et al., 1997; Teeter & Korducki, 1998).

Kaufman (1994) argued that an individual's cognitive pattern "becomes reliable by virtue of its cross-validation" (p. 31) if it is supported by other clinical information and observations. In Kaufman's system, clinicians are thought of as detectives attempting to make sense out of profiles and searching for clues to the individual's strengths and weaknesses within the test and also by supplemental test information (Kaufman & Lichtenberger, 2006). Dawes (1994), however, noted the difficulty (impossibility) of combining different types (and amounts) of information in clinical decision-making, but asserted that the suggestion that unreliable cognitive subtest scores or patterns become valid for the individual when informally and subjectively integrated

with a complex mixture of other assessment data simply is not consistent with the empirical literature (Dawes, Faust, & Meehl, 1989). Psychologists are particularly vulnerable to errors in clinical decision-making precisely in situations such as this (Davidow & Levinson, 1993; Faust, 1986, 1990; Watkins, 2003, 2009). Thus, as Faust (1990) noted, the "common belief in the capacity to perform complex configurational analysis and data integration might thus be appropriately described as a shared professional myth" (p. 478). Kaufman and Lichtenberger (2006) noted, "The validity that comes from group data may never be available for the individual profile approach that we advocate" (p. 413).

Watkins and Canivez (2004) concluded as follows:

- (a) Recommendations based on unreliable ipsative subtest comparisons or subtest composites must also be unreliable;
- (b) Intelligence subtest analysis procedures that lack reliability or agreement across time cannot be valid;
- (c) Most students will exhibit several relative cognitive strengths and weaknesses, so their presence should not be interpreted as unusual or pathognomonic;
- (d) The fact that several strengths and weaknesses will typically be observed makes it more likely that errors will result from inferring pathology from them; and
- (e) Using an essentially random component (i.e., the subtest profile or subtest composite) and then searching for corroborating information, is likely to decrease the accuracy of clinical decision-making.

Meehl and Rosen (1955) noted such impacts in judgement accuracy when attempting to detect low-prevalence strengths or weaknesses. For an elaborative description of the many types of diagnostic decision-making and clinical judgment errors and how clinicians can avoid them, the reader is directed to Watkins (2009), Garb (2005), and Garb and Boyle (2003).

Despite all this negative empirical research, test authors and publishers continue to describe ipsative subtest analysis procedures in test manuals (Bracken & McCallum, 1998b; Elliott, 2007b; Glutting et al., 2000b; Kaufman & Kaufman, 1983, 1993, 2004a, 2004b; Naglieri & Das, 1997b; Reynolds & Kamphaus, 2003; Roid, 2003b; Wechsler, 2002, 2003, 2008b; Wechsler & Naglieri, 2006). Some test authors, however, have

attempted to minimize their use of ipsative subtest comparisons because of their awareness of the lack of empirical support (Glutting et al., 2000b; Reynolds & Kamphaus, 2003). Textbook authors also continue to describe and promote ipsative and subtest composite interpretations (Flanagan & Kaufman, 2004; Kaufman & Lichtenberger, 2000, 2006; Sattler, 2008; Sattler & Ryan, 2009). Continued presentation of such procedures perpetuates the decades-long shared professional myth that such analyses, in the hands of the trained and skilled clinician, provide important clues in understanding the individual examinee. Lilienfeld et al. (2006) presented several reasons why questionable psychological tests remain popular, and two in particular appear to be operating in the domain of ipsative comparisons and profile analyses in intelligence tests. They referred to the belief in special expertise and intuition in combining test scores and other information to render valid interpretations from invalid scores as “the Alchemist’s Fantasy,” and the influence of “Clinical Tradition and Educational Inertia” also seems to perpetuate these practices. Macmann and Barnett (1997) may well be correct in their characterization of these ipsative subtest interpretations as the “myth of the master detective” (p. 197).

### ***Psychometric Interpretation Conclusion***

Each of the psychometric interpretation methods discussed above requires the psychologist to consider the scores and render an inference or decision about the individual based on their judgment. Elliott (2007b) wrote, “Profile interpretation is clinical rather than statistical; suggestive rather than definitive; and concerned with hypothesis generation” (p. 93). However, as Dawes (1994) pointed out, “*The accuracy of the judgment of professional psychologists and other mental health workers is limited, however, by the accuracy of the techniques they employ*” (p. 107). While there is abundant research support for the clinical interpretation of omnibus, Full Scale intelligence test scores, such is not the case for clinical interpretation of factor scores; and especially subtest scores, profiles, or patterns. Clinical interpretation of intelligence test subtests is essentially the interpretation of scores that have too much error for individual use and will lead to significant errors in formulating hypotheses as well as in diagnosis and treatment recommendations. Even factor-based or broad-ability scores are questionable when their incremental predictive validity estimates are unremarkable, as previously illustrated.

At present, ample evidence for clinical interpretation of Full Scale scores from intelligence tests exists and should be the primary, if not exclusive, interpretation focus. For those promoting subtest and factor score or broad-ability score interpretations, it is incumbent on them to provide strong empirical evidence for their interpretation procedures, particularly their utility in the correct prediction of diagnostic groups or disorders, and more importantly, differential treatment (McFall, 1991, 2000). At present, such evidence does not exist.

### **Actuarial Interpretation Methods**

Actuarial test interpretation involves a statistically based decision regarding an individual based on scores from one or more measures (one or more variables). Data could include test scores from standardized tests, but also could include ratings, interview information, and historical information. The statistical combination of available data (i.e., logistic regression, discriminant function analysis, multiple regression, etc.) optimizes the prediction. These statistical procedures are able to differentially weight variables in predictions, and only the variables that have significant contribution to prediction are retained and used. Such complex combinations of variables are something clinicians simply are unable to do (Dawes et al., 1989; Faust, 1990). Decisions one might be interested in making about an individual include classification of the individual’s profile (i.e., “Which empirically based profile does the individual’s profile most resemble; or is it unique?”), diagnostic or classification decisions (i.e., differential diagnosis), or determining the probability of success for a given treatment (i.e., given this individual’s characteristics, treatment  $x$  is expected to produce some likely response). It is sometimes argued that, in order to make an actuarial interpretation of an intelligence test, one must have access to formulae or data that have been developed and (hopefully) cross-validated on a new sample to provide a comparison of an individual’s test score(s). Such methods require available outcome data by which one may derive algorithms for comparison.

Over 50 years ago, Paul Meehl set in motion a debate on actuarial prediction (decision making) by seeking answers to questions about the relationship between clinical and actuarial (statistical) prediction in his seminal book, *Clinical versus statistical prediction: A theoretical analysis and review of the evidence* (Meehl, 1954). His self-proclaimed “wicked book” (Meehl, 1979, p. 564) or “disturbing little book” (Meehl, 1986, p. 370) reviewed

and examined the clinical decision-making (prediction) abilities of clinicians versus actuarial/statistical formula-based predictions. Meehl's conclusion was that the actuarial approach was superior and should be used more frequently. Since that time, there have been numerous studies comparing clinical (informal or impressionistic) and actuarial (formal, mechanical, algorithmic) predictive methods, and it has been fairly consistently shown that the actuarial method is as accurate or more accurate than clinical methods (Dawes, Faust, & Meehl, 1989; Grove & Meehl, 1996; Grove, Zald, Lebow, Snitz, & Nelson, 2000). While 8 of the 136 studies in the Grove et al. (2000) meta-analysis showed superiority of the clinical method, 7 of the 8 benefitted from *more* information via clinical interview not made available to the actuarial method. While most studies in the Grove et al. meta-analysis found a statistical equivalence between the clinical and actuarial methods, it has been argued that in the event of a tie, there should be preference for the actuarial method, because once developed it is less expensive in time and money, less laborious, and allows for consistent application in a dispassionate manner (Dawes et al., 1989; Meehl, 1954).

Why might an actuarial/statistical/mechanical method of prediction be superior? The answer appears to be, in part, its consistent application. All one need do is correctly enter the appropriate scores or data into the formula, and the formula calculates the prediction consistently. It has been reported numerous times that humans (expert clinicians included) are susceptible to numerous errors in judgement, including confirmation bias, overconfidence, fundamental attribution error, misperception of regression, representativeness, insensitivity to prior probabilities or base rates, misperception about chance (i.e., illusory correlations, conjunction fallacy, inverse probabilities, insensitivity to sample size [law of small numbers], pseudodiagnosticity), and hindsight bias (Garb, 1997, 1998; Kahneman, Slovic, & Tversky, 1982; Meehl & Rosen, 1955; Tversky & Kahneman, 1974; Watkins, 2009). McDermott (1981) also noted problems such as the inconsistent application of diagnostic criteria (decision rules), inconsistent weighting of diagnostic cues, and inconsistent decision-making processes (strategies or sequences) among school psychologists. However, entering data into formulae in a consistent manner allows the algorithm or calculations to be applied consistently and resulting decisions from them to be applied consistently as well. Another important aspect of actuarial or statistical

superiority rests in the variables included in the formula. Statistical methods of multiple regression, logistic regression, and discriminant function analysis are able to differentially and optimally weight variables to provide the most accurate predictions of the criterion variable, and this provides another advantage over that of a clinician (Grove & Meehl, 1996). It is for these and other reasons that Grove and Meehl argued that actuarial methods should be widely applied and false arguments against it should be rejected.

Research on actuarial interpretations of intelligence tests is quite sparse. Literature searches crossing key terms such as *intelligence test*, *psychometric intelligence*, *interpretation*, *actuarial*, *statistical*, *classification*, *diagnosis*, or *prediction* produced no empirical research applied to actuarial intelligence test interpretation. There are, however, some applications and approximations worth examining.

### ***Statistical/Actuarial Approaches: Classification of Intelligence Test Profiles***

Intelligence test subtest (or factor score) profile analysis as systematized by Kaufman (Kaufman, 1979, 1994a; Kaufman & Lichtenberger, 2000) and Sattler (1982, 1988, 1992, 2001, 2009; Sattler & Ryan, 2009) is an ideographic method that uses the individual's mean performance as the basis for comparing subtest (or factor) scores, and determination of strengths or weaknesses is based on significant deviation from that mean. As previously reviewed, these ipsative approaches are neither reliable nor valid in distinguishing clinical group memberships. However, another approach to examining subtest profiles in tests is a *normative* method whereby characteristic profiles are identified through procedures such as cluster analysis (Hale, 1981; McDermott, 1998; Ward, 1963).

Several methods of cluster analysis are available and involve examining individuals' scores on a test and grouping similarly scoring individuals into mutually exclusive groups or clusters with a minimal loss of information. McDermott (1998) developed a three-stage hierarchical clustering method, *Multistage Euclidean Grouping* (MEG), which incorporated recommended cluster analysis techniques such as application of Ward's (1963) method (e.g., Konold, Glutting, McDermott, Kush, & Watkins, 1999), combining hierarchical and nonhierarchical clustering algorithms, and included built-in replications (Milligan & Hirtle, 2003). Once clusters are identified, they are then examined for characteristics (internal and external) that deviate from

other clusters' in order to describe distinguishing characteristics. Clusters may differ in proportions of demographic characteristics such as sex, race or ethnicity, and socioeconomic status (SES), as well as performance or scores on other measures (achievement, learning behaviors, personality, psychopathology). When an individual's test scores are compared to the various profiles defined by the clusters, their profile might be assigned to a particular cluster based on similarity, or perhaps the individual has scores that reflect similarity to no other profile, in which case the profile is deemed unique.

A number of intelligence tests have been examined through cluster analysis in order to determine what profiles exist from a normative perspective. Cronbach and Gleser (1953) noted that profiles are defined by three characteristics (a) level/elevation (i.e., average performance), (b) shape/pattern (i.e., highs and lows or peaks and valleys), and (c) scatter/variability (i.e., range of scores); and profile shape/pattern is determined after removing the level and scatter information. Tests such as the WPPSI, WISC-R, WISC-III, WAIS-R, DAS, UNIT, KABC, and McCarthy Scales of Children's Abilities (MSCA; McCarthy, 1972) have had their standardization samples subjected to cluster analysis and resulting normative profiles described (Donders, 1996; Glutting, & McDermott, 1990a, 1990b; Glutting, McDermott, & Konold, 1997; Glutting, McGrath, Kamphaus, & McDermott, 1992; Holland & McDermott, 1996; Konold et al., 1999; McDermott, Glutting, Jones, & Noonan, 1989; McDermott, Glutting, Jones, Watkins, & Kush, 1989; Schinka & Vanderploeg, 1997; Wilhoit & McCallum, 2002). In all of these examples, the primary distinguishing feature appears to be that of profile level/elevation, which is a reflection of overall ability ( $g$ ). The next distinguishing characteristic of normative profiles appears to be shape/pattern, which often is reflected by broad differences between the test's verbal/crystallized and nonverbal/fluid/visual tasks.

What a normative typology based on cluster analysis affords is a means by which an individual's profile may be *empirically* compared and classified and in a manner that does not discard reliable test variance like the ipsative subtest profile method does (Jensen, 1992; McDermott et al., 1992). Also, group similarity coefficient statistics, such as  $r_{p(k)}$  (Tatsuoka, 1974, p. 31; Tatsuoka & Lohnes, 1988, pp. 377-378) or  $D^2$  (Cronbach & Gleser, 1953; Osgood & Suci, 1952), provided an index of similarity to the normative profile types that account for

all three profile characteristics. If, for example, none of the normative core profile type comparisons produces an  $r_{p(k)}$  value  $> .40$  (Konold et al., 1999; McDermott, Glutting, Jones, Watkins, et al., 1989; McDermott, Glutting, Jones, & Noonan, 1989), then the individual's profile was classified as unique or atypical. Another method of profile comparison is based on Euclidian distance or generalized distance theory ( $D^2$ ) (Osgood & Suci, 1952), and although somewhat less precise, it is easier to calculate and apply and thus more convenient.

These nonlinear multivariate profile analysis methods are better than clinically based ipsative methods in that they simultaneously consider both linear and nonlinear characteristics of the profile, simultaneously examine multiple subtest scores, and empirically determine similarity (or uniqueness) to the normative core profiles from a nationally representative sample. However, like other test scores, profile similarity or classification must also demonstrate acceptable reliability, validity, and utility.

## CLUSTER COMPARISON PSYCHOMETRIC SUPPORT

While normative core profiles have been (or can be) developed for intelligence tests, the measurement properties of the profiles need to be investigated, as well as the measurement properties of individuals' profiles. It was earlier shown that ipsative subtest profiles (strengths and weaknesses) and subtest composite scores were not stable across time and therefore could not be (and were not) valid.

Short-term stability of profile classifications has yielded fairly consistent results for the MSCA (general  $\kappa_m = .728$ ; Glutting & McDermott, 1990a), K-ABC (general  $\kappa_m = .497$ ; Glutting et al., 1992), and DAS (general  $\kappa_m = .541$ ; Holland & McDermott, 1996). Partial  $\kappa_m$  coefficients were also found to be statistically significant for MSCA core profiles (Glutting & McDermott, 1990a) as well as for K-ABC core profiles and a group of unusual K-ABC profiles (Glutting et al., 1992). WPPSI profile short-term stability was lower (general  $\kappa_m = .216$ ; Glutting & McDermott, 1990b).

While short-term stability for empirically based profiles was moderate, Livingston et al. (2003) found that empirically derived subtest profiles did not possess acceptable long-term stability; however, they did not evaluate profile stability by comparison to the core taxonomy. Borsuk, Watkins, and Canivez (2006) explored the long-term stability of WISC-III cluster membership based on nonlinear multivariate profile analysis for 585 students across

a mean retest interval of 2.82 years. Individual profiles at Time 1 and Time 2 were classified according to the normative core WISC-III profiles (Konold et al., 1999) using  $D^2$  (Cronbach & Gleser, 1953; Osgood & Suci, 1952) and the critical  $D^2$  value of 98 established by Konold et al. Agreement for all profile types across time ( $\kappa_m = .39$ ,  $p < .0029$ ; Fleiss, 1971) and partial  $\kappa_m$  coefficients for each individual profile (.26 to .51) indicated that cluster membership based on nonlinear multivariate profile analysis was generally not sufficiently stable over a three-year period showing generally poor agreement (Cicchetti, 1994). Profiles 6 and 8 showed fair and statistically significant stability necessary to justify future validity research (Cicchetti, 1994). Although it appears that several intelligence test profile-type memberships possess some degree of short-term stability, long-term stability results for the WISC-III (Borsuk et al., 2006) were generally poor. As such, even the empirically based WISC-III subtest profile-type memberships were not suitable for making educational decisions about students. Thus, at this point, both nonlinear multivariate and clinical (ipsative) approaches to profile analysis lack empirical support for contribution to individual diagnosis or educational decision-making.

If empirically derived profiles were at some point found to be reliable, they then must also provide incremental validity over and above general intelligence scores and must assist in diagnostic utility for clinical use. However, like ipsative subtest interpretive methods, normative approaches to subtest interpretation have inadequate empirical support in their diagnostic utility (Glutting et al., 1992; Glutting, McDermott, Konold, Snelbaker, & Watkins, 1998; McDermott et al., 1992), and it is appropriate to heed the recommendation, even for normatively based profiles, to "just say no" (McDermott, Fantuzzo, & Glutting, 1990) to all subtest analyses and interpretations in clinical practice.

### ***Statistical/Actuarial Approaches to Classification and Diagnosis***

Ultimately, actuarial (statistical) classification and diagnosis should include co-normed measures assessing relevant domains (intelligence, academic achievement, adaptive behavior, personality, learning behaviors, psychopathology) and include large, demographically representative standardization samples. This would allow the generation of multivariate statistical comparisons and enable empirical classification and differential diagnosis. With a demographically representative sample, base-rate

estimates for the population would be available for empirically delineated and defined pathologies. This, however, is not yet available.

One group of instruments that is an approximation is the Adjustment Scales for Children and Adolescents (ASCA; McDermott, Marston, & Stott, 1993), the Learning Behaviors Scale (LBS; McDermott, Green, Francis, & Stott, 1999), and the DAS (Elliott, 1990). In the nationally representative standardization of ASCA by The Psychological Corporation, 1,260 of the 1,400 youths in the ASCA standardization sample were also administered the DAS, and 1,252 had teacher ratings on the LBS. In the cluster analysis of the ASCA (McDermott, 1993, 1994; McDermott & Weiss, 1995) 22 distinct profiles (14 major types, 8 clinical subtypes) were identified based on the six ASCA core syndromes. Following identification of distinct profiles, McDermott and Weiss were able to describe the characteristics of cluster profile types according to features that differed significantly from other profile types on demographic variables (age, sex, SES, race/ethnicity), cognitive abilities (general conceptual, verbal, nonverbal), academic achievement (word reading, numerical skills, spelling), and ability-achievement discrepancies. Using generalized distance scores ( $D^2$ ), an individual's core syndrome profile is classified as most similar to one of the 22 normative profiles producing the lowest  $D^2$  value and characteristics of the profile likely related to the youth in question. While this application is not directed at intelligence per se, a similar procedure could provide greater understanding and empirically based classification. This co-normed set of tests also allowed McDermott et al. (2006) to examine aspects of intelligence, processing speed, classroom learning behaviors, problem behaviors, and demographic variables in identifying differential risk of learning disabilities from an epidemiological perspective. Important differences were identified in differential risk and classification depending on some of these variables as well as the method of determining learning disability (low achievement vs. ability-achievement discrepancy).

### **SYSTEMS ACTUARIAL CLASSIFICATION**

Recognizing the problem of the lack of consistency or agreement among (and within) diagnosticians in child clinical psychology and school psychology diagnostic decision-making, McDermott (1980) developed a multidimensional system for the actuarial differential diagnosis of children with disabilities. This multidimensional actuarial classification

(MAC) was the forerunner of the McDermott Multidimensional Assessment of Children program (M-MAC; McDermott & Watkins, 1985). Implicit in this process is the notion that there must be reliable application of diagnostic criteria and consideration of multivariate analyses. Without reliability in clinical decision-making, there can be no validity. The M-MAC was generations ahead of its time in terms of both technology and comprehensive actuarial classification. Sadly, nothing like it even exists today!

M-MAC (and its predecessor MAC) applied a classification system that considered both abnormal *and* normal development and provided classifications based, in part, on objective measures of intelligence, academic achievement, adaptive behavior, and psychopathology; recognizing that variations within and between these would provide for differential classification or diagnosis. Because the diagnostic decision rules and mathematical comparisons are applied consistently, the classifications across similar or identical cases are reliable. This is a necessary first step for any method of diagnosis. With respect to intelligence test interpretation, M-MAC provided differential diagnosis for mental retardation (e.g., both intelligence *and* adaptive behavior measures were at least two standard deviations below the mean) and learning disabilities (e.g., IQ-achievement discrepancy, consideration of significant and rare achievement problems, and absence of mental retardation, sensory impairment, etc.). Prevalence rates were also applied and increased the validity of classifications (Glutting, 1986a). M-MAC also provided for the development of recommended intervention programs (1,111 specific behavioral objectives in reading, math, learning, and/or adaptive skills) to address the previously identified diagnostic needs of the child (Glutting, 1986b).

Evaluation of MAC (McDermott, 1980; McDermott & Hale, 1982) with a sample of 73 youths referred to an outpatient clinic resulted in agreement across areas (mental retardation, specific learning disability, behavioral/emotional disorder, communication/perceptual, reading problem, mathematics problem) 86% beyond chance when MAC results were compared to experts'. Agreement between two experts for cases averaged 76.5% beyond chance, but experts were not significantly in agreement for classifications of learning disability or mathematics problems. Agreement for MAC (expert applied vs. novice applied) across disorders was perfect! Thus, as observed elsewhere (Dawes, Faust, & Meehl, 1989; Grove & Meehl, 1996;

Grove et al., 2000), actuarial interpretations by MAC were generally better than those of experts. Actuarial classification or diagnosis by programs like MAC or M-MAC provide advantages of basing diagnostic decisions on data (i.e., test scores) that are standardized and normed on representative samples, mathematical comparisons of scores from different tests, and statistical decision rules and application of diagnostic criteria are applied consistently and in accordance with diagnostic standards established by governmental agencies or professional organizations.

### ***Actuarial Interpretation Conclusion***

Research regarding the benefits of actuarial methods for classification and diagnosis has been available for some time, yet clinical application in interpretation of intelligence and other tests has generally failed to capitalize on this. Actuarial interpretation affords systematic and reliable application and ability for multivariate consideration of variables that affect reliable and valid differential diagnosis. Where the M-MAC program from the 1980s required numerous 5.25" floppy disks to be swapped during computations, the technological advances in computer processing power and storage capacity would allow the complex algorithms to be run on today's handheld computers and smart phones. Better clinical practice and more ethical practice would be afforded by actuarial and empirical applications in intelligence test interpretation.

A final note regarding actuarial methods is necessary concerning their limits (Dawes et al., 1989). An actuarial method is only as good as the measures included for predictions and the available outcomes. Research and evaluation of the actuarial algorithms and accuracy of decisions is necessary in order to continually improve. Quality control and revision based on theory development and research are most certainly necessary as the field advances. Also, actuarial methods should not be considered infallible, as there will always be errors in diagnostic decision-making and within psychology, and because there appear to be no biological or positive markers for disorders, we never really know with certainty whether or not individuals have a particular disorder. As such, clinicians must cope with the reality of practicing with uncertainty.

### ***General Conclusion***

Interpretation of intelligence tests requires careful consideration of the empirical support for their reliability, validity, and utility. At present there appear

to be no specific actuarial systems of intelligence test interpretation leading to prediction or differential diagnosis. Available research, considered in its entirety, suggests that most, if not all, interpretation should be based on the overall, or omnibus score (FSIQ). This is not to say that cognitive or intellectual abilities are only one thing (*g*), but at present our ability to measure more than general intellectual abilities is less than adequate when considering important uses such as in prediction of academic achievement and diagnostic decision-making. The inadequacies of lower-level scores beyond the Full Scale score will lead to greater errors in diagnostic decision-making and treatment recommendations. This research has been available for decades, yet numerous test authors and publishers, textbook authors, and university trainers of clinicians continue to perpetuate the clinical interpretation method and the shared professional myth of the utility of subtest and other interpretations and often ignore this research altogether. It is hoped that a new generation of psychologists will heed the empirical evidence and advice of those who have repeatedly called for abandonment of subtest interpretations. It is time to follow Weiner's (1989) sage advice that effective psychodiagnosticians:

(a) know what their tests can do and (b) act accordingly. Knowing what one's test can do—that is, what psychological functions they describe accurately, what diagnostic conclusions can be inferred from them with what degree of certainty, and what kinds of behavior they can be expected to predict—is the measure of a psychodiagnostician's competence. Acting accordingly—that is, expressing only opinions that are consonant with the current status of validity data—is the measure of his or her ethicality. (p. 829)

However, in clinical assessment, intelligence is but one domain to be considered, and any consideration of multiple domains simultaneously requires multivariate analyses that tax human information processing and clinical judgement. Tests covering many important domains (intelligence, achievement, personality, psychopathology, adaptive behavior, learning behaviors) simultaneously normed on representative population samples would help us improve differential diagnosis and better understand psychopathology base rates, and allow for actuarial interpretation for individual examinees. In the absence of such an ambitious venture, perhaps one day soon a systems-actuarial interpretation program like M-MAC will be created to account for the multivariate measurement of psychopathologies,

of which intelligence is one part, to improve the clinical decision-making process when questions of intelligence confront the clinician. Such a method would at least assure that diagnostic criteria would be consistently applied. Only then will there be the possibility of valid classification and diagnosis.

### Author Note

Gary L. Canivez is Professor of Psychology at Eastern Illinois University, principally involved in training school psychologists. His research interests include applied psychometric investigations of the reliability, validity, and utility of intelligence, achievement, and psychopathology measures; and investigations of test bias.

The author would like to thank Drs. Marley W. Watkins, W. Joel Schneider, Scott O. Lilienfeld, and Peter V. W. Hartmann for extremely helpful critiques, comments, and suggestions concerning earlier versions of this chapter.

Correspondence regarding this manuscript should be addressed to Gary L. Canivez, Ph.D., Department of Psychology, 600 Lincoln Avenue, Charleston, Illinois 61920-3099. Dr. Canivez may also be contacted via email at [gcanivez@eiu.edu](mailto:gcanivez@eiu.edu), [gcanivez@gmail.com](mailto:gcanivez@gmail.com), or the World Wide Web at <http://www.ux1.eiu.edu/~gcanivez>.

# The Scientific Status of Projective Techniques as Performance Measures of Personality

Hedwig Teglasi

## Abstract

“Psychological constructs” are phenomena that are not seen directly but exert influence on individuals’ responses to the real world and to items on tests. Constructs such as “intelligence” or “motivation” are valued because they organize otherwise piecemeal observations. Science aims to understand real-world phenomena through systematic observations and iterative refinement of constructs about how observations “go together.” Measurement *per se* is not science but a tool to observe phenomena. The “scientific status” of an instrument rests on its construct validity, meaning that the construct in question causes variation in responses to real-world conditions and to test items. Insofar as variation in projective test responses are caused by constructs’ capturing phenomena that matter in the lives of individuals, projective techniques are legitimate tools for science and practice. Shortcomings of clinical instruments are rooted in some combination of insufficient understanding of the target phenomenon (need to improve theory), flawed conceptualization of causal relations of the phenomenon to variations in scores on the test (need to improve measures), improper selection of real-world criteria (need to improve match between predictor and predicted constructs), or unreliability of the measure (need to improve psychometric properties).

**Key Words:** psychological constructs, scientific status, projective techniques, personality, psychometrics, assessment

## Prelude

Critics of projective techniques have assumed incorrectly that self-report and projective tests of the same variable measure the same phenomenon and hence are interchangeable. Pitting one assessment procedure against another is misguided in light of research documenting that questionnaire and projective methods provide distinct and complementary information about phenomena. “When truth is evident, it is impossible for parties and factions to rise. There never has been a dispute as to whether there is daylight at noon” (Francis Marie Arouet de Voltaire, [1694–1778], *Philosophical Dictionary*, 1764).

The complexities of human behavior cannot be captured by a single method of assessment. Therefore, questions of scientific status and of the practicality of

a given instrument are linked to the larger issue of how well a clinical assessment battery captures the influences of various relevant phenomena. It has been said that “The aim of science is to seek the simplest explanation of complex facts. We are apt to fall into the error of thinking that the facts are simple because simplicity is the goal of our quest. The guiding motto in the life of every natural philosopher should be ‘seek simplicity and distrust it’” (Alfred North Whitehead [1861–1947] English mathematician and philosopher, *Concepts of Nature*, 1920, p. 163).

As researchers in various psychology subfields have backed away from language loaded with excess meaning, particularly those introduced in the context of psychodynamic theory, they have substituted newer terms for similar phenomena (e.g., *implicit*

*memory for unconscious memory; person schema for object representation; cognitive avoidance for repression; pre-attentive processing for preconscious processing; defensive attribution for ego defense; and central executive for ego;* see Bornstein, 2005). In this chapter, use of the term “performance measure of personality” as synonymous with “projective technique” is not meant to signal repudiation of its conceptual foundations in the “projective hypothesis.” Indeed, “most of the change we think we see in life is due to truths being in and out of favor” (Robert Frost, “The Black Cottage,” *North of Boston*, 1914).

The original tenets of the “projective hypothesis” are well supported by current theory and empirical evidence. However, proponents of projective techniques have expressed dissatisfaction with the term *projective* for two basic reasons. First, the central insights of the “projective hypothesis” have been incorporated into current research and theory across multiple psychology subfields (Teglasi, 1998), and terminology such as *personality performance measure* acknowledges this broader conceptual and empirical base. Second, terms that dichotomize personality tests as “projective” versus “objective” are problematic because of the untenable implications that “objectivity” is inherent in questionnaire measures but missing from projective tests, and that the two sources of information are equivalent and interchangeable (Meyer & Kurtz, 2006).

## Introduction

The issue of scientific status, posed in the title of this chapter in reference to projective techniques, applies equally to all measurement. Professionals are accountable for selecting clinical assessment tools with consideration of their strengths and limitations for intended uses. Psychological measurement is not science but a tool that serves science as well as practice.<sup>1</sup> A measure’s utility for applied purposes and its scientific merit are intertwined in that both depend on how well the instrument captures a phenomenon that exists in the real world.

Phenomena of interest to scientists come in two varieties: those that are amenable to being directly observed or sensed (such as temperature, latency of a response, or duration of a specific behavior) and those that are known indirectly from observed patterns (such as intelligence, personality, psychopathology, emotional reactivity, or motivation). The amount of gasoline in a car’s tank, though estimated by the meter inside the cabin, may be glimpsed directly, whereas psychological phenomena such as “intelligence” are invisible.<sup>2</sup> Just like the gasoline in the tank,

these psychological phenomena, called *constructs*, are assumed to exert their influences on what happens in the real world even when there are no instruments to measure them (e.g., a broken fuel gauge). A series of behaviors may be explained in reference to a construct such as a person’s intelligence or motivation. Similarly to scientific theories, constructs are valued because they lend coherence to otherwise piecemeal observations. Measures are useful to the extent that they give a faithful account of the construct to which they refer, provided that the construct itself is sufficiently understood to organize observations in the real world. Phenomena and measures are distinct, and acknowledging shortcomings of a particular instrument does not mean that the phenomenon is irrelevant. The idea of “construct validity” is what ties measurement to science and what makes a test valuable for practice.

The scientific quest to understand a phenomenon is akin to the proverbial story of the blind men exploring different parts of the elephant. The explorers agree that the elephant exists as an entity but, based on limited observations, each comes to his own conclusion about the nature of the *whole* elephant. Reliance on a single observer (or measure) to define the elephant (or a construct, such as “intelligence”) may lead to the elevation of a part to the status of the whole; whereas arguments among the various observers (“the elephant is hard”—tusk; “it is very soft”—the ear; “it is like a rope”—the tail) or low convergence among different measures of a construct has the potential to yield glimpses of the whole: that is, unless the voice of one observer or one measurement approach drowns out the others. Clinical assessment tools measuring a construct in different ways may provide different perspectives on the whole, promoting differentiation and integration of constructs, whereas exclusive reliance on a single mode of measurement may add detail to a limited conception.

If data about a construct accumulate with the use of a single measurement approach, the version of the construct associated with that measure may become accepted by the scientific community but may not adequately capture the phenomenon as it exists in nature. If, on the other hand, different measures lead to different conclusions about the construct, scientists, like the blind men exploring the elephant, may argue about which version is correct. Attempts to chart unknown (or partially known) territory require ongoing revisions of working hypotheses about what the landscape looks like. Keeping in mind that essential features may yet be elusive, scientific criticism should aim not only to improve measures but also to refine constructs.

## Construct Validity and Practical Utility

The idea of “construct validity” is predicated on the assumption that the construct being measured refers to an actual phenomenon, such as intelligence, that causes variation in real-world responses and to responses on test items (see Borsboom, Mellenbergh, & van Heerden, 2003, 2004). The phenomenon (intelligence) is assumed to exist apart from the ways that it is measured (intelligence tests), thereby allowing researchers to take a dual focus, one to refine the construct itself and the other to improve its measures. The task of psychological science is to delineate the constructs accounting for observed regularities in the real world and to devise measures that faithfully capture those constructs. Prediction from a test to a real-life criterion is a function of the constructs influencing variation in both.<sup>3</sup>

Current understanding of construct validity was foreshadowed in the works of Cronbach and Meehl (1955), who argued that demonstration of construct validity depends on a “nomological network” of lawful relations among entities. However, documenting lawful networks of relations among measures of constructs involves complex considerations, including precise understandings of constructs, theory of the relations among constructs, assumptions about the linkages of measures with constructs, and psychometric properties of the measures. The primary evidence bearing on “construct validity” comes from knowledge of the causal influences exerted by the construct on item responses and not directly from a measure’s psychometric properties or correlations with other measures (see Borsboom et al., 2003, 2004; Smith, 2005).

A commonly used validation procedure, the “multi-trait–multi-method (MTMM)” matrix became a fashionable way to tease apart sources of variance attributable to measurement methods versus constructs (Campbell & Fiske, 1959). Support for a construct entails patterns showing higher correlations among different measures of the same construct (*convergent validity*) and lower correlations among similar measures of different constructs (*discriminant validity*). Although providing important information, examining the pattern of convergences and divergences does not settle the core issue of validity, the existence of an attribute that influences responses in the real world, and its causal impact on test responses. Evidence of construct validity, or lack thereof, is not provided by tables of correlations but by substantive psychological theory. Refinement of theory occurs through increasing differentiation of constructs that refer to real-life phenomena.

For instance, the construct of aggression has been unpacked into its various *forms* (overt and relational) and *functions* (proactive and reactive; see Card & Little, 2006) and into components that are *implicit*, influenced by mental sets operating largely outside of awareness, and *explicit*, influenced by values directly attributed to the self (Winter, John, Stewart, Klohnen, & Duncan, 1998). Correlations among undifferentiated measures of aggression or predictions from test scores to external criteria without considering relevant distinctions are not sufficient to inform construct validity.

A measure’s construct validity enables its practical utility. By definition, drawing valid conclusions from tests is possible only if the intended phenomenon causes variation in responses on test items and in real-life conditions. Since the same constructs are assumed to underlie variation in responses to the predictor (test score) and to the predicted (real-life) variables, construct validity applies equally to both (Messick, 1989). This emphasis on construct validity places equal value on prediction and explanation as fundamental to establishing the utility of conclusions based on test scores. The essence of construct validity is the mapping of constructs as causal mechanisms explaining variation in responding to items on measures and to real-life circumstances.

## Incremental Construct Validity

The property of *incremental validity* is ascribed to an instrument if it adds information to other measures in the battery by raising the overall correlation with the criterion (Mayer, 2003; Mischel, 1968). Viewed as a practical matter, incremental validity answers the question of whether a psychologist should or should not include a particular test in a set of measures (Wood, Garb, Lilienfeld, & Nezworski, 2002; Wood, Nezworski, Lilienfeld, & Garb, 2003). However, from the perspective of construct validity, what contributes incrementally to variance in a criterion is the addition of constructs, not measures. Some measures may encompass multiple constructs, whereas others may represent a single narrow construct. Therefore, in the conduct of psychological evaluations, what should be justified is the inclusion of each construct as optimally measured. If measures stand in for constructs, it does not seem logical to think of measures as predictors of other measures. A new term, *incremental construct validity*, is needed to capture the idea that constructs, not measures predict criteria, and that several constructs may contribute to complex and multiply determined criteria.

The foundation of *incremental construct validity* is the *construct validity* of conclusions derived from each measure. *Incremental construct validity* means that the *construct*, as measured by a particular test (with construct validity), contributes to variation in a predicted criterion beyond other constructs as variously measured. In his account of incremental validity in the assessment of adult psychopathology, Garb (2003) focused on the measures without reference to construct validity. Taking a box score approach toward the prediction of specific diagnoses, Garb came to the general conclusion that findings were more encouraging for the use of interviews, personality inventories, and brief self-ratings than for projective techniques. However, from the perspective of *incremental construct validity*, it would be necessary to identify the multiple constructs influencing the criterion, including constructs that play moderating or mediating roles, as well as the impact of method variance. Since adult diagnoses are often based on self-report interviews, constructs measured with similar techniques, such as interviews or questionnaires may share more variance. The demonstration of incremental construct validity requires careful consideration of the constructs and measures involved both in the predictors and criteria. If primacy were given to incremental construct validity, the practical issue of which tests should be selected would depend on answers to two questions: Which constructs are pertinent to a criterion, and what are the best available measures of those constructs (as predictors and as criteria)?

### **Conceptual Distinctions Relevant to Projective Techniques**

The scientific community judges whether or not a phenomenon is worthy of study and whether its measures meet professional standards. Provided that a psychological phenomenon such as *projection* is accepted by (some) members of the scientific community, the measures based on the construct are met with an open mind. Among various scientific communities in psychology, constructs resembling projection masquerade under different names even as the term remains controversial. The development of models across different research traditions to explain phenomena similar to projection, regardless of terminology, may be considered a form of “replication” strengthening the construct. Within the field of projective assessment, the construct of projection has various meanings because they refer to different real-world phenomena, and various

understandings of the term *projection* signal the need for conceptual distinctions that may be informed by findings across psychology subfields.

### **Different Conceptions of Projection**

A fundamental assumption of all projective assessment methods, the “projective hypothesis” posits that stimuli from the environment are perceived and organized by the individual’s specific needs, motives, feelings, perceptual sets, and cognitive structures, and that, in large part, this process occurs automatically and outside of awareness (Frank, 1939; 1948). The influences of preexisting mental sets or schemas on the interpretation of ongoing encounters are ubiquitous, applying to both adaptive and maladaptive modes of processing information. However, some use the term *projection* to refer to faulty information-processing due to mental sets and defense mechanisms that distort reality.

Restricting the concept of projection to faulty information-processing has led to questioning whether or not certain responses to stimuli such as the Rorschach cards are products of projection. Those who view projection as limited to percepts that are idiosyncratic (such as distortions or elaborations) do not consider normative perceptions and classifications of stimuli as involving projection. Exner (1991) explained that the Rorschach Inkblot Method (RIM) is not a projective device because responses are more influenced by stimulus properties, and less by projection. Similarly, reasoning that well-defined stimuli do not elicit projection, the authors Roberts and Gruber (2005) changed the name of the *Roberts Apperception Test for Children* (one of a number of offshoots of the Thematic Apperception Test) to *Roberts-2*, deliberately omitting the word “apperception,” which means “attributing an interpretation to perception.” They asserted that this storytelling measure is not and never has been a projective test because the stimuli are not ambiguous but represent clearly recognized, everyday situations.

Given that projection is about the influence of preexisting mental sets or schemas on current information processing, the “pull” of the stimulus is a key consideration. The aim of projective techniques is not to measure free-floating thoughts without context, but to gauge how individuals use their schemas to negotiate the performance demands set by the stimuli and instructions of a particular task. The ambiguity of the stimulus to be identified or interpreted is an important source of individuality

in responding to personality performance measures. However, restricting projection as pertinent only to ambiguous stimuli does not account for idiosyncratic responses to well-defined stimuli or for individualistic elaborations of commonly given responses. Rorschach cards with easily recognizable blot contours are more likely to elicit certain percepts with high frequency, but such “popular” responses to a blot area may involve embellishment (such as attributing movement) not readily explained by the stimulus. Apart from the nature of the stimuli, potential sources of ambiguity in the Rorschach task include the instructions, the extent to which the responses are open-ended, and the obscurity of performance expectations to respondents (no single correct solution and no awareness of scoring criteria). Presentation of an inkblot with instructions to tell the examiner “what might this be” leaves it up to the individual to decide how many responses to give and whether to focus on the whole blot or the parts. Similarly, well-defined scenes on the *Roberts-2* may elicit story themes consistent with the “popular pull,” but a conventional interpretation is only a starting point, with many aspects of the unfolding narrative bearing the imprint of individuality.

Restricting projection to responses shaped by distorted mental structures is difficult because this view of projection does not fully capture the well-accepted phenomenon that prior knowledge influences all aspects of current information-processing. To clarify the workings of the projective hypothesis, it is necessary to differentiate among different types of schemas and the conditions to which they apply in the contexts of assessment and real life.

### ***Constructs Supporting Projective Techniques Across Psychology Subfields***

Two well-documented conceptual distinctions clarify the contribution of projective methods to clinical assessment. One distinction is between what persons report and what persons actually experience. The other distinction is between how persons function under relatively well-defined and ill-defined performance conditions. Table 5.1 describes three types of measures: (a) performance tasks presenting conditions that are *maximal* (more well-defined, such as IQ and achievement tests); (b) performance tasks presenting conditions that are *typical* (less well-defined, such as personality performance tasks such as storytelling); and, (c) questionnaires and interviews to elicit self-report.

### **WHAT PERSONS REPORT AND WHAT THEY ACTUALLY EXPERIENCE**

Personality constructs come in two varieties, paralleling two modes of thought used by individuals to process information about themselves, others, and the world (Epstein, 1994; Fazio, 1990; Greenwald, Banaji, Rudman, Farnham, Nosek, & Mellott, 2002; Wilson, Lindsey, & Schooler, 2000): *explicit* (i.e., controlled or conscious) and *implicit* (i.e., automatic or non-conscious). Explicit and implicit constructs change and develop through different routes, the former by social influence and the latter by the individual’s synthesis of lived experience (McClelland et al., 1989; Teglasi & Epstein, 1998). Implicit personality develops on the basis of affective experience and authentic encounters, whereas explicit personality is grounded in social values, encompassing what persons think they *should* want to do or believe based on what is important to their identity and promoted by social values (e.g., Burton, Lydon, D’Alessandro, & Koestner, 2006). *Explicit* personality constructs are active in situations that are salient for that construct, due to structures and incentives and are measured with self-report. *Implicit* personality constructs manifest in settings that allow individuals to make choices that are based on preferences and are measured with performance tasks.

Measures of explicit personality, provided by self-report, tend to correlate only modestly with measures of implicit personality, provided by projective techniques, and predict behaviors under different conditions (see Bornstein, 2002; James & Mazerolle, 2002; Kihlstrom, 1999; McClelland et al., 1989; Spangler, 1992). For instance, explicit achievement motivation (self-reported) fosters engagement in motive-relevant actions in the presence of situational prompts, whereas implicit achievement motivation (derived from TAT stories) directs individuals to engage in such behaviors spontaneously (see review, Spangler, 1992).

This duality of implicit and explicit personality as measured respectively with performance tasks and self-report corresponds considerably with two modes of information processing: one that is automatic, operating outside of awareness, and another, which is effortful and subject to awareness (for reviews, see Evans, 2008; Lieberman, 2007). The emphasis of the projective hypothesis on information processing without awareness is in tune with current views of the “unconscious” as qualities of the mind, not in immediate awareness, that influence conscious thought and behavior (James, 1998;

**Table 5.1 Self Report and Performance Measures**

	<b>Self Report/Other Report</b>	<b>Performance Measure Typical</b>	<b>Performance Measure Maximal</b>
Other terms	direct, explicit, objective, report-based	implicit, indirect, projective, performance-based	ability, intelligence, achievement
Basic assumptions	What is reported is accessible to introspection but may or may not be willingly disclosed	What is revealed operates outside of awareness, not necessarily amenable to introspection or to self-report	Responses demonstrate ability in a certain domain (crystallized or fluid, general or specific)
Instructions and stimuli set task demands	Instructions restrict variation in responses to differing degrees (forced-choice or open-ended)	Instructions expand variations in responses (less structure). Stimuli are complex or ambiguous, allowing individuals to select the focus of attention and to define the task	Instructions restrict variation in responses (more structure)
Responses	Responses may be constrained by options (true/false, Likert scales, multiple-choice) or be open-ended (interviews)	Responses are open-ended as to detail and organization, with leeway for individualistic approaches	Responses are guided by the instructions, and information for problem solution is provided
Strengths	Predict relevant criteria, efficient to administer and score	Predict relevant criteria, less subject to faking, not reliant on insight or on willingness to disclose information, reveal what is outside of awareness and give information about the process of thinking	Predict relevant criteria, clear guidelines for scoring
Limitations	Susceptible to self-presentation bias, limitation of self knowledge and reluctance to share information. Respondent may misinterpret items, and answers do not tell about the basis of the response. More predictive when settings are structured to increase salience of self presentation	Labor-intensive administrative and coding procedures, more predictive of performance and adjustment when tasks and settings are less structured	More predictive of performance and adjustment when settings and tasks are more structured
Criteria for judging responses	Responses to questionnaires are judged in relation to norms	Responses are judged by multiple criteria in the absence of a single correct solution; extensive norms may or may not be available	Responses are judged by a single criterion of correctness in line with norms

Uleman, 2005). The powerful role of unconscious information-processing on perception, thought, behavior, and motivation has been convincingly documented (Bargh & Morsella, 2008; Duckworth, Bargh, Garcia, & Chaiken, 2002). The central insights of the projective hypothesis are at the core of contemporary social cognitive theory, which posits that cognitive interpretations are important drivers of behavior and that prior conceptions inform

real-time information processing, often automatically, without deliberate effort.

Individuals bring to their day-to-day encounters both automatic and effortful modes of information processing, along with implicit and explicit components of their personality. However, individuals are not able to report on the implicit cognitive and affective processes that operate outside of awareness (Nisbett & Wilson, 1977), and, when given response

options, may succumb to the desire to present themselves in a particular light (Cronbach, 1990; Edwards, 1957). What individuals report may also be influenced by cues about expected responses (as conveyed by *demand characteristics*, Orne, 1962). The fewer cues provided about response expectations, the more difficult it is to manage impressions (see Teglasi, 1993). Social desirability scales (e.g., Crowne & Marlowe, 1960; Paulhus, 1998; Stöber, 2001) aim to tease apart the contribution of wanting to present the self in a favorable light from the phenomenon the scale intends to assess. Yet, attempts to control for social desirability may not increase construct validity (Borkenau & Ostendorf, 1992; McCrae & Costa, 1983) because socially desirable responding may arise from processes that occur with self awareness through intentional *impression management*, or without awareness through *self-deception*, due to introspective limits (Paulhus, 1984). Self-report sheds light on explicit versions of constructs, being restricted by limits of awareness and the subjects' willingness to disclose information (Greenwald et al., 2002). Discrepancies between implicit and explicit measures of personality may be due to conflicts between two views of the self, not necessarily attributable to conscious impression management. For assessment, the challenge is to comprehend various ways of understanding the self, including the desire to make a certain impression.

#### HOW PERSONS PERFORM UNDER WELL-DEFINED AND ILL-DEFINED CONDITIONS

The performance context is relevant to the assessment of a wide range of psychological constructs. As analogues of real-life settings, the nature of performance tasks, whether tests of ability or of personality, is relevant to the phenomenon being assessed.

Performance tasks vary along a continuum of *maximal* and *typical* conditions. Maximal performance conditions provide clear-cut problems that have a limited number of correct solutions, whereas typical conditions require individuals to identify the problem and to formulate responses that maximize individual discretion (see Table 5.2; Sackett, Zedeck, & Fogli, 1988; Sackett, 2007).

Standard IQ tests, intended to assess the *ability* to solve well-defined (with clearly correct solutions) rather than ill-defined (with many potential solutions) problems (Pretz, Naples, & Sternberg, 2003), provide maximal performance conditions. On the other hand, problem-solving in ambiguous conditions involves both the *ability* to reason and the disposition to do so, including the *sensitivity* to recognize the moments that call for reasoning and the *inclination* to invest the necessary energy (Perkins & Ritchhart, 2004). This distinction between tests of personality and tests of ability is inherent in the *method* of measurement and not in the *content* domain. For instance, social skills may be assessed as *ability* under conditions of *maximal* performance by asking individuals to role play or to select responses to a contrived problem. However, such procedures shed little light on the *personality*, which orchestrates when and how the individual would use that ability under *typical* conditions.

The distinction between maximal and typical performance measures is important because it corresponds to differences in real-life conditions. Performance in an assessment context predicts outcomes in real-life settings, provided that both make similar functional demands. Consider two forms of sustained attention that are salient under different conditions, *contingency-shaped attention* and *goal-directed persistence* (see Barkley, 1997). Contingent attention is driven by novelty, incentives,

**Table 5.2 Typical and Maximal Conditions of Performance**

Typical Conditions	Maximal Conditions
Person is not aware of being observed or evaluated; is not likely to exert unusual effort.	Person perceives the task to be important and puts forth heightened level of effort and attention
Person is not aware of performance criteria and there are multiple correct solutions, hence the task pulls for characteristic ways of responding	Expectations and performance criteria are not equivocal as there is a limited range of correct responses
Person's responses are monitored over extended time or require competencies that are consolidated over time through concerted effort, enabling performance of complex tasks that reflect a history of more typical exertions	Observations of the person's responses are restricted to a short time span, which allows for an uncharacteristic spurt of effort that cannot be sustained

or presence of supervision (external sources of attention regulation), whereas goal-directed persistence is active when the individual pursues tasks or a course of action independently of immediate feedback or ongoing reinforcement (internal sources of attention regulation). Contingency-shaped attention, directed by immediate situational pulls, seems to align with maximal performance conditions and explicit motives, whereas goal-directed persistence, absent incentives or cues, seems to align with typical performance conditions and with the operation of implicit motives.

The maximal–typical distinction applies equally to social interactions and to task performance. Routine social encounters such as ordering a meal in a restaurant require the use of a highly scripted schema representing clear rules as to what is expected, whereas more ambiguous social encounters, such as being teased by a peer, require the synthesis of multiple schemas to consider the context, the peer's intention, one's own immediate or longer term purposes, potential responses, and so forth. Ambiguous social encounters call on the individual to discern the meaning of changing cues, to infer the existence of a problem or conflict and to determine whether and how to respond. Likewise, in daily life, individuals face tasks on continua that range from being clearly delineated (guiding what to do as well as how and when to do it) to being relatively undefined (providing limited cues that point to what information is important to consider or how to prioritize aspects of a complex task).

### Projective Hypothesis and Types of Schemas

Consistent with the projective hypothesis, the schema is the basic mental unit that guides day-to-day information processing, allowing interpretation of the current situation to be informed by what has been learned previously. Prior knowledge shapes subsequent perception and conception in virtually every context, but this all-encompassing formulation of the operation of schemas and of the projective hypothesis is unpacked by making distinctions

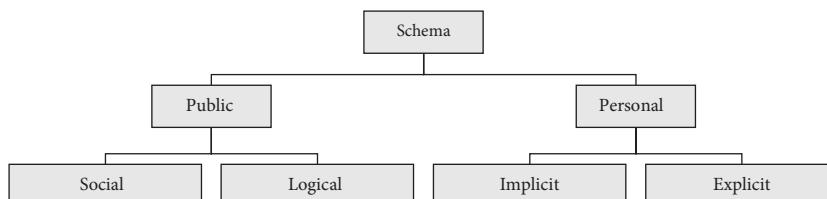

among different types of schemas and among the conditions in which they are relevant.

### Implicit and Explicit Schemas

All schemas are outgrowths of the capacity of human beings to detect, process, and use information about co-variations of stimuli and events in their surroundings (such as a change in contingencies), often without deliberate effort or conscious awareness (Lewicki, Hill, & Czyzewska, 1992). Schemas differ from behavioral skills or factual knowledge in that the schema is a structure, organizing facts and ideas that influence the use of skills and knowledge. Schemas serve as templates for information processing by providing categories to encode information, pointing to what is relevant, filling in what is missing, and connecting ideas. Schemas come in explicit and implicit versions, influencing processing of information through the two modes discussed earlier: a) *automatic, implicit, and outside of awareness* and b) *effortful, explicit, and amenable to awareness*.

### Public and Personal Schemas

As summarized in Figure 5.1, *public schemas* comprise shared knowledge structures or collective perceptions, and *personal schemas* encompass individual knowledge structures or perceptions. In some situations, both public and personal schemas apply. *Public schemas* capture the regularities of the external world and are therefore amenable to proof by logic, evidence, or social consensus. There are two types of public schemas that are subject to different types of proof: *logical schemas*, such as mathematical formulas or scientific principles; and *social schemas*, or scripts for what happens in routine situations. Logical schemas, describing observed relationships among facts or ideas (such as the formula for calculating the circumference of a circle; the layout of an airport) are maintained or changed through critical analysis, logical proof, or direct evidence. *Social schemas* or *scripts* organize regularities in routine events (how to order a meal in a restaurant; what happens when visiting the dentist), are widely

**Figure 5.1** Public and Personal Schemas.

held in a culture, and are maintained or changed by consensus, not necessarily logic. The perceived co-variations of external events may remain tacit or implicit (Dowd & Courchaine, 2002; Lewicki, Czyzewska, & Hill, 1997), playing an important role in recognition of the often-unstated rules that govern the regularities in the milieu. Social skills programs that focus on increasing children's social awareness or prosocial behavioral repertoire in well-defined conditions address public social schemas.

*Personal schemas* coordinate the inner and outer worlds. Explicit and implicit personal schemas apply respectively to assessment with self report and personality performance measures. *Implicit personal schemas* are outgrowths of experiences, incorporating ideas about sources of emotions such as distress or about efficacy to regulate uncomfortable states, to cope with challenges, or to attain desired outcomes. *Explicit personal schemas* are mental models about the self, including motives that a person endorses (self-attributes) on the basis of social values (wanting to be a good student) but not necessarily supported by patterns of regularities in actual experience (enjoying the activities relevant to being a good student). Explicit personal schemas are active in situations structured to provide cues or incentives (reminders, supervision, or clear expectations) salient for a given schema. In contrast, implicit personal schemas operate as the default, often without awareness, in situations that are ambiguous (resembling those of personality performance measures).

As individuals notice patterns in the external world such as links between actions and outcomes as well as regularities in their emotional states in relation to the stream of external events, they form expectations about what actions can or cannot bring about desired effects. A history of faulty information-processing reinforces incomplete or distorted mental sets or schemas that bias subsequent information processing, thereby maintaining vicious cycles. Although qualities of implicit personal schemas (measured by stories ascribed to TAT pictures) such as their accuracy, organization, and complexity, are linked to temperament (Bassan-Diamond, Teglasi, & Schmidt, 1995; Lohr, Teglasi, & French, 2004), once developed, these qualities take on a life of their own with relevance to adjustment, mental health (Lohr et al., 2004), and reading comprehension (Blankman, Teglasi, & Lawser, 2002).

Personality performance measures present standard tasks but allow leeway for individuality in the interpretation of the stimuli and in the organization

of the response. To the extent that the stimuli are not amenable to interpretation by public schemas, individualistic schemas come into play. However, individuals may impose personal schemas on structured stimuli or social scripts on ambiguous stimuli. Assessment clarifies the qualities of the schemas that help or hinder understanding of and responding to relevant real-world contexts, both well-defined and ill-defined.

Schema-based interventions (e.g., Riso, du Toit, Stein, & Young, 2007) are designed to address maladaptive schema-driven information processing due to faulty (distorted, simplified, or incomplete) personal or social schemas or to difficulty balancing among various implicit and explicit schemas. Schema-based interventions may harness effortful processing to bring automatic tendencies to awareness and to reconcile conflicts between implicit and explicit personal schemas. However, to fully address gaps or distortions of information processing promoted by implicit personal schemas, interventions need to account for influences contributing to schema development and continued maintenance (such as temperamentally rooted problems regulating attention or emotion; Teglasi & Epstein, 1998). Otherwise, cognitive therapeutic interventions may produce changes in explicit personality without altering implicit processes or structures (Dowd, 2006).

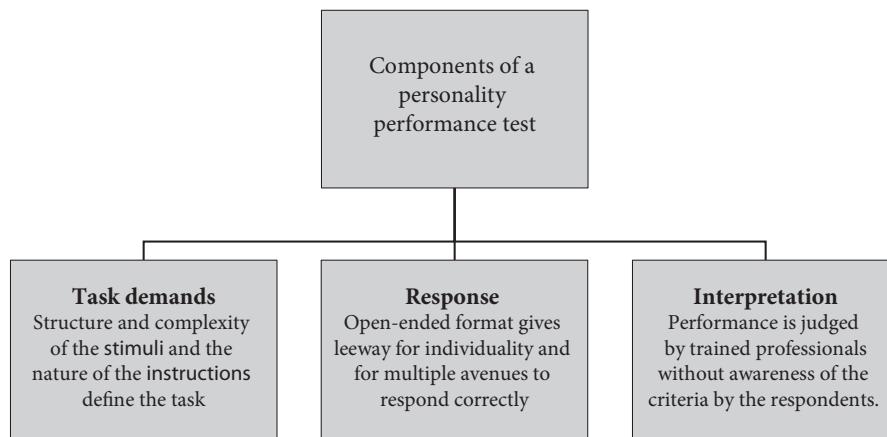

## Projective Techniques/Personality Performance Measures

### Description of Projective Techniques

All projective tests present a task with standard elements, but they vary in their specific stimuli, instructions, leeway for responding, and system for interpreting the responses (see Figure 5.2, below; Rabin, 1981; Lindzey, 1961; Teglasi, 1993). Projective techniques highlight the imprint of individuality by incorporating various degrees of ambiguity into performance conditions that allow many potentially correct solutions.

### STIMULI

Stimuli that are easily recognized in a culture constrain interpretations because they are explained by public schemas. Ambiguous stimuli permit alternative perceptions and interpretations, allowing for assessment of schemas that come to mind as the default in conditions of uncertainty. There are different perspectives on the degree of ambiguity that is ideal for personality assessment. Some researchers favor high ambiguity (e.g., Frank, 1939) but

**Figure 5.2** Components of a Personality Performance Test.

others prefer medium ambiguity (e.g., Murstein, 1965; Kaplan, 1967). Still others maintain that lack of ambiguity is best (Epstein, 1966). The optimal degree of ambiguity in the stimulus may depend on the purposes of the test. As the stimulus pull becomes weaker, the imprint of implicit personal schemas becomes increasingly influential. Yet, if information processing is seriously impaired, the individual may misinterpret even highly structured stimuli.

#### INSTRUCTIONS

Instructions for eliciting responses and procedures to query or encourage responses also pertain to the nature of the task as structured or ambiguous. Some personality performance tasks, such as human figure drawings, do not present stimuli at all, and ambiguity is a function of the instructions and obscurity of standards by which performance is to be judged. For instance, the request to “draw a person” is more structured when followed by the instruction to draw the “best person you can and not a stick figure.” The Rorschach instruction “What might this be?” minimizes cues about how to approach the task.

#### RESPONSES

Regardless of the degree of ambiguity of stimuli and instructions, personality performance tasks that call for open-ended responses expand avenues for individuality in the production and organization of ideas. Stimulus cards that present highly structured scenes to elicit stories may constrain the themes but still allow a great deal of variation in the development of narratives, including the detail and coherence of ideas.

#### INTERPRETATION

Insofar as respondents are unaware of the interpretive criteria, the task demands are equivocal. The same set of open-ended responses may be interpreted in various ways, and the nature of the coding system and the expertise of the interpreter are relevant to what a given projective test actually measures. Even though personality performance measures do not specify a single correct solution, responses are not expected to be random but to be in tune with the task demands set by the stimuli and instructions. In the absence of single “correct” solutions, complex coding systems have been developed to ascertain the meaning of the responses, and it is necessary to document construct validity for each set of stimuli, instructions, and interpretive procedures (see Jenkins, 2008; Teglasi, 2010; Teglasi & Locraft, 2008).

#### *Contribution of Projective Techniques/ Personality Performance Measures*

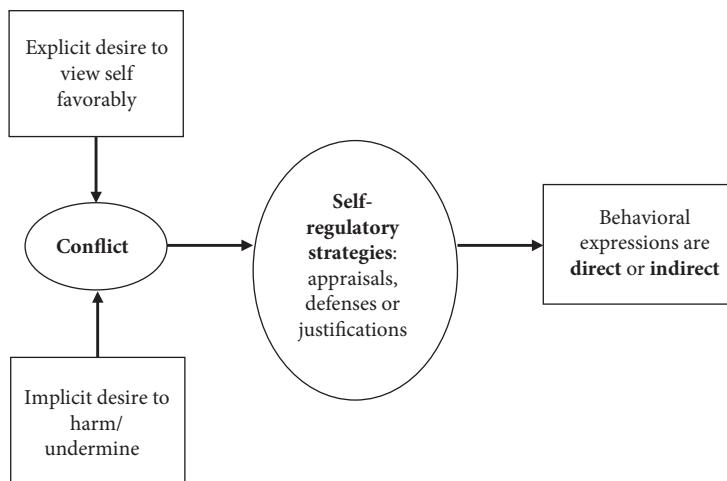

Conceptual distinctions reviewed earlier between implicit and explicit personality constructs and between maximal and typical performance conditions are crucial for the status of “personality” as a scientific construct. In his textbook on personality and assessment, Mischel (1968) reviewed findings about the relationship between personality trait measures and relevant behavioral outcomes, reporting weak correlations (rarely exceeding .30), which led to his questioning the viability of personality as a construct. The transactional position (e.g., Magnusson & Endler, 1977) stressed the idea that behaviors are not only a function of factors within the *person* but also of the *situation* to which the person is

responding. One of the strongest moderators of the link between personality traits and behavior is the extent to which the situation is governed by rules and normative expectations for appropriate behavior, as opposed to the expected responses being obscure (see Snyder & Ickes' [1985] distinction between strong and weak situations). Analogously, tests with well-defined performance conditions assess ability constructs, whereas those with ill-defined performance conditions measure personality constructs.

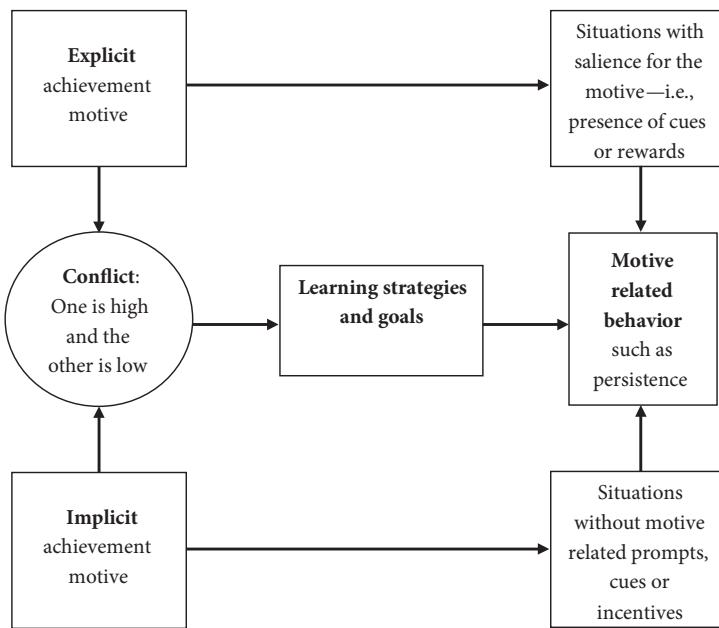

A framework for organizing psychological constructs in terms of transaction with environments is central to the assessment enterprise. Individuals bring implicit and explicit version of constructs to social and non-social domains and use both automatic and effortful modes of information processing in typical and maximal learning and performance conditions. Implicit and explicit versions of personality constructs cannot be averaged together, because they operate in different contexts. Therefore, theoretical formulations are needed to guide their integration. One suggestion is the *channeling hypothesis* (Winter, Stewart, Klohnen, & Duncan, 1998), which states that explicit self-beliefs channel how a motive is expressed. Consider an individual whose implicit inclination to be aggressive is at odds with his self-definition (shown in Figure 5.3; and see Frost, Ko, & James, 2007). To resolve this disparity and maintain a favorable self-view, the individual may engage in reasoning to justify his hostile acts and, depending on the norms of the setting, may express aggression openly or through indirect channels.

Compromises between implicit and explicit inclinations that are not socially sanctioned, such as aggression, may differ in nature from compromises among socially promoted motives such as achievement. Consider a fifth-grade student (with above-average intelligence) who is explicitly motivated to be a good student basing her sense of identity on getting good grades (see Figure 5.4). However, her low implicit motivation plays out in her day-to-day experience of becoming bored and frustrated, avoiding work in the absence of incentives. She puts forth more effort when the task is clear and supported by immediate feedback, such as when her parents supervise her homework. Recently, however, as expectations that she will work more independently have increased, so has her frustration and task incompletion. As seen in Figure 5.4, when explicit achievement motivation is not supported by implicit motivation (interest), the individual processes information more superficially and sets goals that emphasize performance (gain approval, grades) over mastery (understanding the material; see Moller & Elliot, 2006). Cumulatively, superficial information processing takes its toll on the development of mastery.

What do personality performance measures contribute to understanding transactions between persons and environments? They provide unique information to enable understanding of each of three vantage points on transactions between persons and situations: (a) internal dynamics; (b) situation-specific dynamics; and (c) developmental dynamics (see Teglasi, Newman, & Nebbergall, 2012).

**Figure 5.3** Implicit and Explicit Aggression Motives.

**Figure 5.4** Implicit and Explicit Achievement Motives.

### INTERNAL DYNAMICS

The whole person is understood as *the context* in which various psychological constructs (implicit and explicit) and mental processes (effortful and automatic modes of attention, self-regulation) converge to influence responses in a particular setting. Compromises among intra-individual factors and joint influences of various reciprocally interactive attributes (such as attentional and emotional self-regulation) are understood by obtaining information from various sources, including personality performance measures.

### SITUATION-SPECIFIC DYNAMICS

Transactions between individuals and their external worlds are situation-specific, making it necessary to understand persons *in context*. Psychological constructs characterizing persons (schemas, executive functions) play out differently in settings (both in the assessment and real-world contexts) that vary on a continuum of typical and maximal conditions. Accordingly, responses to performance tests and to real-life challenges, as well as reports of various informants (peers, teachers, supervisors), are viewed in reference to applicable performance conditions (e.g., informant rating in a familiar, highly structured setting).

### DEVELOPMENTAL DYNAMICS

Schemas play a pivotal role in developmental dynamics as they are products of *prior*

*contexts* and influence exchanges in current settings. Situation-specific responses are not directly pulled by current conditions but are informed by schemas. As individuals discern regularities in their transactions with certain contexts, they form mental sets housing knowledge about self, others, and the world that inform their subsequent appraisals, emotions, and behaviors in those contexts. To learn from experience, the individual must incorporate new categories into preexisting schemas by recognizing when the current repertoire is not adequate to understand or respond to the situation. Personality performance measures are used to assess implicit personal schemas and clarify the processes by which existing mental sets are adapted to impose meaning on ill-defined stimuli and to organize ideas (Teglasi, 2010).

The administration of measures that reveal implicit and explicit versions of targeted constructs in typical and maximal conditions, social and non-social, allow for case conceptualizations that are systematically organized around these elements to understand persons *as context, in context, and of prior contexts* (see Teglasi, Simcox, & Kim, 2007; Teglasi et al., 2012).

### Scientific Status of Projective Techniques

The provocative title of one critique, "The Scientific Status of Projective Techniques" (Lilienfeld, Wood, & Garb, 2000), incorrectly implies that the evidence presented, in the form of

box scores of hits and misses of hypothesized correlations, speaks to the issue of the scientific merit of this class of instruments. Reviews of the empirical evidence regarding the use of projective or other clinical assessment techniques have the potential to advance research and practice, provided that they address construct validity, the core elements of which are (see Smith, 2005): theory development, hypothesis specification, research design, empirical evaluation, and implications of data for theory. The scientific rigor of a review of empirical findings should be judged by how well it accounts for each of these elements of the construct validation process.

### 1. Theory

*Does the review recognize the theoretical grounding of the assessment tool in question, including recent advances in theory and implications for use of the measure?* Lilienfield and colleagues (2000) treated projective techniques as if they were alternatives to self-report methods (Hughes, Gacono, & Owen, 2007), basing their largely negative conclusions on a mere caricature of the projective rationale (Hibbard, 2003). They dismiss construct validity as being independent of practical utility, asserting that... “an index derived from a projective technique may possess construct validity without being useful for predictive purposes in real world settings” (p. 28). By sidestepping the issue of construct validity, Lilienfield and colleagues give up the opportunity to contribute to theory development.

### 2. Informative hypotheses

*Does the review differentiate between studies that pose informative tests of hypotheses from those that do not?* It is incumbent on reviewers to flag studies that do not pose adequate tests of hypotheses and to raise questions about the relationship of the construct to both the predictor (measure) and the predicted (criterion). As Hibbard points out, Lilienfield and colleagues do not distinguish between studies designed to validate aspects of the measures from those aiming to explore relations among variables.

### 3. Sound research design

*Does the review provide an accurate and comprehensive treatment of the extant literature by including the relevant studies and judging their adequacy to test the hypotheses and to rule out alternative explanations?* Credibility of the conclusions drawn from a review of the evidence bearing on the value of a clinical measure depends on the inclusion and scrutiny of the research design

of individual studies. The review of Lilienfield and colleagues provided a tally of findings that do or do not support the use of projective tests for the purpose of diagnosis without sufficient scrutiny of the quality of the research design and, as noted by Hibbard (2003), they included studies using the measure in ways that do not resemble their use by clinicians.

### 4. Explanation of the degree to which observations confirm hypotheses

*Does the review provide possible explanations for patterns in the data within and across studies, explaining correspondences or disparities between observations and hypotheses?* A tally of positive and negative correlations (zero order and multiple) does not substitute for a conceptual accounting of patterns of findings such as given by Spangler (1992), who highlighted different patterns of external correlates associated with self-reported and performance (TAT) measures of achievement motivation.

### 5. Ongoing revisions of both theory and measures

*Does the critique treat empirical data in ways that are relevant to advancing theory?* With respect to Lilienfield and colleagues’ 2000 review, Hibbard (2003) points out numerous flaws, including their ignoring of longstanding and contemporary arguments (or simple extensions thereof) relevant to the scientific consideration of reliability, incompletely or inaccurately reporting data published in the time frame of the review, and excluding or misreporting relevant validity studies. Apart from the aggregation of multiple errors noted by Hibbard, a major shortcoming of the review is its failure to address issues of construct validity, which limits its usefulness in informing practice, research, and theory.

## Conclusion

Comprehensive reviews of the evidence about projective (or any other) clinical instruments (personality performance tests) appropriately raise questions about the psychometric properties and utility of instruments for certain purposes. However, the scientific status of an instrument can only be addressed by reviews that scrutinize the accumulated evidence to answer the two interrelated questions: How well does the instrument measure the target phenomenon, and how well does that phenomenon explain responses in real-world contexts? Together, these two questions address the issues of construct

validity and scientific status. The phenomena on which projective devices are based are robust, having received support across multiple psychology subfields. Theory-grounded reviews that distinguish between measures of implicit and explicit personality constructs (e.g., Spangler, 1992; Winter et al., 1998) support the scientific merit of the distinction as capturing unique phenomena that are measured with different techniques, develop via different routes, and have different relations with external correlates. Accordingly, policy and ethics guidelines regarding the clinical use of psychological tests must be mindful of the implications of relevant distinctions within a single construct for generalizing from test responses to functioning in real world contexts. Moreover, testing guidelines should extend beyond a focus on the *construct validity* of single instruments to consider *case validity*, which rests with the selection and the synthesis of the measures to be included in a given protocol (*case validity*; Teglasi et al., 2012).

## Notes

1. *Science* is defined in *Webster's Dictionary* as (a) "knowledge or a system of knowledge covering general truths or the operation of general laws, especially as obtained and tested through scientific methods"; and as (b) "a system or method reconciling practical ends with scientific laws."
2. Techniques such as brain imaging show activation of neural networks during mental processes.
3. Not all measures claim to assess a construct, and the relationship between a construct and its measure is not necessarily causal. In such cases, the idea of construct validity does not apply (see Borsboom et al., 2004).

# Large-Scale Group Score Assessments: Past, Present, and Future

Bobby Naemi, Eugene Gonzalez, Jonas Bertling, Anthony Betancourt, Jeremy Burrus, Patrick C. Kyllonen, Jennifer Minsky, Petra Lietz, Eckhard Klieme, Svenja Vieluf, Jihyun Lee, and Richard D. Roberts

## Abstract

The influence of large-scale group score assessments on research, policy, and practice in education has increased dramatically over the past few decades. The goal of this chapter is to provide an overview of the value and scope of this program of research. The chapter begins by providing an overview of the history of large-scale assessment. Next, it focuses on current research and development surrounding the National Assessment of Educational Progress (NAEP, a government-mandated assessment in the United States) and the Programme for International Student Assessment (PISA, a large-scale survey and assessment commission by the Organisation for Economic Co-operation and Development, OECD). We also briefly review other landmark large-scale group score assessments. Throughout, we highlight the growing use of noncognitive variables in these assessments. The chapter concludes with a discussion of some of the topics and approaches likely to guide future directions in this domain.

**Key Words:** large-scale group score assessment, international assessment, noncognitive assessment, NAEP, PISA

## Introduction

Large-scale assessments, in the broadest sense, are defined as surveys of knowledge, skills, or behaviors in a given domain, usually with an attempt to describe a population of interest. They typically involve sampling (a) knowledge and skills using a comprehensive theoretical framework, (b) a relatively large number of items or tasks to cover the domain, and (c) relatively large samples of people representative of the population of interest. Results tend to be reported and aggregated at the group level, which is why “group score” is sometimes added to the description. To avoid overburdening the people surveyed, large-scale assessments often make use of multiple-matrix sampling designs, which allow them to survey smaller subsets of participants with a fewer number of items. Through the use of these methods, large-scale group score

assessments produce reliable scores for groups at the expense of reliable scores for individuals.

Large-scale assessments are administered nationally or internationally. The classic example of a national large-scale assessment is the U.S. National Assessment of Educational Progress (NAEP). NAEP has been administered to samples of students within the United States since the 1960s, and covers a wide range of school-based subjects, such as mathematics, science, reading, writing, history, civics, and so forth. NAEP is usually administered at the fourth, eighth, and twelfth grades, which means, by default, it is concerned with different age groups at different levels of schooling. Note that the United States is not alone in administering national assessments, though it is relatively unparalleled in terms of its scope and frequency. For example, between 1995 and 2006, 22 countries in Sub-Saharan Africa alone

administered one form or another of a national assessment (see United Nations Educational, Scientific and Cultural Organization [UNESCO], 2007). Table 6.1 provides a listing of countries across the globe (by regions given in the aforementioned report) that have administered one form or another of a national assessment over this time period.

International large-scale assessments are no less prevalent. Major surveys include the Trends in International Mathematics and Science Study (TIMSS; see Mullis, Martin, & Foy, 2008), the Progress in International Reading Literacy Study (PIRLS; see Mullis, Martin, Kennedy, & Foy, 2007), the Programme for International Student Assessment (PISA; see OECD, 2010a), and the International Civic and Citizenship Education Study (ICCS; see Schulz, Ainley, Fraillon, Kerr, & Losito, 2010). There also assessments of a regional nature, such as those sponsored by UNESCO in Latin America and Southern Africa, and those covering out-of-school populations such as the International Adult Literacy Study (IALS; see Kirsch, 2001), and the Programme

for International Assessment of Adult Competencies (PIAAC; see PIAAC Literacy Expert Group, 2009).

The use of these large-scale international assessments to measure educational processes and outcomes has become more and more prominent over the past few decades. In particular, the ubiquity of country rankings and cross-national comparisons, often heavily discussed in the media, serve as a testament to the perceived importance of the indicators and outcomes measured by these assessments. For example, PISA, conducted by the Organisation for Economic Co-operation and Development (OECD) grew from 43 participating countries in 2000 to 67 participating educational systems in 2012. This growth also applies to other large-scale international assessments operated by the International Association for the Evaluation of Education Achievement (IEA). TIMSS, for example, grew from 40 eighth-grade educational systems in 1995 to 56 in 2007, while PIRLS grew from 35 participating systems in 2001 to a projected participation of 55 in 2011. Current projections suggest that TIMSS and

PIRLS will be administered to a combined set of 85 educational systems in 2011. Further support for the increase in the use of large-scale assessment data comes from Rutkowski, Gonzalez, Joncas, and von Davier (2010), who reported an increase in research interest in these large-scale assessments through a search of the Wilson Education Full Text database. Findings demonstrated a growth in published research involving TIMSS, PIRLS, or PISA from 340 articles between 1995 and 1999 to 851 articles between 2005 and 2009. Clearly, the prevalence of international large-scale assessment is on the rise. The goal of this chapter is to give the reader the flavor of these large-scale assessments, while simultaneously outlining important issues these studies address that can benefit educational research, policy, and practice.

The data gathered by large-scale international assessments represents an enormously valuable source of information on a host of issues and topics relevant to educational research and policy, data that can be difficult or impossible to gather in smaller, within-country contexts. Performance results in many cases are reported as a series of scores, with the goal of providing information about how students are performing at a given threshold or score category (Ercikan, 2006). These score reports have led to increasingly high stakes for many large-scale assessments as accountability measures.

The chapter begins with a brief history of large-scale international assessment, which has a colorful and vibrant past. Next, we focus on one particular national large-scale assessment, with a long history: NAEP. We then discuss a small selection of these programs, including their current status and general features. Space simply precludes covering all of the programs that have been conducted, as attested by the list of assessment programs identified in Table 6.1, as well as Table 6.2, which highlights major studies and large-scale student assessment administrations since 1961. We conclude with a discussion of where large-scale group score assessment research might head in the future.

## **The Past: A History of Large-Scale Group Score Assessment**

The end of the Second World War and the associated reconstruction of economic and educational systems were accompanied by an unprecedented expansion of education. This expansion extended across all levels, from early childhood education through universities and institutes for adult education (Connell, 1980). This growth, among other

things, led to the development of educational research as a major field of scholarly inquiry.

### **Origins**

In 1946, the constitution of the United Nations Educational, Scientific and Cultural Organization (UNESCO) was ratified by 20 countries with the aim of integrating educational, scientific, and cultural activities across countries and cultures in the quest for world peace. In 1952, a group of scholars met at the UNESCO Institute for Education in Hamburg, Germany, in what might nowadays be called a think-tank. The goal of this group was to consider how information might be obtained more systematically in terms of educational processes and outcomes across the world, beyond the national studies that had been undertaken in some countries up to that time. Specifically, the aim of the group was to obtain this information and determine what educational systems could learn from each other (UNESCO, 2010).

Against this background, the IEA was founded in 1958 with the goal of studying the process of education across the world. As one of its first activities, the Pilot Project was undertaken from 1959–1961 in twelve education systems (i.e., Belgium, England, Germany, Finland, France, Israel, Poland, Scotland, Sweden, Switzerland, the United States, and then-Yugoslavia) to examine the feasibility of a cross-national study of educational achievement. The project assessed achievement in the areas of reading comprehension, mathematics, science, geography, and non-verbal ability from samples of about 1,000 13-year-old students in each country. This particular age group had been chosen because, at that time, this was the oldest age group for which nearly the whole cohort was still at school in the participating countries. The Pilot Project showed, for the first time, that it was possible to conduct an international assessment study on a relatively large scale, despite major challenges in terms of logistics and translation (Foshay, Thorndike, Hotyat, Pidgeon, & Walker, 1962).

The Pilot Project was followed by a study in 1964 of mathematics achievement levels of 13-year-olds and students at the pre-university year (Husén, 1967). The study design improved in that probability samples of the two target populations were drawn to enable proper population estimates and the estimation of sampling error. Again, twelve countries (i.e., Australia, Belgium, England, Germany, Finland, France, Israel, Japan, the Netherlands, Scotland, Sweden, and the United States) participated, with

*Note:* Abbreviations for columns: Year (Year), Study Name (Study), Repeated Design (RD), Organization, Conducted By (Conducted By), Constructs and Subjects Measured (Constructs Measured), Population and Age (Pop/Age), International Study (Intl), Number of Countries (# count). Asterisk (\*) indicates that only grade-level information was provided and an approximate age was given for the students' grade level.

the project involving over 133,000 students from 5,400 schools. In addition to achievement data, background information was collected from these students as well as from 13,000 teachers and 5,400 principals by way of questionnaires. Analyses were aimed at testing specific hypotheses in four main areas: (a) the effects of school organization on mathematics achievement, (b) curriculum and instruction, (c) support for education, and (d) the relationships of socio-economic and geographic factors with mathematical achievement.

Around this time period, the United States Department of Health, Education, and Welfare commissioned the Equality of Educational Opportunity Study (EEOS), more commonly known as the “Coleman Study” (Coleman, 1968). The study grew out of efforts to address social policy issues relating to ethnicity, religion, and national origin prompted by the Civil Rights Act of 1964. As part of the survey, students from five grade levels (first, third, sixth, ninth, and twelfth grades) completed questionnaires assessing demographic and background variables, attitudes towards learning, education and career goals, and racial attitudes, alongside tests of verbal ability, reading comprehension, non-verbal associations, and mathematics. In addition, principals and teachers completed questionnaires examining education and teaching experience, salary, academic discipline, verbal facility, and racial attitudes. The study proved to be a landmark effort in linking national social policy goals to large-scale surveys and assessments.

Both the Pilot Project and the Coleman Study represented examples of how meaningful analyses could be undertaken with comparable data from large-scale assessments of school-aged children. For the Pilot Project in particular, two additional developments took place. First, the theoretical foundations to guide these assessments were further developed. Second, the scope of the assessments was extended to cover a wider range of school subjects.

The theoretical developments involved the consideration of a number of models. These included a general model for cross-national comparisons in education, which started with the environment and the economy, which then gave rise to a demand for human resources and curriculum development (Dahlöf, 1967). These demands were translated into objectives, and finances were used to fund processes that resulted in educational attainment. Based on this schema, a comprehensive model of educational processes was put forward by Super (1967). This model started with the social and cultural capital

that was evident in inputs categorized as financial conditions, production conditions, and human conditions. Processes followed that covered educational structure, equipment, agents, curricula, and instructional methods. These were modeled to lead to outputs in the form of performance in terms of knowledge, skills, attitudes, educational levels, and competencies, which, in turn, were utilized in the contexts of employment, community, and family. These contexts were identified as being reflective of national development in terms of human, economic, and political development.

Several additional models highlighted other important aspects thought to have an impact on performance in large-scale group score assessments. For example, the model of selectivity and retentivity argued that differences in countries' performance in mathematics were a consequence of the number and type of students retained in a cohort (Walker, 1967). Carroll's (1963) model of school learning specified the relationships between aptitude, perseverance, opportunity to learn, ability to understand instruction, and quality of instruction and their impact on student performance. In addition, the model put forward by Rosier and Keeves (1991) underlined the importance of the intended, implemented, and achieved curriculum in describing and understanding student performance.

### ***Large-Scale Assessment Research: The Second Wave***

The Six-Subject Survey was the second major development in large-scale group score assessment research. Specifically, it extended the content coverage of large-scale cross-national assessments in schools and enabled the testing of the conceptual models described above. Conducted between 1970 and 1971, the Six-Subject Survey assessed performance in science (Comber & Keeves, 1973), reading comprehension (Thorndike, 1973), literature (Purves, 1973), French as a foreign language (Carroll, 1975), English as a foreign language (Lewis & Massad, 1975), and civic education (Torney, Oppenheim, & Farnen, 1976). The Six-Subject Survey also increased coverage as far as geography and economic development were concerned in comparison to past assessments. A total of 23 different education systems participated across the six subjects, although not all systems participated in each subject area (Peaker, 1975).

Led by the IEA, conceptual and content development came together during this period, based on extended content area coverage and improved

test design. For example, Carroll's model was tested using data from the French as a Foreign Language study, while the curriculum model was examined using data from the First and Second IEA Science Studies (Comber & Keeves, 1973; Postlethwaite & Wiley, 1992), as well as the Second International Mathematics Study (Robitaille & Garden, 1989).

Over the next two decades, IEA conducted the following studies: the Second International Mathematics Study (Robitaille & Garden, 1989); the Second International Science Study (Keeves, 1992); the Reading Literacy Study 1990–91 (Elley, 1994); the Third International Mathematics and Science Study (Beaton, Martin, Mullis, Gonzalez, Kelly, & Smith, 1996; Beaton, Mullis, Martin, Gonzalez, Kelly, & Smith, 1996); and the Third International Mathematics and Science Study Repeat (or TIMSS-R) in 1999 (Martin et al., 2000; Mullis et al., 2000). The IEA also extended to new areas of interest as they arose (e.g., Computers in Education [Pelgrum & Plomp, 1993]; Written Composition [Purves, 1992]; and the Pre-Primary Project [Olmsted & Weikart, 1994]).

Each of these large-scale assessments also had new design elements that resulted in fresh insights. For example, TIMSS-R 1999 allowed for the comparison of different age cohorts between the first wave of data collection in 1995 and the second wave of data collection in 1999 (as students progressed from Grades 4 to 8). Often these studies were prompted by important policy issues. Take again the TIMSS. The background for these studies began in the late 1980s, when the U.S. government decided to set a goal that, by the year 2000, the nation would be number one in educating students. A series of reforms were thus put into place in the late 1980s and early 1990s. The results for the United States in 1995 indicated a relatively good performance for the fourth graders, but showed that American eighth graders lagged behind their peers from around the world. TIMSS-R in 1999 was designed, among other reasons, to investigate whether the cohort of fourth graders in 1995, once they reached the eighth grade, would still hold on to their relatively high results compared to the rest of the countries. Researchers hypothesized that in 1995, the reforms from the 1980s and 1990s may have resulted in favorable results among fourth graders, but might not have yet reached the older cohort of students. The results did not support this hypothesis: American eighth graders were still lagging behind their peers in 1999. Similarly, the Pre-Primary Project (Olmstedt & Weikart, 1994)

enabled the nine education systems that participated in Phases 1 and 2 to examine how the quality of life of preschool children in various care and education environments influenced these children's development, as participants were first assessed at age four with a follow-up at age seven.

### ***Large-Scale International Assessment Research: Towards the Current Major Programs***

Out of these earlier studies, the two current main large-scale assessments conducted by the IEA emerged. These are the Trends in International Mathematics and Science Study (TIMSS) and the Progress in International Reading Literacy Study (PIRLS). TIMSS has been conducted every four years since 1995 and assesses the mathematics and science achievement of a representative sample of students in Grades 4 and 8. Twelfth graders were assessed in 1995 and in 2008. At the time of writing, fifty-eight fourth grade education systems and 59 eighth grade education systems were participating in the current form of the assessment (i.e., TIMSS 2011). Data collection for PIRLS, which is conducted every five years, also occurred in 2011. The target population for PIRLS is the grade level that represents four years of schooling in the 53 participating education systems, providing that the mean age at the time of testing is at least 9.5 years.

TIMSS designs the studies based on the intended curriculum (what is supposed to be taught), the implemented curriculum (what is actually taught), and the achieved curriculum (what students have actually learned). PIRLS focuses on the achievement of young children (between 9 and 10 years) and the experiences that they have at home and school in learning to read. In the PIRLS framework, *reading literacy* is defined as "the ability to understand and use written language forms required by society and/or valued by the individual" (Mullis et al., 2011, p. 11) Options for young readers include reading to learn, reading for enjoyment, or reading to participate in various communities of readers. The choice of age for PIRLS is based on the general understanding that, at that age, students have made the transition from learning to read to reading to learn.

In 2012, the Organization for Economic Cooperation and Development (OECD) will have conducted the fifth cycle of its Programme for International Student Assessment (PISA), which began in 2000 and is undertaken every three years. PISA regularly assesses three domains: reading literacy, mathematics literacy, and science literacy. Each

cycle, one of these domains is tested in greater depth to allow for greater coverage in every third cycle or every nine years. In addition to these domains, PISA occasionally assesses other aspects considered important, such as problem-solving (in 2003 and in 2012) or financial literacy (in 2012). In addition to the cognitive assessments, PISA includes background questionnaires for students, parents, and schools that provide a rich database on attitudes and behaviors of 15-year olds (e.g., mathematics motivation, self-concept, or enjoyment of reading) as important performance predictors and noncognitive outcomes of education.

Unlike TIMSS and PIRLS, which are studies developed and based largely on an analysis of what is taught across the participating countries, PISA assesses students' literacy in the three subject areas mentioned above. In other words, the guiding principle in the PISA test design is to assess the extent to which students have acquired reading, mathematics, and science literacy skills deemed necessary to be fully functioning citizens. "Fully functioning citizens" are defined here as individuals who will be able to constructively contribute to the economies in which they are educated (in OECD countries, e.g.; OECD, 2010a). A more detailed review of constructs assessed in PISA appears below. Because its goal is to measure whether students have the skills necessary to be fully functioning citizens, PISA focuses on 15-year-old students. This is the age group that in most OECD countries is considered the year prior to being able to join the workforce. These students are also generally found to be towards the end of compulsory education in OECD countries.

There are 67 participating systems in PISA 2012, 34 of which are OECD member countries. PISA assessments produce a large array of technical reports. For example, in the 2009 cycle, six volumes were produced, each focusing on a specific issue: students' literacy (OECD, 2010a), equity of educational opportunities (OECD, 2010b), characteristics of successful students (OECD, 2010c) characteristics of successful schools (OECD, 2010d), changes in reading performance from 2000 to 2009 (OECD, 2010e), and digital reading (OECD, 2011).

### ***Large-Scale National Assessments: The History of NAEP***

The preceding review concerned itself mainly with international large-scale assessments. National assessments, as we suggested earlier, have a long and colorful history as well, though providing an

exhaustive history of all such programs might well fill a book (or two). To ensure some historical coverage of these programs, we focus on the National Assessment for Educational Progress (NAEP), the large-scale assessment regularly conducted in the United States, which is something of a flagship for this approach.

NAEP has been measuring student progress since 1964 and has become the "Nation's Report Card." The development of NAEP was spearheaded by Francis Keppel, the U.S. Commissioner of Education from 1962 to 1966, with the goal of obtaining empirical evidence concerning the condition of American schools in order to report on the progress of students for the U.S. Office of Education. Planning for the development of such an assessment program sprang from two conferences and the establishment of an Exploratory Committee on Assessing the Progress of Education (ECAPE), all funded by the Carnegie Corporation (Jones, 1996).

The idea for the assessment was initially conceptualized by psychologist Ralph Tyler, who thought it necessary to measure what students know and how they compare to their age cohort (Carr, Dogan, Tirre, & Walton, 2007). The main goal was to examine changes in student performance over time. Tyler conceived that the assessment should: (a) test general knowledge; (b) not discriminate among individuals; (c) provide a more accurate measure of the least, average, and most educated individuals in society; (d) include adults; and (e) be administered to individuals of certain ages (Greenbaum, Garet, & Solomon, 1975). Furthermore, Tyler emphasized the importance of considering the outcomes of the assessment, including the potential that the assessment could become part of the standards for curricula. Another expectation was that student data should be assessed at the state and local levels. This suggestion was met, however, with criticism. Various educational institutions became concerned that the results of the assessment would be used to make improper comparisons (Vinovskis, 1998). Thus, it was initially decided that reporting would be done on the basis of the four regions of the United States.

Tyler, along with ECAPE and a technical advisory committee (including members such as Lee Cronbach and John Tukey) proposed possible content areas to be assessed and developed, sampling guidelines, as well as procedures for scoring, data analysis, and reporting (Jones, 1996). The following content areas were chosen based on their

correspondence to school curricula: reading, mathematics, writing, literature, science, social studies, citizenship, art, music, and career and occupational development. The initial plan was to assess two of these areas per year, in five-year cycles, for all U.S. residents, including those of ages 9, 13, and 17, as well as young adults (26- to 36-year-olds; Vinovskis, 1998).

The ideas put forth by Tyler and the various committees were generally kept intact, although some amendments and refinements were made. The first national assessments were conducted in 1969. During this year, the administration and management of student assessments came under the jurisdiction of the Education Commission of the States (ECS), which was composed of various states. ECS then created a Project Policy Board to oversee operations, and the project was then renamed the National Assessment of Educational Progress (Vinovskis, 1998). Funding for NAEP primarily came from the Carnegie Foundation and received some support from the federal government. By 1972, funding was exclusively provided by the federal government.

The first administration of NAEP occurred in 1969, at about the same time as the International Association for the Evaluation of Educational Achievement began conducting international large-scale assessment studies. In its first administration, NAEP assessed science, writing, and citizenship content areas for students aged 9, 13, and 17, out-of-school 17 year-olds, as well as adults aged 16 to 35. The second administration in 1971 assessed the same age groups in reading and literature content areas. Reports of student performance emphasized the individual items, about half of which were printed in the report along with their *p* values, however, an overall summary of results was not supplied (Linn, 2001). In 1982, the Educational Testing Service (ETS) won the NAEP contract, and significant changes were made. Documentation for the new design of NAEP was disseminated in a report by Messick, Beaton, and Lord (1983). The report encompassed an overview of the conceptual framework along with rationalizations for the new design that focused on improving the relevance of NAEP to educational policy by addressing performance standards and school effectiveness. An additional focus was on technical innovations, such as sampling by grade and age, which allowed for direct links to other state and local assessments, as well as school practices. Sampling by grade was based on the idea that age alone would not necessarily capture the

relevant populations of interest to inform schools and policy makers. Furthermore, the adoption of item-response theory and plausible values methodology allowed for the reporting of average scaled performance for groups of students and improved measurement. Around this time, it also became possible to track the trends of the different assessments and especially those that had common items (Linn, 2001).

In 1988, the National Assessment Governing Board (NAGB) was established for the purpose of independently providing policy guidance to NAEP (Jones, 1996). NAGB was given responsibility for selecting the subject areas to be assessed, as well as the frameworks that provide information concerning the content of each of the assessments (Linn, 2001). That same year, Congress allowed states to receive state-level NAEP results if they participated in the Trial State Assessment (TSA) during the 1990 and 1992 NAEP administrations. New programs subsequently emerged (e.g., Trial Urban District Assessment [TUDA], which began in 2003 and assesses samples of students from across the nation's largest cities).

Currently, state-level participation in NAEP is mandatory for reading and mathematics in the fourth and eighth grade; however, it is voluntary for states to participate in other NAEP subjects and grades (NAGB, 2010). The day-to-day operations associated with NAEP are exceedingly complex. The responsibility for the overall project is the National Center for Education Statistics (NCES) in the U.S. Department of Education. As mentioned earlier, NAGB continues to set the policy and develop the assessment specifications. The actual assessments are presently administered with the help of nine contractors, who are variously involved in sampling, item development, test delivery and production, psychometrics, and reporting.

## **Current State of the Art in Large-Scale Group Score Assessments**

Over the past 60 years, large-scale group score assessments in school education, whether international (e.g., PISA, TIMSS and PIRLS) or national (e.g., NAEP), have come a long way, such that a wealth of data is now available for use by researchers to inform practitioners and policy makers in education. The remainder of this chapter provides a more detailed overview of constructs measured and items used by NAEP and PISA, which serve as exemplars of national and international large-scale assessments, respectively. In addition, we highlight three other

major large-scale assessments mentioned in the overview; specifically, TIMSS, PIRLS, and ICCS. Note this is a very small subset of large-scale group score assessments as our preceding review suggests, though these five assessments do represent those having some of the greatest impact on research and public policy.

### ***The National Assessment of Educational Progress (NAEP)***

The National Assessment of Educational Progress assesses and reports on students' knowledge of academic subjects, including mathematics, reading, geography, writing, civics, economics, U.S. history, science, and the arts. A few additional subject areas are also currently in development, including foreign language, world history, and technology and engineering literacy. Subjects are assessed at grades 4, 8, and 12, and reporting is done on an aggregate national level, with the exception of mathematics, reading, science, and writing, which are also reported at the state level. State assessments began in 1990 (Linn, 2001), but by law, results cannot be reported for individuals or schools (Beaton & Zwick, 1992).

The main NAEP assessments are also augmented by long-term-trend NAEP assessments. Although both main and long-term-trend NAEP assessments examine the content areas of mathematics and reading, there are four differences that do not allow for a direct comparison between them:

(1) *Frequency*. Long-term-trend NAEP is measured every four years, while main NAEP assessments are measured every two years.

(2) *Content*. Long-term-trend NAEP has remained almost unchanged, while main NAEP frameworks are updated around every decade.

(3) *Sample*. Long-term-trend students are chosen based on age (9, 13, and 17 years), while main NAEP students are selected by grade (4, 8, and 12).

(4) *Results*. Long-term-trend NAEP reports results on a national level using scale scores and performance levels in order to see how student performance has changed over time. Main NAEP reports results using scale scores and achievement levels.

### **COGNITIVE ASSESSMENT**

Each NAEP cognitive assessment is built around an organizing framework, which is the blueprint that guides the development of the assessment instrument

and determines the content to be assessed (NAEP, 2010). Developing a framework generally involves the following components: (i) widespread participation and reviews by educators and state education officials; (ii) reviews by steering committees whose members represent policymakers, practitioners, and members of the general public; (iii) involvement of subject supervisors from education agencies; (iv) public hearings; and (v) reviews by scholars in the field, including staff in the National Center for Education Statistics (NCES), and by a policy advisory panel (NAEP, 2010). NAEP has developed frameworks for a variety of subjects, including: arts; civics; economics; foreign language; geography; mathematics; reading; science; U.S. history; and writing (NAEP, 2010).

As the content and nature of the NAEP assessments evolve to match instructional practice and the latest research, the ability of the assessment to measure changes over time is reduced. While short-term trends can be measured in many of the NAEP subjects (e.g., mathematics, reading), the most reliable instruments of change over time are the NAEP long-term-trend assessments (Rampey, Dion, & Donahue, 2009).

The NAEP long-term-trend assessments in reading and mathematics were administered throughout the U.S. in 2007 and 2008 to samples of students aged 9, 13, and 17 years. Because the long-term-trend program uses substantially the same assessments decade after decade, it has been possible to chart educational progress since 1971 in reading and 1973 in mathematics (Rampey et al., 2009). Overall, the national trend in reading showed gains in average scores at all three ages since 2004. Average reading scores for 9- and 13-year-olds increased in 2008 compared to 1971, but the reading score for 17-year-olds was not significantly different (Rampey et al., 2009). In mathematics, average scores for 9- and 13-year-olds increased since 2004, while the average score for 17-year-olds did not change significantly. Average scores were 24 points higher than in 1973 for 9-year-olds and 15 points higher for 13-year-olds. The average mathematics score for 17-year-olds was not significantly different from that in 1973 (Rampey et al., 2009).

In terms of achievement gaps, most racial/ethnic score gaps were narrowed compared to that observed with the first assessment. While the reading score gaps between White and Black students at all three ages showed no significant change from 2004 to 2008, the gaps did narrow in 2008

compared to 1971. White–Hispanic gaps in reading scores also showed no significant change from 2004 to 2008 but were smaller in 2008 than in 1975 at ages 9 and 17 years. Across all three age groups, neither the White–Black nor White–Hispanic gaps in mathematics changed significantly from 2004 to 2008, but both were smaller in 2008 than in 1973 (Rampey et al., 2009).

In addition to achievement scores, results indicated higher percentages of 13- and 17-year-olds enrolled in advanced mathematics in 2008 than in past years (Rampey et al., 2009). Taking higher-level mathematics courses was generally associated with higher scores on the 2008 mathematics assessment at ages 13 and 17. For example, 13-year-olds who were enrolled in algebra classes scored higher on average than those enrolled in pre-algebra or regular mathematics. The percentages of 13-year-olds who reported taking pre-algebra or algebra in 2008 were higher than the percentages in 1986. The percentage of 17-year-olds who reported they had taken pre-calculus or calculus was higher in 2008 than in 1978, as was the percentage who had taken second-year algebra or trigonometry (Rampey et al., 2009).

#### NONCOGNITIVE INDICATORS AND OUTCOMES

In addition to the subject-specific cognitive items, NAEP also administers a series of background questions, which collect information from students, teachers, and school administrators about background variables (including several noncognitive factors) that are related to student achievement (National Assessment of Educational Progress, 2011a). Gathering this information serves, in part, to fulfill reporting requirements of federal legislation. Specifically, under the No Child Left Behind Act (No Child Left Behind Act of 2001, 2008), NAEP is required to collect information on and report achievement results disaggregated by the following variables: gender, race, ethnicity, socioeconomic status (SES), disability status, and English language learner (ELL) status. In addition to fulfilling federal requirements, information from the background items also serves to give context to NAEP results and allow researchers to track factors associated with academic achievement (National Assessment of Educational Progress, 2011b).

While some differences exist in the way that each type of background questionnaire is developed, there are shared principles that underlie the forms given to student, teacher, and school. First, the Governing Board provides initial guidance on

what is developed, and the Governing Board has multiple opportunities to review and provide input. Additionally, all background questionnaires share a development process that seeks to reduce burden on respondents and ensures data quality while continuing to meet the needs of the NAEP program (NAEP, 2011b).

There are three types of noncognitive data collected in the background questionnaires: (1) student reporting categories (or demographics), (2) contextual/policy information, and (3) subject-specific information (NAEP, 2011b). With regard to general student reporting categories, since the first NAEP assessment in 1969, achievement results have always been disaggregated by subgroups of the population (i.e., as previously noted, gender, race, ethnicity, socioeconomic status, disability status, and English language learner status [NAEP, 2011b]). In addition to the required reporting categories, NAEP also collects information about factors presumed to be associated with academic performance, including homework habits, the language spoken in the home, and the quantity of reading materials in the home (National Assessment of Educational Progress, 2011c).

Contextual and policy information items primarily focus on students' educational settings and experiences, and collect information about students' attendance (days absent), family discourse (talking about school at home), reading load (pages read per day), and exposure to English in the home (NAEP, 2011c). There are also items that ask about students' effort on the assessment, and the difficulty and importance of the assessment. Answers on the questionnaires provide information on how aspects of education and educational resources are distributed among different groups. Policy-related questions are reserved for the teacher and school questionnaires. These items collect data on basic characteristics of the school, the student body, and teachers, including factors such as: grade span of school, school enrollment, expenditures per pupil, student/teacher ratios, teacher background and training, qualifications, and classroom organization (NAEP, 2011b). Together, these school, teacher, and student level variables provide a basic context for understanding achievement.

The subject-specific items in NAEP are focused and limited. These items cover three categories of information: (1) time spent studying the subject; (2) instructional experiences in the subject; and (3) motivation and perceptions about the subject and the assessment (NAEP, 2011c).

## **Programme for International Student Assessment**

As mentioned above, the Programme for International Student Assessment (PISA) assesses three domains in each three-year cycle: reading, mathematics, and science. Questionnaires are provided to students (15-year-olds), schools, and (in some, but not all countries) parents. For the 2012 cycle, a greater effort was made to expand the scope and depth of the assessment to incorporate both innovative new item types and constructs that have not been typically measured in past PISA cycles, yet were included in other international studies. An overview of these constructs is discussed below.

A central goal of PISA is to collect and report on indicators of student achievement. These include student performance (literacy, or more generally, life skills), noncognitive outcomes (such as student motivation and well-being), educational careers, context variables (such as the students' cultural, ethnic and socioeconomic backgrounds) and, finally, process characteristics at the school and system levels (including evaluation and accountability policies, student selection and allocation, parental involvement, staff cooperation, and opportunities to learn). PISA also provides indicators that cover relationships between these factors (e.g., the so-called social gradient, which measures the strength of the relationship between socioeconomic status and performance, or the relationship between educational resources and outcomes).

PISA defines *literacy* as the capacity of students to use texts of various kinds, mathematical tools, and science-based reasoning as they encounter, interpret, and solve problems and make decisions in real-life situations. PISA also attempts to measure broader cognitive skills, such as strategies for learning and thinking and problem-solving competency. A central tenet of PISA is that success in school—and in life—depends on being committed, sharing values and beliefs, respecting and understanding others, being motivated to learn and to collaborate, and being able to regulate one's own learning behavior. These constructs can be perceived as prerequisites of cognitive learning, but may also themselves be judged as goals of education, as the OECD project Defining and Selecting Key Competencies (DeSeCo) has elaborated (Rychen & Salganik, 2003). Therefore, PISA addresses noncognitive outcomes like attitudes, beliefs, motivation, aspirations, and learning-related behavior (e.g., self-regulation, strategies, and invested time). Another important noncognitive outcome, truancy, has received

increased attention as an important (negative) indicator of student's use of learning opportunities, which is also predictive of school drop-out and deviant behavior (Kearney, 2008; Lee & Burkam, 2003). In summary, PISA represents a rich and wide source of data for a host of potential research questions, bringing together both cognitive and noncognitive indicators and outcomes at multiple levels in a single large-scale assessment.

## **Progress in International Reading Literacy Study (PIRLS)**

The Progress in International Reading Literacy Study (PIRLS) is an international comparative study of the reading literacy of young students coordinated by the IEA. PIRLS examines the reading achievement and reading behaviors and attitudes of students in the grade where most nine-year-old students can be found (which is the equivalent of fourth grade for the United States and most participating countries).

In addition to measuring achievement, PIRLS collects information about students' attitudes towards reading and their reading habits. Furthermore, parent, teacher, and school principal questionnaires gather information about students' home and school experiences in developing reading literacy, while curriculum questionnaires provide information about national context such as reading goals and curricula.

Results from the 2006 administration of PIRLS show that countries can make progress in improving children's academic achievement (Mullis et al., 2007). Most of the highest-achieving countries in 2006 showed significant improvement since 2001, including the three top-performing countries. The results also show that girls have had higher reading achievement than boys in all countries since 2001. The difference was substantial in many countries, raising concerns about the educational prospects of so many low-achieving boys during their adolescent years and beyond (Mullis et al., 2007).

Additionally, the questionnaires revealed that only about half the students across the countries assessed in 2006 agreed that they enjoyed reading and appreciated books, reflecting a troubling downward trend since 2001. Moreover, fewer students in 2006 reported reading for fun. Almost one-third hardly ever read for fun (twice monthly at most) (Mullis et al., 2007). However, PIRLS 2006 reinforces on a worldwide basis the well-established finding that children from homes fostering literacy become better readers. Students had higher reading achievement when they were from homes

where their parents enjoyed reading and read frequently, books were in abundance, and students were engaged in literacy activities—from alphabet blocks to word games—from an early age (Mullis et al., 2007).

### ***Trends in International Mathematics and Science Study (TIMSS)***

The Trends in International Mathematics and Science Study (TIMSS) provides data on the mathematics and science achievement of U.S. fourth- and eighth-grade students compared to that of students in other countries. Designed to align broadly with mathematics and science curricula in the participating countries, TIMSS examines the degree to which students have learned mathematics and social concepts and skills likely to have been taught in school. TIMSS assessments emphasize questions and tasks that offer better insight into the analytical, problem-solving, and inquiry skills and capabilities of students. In addition, students, teachers, and school principals in each participating country are asked to complete questionnaires concerning the context for learning mathematics and science, so as to provide a resource for interpreting the achievement results and to track changes in instructional practices.

Results from the 2007 administration of TIMSS show that fourth graders, in both mathematics and science, showed improvement rather than decline in more countries (Mullis et al., 2008). Steady improvement since the first TIMSS in 1995 was seen in a range of countries. However, this pattern is less pronounced at the eighth grade level. Although close to a dozen countries showed improvements, most countries either showed little change or declined. At the fourth and eighth grade levels, the differences in achievement between boys and girls were negligible in mathematics and science for over a third of the countries sampled. In the remaining countries, girls had higher achievement scores than boys, especially in mathematics (Mullis et al., 2008). In addition, a key noncognitive finding was that at both grade levels, high achievement in both math and science was associated with positive attitudes toward these subjects, high levels of self-confidence in learning mathematics and science, and high values placed on these subjects as important to future success (Mullis et al., 2008).

### ***International Civic and Citizenship Education Study (ICCS)***

The International Civic and Citizenship Education Study (ICCS) examines how young people

undertake their citizen roles in their respective countries. The study is based on a previous pioneering IEA study known as The Civic Education Study (CIVED), which was carried out from the year 1999 to 2000 in 28 countries. Similar to TIMSS, the ICCS targets students who are determined to be in their eighth year of schooling; for most countries, this represents the eighth grade, with a minimum mean student age of 13.5 years.

ICCS includes cognitive tests designed to examine knowledge, competencies, and conceptual understanding of civic and citizenship education. The assessment also includes noncognitive background questionnaires that collect information concerning student dispositions, activities, attitudes, and behaviors relating to civics and citizenship. Similarly, questionnaires for teachers and schools examine information about teaching and class management practices, school governance, climate, and other background variables. In order to address important culture-specific issues associated with each country sample, a National Context Survey is also used to assess the political, cultural, and educational contexts associated with civic and citizenship education in each country. To this end, regional modules are also used to examine and account for region-specific issues for groups of countries, with existing regional modules focusing on Latin America, Europe, and Asia.

Initial results from the 2009 administration of ICCS in 38 countries, based on 140,000 Grade 8 students, 62,000 teachers, and 5,300 school principals, provide a bounty of information on citizenship and civic education in an international context. Specific findings point to differing approaches in each country towards delivering civics and citizenship education. In addition, results demonstrated that, on average, a substantial proportion of students performed below minimum proficiency levels on a scale of civic knowledge (Schulz et al., 2010). Background questions also provided interesting results. For example, female students demonstrated significantly more civic knowledge than male students in most countries. In general, factors such as school experiences, having an open or receptive climate for classroom discussion, and socioeconomic status were all shown to be important contributors to civic and citizenship education. Overall, this assessment contributes a more nuanced and richer understanding of the role of citizenship and civic education in issues of importance for educational reform.

## The Future of Large-Scale Group Score Assessments

Large-scale or group score assessments have the potential to answer important research questions of great value to researchers, practitioners, and policy-makers. In light of lessons learned from each of these assessments, we offer the following overall considerations for future large-scale educational assessment research. These questions need to be answered with a certain degree of consensus amongst participating countries, and to make these guidelines more concrete, we will use an assessment of critical thinking as a running example.

### Policy Relevance and Interest

- The issues identified should be relevant to policy concerns in many countries. Do policy-makers around the world care if their students can think critically? How is critical thinking related to the performance of a country in terms of important educational, political, and economical indicators?
- There should be public interest in the particular issue. Do the citizens of many countries care if their students can think critically?
- The information obtained should be of value in understanding, and taking steps to improve, student performance and other outcomes. Will an assessment of critical thinking ultimately lead to improved academic and economic performance within countries?
- The issue should be related to a construct in which trends over time are of importance. Do we care if critical thinking skills improve from year to year? Do we expect students to become better at critical thinking as a function of their education?
- International comparisons should relate to important policy issues. If it is found that students from some countries tend to be more critical thinkers than others, will that lead to the implementation of policy designed to improve critical thinking in the lower performing countries?

### Appropriateness for an International Assessment

- The issue should be one that can be addressed cross-culturally and should have a similar meaning across countries. If students from different countries achieve the same score on critical thinking, does that mean they are equivalent in critical thinking skills? Would we expect these students to produce responses that are equivalent

to critical thinking problems? These questions are reflective of concerns relating to Differential Item Functioning (DIF; see Magis, Beland, Tuerlinckx, & De Boeck, 2010), which can appear when test items are highly culturally complex. Test items with high cultural complexity require large amounts of specific culturally shared knowledge that is not part of the construct that should be measured. As such, items developed for international assessments should avoid relying on any specific culturally shared knowledge.

- The assessments used to measure these constructs should be reliable and valid. Do large-scale assessments of critical thinking measure the construct consistently? Can they predict important outcomes such as academic and economic output?

### Technical Feasibility

- It should be technically feasible to address the issue within the context of the assessment design. Is it possible to design assessments of critical thinking for large-scale assessments?
- The time and cost associated with developing the assessments used to measure these constructs should be reasonable. Are assessments of critical thinking so complex that building them becomes prohibitively expensive?
- Researchers should consider whether there are less expensive ways to collect the information. Are there cheaper ways to assess critical thinking in a large-scale fashion? Is there some existing database already available that can be integrated into the existing assessment?

Given these constraints and guidelines, large-scale assessment research has the potential to contribute greatly to a base of scientific knowledge. There are also many examples where large-scale assessment results have been used to change educational systems and influence the direction of educational policy around the globe (see Dossey & Lindquist, 2002; Robitaille, Beaton, & Plomp, 2000; Wiseman, 2010). For instance, the term *Pisa-Schock* was coined to refer to a large and long-lasting discussion in the German political world after the results of the first PISA study showed poor student performance in Germany, which led to a wide-ranging reform agenda (Ertl, 2006). Specific outcomes included giving far greater attention to educational topics in politics and policy discussions, the introduction of national educational standards, and the formation of new curriculum development processes, which

resulted in concrete changes in testing in German schools and universities.

Similarly, the reaction to recently falling PISA scores in Japan was also dubbed “PISA shock” by the Japanese media, and it has led to a number of specific educational policy changes (Foster, 2010). These changes come in the context of a previous 10-year program of “pressure-free education” that was designed to encourage more application of knowledge and less rote memorization. Faced with criticism for PISA results indicating Japanese students were falling behind rival nations, Japanese education administrators ordered a number of changes, such as adding 1,200 pages to elementary school textbooks and adding one to two hours of school for most students. These changes are themselves facing both praise and criticism as a potential regression to the stricter, rote-memorization methods that “pressure-free education” was designed to discourage.

The German and Japanese reactions to the results from PISA were notable, but certainly not unique. To demonstrate a flavor for political and policy reactions to large-scale assessment research results from a wider spectrum, see Table 6.3 for a select number of quotes from leading figures in the United States and across the globe.

Large-scale group score assessments such as PISA have clearly had an impact, both at the level of political and educational leadership, and school policy. Along these lines, and based on the advances and accomplishments made through existing studies and frameworks, we see the future of large-scale assessment research following a number of potentially fruitful paths. In particular, we highlight several approaching areas of innovation.

### ***Computer-Based Assessment***

Computerized (or electronic methods) represent the most obvious area for new and unique

**Table 6.3 Selected Reactions to PISA 2009 Results from World Leaders and Governments**

Quote	Leader	Nation	In response to	Source
“For me, it’s a massive wake-up call... have we ever been satisfied as Americans being average in anything? Is that our aspiration? Our goal should be absolutely to lead the world in education.... I know skeptics will want to argue with the results, but we consider them to be accurate and reliable, and we have to see them as a challenge to get better.... the United States came in 23rd or 24th in most subjects. We can quibble, or we can face the brutal truth that we’re being out-educated.”	Arne Duncan, Secretary of the Department of Education	United States of America	Poor U.S. ranking in PISA 2009 results	(Anderson, 2010)
“Fifty years later, our generation’s Sputnik moment is back.... As it stands right now, America is in danger of falling behind.”	Barack Obama, President	United States of America	Poor U.S. ranking in PISA 2009 results	(Dillon, 2010).
“Since 2000, Finnish reading skills have decreased somewhat.... Ten years ago, one in five youths said they did not read for pleasure. Now that figure is one in three, and 50% for boys.”	Henna Virkkunen, Minister of Education	Finland	Finland dropping from first place in PISA 2009 results	BBC, 2010)
“[Mexico] not only achieved but surpassed the goals we had set ourselves [in reading comprehension and math].”	Felipe Calderon, President	Mexico	Improved ranking in PISA 2009 results	(Oppenheimer, 2010).

approaches to large-scale group score assessment. Computer-based approaches can provide benefits in two different ways: 1) better or more efficient assessments of skills that are already widely measured, and 2) assessment of newer skills that are currently difficult or impossible to measure with paper-and-pencil approaches.

Adaptive approaches that are calibrated to a student's level of knowledge or competence are an example of how computer-based assessments can be designed to provide both more accurate measurement and a more stimulating and targeted method of measurement than traditional paper-and-pencil multiple-choice assessments that require a simple linear approach. The stimulation in this sense can come from students' ability to answer questions through a more interactive method that is based on their moment-to-moment responses.

Additional advantages of computer-based approaches to assessment include the potential to use multimedia stimuli and unique item formats; a lack of a need to store, distribute, or print test materials; the possibility of scrambling item sequences to improve security, and the potential to provide immediate results or feedback to students. An additional important benefit of computer-based assessment is its ability to capture item response-time data, which can both inform item development and serve as an important validity check. Sheuermann and Björnsson (2009) offer a more detailed discussion of these advantages, but even a brief overview is enough to demonstrate that the future of large-scale assessment research is almost inextricably tied to advances afforded by computer-based testing. Even though there are disadvantages to this approach, such as the potential for students to experience computer anxiety, and the questionable economic or practical utility of using computer-based testing across the globe (e.g., in rural areas), the potential advantages remain compelling. One approach in particular provides an advantage in promoting greater stimulation or engagement from students than do traditional paper-and-pencil methods: by the use of computer-based simulations.

### ***Simulations***

Simulations have the potential to better contextualize skills by providing real-life situations with which students can interact. In this way, the competencies or skills being assessed can be examined to give us a richer and more complete picture than typical Likert-type or multiple-choice questions.

For example, recent work at the Educational Testing Service involved the use of video-based situational judgement tests where students were asked to judge the effectiveness or ineffectiveness of specific behaviors observed in videotaped school and workplace scenarios. The contextualized scenarios provided a simulation-based method of assessment that was engaging and shown to predict achievement outcomes (Roberts et al., 2011). We believe such simulation-based approaches have promise for promoting engagement and connecting the constructs measured in large-scale studies to relatable real-life scenarios for students. Advances in simulation approaches will lead not only to better measurement, but also to better prediction of important outcomes for large-scale group score assessments.

### ***Collaboration and Exploration***

A final future area of innovation relates to the idea of collaborative or connective large-scale assessment research. Given modern technological capacities that have made collaboration and the dissemination of information more feasible than at any moment in history, we see the future of large-scale assessment research as involving further collaboration and cooperation. Along these lines, organizations and countries could ideally work together to develop concurrent assessments that complement rather than duplicate efforts, forming frameworks that allow the exploration of distinct but still vital research questions.

For example, researchers are currently exploring how NAEP data can be "cross-walked" with U.S. Census data in order to form a richer and more coherent picture of the measured constructs. These efforts specifically involve providing a more complete operationalization of socio-economic status than is currently provided by the NAEP questionnaire. Future collaborations along this line can allow for data sets to complement one another, and communicating in this way can provide a great benefit for analysis and conceptualization of important antecedents of student achievement.

NAEP also provides a specific tool that we see as representing an emblematic and extremely promising direction for the use and dissemination of large-scale assessment data: the NAEP Data Explorer (NDE). The NDE is a freely available online tool that allows for researchers to generate customized tables and graphics based on data from past NAEP administrations. Users can conduct regression analyses, compare variables, examine

trends, and otherwise freely analyze and explore the data sets in both a versatile and user-friendly way. In terms of both accessibility and transparency, we see this tool as a promising way for researchers to collaborate and more easily disseminate results from large-scale assessments, which should lead to further innovations and progress in the field of large-scale group score assessment research.

## Conclusion

The work being done in large-scale assessment studies is vital and groundbreaking, and although the chapter highlights the current innovations in the use of selected noncognitive predictors and outcomes, the authors suggest that the potential for further expansion of the outcome space in the field of international large-scale assessment research is great. The growth of noncognitive variables represents a promising avenue for future research, as evidenced by the use of such measures in PISA and NAEP. A growing consensus on the value of such measures and outcomes has formed, not just in the fields of psychology and education, but also through the work of economists such as Lindqvist and Vestman (2011), who found that noncognitive skills measured at age 18 predicted labor market outcomes such as wages and employment status for 30+-year-olds. In fact, noncognitive predictors outperformed cognitive predictors of these outcomes by as much as a factor of three, providing further evidence that such constructs can no longer be ignored in future large-scale assessment research.

Overall, we believe that the use of sound conceptual and methodological frameworks and an expanded set of cognitive and noncognitive predictors and outcomes can allow international large-scale assessment studies to be improved for the future. In this chapter, we have attempted, albeit in a limited amount of space, to present at least a broad overview of the past, present, and future of large-scale group score assessments. From the landmark studies of 1955, to the modern research of today, we hope that we have outlined how the work in NAEP, TIMSS, PISA, PIRLS and a host of additional assessments has contributed immensely to our knowledge of student performance across the globe. As we have argued, the results of large-scale assessment research has had an impact on schools and children from Washington to Hong Kong, and by understanding the history of this work, we will be able to better prepare a plan for future research that will benefit both science and practice.

## Author Note

# Testing, Assessment, and Cultural Variation: Challenges in Evaluating Knowledge Claims

Craig L. Frisby

## Abstract

The academic and psychometric literature is filled with many competing knowledge claims related to the confidence with which cognitive and personality tests can be selected, administered, and interpreted with test-takers from culturally diverse groups. There are three broad sources of knowledge claims that can inform consumers about the appropriateness of test usage with individuals from culturally different examinees: (1) conclusions drawn from high-quality empirical research, (2) claims and criticisms embedded in sociopolitical ideologies and crusades, and (3) ethical and legal professional testing standards. Major claims from each of these sources are identified and summarized, followed by an analysis of the compatibility and conflict between information emanating from these knowledge sources.

**Key Words:** cognitive and personality testing, assessment, legal and ethical test standards, cultural groups, test bias

There is no shortage of resources purporting to raise awareness among professionals concerning how the design, administration, and interpretation of psychological tests may need to be altered in light of ethnic, racial, or language subpopulation differences both within and between countries (e.g., Grigorenko, 2009; Hambleton & Li, 2005; Kaufman, 2005; Reynolds & Lowe, 2009; Suzuki & Ponterotto, 2008; Valencia & Suzuki, 2001).

Most writing on this topic begins with the implicit assumption that test usage, scoring, and administration with culturally diverse groups is fraught with certain dangers, which need to be understood in order for test users to use tests fairly. What is rarely discussed are the sources of the knowledge claims from which test users derive their information; their credibility, and how these sources may sometimes reinforce or contradict each other.

The purpose of this chapter is twofold. First, the essential characteristics of three sources for

knowledge claims about the development, administration, and interpretation of psychological tests for “culturally diverse” groups will be discussed. No knowledge source exists in a vacuum, but rather influences, and is influenced by, other sources. Second, the interrelationships between these three sources for psychological test knowledge claims (as these relate to test use with culturally diverse groups) are discussed. The chapter ends with concluding thoughts and suggestions for professionals who use psychological tests.

## Sources for Knowledge Claims About Psychological Tests and Culturally Diverse Groups

Knowledge claims about the use of psychological tests with culturally diverse groups arise from three primary sources: (1) converging conclusions drawn from high-quality empirical research, (2) tenets embedded within sociopolitical ideologies, and

(3) ethical and legal professional standards related to the use and interpretation of tests and assessments with individuals from culturally diverse groups.

### ***Conclusions from High-Quality Empirical Research***

When investigators are described as engaging in “high-quality” empirical research, this means that a body of techniques, referred to collectively as the *scientific method*, is used to investigate naturally occurring phenomena, test hypotheses, acquire new knowledge, correct misconceptions or inaccuracies in existing knowledge bases, and integrate disparate pockets of previous or existing knowledge (Maxim, 1999). Research is labeled as “scientific” when evidence (data) is measurable and observable; clearly articulated hypotheses are formulated and subsequently tested using a wide variety of experimental designs and the statistical analysis of data. Parallel to this process, well-supported hypotheses (independently investigated) coalesce to form *theories*—which, in turn, guide the formulation of new hypotheses and the collection and statistical analysis of new data. Good theories enable predictions to be made, which in turn help researchers interpret their research findings within a meaningful context. Scientific research is contrasted with “unscientific” methods for formulating knowledge claims, which include (but are not limited to) appeals to authority, popular opinion, ideological biases, custom and tradition, or wishful thinking (Ruggiero, 2001).

Although investigator bias and errors (i.e., in the interpretation of results) are present to some degree in most empirical research, they are kept to a minimum partly through rigorous methodology (e.g., randomization of participants within samples), as well as through allowing one’s data to be open for scrutiny by other scientists who have no personal or ideological stake in the outcome of the investigations. As studies are repeated over time by different researchers, in different locations, and with different samples—and the same pattern of findings begins to reliably emerge (and studies designed to test rival hypotheses consistently fail to support them)—then such findings gradually move from speculation into the arena of scientifically established facts.

### ***Methods for Assessing Cultural Bias in Psychological Tests***

There are a variety of statistical methods that have been used to investigate test bias. Rigorous empirical investigation of test bias begins first with

a clear definition of what bias *is not* (which includes the identification of incorrect methods of determining bias). A test is not to be considered biased simply from (1) observation of group differences in the mean or variability of scores on tests; (2) subjective negative judgement of the content of particular test items; or (3) criticisms directed at the constitution of a test’s standardization sample (Jensen, 1980; Reynolds & Ramsay, 2003).

Consistent with the principles discussed previously, “cultural bias” has been defined conceptually as the effects of *construct-irrelevant variance* on examinees’ performance/responses on all or parts of tests (AERA, APA, & NCME, 1999). “Construct irrelevant variance” refers to something that is measured by a test that is irrelevant to the construct that the test was designed to measure, thereby creating a contaminating source of individual differences in scores. If select subgroups differ significantly in a construct that is irrelevant to what the test purports to measure, then there could be “systematic errors in the predictive validity or the construct validity of test scores of individuals that are associated with the individual’s group membership” (Jensen, 1980, p. 375). Consistent with the principles discussed previously, the scientific investigation of test bias is a “purely objective, empirical, statistical, and quantitative matter entirely independent of subjective value judgements and ethical issues concerning fairness or unfairness of tests and the uses to which they are put” (Jensen, 1980, p. 375).

Psychometricians and researchers use empirical methods (some more sophisticated than others) to investigate bias in tests that are tailored to the particular research question under investigation. First, two or more racial, ethnic, language, social class, or gender groups are identified for comparison. The examination of *content bias* refers to investigating the possibility that certain groups may be unable to correctly answer test questions due to a “lack of access” to skills or knowledge necessary for successful completion (Reynolds & Carson, 2005). Content bias questions are investigated by identifying:

- (1) significant differences between groups in the rank order of test item difficulties;
- (2) significant Group X Item interactions identified by Analysis of Variance and related techniques;
- (3) significant differences in Item X Group correlations when the influence of group membership on the total test score is removed (partial correlations); or

(4) differential item functioning (or DIF), identified through the examination of item-characteristic curves and model parameters in large samples (or contingency tables when sample sizes are limited; see Nandakumar, Glutting, & Oakland, 1993; Reynolds & Carson, 2005, for a more detailed discussion).

*Construct bias* occurs when a particular test is discovered to measure different psychological constructs for one group than for another, or to measure a trait with significantly reduced accuracy for one group compared to another (Reynolds & Carson, 2005). Construct bias questions are investigated by:

(1) conducting factor analyses (exploratory or confirmatory) separately for different groups under investigation, in order to determine if a different factor structure emerges for one group compared with another;

(2) correlating the factor loadings on the same test between pairs of groups, in order to determine the degree of agreement (see Georgas, van de Vijver, Weiss, & Saklofske, 2003);

(3) comparing internal consistency, alternate forms reliability, or test-retest reliability estimates across groups; or

(4) testing for the significance of the difference in the correlation, conducted separately by group, between age differences and raw test scores (see Reynolds & Carson, 2005, for a more detailed discussion).

*Predictive/criterion bias* occurs whenever there is a statistically significant difference between groups in the slopes, intercepts, or standard error of estimates of each groups' regression lines when test scores (corrected for unreliability) are used to predict a criterion. When test scores that are not corrected for unreliability are used, then predictive bias can be identified in significantly different regression slopes and standard error of estimates (see Jensen, 1980, for a more detailed discussion). Path analysis can be used to investigate bias in relation to multiple independent and dependent variables (both of which may involve test scores). Whenever group membership is systematically related to residual variance after model-based variance is accounted for, bias is present. In a typical application of path analytic techniques, when group membership exerts a significant influence on ability test scores over and above the influence expected from the latent variable (e.g., true ability), bias is suggested (see Reynolds & Carson, 2005, for a more detailed discussion).

*External sources of bias* have been defined as "[biases] that do not involve the test per se, but result from factors in the external testing situation that interact with individual or group differences to produce a systematic bias in the test scores of individuals or groups" (Jensen, 1980, p. 589). Such sources include, but are not limited to, examinee factors (e.g., effects of anxiety level, test sophistication, prior practice, behavior during the testing session); examiner factors (e.g., effects of examiner race, rapport-building efforts, coaching procedures); test administration and scoring (e.g., language of test administration, administration of reinforcers, waiving of time limits for speeded items); or characteristics of the testing environment (e.g., room lighting, ventilation).

## **Personality and Behavior Assessment**

The assessment of mental ability involves examinees' being asked to recall information, recognize correct answers, or solve problems in response to test items (i.e., tasks, problems, questions) that are scored along a continuum of quality, or are scored as correct/incorrect, or scored as pass/fail, and that may or may not be timed. Here, examiners can observe directly the extent to which examinees can or cannot obtain scores (to a given criterion) on prescribed tasks (see additional criteria for categorizing ability measurement in Jensen, 1998, p. 51).

In contrast, the assessment of personality or behavioral constructs involves ratings of the presence, absence, and/or frequency of behaviors, thinking, feeling, or attitudes observed in oneself or in others in multiple settings. Personality and behavioral constructs do not have a general factor, but are typically reported as profiles of (positively or negatively) correlated subscales.

As with cognitive assessment, bias in personality/behavioral assessment cannot be defined simply on the basis of observed differences between subgroups in mean scores or subscale profile elevations, scatter, or shapes (Timbrook & Graham, 1994). Scale construction concerns related to linguistic equivalence, construct equivalence, psychological equivalence, and psychometric equivalence are applicable to personality/behavior scales as well (Butcher, Cabiya, Lucio, & Garrido, 2007; Graham, 2006; Reid, 1995).

However, it remains unclear how significant subscale profile differences between ethnic/racial/language subgroups should be interpreted. Some writers argue that subscale profiles can only be interpreted properly in the context of a standardization group

that has the same demographic characteristics as the target child/youth (Butcher et al., 2007). This argument implies that the interpretation of a construct (along a continuum from “normality” to “clinical relevance”) has no objective anchor, but is instead to be interpreted relative to a “cultural” group.

Additionally, the determination of bias in personality/behavioral assessment becomes more salient given the potential subjective nature of raters’ judgements. “Lie” scales are integrated into many personality scales in order to objectively assess this issue. The assessment of bias becomes complicated when comparing differences in ratings across different informants (e.g., mother vs. father). Here, it is difficult to discern whether rating score differences are due to errors in informants’ judgements, or due to actual differences in the target child/youth’s behavior in different settings.

Perhaps the strongest methodology for determining bias in personality/behavior assessment involves correlating scores on these scales with external criteria, and evaluating the statistical significance of the magnitude of the correlation differences across subgroups of interest (Graham, 2006).

### **Testing Adaptations Across Widely Divergent Cultural Groups**

When tests are used in two or more groups separated by examinees’ spoken language and/or continent of habitation, test developers must adhere to established guidelines in test adaptation to ensure that factors that have a deleterious effect on test interpretation be kept at a minimum (e.g., see Georgas, Weiss, van de Vijver, & Saklofske, 2003). Sireci, Patsula, and Hambleton (2005) articulate a crucial distinction between the oft-confused concepts of “test translation” and “test adaptation.” The former term refers more narrowly to the application of linguistic skills and knowledge to rewrite the purely verbal components of test items in order to enable one or more language groups to understand a test originally designed for a different language group. In contrast, the concept of “test adaptations” refers to a broader class of activities that Hambleton (2005) defines as:

includ(ing) all the activities from deciding whether or not a test could measure the same construct in a different language and culture, to selecting translators, to deciding on appropriate accommodations to be made in preparing a test for use in a second language, to adapting the test and checking its equivalence in the adapted form. (p. 4)

The following four principles for adapting tests for use in widely divergent cultural groups have been established by large international testing associations and organizations with extensive experience in field settings (see Hambleton, Merenda, & Spielberger, 2005):

### **ENSURING CONSTRUCT EQUIVALENCE**

Johnson (1998) summarizes more than 50 terms found in the social science literature for describing different types of “equivalence” that are of concern to cross-cultural researchers. In adapting and/or translating a test used in one cultural context to a different cultural context, the psychological construct measured by the test must be conceptually and functionally equivalent across groups. Although Hambleton (2005) opines that subjective judgement (usually by “expert” judges representing language/cultural groups) can play an important role in evaluating construct equivalence (e.g., see Hui & Triandis, 1985), the use of subjectivity in evaluating construct equivalence has been abused in the assessment literature (see next section on sociopolitical ideologies/crusades).

Individual test items can have a straightforward translation to a linguistically different population, but not have an equivalent *psychological* meaning in the different population. For example, a cognitive ability test used in America may include a general information question related to an American historical figure, but the same question translated for a Dutch population may, understandably, have a significantly higher difficulty (van de Vijver & Poortinga, 2005). Put another way, failure to respond correctly to such an item may have implications for the construct of intelligence in an American sample, whereas the same failure in a Dutch sample has little significance in assessing the intelligence construct.

### **TEST ADMINISTRATION PROCEDURES**

Test administration procedures, such as those found on individually administered nonverbal scales of cognitive ability (e.g., Bracken & McCallum, 1998), must necessarily involve substantial modifications (such as the use of pantomime instructions rather than verbal instructions) in order to accommodate substantially diverse test-takers. Such procedures are consistent with the intended purposes of the test, and are appropriate provided that test administration is standardized for all examinees. However, some writers advocate that administration procedures for the same test be altered (e.g., removal of time constraints on timed tasks, additional

repetition or alteration of test instructions to ensure comprehension, acceptance of unconventional responses to test items) for certain subgroups but not for others (Armour-Thomas & Gopaul-Mcnicol, 1998; Elliott, 1987; Gopaul-Mcnicol & Armour-Thomas, 2002). Unfortunately, when test administration procedures are not standardized for all examinees, an additional source of variance in test scores is potentially introduced that undermines test score reliability (Mpofu & Ortiz, 2009).

## TEST CONTENT

According to Hambleton (2005), “choice of item formats, stimulus material for the test, vocabulary, sentence structure, and other aspects that might be difficult to translate well can all be taken into account in preparing the test specifications. Such preventive actions can minimize later problems” (p. 10). Examples of such situations are isolated and unique to specific cultural applications, and do not form a coherent pattern of universal principles. For example, Serpell (1979) found that, when compared to British children, African Zambian children were better able to reproduce patterns using wire models—while British children were better able to reproduce models using pencil and paper drawings. This finding is interpreted to suggest that the construct of “perceptual skills,” assessed via pattern recognition, is best understood using response modes that are most familiar to a particular cultural group. For a more detailed discussion of ability test content adaptation factors that must be addressed in cross cultural work (particularly with developing countries), see Frisby (1999b).

Exploratory factor analysis, confirmatory factor analysis, and multidimensional scaling methods are typically used to examine factorial and/or structural similarity of the same test items across culturally different populations (e.g., see Byrne, Shavelson, & Muthen, 1989; Little, 1997; Sireci, Patsula, & Hambleton, 2005; van de Vijver & Leung, 1997; Watkins, 1989). When one-to-one correspondence in item loading patterns cannot be reasonably expected across test adaptations for groups that differ widely in cultural milieus, then the correlations between a target measures’ total score and total scores for other similar or different measures (within the cultural milieu) must be examined (van de Vijver & Poortinga, 2005).

## TEST TRANSLATION/ADAPTATION ISSUES

When tests or other assessment instruments (such as rating scales, surveys, and questionnaires)

are translated and/or adapted to a widely differing cultural group, a number of potential problems have been identified from field observation and research. Hambleton and Kanjee (1995) discuss a variety of potential sources of problems that can occur during the selection and training of translators, as well as the linguistic difficulties that can occur when “forward-adaptation” and “back-adaptation” designs are used. Depending upon the cultural groups studied, the extent to which a source test/assessment instrument must be altered in the test adaptation process (which involves broader issues in addition to linguistic translation) varies along a continuum of least to most alterations (van de Vijver & Poortinga, 2005). At one end of the translation/adaptation continuum, test items can be linguistically translated with no loss of literal meaning and no alteration of psychological meaning. Test stimuli and procedures for administering the test remain intact. Toward the middle of this continuum, there are occasions where a literal linguistic translation of a test item does not yield equivalence in psychological meaning across two or more groups (see van de Vijver & Poortinga, 2005, p. 41, for specific examples). In these instances, the item may need to be discarded, or its translation may not match exactly the literal translation from the target source. In addition, some elements of the test instructions and/or use of examples may need to be modified somewhat (e.g., see Elbeheri, Everatt, Reid, & Mannai, 2006; Georgas, Weiss, van de Vijver, & Saklofske, 2003). Toward the opposite end of the continuum, the construct to be measured and the method for measuring it may be so inappropriate for translation from one group to another that the test developer finds it necessary to develop an entirely new instrument (see van de Vijver & Poortinga, 2005, p. 54, for a discussion of the “assembly option”). For example, Kathuria and Serpell (1999) discuss the development and use of an ability test for rural African Zambian children that requires constructing a representation of a human figure from wet clay.

## *Psychological Testing with Culturally Diverse Groups: Empirically Established Conclusions*

The accumulation of evidence resulting from the application of these principles to the interpretation of the cognitive ability test performance of culturally diverse groups is substantial (e.g., see Chen, Keith, Weiss, Zhu, & Li, 2010; Edwards & Oakland, 2006; Frisby, 1999a, 1999b, 2007; Georgas, Weiss, van de Vijver, & Saklofske, 2003; Gottfredson, 1997,

2005; Graham, 2006; Herrnstein & Murray, 1994; Jensen, 1980, 1991, 1993, 1998, 2003; Jencks et al., 1979; Konold, Glutting, Oakland, & O'Donnell, 1995; Kush et al., 2001; Lynn & Vanhanen, 2002; Nandakumar, Glutting, & Oakland, 1993; Rushton & Jensen, 2005; Reynolds & Kaiser, 2003; Reynolds & Lowe, 2009; Reynolds & Ramsay, 2003). The most salient of these results are briefly summarized below:

1. An examination of the “surface” characteristics of test items, by itself, provides little insight into the nature of the fundamental source of individual differences in scores on the full test battery (see discussion of “the indifference of the indicator,” Jensen, 1998).

2. Although a variety of mental abilities exists, it is the general mental ability factor, or “*g* factor,” that is the most fundamental source of individual differences in human cognitive abilities. The *g* factor accounts for a third to half of the variance in scores on any broad battery of mental tests.

3. Despite relatively minor imperfections, commonly used individually administered IQ tests are very good measures of the *g* factor. The average *g* loading of IQ scores derived from a variety of standard IQ tests is in the .80s.

4. IQ test batteries given to a wide variety of ethnic, racial, age, and gender groups reveal measurement of the same general and specific ability factors. In addition, these same constructs are measured equally well in all ages under examination.

5. The same *g* factor has been empirically shown to be responsible for intellectual variation in North American, European, Asian, and African groups.

6. Although all human groups display a wide range of IQ scores, racial/ethnic subgroup differences in the mean (and to a lesser extent, the standard deviation) of their IQ score distributions is the rule, not the exception, worldwide.

Subgroup differences remain (although to a slightly reduced degree) even when social class is controlled or when the tests are completely nonverbal. Differences between American subgroups in mean IQ distributions have been observed in samples as young as 2.5 years of age on well developed standardized tests. In the United States and other developed nations, the mean IQ of Blacks, Hispanics, Native Americans, Whites, and East Asians is approximately 85, 90, 90, 100, and 106, respectively (assuming an IQ score distribution with a mean of 100 and a standard deviation

of 15). Even finer subgroup distinctions among these broad groups may differ slightly in mean IQ.

7. The use of completely nonverbal tests in individual cognitive assessment (where the test stimuli are completely pictorial, directions are pantomimed by the examiner, and the examinee is not required to verbalize responses) continues to reveal smaller but reliable average racial/ethnic subgroup differences in total test scores.

8. Whenever statistical methods for detecting item bias in cognitive and ability tests are used (e.g., see Camilli, 2006; Reynolds & Carson, 2005), the amount of bias found is so slight and unsystematic across items as to be totally inadequate in accounting for large group differences in mean total test scores.

9. When examiners rate the testing behaviors of examinees using a behavior rating scale standardized on a specific IQ test, such rating scales reveal slight but non-significant group differences when the correlation between test session behavior ratings and IQ scores are removed (some of which show lower-scoring IQ groups displaying more *favorable* testing behavior). That is, behavioral ratings across racial/ethnic groups do not differ significantly with respect to qualitatively distinct categories of more positive or negative testing behaviors.

10. The *g* factor measured by cognitive tests is significantly and negatively correlated with such social problems as school dropout rates, poverty and welfare status, illegitimacy, delinquency, and crime. Thus, racial/ethnic group differences in these importance life outcomes are significantly correlated with racial/ethnic group differences in the *g* factor measured by cognitive tests. Performance on appropriately developed cognitive tests predict learning ability in school, academic and intellectual achievements during childhood and adolescence, and other important adult life outcomes equally well for all racial/ethnic groups.

### ***Knowledge Claims from Sociopolitical Ideologies/Crusades***

A second source for what many believe about test usage and interpretation with culturally diverse groups originates from the influence of sociopolitical ideologies that have come into vogue during various periods in history (Heywood, 2010; Phelps, 2009). These sociopolitical movements lay the groundwork for negative attitudes toward test use in education and psychology. At the time

of this writing, “multiculturalism” is arguably the most pervasive sociopolitical ideology in education (Webster, 1997) and psychology (Pedersen, 1999), which in turn influences perceptions of psychological testing.

*Multiculturalism* is a sociopolitical ideology that is ubiquitous in contemporary education and applied psychology. There exists little consensus among explicit definitions for multiculturalism, as these vary considerably as a function of each writer’s philosophical perspective. Nevertheless, it is easier to distill multiculturalism ideology down to a smaller number of component doctrines, each of which contributes substantially to explaining beliefs and practices associated with cultural minority groups and testing. The component doctrines of multiculturalism ideology (for an expanded treatment, see Frisby, 2005a, 2005b), followed by their application to testing, are given in the next section.

### ***Multiculturalism Doctrines and Testing***

According to the *Group Identity Doctrine*, individuals are characterized as little more than representatives of “identity” groups defined by race, ethnicity, national origin, language, social class, or religious status. This doctrine assumes that knowledge of an individual’s group membership is important for understanding the psychology of the individual, and conversely, that the psychology of individuals is inextricably tied to relevant information about their identity group. Thus, when testing texts encourage professionals to be “culturally competent” test users, directives are couched in the context of test usage with particular “groups” (as opposed to individuals). The following quote typifies this doctrine (Butcher et al., 2007):

As for criterion validity, test users must be aware of the potential for differential prediction. This may occur when the relationship between the predictor (test score) and the criterion is significantly different between groups. This may indicate that a test is invalid for a given group and that a different instrument altogether may be needed for that group. (p. 15)

As typified in this and numerous other statements from the testing literature, the individual examinee’s group membership is viewed as the only necessary and sufficient condition for invalidating (or validating) test usage for that particular examinee. Following this logic, test critics can therefore explain any behavior during testing as being attributable to a person’s group membership. Thus, if an

examinee from a racial/ethnic minority group fails to answer correctly a question on an IQ test, the test critic can claim (on the basis of the Group Identity Doctrine) that cultural processes associated with his/her group membership are probably responsible (see Helms, 1992, 1997).

Testing ethics and standards documents (e.g., AERA, APA, & NCME, 1999) promote the Group Identity Doctrine through the implicit assumption that the design of national standardization sampling and stratification schemes or results from test-bias studies have direct implications for the appropriateness of test use with individuals belonging to identity groups on which such research is based (e.g., see item #5 under Interpretation and Application of Assessment Results, Association for Assessment in Counseling, 2003). For a related discussion of these issues and “test fairness,” see discussion of the “social address model” in Camilli (2006).

Once identity groups have been defined, the *Difference Doctrine* assumes that such groups display unique, “culturally specific” thinking patterns, attitudes, and behaviors that are more or less homogeneous within groups and mutually exclusive between groups. Test critics use this doctrine to promote three distinct messages: (1) the latent psychological constructs measured by commercially popular intelligence or personality tests are presumed not to have the same meaning for different cultural groups (Armour-Thomas & GoPaul-McNicol, 1998; GoPaul-McNicol & Armour-Thomas, 2003; Greenfield, 1997; Helms, 1997; Sternberg & Grigorenko, 2008); (2) culturally distinctive characteristics are presumed to be reliably displayed by examinees in the context of cognitive testing sessions (Helms, 1997; Kwate, 2001); and (3) as a result of the first two assumptions, the behavior of members of cultural minority groups is likely to be misunderstood, misinterpreted, and therefore “misreported” by non-minority group examiners and/or raters on psychological scales (Helms, 1992, 1997). Such claims are based solely on either speculative or anecdotal evidence (for a detailed critique, see Frisby, 1999a).

The *Equity Doctrine* is rooted in the moral imperative that cultural minority groups (1) be treated similarly to non-minority groups when served by professionals in educational and psychological settings, and (2) be represented in the same proportion as their general population numbers in desirable or undesirable social, educational, occupational, or economic outcomes in society. The first assumption is not controversial, and is a value that has nearly

universal consensus among professionals who serve cultural minority clients. The second assumption is controversial, as there exist wide differences of opinion as to whether proportional representation in outcomes is desirable or attainable.

As applied to testing, then, the *Equity Doctrine* has both “politicized” and “non-politicized” applications. In the non-politicized sense, psychometricians work hard to ensure that linguistic and psychometric “equivalence” is maintained whenever tests are used with widely differing cultural and or language groups (Hambleton, Merenda, & Speilberger, 2005). In the politicized sense, this doctrine holds that test selection and use can only be considered “fair” if identity groups display “equal” score distributions, which in turn would presumably lead to proportionally equal selection outcomes resulting from decisions that are based on test results (see Reynolds, 2000). If groups do not achieve equal score distributions, then something is assumed to be deficient in the design, interpretation, and use of tests for lower-scoring groups (see discussion of the “cultural test bias hypothesis” in Reynolds, 2000; see also Helms, 1992, 1997, 2006). As such, belief in the *Equity Doctrine* is the root cause responsible for driving most, if not all, criticisms of test use with cultural minority groups. Put another way, if it were possible for groups to obtain equal score distributions on standardized tests, then most test criticisms would literally vanish overnight.

The *Inclusion Doctrine* is best known by its most popular synonym, which is “diversity” (Wood, 2003). According to the Inclusion Doctrine, desirable outcomes that reflect an inclusion of persons representing a variety of arbitrarily defined groups are assumed to be morally, philosophically, or socially preferable than outcomes that do not.

As applied to testing, adherence to the Inclusion Doctrine is manifested in a test publisher’s rigorous stratification of a test’s standardization sample in order to most accurately represent diversity in demographic characteristics of the target population for whom the test was designed. This standard practice may (inappropriately) lead test critics to assert that tests are “biased” against certain examinees if their ethnic/racial group is not adequately represented (according to critics’ subjective standards for sufficient “diversity”) in a test’s standardization sample (Dent, 1996). For an empirical refutation of this claim, see Fan, Willson and Kapes (1996).

In addition, tests can be criticized as a selection measure if decision-making based on test scores does not lead to selection rates that are consistent with a

predetermined vision of what are “acceptable” rates of inclusion for various racial/ethnic groups (Elliott, 1987; Gottfredson, 2000; 2004a; 2004b; Jensen, 1980).

The *Sensitivity Doctrine* is the belief that researchers, educators, and applied psychological practitioners are morally obligated to avoid any research, behavior, or speech that would inadvertently “offend” members of particular ethnic/racial groups, or important individuals who style themselves as vocal “spokespersons” for a particular group. Those who violate these norms (either intentionally or unintentionally) can thus be accused of harboring nefarious motives (i.e., prejudice, racism), or are said to suffer from “cultural insensitivity” or “cultural incompetence.”

A step in the development of a potentially profitable test is for test companies to send early drafts of the test to select representatives of cultural/language minority groups for the purpose of evaluating potential “item bias” (sometimes called “sensitivity reviews”; see Bond, Moss, & Carr, 1996). Typically, reviewers are instructed to examine the surface characteristics of test items (e.g., wording of item instructions, words used in item content, item pictures depicting objects, situations, or human actors doing something) and judge the extent to which particular items may be “offensive” or “insensitive” to given groups. Although there is no empirical evidence that the judgements of ethnic-minority item review experts are more valid than those of non-minority experts (e.g., see Jensen & McGurk, 1987; Sandoval & Miille, 1980), or that potentially faulty items contribute substantially to subgroup mean differences in total test scores, test companies continue to condone such practices primarily for public relations purposes.

Writings on multicultural topics are suffused with the unspoken but palpable assumption that ethnic, cultural, or language minority status is a necessary condition for credibility and expertise on issues related to minority populations, and that those with non-minority status have a structurally imposed limitation (or inability) for understanding the culture and behavior of culturally different individuals. Thus, it is assumed implicitly that cultural minority groups have *sovereignty* in defining how psychological concepts such as “intelligence” and “psychopathology” are conceptualized, measured, and interpreted for the group of which they are designated representatives. Thus, the *Sovereignty Doctrine* assumes that ethnic, cultural, or language minority academicians have special knowledge,

unavailable to non-minority academicians, on the interaction of minority status and attitudinal or behavioral responses to test item content (e.g., see Helms, 1992, 1997).

As stated previously, the fundamental issue that fuels criticism of testing is the observation of reliable differences in cognitive test score means between representative samples of racial, ethnic, language, and socioeconomic status groups. Therefore, anti-test advocates must advance knowledge claims that generate doubt and suspicion about the manner in which tests are used and interpreted with diverse cultural groups. The essential difference between knowledge claims advanced through empirical research, versus those advanced through anti-test sociopolitical advocacy, is succinctly articulated by Gottfredson (2009), who writes:

Advocacy is different from science....For the zealous advocate, cause and effect are predetermined to serve one's interests. An advocate need not even believe a cause or effect that she claims; her goal is to persuade others to believe it. An advocate searches not for probable causes and effects but, rather, for merely plausible ones—ones that others are willing to believe...the desired outcome is neither truth nor understanding, but conversion—getting others to view a situation in a manner that serves one's own interests. (p. 250)

Evidence for Gottfredson's observation can be clearly seen in Helms' (1997) attempts to advance a plethora of "plausible" shortcomings of intelligence tests, in order to undermine confidence in their use and interpretation with African Americans. Helms lists a number of "hypothesized" biases in tests (e.g., "language and stylistic differences *may be* misinterpreted," "Examiners of a different race *may be* suspect") absent any hard data that actually document their existence empirically (see Helms, 1997, p. 521).

Sociopolitical advocacy manifests itself as a morality play pitting the forces of "good" (those who oppose "traditional" test use and interpretation with cultural minority groups) against the forces of "evil" (those who defend traditional test use and interpretation with cultural minority groups). According to Phelps (2005), "anti-testing" advocacy:

...view(s) testing generally as an impediment to reform, an antiquated technology that reflects an antiquated view of teaching, learning, and social organization, perpetuates inequality, and serves the ends of cultural, political and educational oppression. (p. xi)

The goal of sociopolitical advocacy is to sow seeds of doubt about traditional test usage and interpretation with examinees from cultural minority groups, and to advocate one or more of the following practices:

1. The complete prohibition of "traditional" test use with certain racial/ethnic groups (e.g., Williams, Dotson, Dow, & Williams, 1980), which may or may not involve the substitution of assessments that are better aligned with an ideological viewpoint, but are characterized by inferior construct measurement and/or psychometric quality (Gottfredson, 2004b).
2. Altering the manner in which "traditional" tests are administered to certain racial/ethnic groups—typified by the incorporation of unstandardized procedures such as task coaching and/or relaxed time standards (e.g., Feuerstein, Feuerstein, & Gross, 1997; Hilliard, 1987; Lidz, 1997).
3. Including subtests in multi-test IQ batteries that are constructed (either intentionally or unintentionally) to have significantly reduced loadings, which has the effect of artificially reducing the size of subgroup differences in mean total scores (Jensen, 1984b).
4. Allowing "traditional" test administration for certain racial/ethnic groups, but requiring adoption of an additional set of elaborate assessments and/or problem-solving rubrics that supplement test interpretation (e.g., Armour-Thomas & GoPaul-McNicol, 1998; Rhodes, Ochoa, & Ortiz, 2005).
5. Altering the manner in which "traditional" test scores are interpreted, most often by using group-specific norms to reinterpret the same scores differently for certain racial/ethnic groups than for other groups (see Figueroa, 1979, for an example involving children; see Gottfredson, 1994a, for application to adults).

### *An Analysis of Sociopolitical Advocacy Anti-Test Arguments*

As sociopolitical advocates gain power and influence in academia, the media, and the legal system, this ignites an "anti-testing" sentiment (e.g., see Phelps, 2003, 2005), in which "unfairness" to cultural minority groups is trumpeted as one of many negative consequences of test use. The political interests of the anti-test movement are to reduce or eliminate test use in society, and to undermine the credibility and traditional interpretation of test

scores (particularly for cultural minority groups in the context of high-stakes decision making). In attempting to accomplish these goals, the knowledge claims advanced by anti-test sociopolitical ideologies have the following characteristics:

1. *Using implicit definitions of “culture” (and its related derivatives) that are built on narrow, simplistic assumptions.* Cultural variation among human populations worldwide is extremely vast in scope and complex in its nuances (e.g., see Kitayama & Cohen, 2007). The “cultural backgrounds” of individuals are shaped by differences in parental childrearing practices, the nature of religious upbringing, political beliefs, parochial differences in the region of the country in which one is raised, a family’s economic status, as well as life experiences shaped indirectly by a person’s racial, ethnic, and language group membership. Unfortunately, the word “culture” has become synonymous with racial and ethnic status *alone*, such that persons who belong to different racial and ethnic groups are assumed implicitly to belong to homogeneous, mutually exclusive “cultural” groups. The reality is that many different “ethno-cultural groups” exist within any given racial group, and conversely, many different racial groups exist within any given cultural group. This results in a tremendous degree of overlapping in “cultural” characteristics across groups, so that any group of individuals can be thought of as being *both* culturally different *and* culturally similar *simultaneously*. On the basis of this misunderstanding, test critics continue to promote the belief that average group differences in mean scores across broad ethnic/racial groups imply that tests are deficient in their sensitivity to “cultural differences” (which implies that if they were “sensitive,” then such group differences would not exist; see Helms, 1992).

2. *Asserting that a history of test criticism is in itself sufficient for doubting the efficacy of testing.* Critics merely state that “traditional” test use and interpretation with culturally different groups have been vigorously criticized in the past (either because tests do not measure up to some standard of perfection, or that test use with such groups has been “controversial”), and that this fact alone justifies either discontinuance of test use with such groups, or the preferred use of some alternative assessment/test interpretation method (e.g., see Armour-Thomas, 1992; Valencia & Suzuki, 2001). The unspoken implication here is that the absence

of criticism (and/or controversy) is a sufficient standard for approving the use of a particular assessment method with cultural groups. Test critics who use this method fail to inform their audiences of the next logical step, which is to *evaluate* the quality of test criticisms in order to determine whether such criticisms are indeed valid.

3. *Portraying established empirical findings as inconclusive or “open” to debate or alternative interpretations.* Many test critics reluctantly acknowledge that well standardized tests are not technically “biased” as gleaned from the accumulation of test bias research, yet will evoke the subjective criterion of “cultural equivalence” as grounds for criticizing commonly used tests (Helms, 1992, 1997; Valencia & Suzuki, 2001). Given the complexity of the culture concept (see previous point), such hypotheses are literally impossible to test or evaluate in a conceptually coherent or empirically rigorous manner. Not only do “cultural equivalence” explanations fail to explain differential gaps in test performance that very as a function of test characteristics (parsimoniously explained by Spearman’s hypothesis; see Jensen, 1998), but no adequate “cultural equivalence” explanation has been advanced to explain the bewildering pattern of slight and unsystematic DIF (differential item functioning) findings in individual items on cognitive and achievement tests (Bond, 1994; Reynolds & Lowe, 2009).

4. *Advancing anti-test arguments riddled with cognitive or logical fallacies.* As previously mentioned in the Gottfredson (2009) quote, the goal of anti-test advocacy is to generate distrust and hostility toward tests through verbal persuasion. When coupled with an ignorance of the empirical literature, naïve audiences are susceptible to this persuasion when they are either unwilling or unable to identify the cognitive or logical fallacies inherent in common arguments against testing. A sampling of anti-test arguments, and their associated logical/cognitive fallacies, are shown in Table 7.1.

5. *Selective reporting of research results.* Sometimes preliminary empirical findings superficially appear to support a desired interpretation, but upon closer inspection such findings are either unpersuasive, misinterpreted, or have not been replicated by a systematic program of empirical research (e.g., see discussions of “stereotype threat” research in Jensen, 1998; Sackett, Hardison, & Cullen, 2004). Sociopolitical

**Table 7.1 Common Cognitive/Logical Fallacies Associated with Psychological Test Development, Administration, and Interpretation/Usage with Culturally Diverse Groups**

Cognitive/ Logical Fallacy	Definition	Citations Illustrating Advocacy for the Fallacy	Citations Identifying and/or Refuting the Fallacy
<b>Psychological Test Development</b>			
“Vehicle Equals Construct” Test Design Fallacy	Superficial characteristics of test items reflect the inner essence of the construct they measure	Helms (1992); Kwate (2001); Sternberg, Wagner, Williams, & Horvath, 1995	Gottfredson (2009); Jensen (1984a; 1998)
Guilt by Association	Some test researchers and developers in the past have held or voiced offensive ideas about the capabilities of minority groups, therefore modern test interpretation and usage is motivated by the same ill-will toward minority groups	Gould (1996) Valencia & Suzuki (2001)	Jensen (1982)
Standardization Fallacy	If the standardization sample for a test is not composed of a sufficient percentage of a given subpopulation, it is, by this fact, “biased” or “unfair” when used with that subpopulation	Dent (1996)	Fan, Willson, & Kapes (1996); Jensen (1980)
<b>Psychological Test Administration</b>			
Behavior Generality Fallacy	“Cultural” behaviors presumed to occur outside of the test administration context are reliably manifested within the test administration context	Helms (1997)	Glutting, Oakland, & McDermott (1988)
Outgroup Homogeneity Bias	Groups that are not English-speaking, white, and/or middle class are believed to manifest homogeneous behavioral/cognitive tendencies, particularly during test administration	Helms (1997); Kwate (2001)	Camilli (2006); Frisby (1999a); Frisby & Osterlind (2007); Mullen & Hu (1989)
<b>Psychological Test Interpretation/Usage</b>			
Dangerous Consequences Fallacy	Scientific conclusions judged to be socially divisive (e.g., group differences in intelligence) are so dangerous that they should not be entertained until proved beyond all possible doubt	(See discussion of unnamed sources in Gottfredson, 1994b)	Gottfredson (2007, 2009)
Appeal to Non-equivalent Exemplars	Wide differences between two culturally distinct groups (in test validity) justifies the <i>a priori</i> assumption of wide differences between any different pair of culturally distinct groups	Greenfield (1997)	Frisby (1999a)
Standard of Evidence Fallacy	Valid, unbiased cognitive ability and academic achievement tests should not be used for making decisions about individuals until the tests are made “error-free”	FairTest (2007)	Gottfredson (2009)
Egalitarian Fallacy	If population subgroups do not show equal distributions of test scores, then the test is “biased” in favor of the higher-scoring groups and against lower-scoring groups	Alley & Foster (1978); Williams (1971)	Jensen (1980); Rushton & Jensen (2005)

(continued)

Table 7.1 (Continued)

Cognitive/ Logical Fallacy	Definition	Citations Illustrating Advocacy for the Fallacy	Citations Identifying and/or Refuting the Fallacy
Confirmation Bias	If minority groups achieve lower scores on cognitive tests after being given anxiety-producing directions, then this presumably illustrates “stereotype threat,” and is assumed to not reflect real differences in the trait measured	Steele & Aronson (1995, 1997)	Jensen (1998; pp. 513–516); Nickerson (1998); Sackett, Hardison, & Cullen (2004)
Culture-Bound Fallacy	Test “bias” or test “unfairness” can be determined subjectively by a visual inspection of specific test items	Helms (1992, 1997)	Jensen (1980); Jensen & McGurk (1987); Sandoval & Miille (1980);
Specificity Doctrine	Intelligence tests measure isolated bits of knowledge gained from prior learning and experience; therefore group differences in intelligence test scores merely reflect different opportunities to acquire such knowledge	Eells, Davis, Havighurst, Herrick, & Tyler (1951); Dent (1996)	Jensen (1984a, 1992a, 1992b)

ideologies highlight research findings that appear to support the ideology, which in turn presents a dilemma for how to handle research results that do not support the ideology. Typically, contrary research results are summarily dismissed or ignored. When research that is favorable to testing is overwhelming, however, the problem for sociopolitical ideologies is doubled (Gottfredson, 2000).

*6. Advancing hypotheses or knowledge claims that are impossible to test or evaluate empirically.* Some have suggested that the scientific community should remain agnostic about the very existence of the construct of intelligence until everyone agrees on its definition (see Armour-Thomas & GoPaul-McNicol, 1998; Sternberg & Grigorenko, 2008), a condition that has never existed (Thorndike, 1921; Sternberg, 1985; Sternberg, Conway, Ketron, & Bernstein, 1981; Sternberg & Detterman, 1986) and will most likely never exist. Similarly, Helms (1992) makes the argument that test developers have not conducted adequate research to investigate the extent to which test items have a different “cultural meaning” for different racial and ethnic groups—which, in her view, will presumably enable tests to have “cultural equivalence.” Ignoring the fact that cognitive tests continue to show the same degree of predictive validity for English-speaking American-born groups (Gottfredson, 2005; Jensen, 1998)—such a proposal assumes (1) a (heretofore elusive) consensus among researchers on the meaning and measurement of

“culture,” and (2) that it is somehow possible to assign cultural “meaning” to individual test items.

*7. Quick promotion of “alternative” assessment techniques before they have been thoroughly vetted.* “Alternative” test procedures burst on the scene with much fanfare and hope for equalizing score distribution outcomes for subgroups. As examples, the System of Multicultural Pluralistic Assessment (SOMPA) was touted in the late 1970s as a fairer method of taking into account “sociocultural” variables in assessing cognitive functioning of different American subgroups (see Figueroa, 1979). Similarly, the Learning Potential Assessment Device (Feuerstein, Rand, & Hoffman, 1979) was marketed in the 1980s as an innovative “paradigm shift” in assessment that incorporated “innovative” theories of structural cognitive modifiability and mediated learning (Feuerstein, Feuerstein, & Gross, 1997). At the time of this writing, both of these assessment methods have largely disappeared from the psychometric scene, having been exposed to withering conceptual and empirical criticisms by researchers and disappointing outcomes from field research (Frisby, 1992; Glutting & McDermott, 1990; Goodman, 1979; Oakland, 1979; van de Vijver & Phalet, 2004; Wurtz, Sewell, & Manni, 1985). Whenever this happens, however, there is no corresponding well-publicized explanation from authors as to why the “innovative” method failed, or any attempt to revise the underlying theory. As time passes, another highly publicized “fad”

quickly captures the public's interest as a promising challenge to traditional testing.

8. *Generating fear of real or imagined negative social consequences of high stakes testing for culturally diverse minority groups.* Whether intentionally or unintentionally, test critics communicate the message that the general public has something to fear when tests are used with cultural minority groups, particularly those who tend to score lower relative to other groups (e.g., Samuda, 1998). Hale-Benson (1986) claims that, unless the "black community" of educational and psychological scholars discover their own "culturally specific" methodologies for defining and using intelligence tests for black children, the dire consequences will be that "the majority of black children...[will] continue to struggle through special classes, educable mentally retarded labels, SAT and GRE scores to make it in this society" (p. 4). Skiba, Knesting, and Bush (2002) acknowledge that the empirical research demonstrating significant test bias for African Americans is weak. Thus, they seek sources of racial bias in various aspects of public schooling (e.g., curricula, teacher expectations, school discipline practices), for fear that disproportionate results from IQ testing may lead to "a conclusion of unequal ethnic aptitude" or "genetic inferiority" (p. 66).

### ***Ethical/Legal Professional Standards***

Psychologists, educators, test developers, and researchers are represented by one or more professional organizations who advocate that tests be used responsibly, ethically, and within legal guidelines with examinees from culturally diverse groups. *Ethics* generally refers to "a system of principles of [appropriate] conduct that guide the behavior of an individual" (Jacob & Hartshorne, 2007, p. 2), and the application of ethical principles to problems that arise in professional practice is called *applied professional ethics* (Beauchamp & Childress, 2001). Applied professional ethics principles for test construction, interpretation, and use are generally embedded in professional ethics codes and professional standards documents—or are found in separate "stand-alone" documents that specifically govern testing. Such documents serve the dual purpose of protecting the public and promoting the self-interests of the profession (Jacob & Hartshorne, 2007).

Professional ethics codes involving testing and cultural minority groups are not bound by law. However, many ethics codes require professionals to know and respect the law, generally, as well as specific

law that is applicable to their professional areas. At times, professional ethics codes may advocate adherence to decisions that are more stringent than those required by law (Jacob & Hartshorne, 2007).

At the time of this writing, perhaps the most well-known document that outlines criteria for evaluating test development, the psychometric properties of tests, and test use is *Standards for Educational and Psychological Testing*, published by the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education (AERA, APA, & NCME, 1999). In addition, there are a variety of professional standards and guidelines for test use that are associated with professional organizations for psychologists, counselors, and test publishers (see p. 105 in Phelps, 2007; Exhibit 2, p. 7, in Phelps, 2009). The most well-known ethics and "best practices" guideline documents governing test use for educators, psychologists, and counselors—as these interface with cultural/ethnic minority groups—are given in Table 7.2.

### ***General Themes in Professional Ethics Codes Governing Test Use with Ethnically and Linguistically Diverse Populations***

As derived from documents listed in Table 7.2, guidelines for selecting, using, and interpreting tests for diverse groups generally fall into three categories: (1) practices that are encouraged, (2) practices that are to be avoided, (3) and areas in which "caution" is required. Although recommendations in testing ethics documents are often suggested for test developers (e.g., see Standards 7.1, 7.3, 7.4, 9.2, 9.4, 9.6, 9.7, and 9.9 in AERA, APA, & NCME, 1999) and test researchers (e.g., see Standard 7.6 in AERA, APA, & NCME, 1999), only recommendations for test users are discussed here.

#### **PRACTICES THAT ARE ENCOURAGED**

According to Standard 9.3 in the *Standards for Educational and Psychological Testing* (hereafter referred to as SEPT; AERA, APA, & NCME, 1999),

when testing an examinee proficient in two or more languages for which the test is available, the examinee's relative language proficiencies should be determined. The test generally should be administered in the test taker's most proficient language, unless proficiency in the less proficient language is part of the assessment. (p. 98)

Furthermore, Standard 9.10 states that "inferences about test takers' general language proficiency should be based on tests that measure a range of

---

language features, and not on a single linguistic skill” (p. 99). Standard 11.23 states,

If a test is mandated for persons of a given age or all students in a particular grade, users should identify individuals whose disabilities or linguistic background indicates the need for special accommodations in test administration and ensure that these accommodations are employed. (AERA, APA, & NCME, 1999, p. 118)

A common application of this standard involves the use of interpreters for instances in which an

English-language test is individually administered to an examinee who is not fluent in the English language. These same standards stipulate that when an interpreter is used, the interpreter should be fluent in both the language of the test and also the language of the examinee, as well as having a basic understanding of the assessment process (Standard 9.11, AERA, APA, & NCME, 1999). According to Standard 11.22, “When circumstances require that a test be administered in the same language to all examinees in a linguistically diverse population, the test user should investigate the validity of the score

interpretations for test takers believed to have limited proficiency in the language of the test." (p. 118).

Some directives from testing-standards documents are worded in vague generalities that leave much "wiggle room" for a variety of interpretations. For example, the American School Counselor Association and Association for Assessment in Counseling (ASCA & AAC, 1998) encourage professionals to "evaluate their own strengths and limitations in the use of assessment instruments and in assessing students with disabilities or linguistic or cultural differences. [Counselors] know how to identify professionals with appropriate training and experience for consultation" (ASCA & AAC, 1998). The American Counseling Association (2003) encourages counselors to interpret test scores "in light of the cultural, ethnic, disability, or linguistic factors that may impact an individual's score" (American Counseling Association, 2003). Similarly, under "Interpretation and Application of Assessment Results," Guideline Number 5 states, in part, "the test user should evaluate how the test taker's gender, age, ethnicity, race, socioeconomic status, marital status, and so forth, impact on the individual's results" (Association for Assessment in Counseling, 2003, p. 7).

Another example illustrating the use of vague terminology is the frequent use of the term "test fairness." Although Jensen (1980) cautioned audiences to avoid misinterpretations and misapplications of this term, some testing-standards documents encourage test users to be "committed to fairness in every aspect of testing" (American Counseling Association, 2003) and "select tests that are fair to all test takers" (Association for Assessment in Counseling, 2003, p. 3).

The Standards for Educational and Psychological Testing (AERA, APA, & NCME, 1999, p. 74) articulate four interpretations of the concept of "test fairness." Two interpretations (i.e., absence of psychometric bias in tests and equitable treatment in the testing process) have broad consensus among psychometricians and test users. However, characterizations that define "test fairness" as "equal test score outcomes across groups" are rejected. Characterizations that define test fairness as "equal opportunity to learn the material covered in tests" are judged as "clearly relevant to some uses... (but) clearly irrelevant to others" (p. 74)—with the proviso that "disagreement might arise as to the relevance of opportunity to learn to test fairness in some specific situations" (p. 74).

## PRACTICES TO AVOID

SEPT states that a test should not be used for subgroups for which credible research reports differences in the effects of construct-irrelevant variance on at least some part of the test (AERA, APA, & NCME, 1999).

Under "Interpretation and Application of Assessment Results" from the "Standards for Multicultural Assessment," Point #4 states, "When test results are influenced by irrelevant test-taker characteristics (e.g., gender, age, ethnic background, cheating, availability of test preparation programs) the use of the resulting information is invalid and potentially harmful" (Association for Assessment in Counseling, 2003, p. 7).

## AREAS REQUIRING CAUTION

Under "Selection of Assessment Instruments" from the "Standards for Multicultural Assessment," Point #13 urges counselors to be cautious when selecting tests for culturally diverse populations to avoid inappropriateness of testing that may be outside of socialized behavioral or cognitive patterns (Association for Assessment in Counseling, 2003, p. 3).

Test users are encouraged in the SEPT to include "cautionary statements" in their public reports whenever test scores are disaggregated by ethnic groups and credible research suggests that such scores may not have comparable meaning across groups (Standard 7.8, AERA, APA, & NCME, 1999).

When there are reports of group differences in average scores for a test, and relevant "contextual information" that would enable "meaningful interpretation" of these differences is not available, test users "should be cautioned against misinterpretation" (Standard 15.12, AERA, APA, & NCME, 1999, p. 169).

Another frequent admonition in testing ethics codes is for professionals to "use caution" when using tests with, and/or interpreting scores from, individuals representing groups that were not represented in the tests' standardization sample (American Counseling Association, 2003; American School Counselor Association, 2004).

## *Influence, Compatibility, and Conflict Between Knowledge Claim Sources: Blurred Boundaries*

For pedagogical purposes, the three sources of knowledge claims (empirical, sociopolitical, and professional/ethical guidelines) are discussed as mutually exclusive and separate categories. In reality, the lines of demarcation between these sources are somewhat blurred, particularly as these relate to

the appropriateness of test use and interpretation with culturally diverse groups. For example, socio-political ideologies are, by their very nature, resistant to acknowledging that their central tenets are contradicted by rigorous empirical data. Gottfredson (2009) summarizes this point as follows:

That the testing controversy is today mostly a proxy battle over fundamental political goals explains why no amount of scientific evidence for the validity of intelligence tests will ever satisfy the tests' critics.... Tests may be legitimately criticized, but they deserve criticism for their defects, not for doing their job. (p. 14)

Further complicating matters, Marxist-inspired sociopolitical ideologies have often argued that the notion of an objective empirical science is itself an illusion. Jensen (1982) summarizes this view as follows:

In [the Marxist] view, science is motivated to promote that form of socioeconomic class structure that most favors the privileged elite, reinforcing its position of political and economic power. By the same token, any unwitting biases of scientists are deemed most prone to line up against the socially underprivileged and economically disadvantaged classes. Presumably, such ideological science only pretends to test its hypotheses in the idealized, objective manner we learned about in our introductory high school and college science courses. In this view, scientists actually begin with prejudices, then frame them as theories, and create only the illusion of demonstrating the validity of their hypotheses. The conclusions are... “advocacy masquerading as objectivity.” This end is accomplished through “biased selection”—of data, of methods of analysis, and of various possible interpretations of evidence—such that the final outcome will confirm whatever dogma originally motivated the supposedly objective search for the truth. (Jensen, p. 122)

Marxist criticisms have been particularly aggressive when directed toward the notion of intelligence, the IQ, and tests' claim to be fairly objective measures of intelligence (Gould, 1996; Sanders, 1985).

Unfortunately, both arguments supporting and arguments criticizing tests and their use with cultural minorities are published in scholarly journals. As a result, it becomes especially difficult for naïve readers (particularly those who are prone to believe anything they read in print) to discern which (among a litany of contradictory viewpoints)

is the more credible position (absent more in-depth study of psychometrics and cognitive psychology). To help in this regard, readers would also need to familiarize themselves with the academic philosophy, reputation, and rejection rates of different journal outlets, as some manuscripts prominently featured in some journals would not see the light of day in other journals.

Professional standards and ethics documents must often walk a fine line between acknowledging results from rigorous test research and at the same time acknowledging and guarding against abuses in test use frequently voiced by sociopolitical ideologies. Often such standards attempt to “please both masters.” As one among many examples, *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999) acknowledges the conflict between those who argue that standards for test fairness have been met through technical criteria, versus those who argue that “fairness requires more than satisfying certain technical requirements” (p. 80). They then add the vague admonition that “matters of values and public policy are crucial to responsible test use” (p. 80), with no specification as to how these issues interact in making testing decisions. The authors of the *Standards* leave the issue unresolved with the statement: “It is unlikely that consensus in society at large or within the measurement community is imminent on all matters of fairness in the use of tests” (p. 80).

The tension between the need to avoid criticism from anti-test ideologies (which claim that test use with cultural minority groups is “unfair”) and the need to follow research-based testing principles arises in a variety of contexts. For example, some test developers claim that the deliberate omission of cognitive test items involving “speed” should logically reduce a test’s potential for cultural bias (Bracken & McCallum, 1998). Yet at the same time, Hambleton (2005) states:

[S]ometimes speed of performance is an integral part of the construct being measured such as it is with the ability to solve analytic reasoning problems. Then, speed is an important part of the construct, so examinees need to understand the need to work quickly. (p. 9)

Thus, if a test is not measuring speed of solving problems (in order to avoid criticisms of cultural bias), then to what extent can it be said that the full range of intelligence is truly being measured?

A similar dilemma is posed in the context of understanding the relationship between the makeup

of a test's standardization sample and proper test use and score interpretation with individual test takers. Sociopolitical ideologies capitalize on the idea that administering a test to an individual belonging to a racial/ethnic group that is not adequately represented in the standardization sample, to varying degrees, compromises best practice due to the possibility of test score misinterpretation (Dent, 1996; Harrington, 1975). Driven by the need to protect the public against poor practice, *Standards for Educational and Psychological Testing* includes guidelines that address this issue. These Standards state: "Tests selected for use in individual testing should be suitable for the characteristics and background of the test taker" (Standard 12.3, p. 131). The Standards then elaborate that test selection should be based, in addition to test characteristics, on validity evidence from the population that is representative of the test taker. According to Standard 4.5, clearly described populations on which test norms are based "should include individuals or groups to whom test users will ordinarily wish to compare their own examinees."

Yet even such straightforward language raises the question, What "background" characteristics should be considered as "representative" of a particular test taker? Such standards sound good as long as these are framed as abstractions. Application is not as straightforward when applied to complex individuals. For example, suppose that a test user wanted to administer a cognitive test to a middle-class Filipino-American girl living in Hoboken, New Jersey. Although the standardization sample includes individuals from Hoboken, no Filipino-Americans of this girl's social-class strata were included in the standardization sample. Should the test user feel comfortable using this test with this particular girl on the grounds that Hoboken residents were sampled, or is this test user violating best testing practices by administering a test with no comparable Filipino-Americans in the standardization sample? Furthermore, on what basis is the test user to decide which of these two variables (ethnicity or place of residence) is most important for making these decisions?

This is where empirical research can be helpful. When compared against United States norms (which included virtually no Japanese children), Japanese children at every age group between five and 15 obtained higher average scores on the Wechsler Intelligence Scale for Children (WISC) Performance scale, compared to the mostly white American WISC standardization group (Lynn, 1977).

Fan, Willson, and Kapes (1996) conducted one of the most thorough and original empirical tests of the standardization fallacy found in the testing literature. She examined data from 190,000 eleventh-grade students who had already taken the Texas Assessment of Academic Skills (TAAS) reading and math tests. This subject pool consisted of large sub-samples of Caucasian, Black, Hispanic, and Asian students. She began by dividing this large pool into two halves, and conducted her original study on one half, followed by a replication of her methods conducted on the second half. Using the first half of the subject pool (approximately 95,000 students), Fan constructed four equal sub-samples ( $n = 300$  in each), each of which included different proportions of ethnic representation (i.e., each sample had 60%, 30%, 10%, and 0% representation of the different ethnic groups). From subjects' scores on the TAAS, she computed item/total correlations for each item, within each of the four ethnically heterogeneous sub-samples. A high item/total correlation would indicate that the higher probability of passing an item is associated with higher test scores on the entire test. Thus, the higher the item/total correlation, the better the item.

Fan et al. (1996) selected the 24 reading test items and 30 math items that had the best item/total correlations within each sub-sample. This created four (one for each ethnically heterogeneous sample of  $n = 300$  each) "mini-tests" of the best items from each of the four sub-samples.

Fan et al. then constructed four additional sub-samples of 200 subjects, each of which was ethnically homogeneous (i.e., 200 White, 200 Black, 200 Hispanic, 200 Asian). Within each ethnically homogeneous sample, Fan et al. calculated their scores from each of the four "minitests" (comprising items with the best item/total correlations calculated from each of the four heterogeneous samples). Her hypotheses were straightforward. If bias was present (i.e., if the standardization fallacy were true), then the ethnically homogeneous sample should manifest the highest scores on mini-tests created from the heterogeneous sample in which their group was most represented. Thus, the White homogeneous sample should "achieve" their highest score on the "minitest" made from the heterogeneous sample made up of 60% whites, the next-highest score on the "minitest" made from the heterogeneous sample of 30% whites, and so on, culminating in the lowest score "achieved" on the minitest made from the heterogeneous sample in

which no whites were represented. The same predictions were then applied to the homogeneous Black, Hispanic, and Asian samples.

Fan et al. found no relationship between the ethnic composition of the “minitest” subsamples and any homogeneous groups’ ability to achieve higher scores from minitests constructed on a majority of their ethnic group. Fan et al. repeated the same procedures, only instead of constructing four “minitests” from a heterogeneous mixture of ethnic groups, “minitests” were constructed from 100% ethnically homogeneous samples. Even with this modification in procedures, the standardization fallacy was not supported. Fan et al. then repeated the same procedures on the second half of the subject pool ( $n = 95,000$ ), and obtained the same (lack of) results.

### Implications

These examples illustrate some difficulties in providing unambiguous direction for practitioners in using tests with culturally diverse groups. Using the previous example, it can be concluded that, for some tests, ethnic representation in a test’s standardization sample has no effect in “biasing” test results for examinees. However, in the light of ethical and professional test standards, using a test for subjects not represented (in terms of racial/ethnic group membership) in the standardization or item-tryout sample is not viewed as best practice. If the particular group in question is traditionally a lower-scoring group on average, sociopolitical ideologies will use this as ammunition to criticize test usage with examinees from particular groups. However, no matter how vociferous these attacks, the previous examples have shown that empirical data do not support such criticisms.

It remains unknown how many other situations represent points of conflict between empirical research, sociopolitical ideology, and test standards. Part of the problem originates from scholars’ attempts to impose subjective definitions on concepts of “culture,” “fairness,” “equivalency,” and “opportunity to learn.” Progress has been achieved in our attempts to provide objective, testable definitions for “test bias”—as well as empirically based evidence that would support the existence of unbiased tests. However, even research evidence demonstrating the lack of statistical bias in tests has not stopped claims that tests are “unfair” to particular groups (e.g., see Helms, 1992, 1997, 2006).

As subjective definitions for concepts increasingly appear in the psychometric literature, the potential for perceived “unfairness” multiplies

exponentially. In making the argument supporting equity in assessment and school instruction, for example, Camilli (2006) argues that “students should have an opportunity to learn all of the material on a test” and that teachers may need to “compensate for such differential access to knowledge” (pp. 247–248). Although one can easily interpret these statements in the context of achievement testing, there is no easy application of these arguments to intelligence tests (which, in theory, are composed of items that the student cannot “learn” from practice). Yet, when psychometricians openly discuss these concepts, no matter how innocently, sociopolitical ideologues will use them as an “open door” for criticizing tests and their use with select cultural minority groups. Test standards and professional ethics documents are then left to grapple (sometimes unsuccessfully) with how to interpret these terms in the context of ethical practice. Clarity in, and an achieved consensus regarding, various loaded concepts in the testing literature is not likely to resolve contentious sociopolitical value conflicts surrounding test use and interpretation with cultural minority groups. Nevertheless, there is value in first untangling the components that contribute to these debates.

# Methods for Translating and Adapting Tests to Increase Cross-Language Validity

Ronald K. Hambleton and Minji Kang Lee

## Abstract

Translating and adapting tests for use in multiple language and cultural groups has become immensely important to psychologists and cross-cultural researchers. Psychologists want to use popular tests from one language and culture in others; cross-cultural researchers need tests they are interested in to be available in multiple languages and cultures; and credentialing agencies often need to make their tests available in multiple languages. Unfortunately, the methodology for conducting translation and adaptation studies is more comprehensive than is often assumed, and many myths about the process itself exist, and so all too often, the process is handled poorly. In this chapter, three goals will be addressed: (1) several of the popular myths will be described, (2) steps for translating and adapting tests will be presented, and (3) the International Test Commission Guidelines for Test Adaptation will be introduced.

**Key Words:** backward translation design; forward translation design; International Test Commission (ITC) guidelines for test adaptation; judgmental review; measurement invariance; multiple indicator and multiple cause model; partial invariance; structural equating modeling

With the substantially increasing number of tests being translated and adapted into many languages, for example, tests used in international assessments such as TIMSS and PISA are normally translated and adapted into more than 30 languages, and many popular intelligence tests and personality tests are now available in over 75 languages, it is important to use the best methods to maximize the validity of adapted tests. In two recent issues of the *European Journal of Psychological Assessment* (Issues 3 and 4, 2011), nearly 40 percent of the articles involved test translation or adaptation. With other journals reporting research studies that are in an international context, the percentages are often higher—see for example, the *Journal of Cross-Cultural Psychology* and the *International Journal of Testing*.

Prominent examples of test adaptation projects in the United States include adaptation efforts to prepare Spanish versions of College Board's Scholastic

Assessment Test (SAT), ACE's General Educational Development (GED) Test, and the United States Department of Education's National Assessment of Educational Progress (NAEP). Also, in many states, school achievement tests in mathematics and science are available to students in both English and Spanish. Substantially more test adaptations can be expected in the future as (1) international exchanges of tests become more common, (2) more credentialing exams are adapted into multiple languages (Hambleton & Patsula, 1999), and (3) interest in cross-cultural research grows (Matsumoto & van de Vijver, 2011). On this last point, van de Vijver (2009) reported that the number of test adaptation studies had increased by a factor of four in just five years between 2000 and 2005!

Test adaptations, if they are properly carried out, can increase fairness in testing—in Israel, for example, high school students can take their graduation

tests in their choice of any of five languages; test adaptations permit important constructs such as intelligence, personality, and school achievement to be studied in new populations (Matsumoto & van de Vijver, 2011); and test adaptations create possibilities for more cross-cultural research (Hambleton, Merenda, & Spielberger, 2005).

Translating and adapting tests into multiple languages and cultures has a long history in education and psychology—beginning with the French psychologist Alfred Binet's famous intelligence test in the early 1900s. Unfortunately, these translation and adaptation initiatives (e.g., “back translations”) have not always been successful, thus reducing the validity of the intended uses of these tests in additional languages. The reasons for the many failures of test translations/adaptations include (1) lack of appreciation by researchers for the technical challenges that arise in the test translation/adaptation process (for example, a belief that someone who knows the languages can do the translations); (2) limited time and resources committed to doing the test adaptation properly (an all too common problem among test publishers and researchers); and (3) lack of awareness among researchers of the necessary steps and methodologies that can be used. For example, it is a common belief that a good translator and judgmental reviews of the translation/adaptation itself are sufficient to validate a translated/adapted test. But there are many examples in the testing literature showing that a good translation is not sufficient technical justification for insuring validity of the target language version of a test. *The International Test Commission Guidelines for Test Adaptation* (see Hambleton, 2005) certainly are much more demanding of researchers, and emphasize that both judgmental and empirical evidence are needed to support a test being valid in a second language and culture (see [www.intestcom.org](http://www.intestcom.org)).

Often, too, what researchers think is correct about the test adaptation process is not, and this misinformation further exacerbates the problem. Misunderstandings and myths are rampant in the field. Interestingly, many of the current methodological advances such as structural equation modeling, item response theory, and differential item functioning (DIF) studies are highly relevant, but these technical methods are not well known in the field.

The goals of this chapter are:

1. to describe several of the myths associated with translating and adapting tests (e.g., that

almost anyone with knowledge of another language can prepare a good translation; or that judgmental reviews of a translated test are sufficient to establish the validity of scores from a test in a second language);

2. to offer steps for translating and adapting tests, along with a discussion of the methodology associated with several of the more technically challenging steps (e.g., translation designs, comparison of test structures in multiple languages, and the identification of potential item-level bias across language versions of a test); and

3. to provide the guidelines for translating and adapting tests that were prepared by the International Test Commission (and these guidelines require testing agencies and researchers to compile both judgmental evidence and statistical evidence).

Numerous examples will be provided throughout the chapter to highlight good and not so good test adaptation practices.

Before going further, we would like to mount a case for using the term *test adaptation* rather than the more popular and frequently used term *test translation*. The former term is broader and actually reflects what should happen in practice when preparing a test constructed in one language and culture for use in a second language and culture. Test adaptation includes everything from deciding whether an adapted test could measure the same construct in a different language and culture, to selecting qualified translators, to deciding on appropriate accommodations to be made in preparing a test for use in a second language, to adapting the test and then checking its equivalence in the adapted form. Test translation, on the other hand, is only one of several steps in the process of test adaptation, and even at this step, *adaptation* may be a more suitable term than *translation* to describe the process that actually takes place—for example, item formats may need to be revised, new words and concepts may need to be substituted, directions can be revised, and even the time limit may need to be changed (see for example, Hambleton, Merenda, & Spielberger, 2005). In the remainder of this chapter, we will use the term “test adaptation” rather than “test translation” to describe the process of making a test valid for use in a second language and culture. Also, we will use the term “test” to represent a wide array of terms that are used to describe data collection methods in education and psychology, including “instrument,” “assessment,” “scale,” “survey,” and “questionnaire.”

## Popular Myths About the Test Adaptation Process

Five popular myths about test adaptation will be addressed next.

### ***The Preferable Strategy Is Always to Adapt an Existing Test***

Translating and adapting a test is typically faster and cheaper than the alternative, which is to build a new test and validate that new test in the target language of interest. It could take several years to define the construct in an acceptable way, and then develop, field-test, and ultimately finalize a test with norms and a technical manual. This alternative is not even a possibility if the goal is to make comparisons across cultural and language groups. A new test in the second language group would raise major questions about the meaningfulness of the comparability of scores—is the new target language test measuring exactly or nearly the same construct? Are the score scales for the two tests comparable, or can the scores from the two tests be placed on a common scale so that comparisons can be made?

Many researchers, too, feel a sense of security that comes with adapting an established test that is being used in one culture and language group. The security comes from knowing that the source language test has usually been validated for many possible uses (as is the case with many popular American tests of intelligence and personality). The standard view is that a good adaptation will lead to that test's being useful again, this time in the new language. Of course, that adapted test still needs to go through the validation process, but the expectation is that the results are more likely to be successful than validating a newly constructed test.

The Minnesota Multiphasic Personality Inventory (MMPI) is an example of a personality inventory that has been widely adapted for use in multiple cultures and languages. When using an existing test, there are often a number of studies which can be compared with newly acquired data. This is an important advantage to consider. Comparing the results from one study to results from others can increase both the generalizability and even the credibility of the findings. “Such comparisons allow a literature to be built up around a commonly shared set of concepts and operational definitions, an advantage admittedly more difficult to achieve if different researchers use different instruments” (Brislin, 1986, p. 138).

At the same time, if the goal is to have a test to measure a construct in a second language for the

purpose of doing research in that language group only, a case could be made for developing and validating a new test (see Tanzer, 2005). One major advantage would be that then it would be possible to revise the definition of the construct to fit local needs and conditions. One example would be the construct of “quality of life.” In some cultures of the world, the construct may have to do with meeting basic health needs and having sufficient food. In others, quality of life may have to do with having sufficient money for travel and ready access to stores and doctors. Test adaptation of a quality of life measure from one language and culture to another would be possible, but unless that test is chosen carefully, the construct itself may not be relevant in the target language culture, and so the adapted test will be of limited or possibly no value at all. Developing a new test from an acceptable definition of the construct, and with a format familiar to respondents, may be the preferred choice.

On the other hand, for cross-national, cross-language, and/or cross-ethnic comparative studies, adapted tests are required. Such studies have become popular in recent years, as many countries strive to set world-class educational standards and want to compare their progress to that of other countries. The TIMSS project is a good example. Tests prepared in each country, even using the same test specifications, would be sufficiently different that valid comparisons across countries could not be made. Test adaptation is essential.

In summary, there are typically good reasons for and against adapting an existing test compared to developing a new test in that second language and cultural group. It should not be a certainty that a test that is needed can be adapted from another language and culture. Often the intended use of the information dictates the final decision.

### ***Know Two Languages and You Can Be a Translator***

Ype Poortinga, a world-class cross-cultural psychologist and a past editor of the *Journal of Cross-Cultural Psychology*, once reported that he felt a high percentage of the papers published before 1990 were fundamentally flawed because of a failure of researchers to take the test adaptation process seriously. The myth in practice is that if you know a second language you can do at least an adequate job of translating a test from one language and culture to another. But the International Test Commission Guidelines for Test Adaptation (2005) are very clear on this point: A good translator must

know not only the languages, but the cultures, too, and often it is very helpful if the translator has subject-matter knowledge and knowledge of how tests are developed. (These latter two skills are not common among test translators, so some modest training can be provided to close the gap in knowledge and skills needed to do an effective translation.) For example, one common mistake of translators of multiple-choice questions is to translate the correct answer very precisely, often making the correct answer choice longer. The goal of the translator clearly is to be sure that the correct answer remains correct in the translation, but the extra precision can make the answer choice longer, giving a clue to the correct answer to test-wise candidates. Good translators are essential to the test adaptation process but they need to know much more than languages, and the process of test adaptation is much more than translation.

### ***A Good Translation Guarantees Validity***

We have observed test publishers working hard to find translators and then giving them time to do their work. But often tests may not have content validity in the second language group, perhaps because of different curricula (see Hambleton, Yu, & Slater, 1999) and/or culture. We have also found that if that second language group performs very well on a test, test scores may be so homogeneous that score reliability is low, and its predictive validity is limited. There is more to ensuring validity of test scores in a second language than simply a good translation. We have even found that a translation of items in the multiple-choice format may not be meaningful (i.e., valid) if the item format is unknown to translators, or only minimally familiar to examinees in the second language group.

A good example of the misinterpretations that can follow from poor adaptations is the following (the example was passed on from Richard Wolf when he was at Columbia Teachers College and actively involved with one of the international assessment studies). In an international comparative study of reading, American students were asked to consider pairs of words and identify them as similar or different in meaning: *sanguine*—*pessimistic* was one of the pairs of words where American student performance was only slightly above chance (i.e., 50% in the case of this binary scored item). In the country ranked first in performance, about 98 percent of the students answered the question correctly. In the process of attempting to better understand the reason for the huge difference in performance,

it was discovered that “*sanguine*” had no equivalent word in the language of this top-performing country, so the equivalent of the English word “*optimistic*” was used. This substitution made the question considerably easier, and it would have been answered correctly by a high percentage of the American students as well, had they been presented with the pair *optimistic*—*pessimistic*. The point of this example is to highlight the danger in drawing conclusions from international studies without strong evidence that the test adaptation process resulted in two equivalent tests. A careful empirical analysis would have spotted the problem, and we suspect that the item would have been deleted from the assessment or revised, preferably following a field test administration.

### ***Psychological Constructs Are Universal***

The fields of psychology and education are full of examples of studies where it was found that constructs can have different definitions in different cultures—*intelligence*, *quality of life*, and *depression* are three examples. For example, the construct of *intelligence* in the United States includes a big component of *speed of performance*. In many cultures, speed of performance does not play nearly as important a role in the definition of the construct. *Quality of life* researchers have found that the construct can have very different meanings across the world. *Depression* is another construct that may take on a different meaning in some cultures (see some of Spielberger's research, for example).

### ***A Judgmental Review of the Adaptation Is Sufficient Evidence to Justify the Use of the Test***

Certainly, using qualified translators can be a very important step in the test adaptation process. At the same time, it is a mistake to think that this first step in the process is sufficient for insuring a valid test in a second language. Problems arise that can only be spotted through field-testing the adapted test items. In one study recently, it was discovered that, in translation, the test items were longer and required more time to read. It was learned only after the test became operational that the target-language version of the test was speeded up for examinees, an unintended consequence of the translations process and the language itself. The fact was that the words themselves were simply longer in German than they were in English. Field test work can be used to spot problematic test items or statements, inappropriate item formats, test timing issues, unintended

multi-dimensionality, and so on. Rarely would these analyses, from our experience, not reveal shortcomings in the adapted test that could be fixed before the test is used operationally or in a research study. PISA and TIMSS, for example, routinely carry out field test studies prior to finalizing tests for use in these international studies of achievement.

## Summary

Each of the five myths can have a negative impact on the utility of tests in a second language and culture. Sometimes it may be best not to embark on an adaptation process—perhaps because of the intended use of the test in the second language group (an adapted test may not be needed), or because the construct itself may have a different meaning in that second language and cultural group. Good translators of the language are valuable, but the translators need more than simply the language skills to be effective, and a good language translation of a test may not be what is needed. Most importantly, empirical evidence (e.g., reliability and validity evidence) is needed to support a test adaptation. A good judgmental review is rarely sufficient and should be criticized when it is the sole piece of evidence (important as it is) to support the validity of scores from an adapted test.

## Steps for Conducting a Test Adaptation Study

Over the years, steps have been advanced for testing agencies and researchers to follow in enhancing the validity of a test adaptation. In this chapter, steps from a paper by Hambleton and Patsula (1999) have been edited and updated.

*Step 1. Ensure content equivalence exists in the two language and cultural groups.* Before embarking on a major test adaptation initiative, the researcher should do some checking to be sure that the construct definition in one language and culture is applicable in the other. This step can be accomplished by compiling judgmental evidence from psychologists and educators who know both cultures and understand the definition of the construct in the source language.

*Step 2. Decide whether to adapt an existing test or to develop a new test.* This step was discussed in some detail earlier in the chapter. The more similar the construct is in the two language groups, the more likely it is that an adaptation would be successful. The final decision regarding this step surely requires (1) some reasonable level of

assessment expertise, (2) knowledge of just what might be involved in conducting an adaptation, (3) knowledge of the relevant literature and the validity of the source language version of the test, and (4) some knowledge of the language and culture of the target language version of the test.

*Step 3. Select well-qualified translators.* A broader definition of “well-qualified” must be adopted to suffice. Knowing the two languages is only the first criterion to be met. Knowledge of the culture is second. Also, knowledge of the construct being measured and testing practices is helpful, too. As few translators can meet these criteria, often some training may be helpful. Without it, awkward translations can result, and good testing practices can be violated. Using multiple translators is also a good idea so that they can share their knowledge and insights.

*Step 4. Adapt the test.* Often this step is what is called the “translation process,” but often it is more than that. Test directions may need to be revised, answer sheets may need to be redesigned to accommodate the background of the respondents, etc. The presence of multiple translators can also greatly aid the process of obtaining an acceptable adaptation.

*Step 5. Conduct a judgmental review of the adapted test and revise the test adaptation as necessary.* Of course this is one of the critical steps in the process, and for some agencies, this may be the last step. At least two judgmental designs are popular: backward translation designs and forward translation designs.

With the backward translation design, one group of translators signs off on the adaptation, and then a second group back-translates the test. Finally, a new group compares the original source language test and the back-translated version. Any problems that are identified can be fixed in the target language version of the test. The design has merit, and many problems in the adaptation can usually be identified. The downside is that the target-language version of the test is not investigated. Researchers like the design because they do not need to be bilingual to judge the similarity of the two source-language versions of the test.

The forward-translation design involves a comparison by translators of the source and target-language versions of the test. This design has more merit than the first because the target-language version of a test is reviewed. In many comprehensive studies of test adaptation,

a back-translation design is used to spot and fix problems in the target language version, and then the second design is used to further the evaluation. But the consensus among experts is that the second design is preferable to the first, if only one is to be used, because of the review of the target-language version of the test. In many studies today, both designs are used.

*Step 6. Conduct a small tryout of the target language version of the test.* This step can be used to detect problems in the target language version of the test, prior to investing considerable time and expense in carrying out more ambitious reliability and validity studies. Clarity of directions, the suitability of the test format, and the time limit (if one exists) can be studied and fixed. A small-scale item analysis and reliability study can also be insightful.

With respect to the item-review process itself, Hambleton and Zenisky (2011) published a chapter in which they described an item translation and adaptation review form they designed. The review form contains 25 questions organized into five categories that address the test items in the target language version of the test: General (4 questions), Item Format (5 questions), Grammar and Phrasing (6 questions), Passages (if present; 4 questions), and Culture (5 questions). The 25 questions were all associated with problems that have arisen in practice, and documentation for the importance of each question is contained in their chapter. A sample of the questions follows:

- Does the item have the same or highly similar meaning in the two languages?
- Is the item format, including physical layout, the same in the two versions of the test?
- Are there any grammatical clues that might make this item easier or harder in the target language version?
- Are there any words in the item that, when translated, change from having one meaning to having more than one common meaning?

The item review form should help to standardize the item review process for translators and other reviewers but it can also be used to alert test translators to problems that may arise in their adaptation initiatives. Knowledge of these problems in advance can help to improve the adaptation process as well.

*Step 7. Design and carry out a more substantial study to investigate test reliability and validity.* At this step, the testing agency or researcher has many options. The goal is to compile additional evidence

for validity of the scores with the target language version of the test. Here is a partial list of analyses that could be carried out:

1. Conduct a reliability study (e.g., internal consistency, test-retest). It is basic information, but it is useful to establish.
2. Conduct an item analysis with a suitably sized sample.
3. Conduct an analysis, item by item, comparing performance on the source- and target-language versions of the test (e.g., Holland & Wainer, 1993; Sireci, 2011)—these are often called “differential item functioning (DIF)” studies, and the two language groups are often called “reference” and “focal” groups (corresponding to the source language and target language groups).
4. Check the factorial structure of the target language version of the test and compare to the source language version. Often it is here that “structural equation modeling” is used, and this topic will be considered in more detail in the next section.
5. Carry out a “linking” study if the goal is to report scores from the source- and target-language versions of the test on a common reporting scale (see Angoff & Cook, 1988; Cook & Schmitt-Cascallar, 2005).

For more details on possible methodologies, see the next section and Hambleton, Merenda, and Spielberger (2005), van de Vijver and Tanzer (1997) and special issues of *Language Testing* (Issue 2, Volume 20, in 2003) and the *International Journal of Testing* (Issue 2, Volume 9, in 2009).

*Step 8. Prepare technical and user documentation, and continue monitoring the target language version of the test adaptation.* A paper trail documenting the process of adapting the test, how certain problems may have been handled, and the design and validity results can be invaluable to those interested in checking the validity of the target-language version of the test. Of course, details for the test user administration are needed, too, so that this portion of the process can be standardized across language groups. Finally, if the test adaptation continues to be used, periodically compiling validity evidence would be valuable as well.

## Checking the Equivalence of the Source- and Target-Language Versions of a Test

*Structural equation modeling (SEM)* is one of the most widely applied statistical methods for testing the comparability of how different language

or cultural groups perform on the source- and target-language versions of an educational or psychological test (see for example, Byrne & van de Vijver, 2010). One strength of SEM is that it allows one to assess a global hypothesis regarding *measurement invariance* across the different groups. For example, the loadings of a factor model (i.e., the relationship between an item and a factor) can be constrained to be equal across groups, and the relationships between items (or sets of items or parcels) and the latent variables across groups can be examined in the same analysis. Because this type of analysis has become common in addressing the equivalence of a test across two (or even more) language versions, SEM will be described in detail next. Other popular statistical methods such as DIF can be found in the writings of many researchers. See for example, the recent publication of Sireci (2011).

### Testing Measurement Invariance with SEM

Both exploratory and confirmatory factor analysis can be conducted in the SEM framework. In exploratory factor analysis, one does not have an *a priori* theory about the test structures. Whenever one does exploratory factor analysis in SEM, it is advised that cross-validation with different samples be conducted to guard against chance findings (Boomsma, 2000). In the test adaptation context, however, one would often be interested in testing whether the structure underlying the original tests carries over to their adapted versions. That is, one already has a theory of the test structure that one wants to validate in other language or culture groups; the appropriate approach for carrying out this validation is multi-group confirmatory factor analysis (MG-CFA; Byrne & van de Vijver, 2010; Gierl, 2000; Konishi et al., 2009; Loner & Peri, 2009). In particular, MG-CFA based on mean and covariance structures (MACS) instead of the more commonly used covariance structure (CS) analysis is advocated to check for increasingly stringent levels of measurement invariance (Wu, Li, & Zumbo, 2007; Gregorich, 2006).

A regression equation that represents the factor analysis model incorporating MACS can be written as follows:

$$y_{ij} = \tau_j + \lambda_{j1}\eta_{1i} + \lambda_{j2}\eta_{2i} + \dots + \lambda_{jp}\eta_{pi} + \varepsilon_{ij},$$

where  $y_{ij}$  denotes the  $i$ th person's score ( $i = 1, \dots, N$ ) on the  $j$ th indicator ( $j = 1, \dots, J$ ). Each person's indicator score is a linear combination of the intercept ( $\tau_j$ ), one or more factors ( $\eta_{pi}$ ,  $p = 1, \dots, P$ ), and a

normally distributed random residual ( $\varepsilon_{ij}$ ). Each  $\lambda_{jp}$  is the loading of indicator  $j$  on factor  $p$ , and  $\tau_j$  is the indicator score when the factor scores are zero.

A prerequisite to testing measurement invariance is *configural invariance*, in which one investigates whether the same number of factors and the same pattern of free and fixed factor loadings hold across groups. Lack of configural invariance demonstrates that different constructs were measured across groups. Once configural invariance is satisfied, one can proceed to check the more demanding criterion of *weak invariance* by placing equality constraints on factor loadings ( $\lambda_{jp}$ ) across groups. If these constraints do not significantly worsen model-data fit, then weak invariance is supported. This allows one to set the unit of measurement equal across groups. That is, one unit change in the factor results in the same change in the indicator, regardless of group membership. In addition to the equality of factor loadings, *strong invariance* requires equality of the intercepts ( $\tau_j$ ), which is tested by the application of MACS. A finding of strong invariance allows one to make comparisons of the group means of latent variables. Finally, *strict invariance* requires the equality of residual variances ( $\text{Var}(\varepsilon_{ij})$ ) in addition to that of factor loadings and intercepts. One might argue that strict invariance is not necessary for test scores to be comparable across groups. The residual  $\varepsilon_{ij}$  is composed of two parts: A stable unique part that indicator  $j$  measures in addition to the common factor, and a random error. An indicator might fail a check for strict invariance because the two groups have different variances in either part of the residual. For example, one group might have a larger residual variance because its members are more diverse in their exposures to specific bits of knowledge required to do well on a particular test; that is, one group has greater variance in the stable unique part measured by that test. If this is the case, then it does not seem that the failure of strict invariance is a shortcoming of the test. However, it is also possible that one group has a larger residual variance because the random errors tend to be larger for members of that group, and this does seem to be a shortcoming of the test. For this reason it is desirable to test the hypothesis of strict invariance. In this way, all four levels of the nested hierarchy of measurement invariance can be tested to investigate the comparability of test performance across different language or cultural groups.

### Partial Invariance

It is quite possible that one often finds a lack of invariance, given the stringent nature of the

hypotheses of invariance. In this case, it can be more meaningful to check the degree of partial measurement invariance. If a better fit can be obtained by freeing some estimates, then one should document the proportion of freed parameters when reporting the degree of invariance. Although there is no strict rule of an acceptable degree of partial invariance, less than 20% freed parameters are recommended for many practical applications (Dimitrov, 2010).

### ***Multiple Indicator and Multiple Cause (MIMIC) Model***

MIMIC is a special case of MG-CFA. A MIMIC model examines whether different groups have the same intercepts in the regression of indicator scores on the common factor. Note that there can only be two levels in the grouping variable. The MIMIC model can be written as

$$X_j = \alpha_j + \delta_j G + \lambda_j \theta + \varepsilon_j$$

in which  $X_j$  denotes the  $j$ th parcel score,  $\alpha_j$  denotes the intercept,  $\delta_j$  denotes the difference in intercepts between the groups,  $G$  denotes the group dummy variable,  $\lambda_j$  denotes the factor loading,  $\theta$  denotes factor score, and  $\varepsilon_j$  denotes the error. The MIMIC model uses a path from the grouping variable to the common factor to account for the average difference of the common factor in the two groups. The significant path from the group variable to the common factor means that the two groups differ on average in the value of the common factor. This is permissible as far as the measurement is concerned, because the fact that the two groups differ in abilities does not necessarily mean that there is something wrong with the test. However, if there is a significant path from the group variable to an indicator, that means that there is something wrong with that indicator. Someone from one group with the same value of the common factor as someone from the other group is still expected to obtain a different score on the indicator. We can say that the indicator is *biased*. This is analogous to the lack of intercept equality, or differential item functioning with group differences in item difficulty.

### ***Methodological Challenges***

Some methodological challenges for the construct validation of a test across different language groups are small sample size and distributions differing greatly in shape or central tendency. Small sample size will lead to larger estimation errors and overestimation of goodness-of-fit indices, especially

when the sample size is less than 200 (Dimitrov, 2010). If the ranges or shapes of the two score distributions are different, then any differences in obtained parameter estimates may reflect either true group differences or simply one group's being located at a part of the score scale where any kind of statistical estimation is problematic.

A study by Sireci and Wells (2009) shows how they dealt with this problem. They randomly matched the examinees in the bigger sample to those in the smaller sample based on proficiency so that their distributions perfectly overlapped.

### ***International Test Commission Guidelines for Test Adaptation***

In 2005, the International Test Commission (ITC) published a set of guidelines for translating and adapting educational and psychological tests (see Hambleton, 2005). Several organizations assisted the ITC in preparing the guidelines: the European Association of Psychological Assessment, the European Test Publishers Group, the International Association for Cross-Cultural Psychology, the International Association of Applied Psychology, the International Association for the Evaluation of Educational Achievement, the International Language Testing Association, and the International Union of Psychological Science, and their assistance helped enhance both the importance of the guidelines as well as the quality of the guidelines themselves. The guidelines were organized into four categories, and the guidelines are reported below, organized by category:

#### *Context*

C.1 Effects of cultural differences that are not relevant or important to the main purposes of the study should be minimized to the extent possible.

C.2 The amount of overlap in the construct measured by the test or instrument in the populations of interest should be assessed.

#### *Test Development and Adaptation*

D.1 Test developers/publishers should insure that the adaptation process takes full account of linguistic and cultural differences among the populations for whom adapted versions of the test or instrument are intended.

D.2 Test developers/publishers should provide evidence that the language use in the directions, rubrics, and items themselves as well as in the handbook are appropriate for all cultural and

language populations for whom the test or instrument is intended.

D.3 Test developers/publishers should provide evidence that the choice of testing techniques, item formats, test conventions, and procedures are familiar to all intended populations.

D.4 Test developers/publishers should provide evidence that item content and stimulus materials are familiar to all intended populations.

D.5 Test developers/publishers should implement systematic judgmental evidence, both linguistic and psychological, to improve the accuracy of the adaptation process and compile evidence on the equivalence of all language versions.

D.6 Test developers/publishers should ensure that the data collection design permits the use of appropriate statistical techniques to establish item equivalence between the different language versions of the test or instrument.

D.7 Test developers/publishers should apply appropriate statistical techniques to (1) establish the equivalence of the different versions of the test or instrument, and (2) identify problematic components or aspects of the test or instrument that may be inadequate to one or more of the intended populations.

D.8 Test developers/publishers should provide information on the evaluation of validity in all target populations for whom the adapted versions are intended.

D.9 Test developers/publishers should provide statistical evidence of the equivalence of questions for all intended populations.

D.10 Non-equivalent questions between versions intended for different populations should not be used in preparing a common scale or in comparing these populations. However, they may be useful in enhancing content validity of scores reported for each population separately.

### *Administration*

A.1 Test developers and administrators should try to anticipate the types of problems that can be expected, and take appropriate actions to remedy these problems through the preparation of appropriate materials and instructions.

A.2 Test administrators should be sensitive to a number of factors related to the stimulus materials, administration procedures, and response modes that can moderate the validity of the inferences drawn from the scores.

A.3 Those aspects of the environment that influence the administration of a test or instrument

should be made as similar as possible across populations of interest.

A.4 Test administration instructions should be in the source and target languages to minimize the influence of unwanted sources of variation across populations.

A.5 The test manual should specify all aspects of the administration that require scrutiny in a new cultural context.

A.6 The administrator should be unobtrusive and the administrator-examinee interaction should be minimized. Explicit rules that are described in the manual for administration should be followed.

### *Documentation/Score Interpretations*

I.1 When a test or instrument is adapted for use in another population, documentation of the changes should be provided, along with evidence of the equivalence.

I.2 Score differences among samples of populations administered the test or instrument should not be taken at face value. The researcher has the responsibility to substantiate the differences with other empirical evidence.

I.3 Comparisons across populations can only be made at the level of invariance that has been established for the scale on which scores are reported.

I.4 The test developer should provide specific information on the ways in which the socio-cultural and ecological contexts of the populations might affect performance, and should suggest procedures to account for these effects in the interpretation of results.

The guidelines themselves have been adopted for use in many countries and by many testing agencies. A second edition is now being developed and is likely to be released for use in 2013. For more details on the guidelines, readers can refer to Hambleton (2005) or check [www.intestcom.org](http://www.intestcom.org).

# Diagnosis, Classification, and Screening Systems

R.W. Kamphaus, Erin Dowdy, Sangwon Kim, and Jenna Chin

## Abstract

This chapter serves as a primer devoted to the main issues involved in the diagnostic and classification process of children, including an overview of widely used nosological systems and the empirical support associated with them. New directions and systems of classification and diagnosis are also presented in some detail. An overview of concepts and issues in behavioral and emotional problem screening assessment associated with prevention and early intervention concludes the chapter. Two primary conclusions are drawn. First, the amount of unsupportive evidence associated with currently used systems requires that radical changes be made to these systems going forward. Second, the newfound emphasis on early identification and screening associated with prevention practice and science requires the incorporation of classification of risk and subsyndromal problems into new and revised classification systems.

**Key Words:** classification, diagnosis, screening, assessment

## Classification and Diagnosis

Classification of phenomena is necessary to advance any discipline, whether applied or theoretical (Kamphaus & Campbell, 2006). A “diagnostic system” is a specific type of classification system, one designed to describe clinical phenomena for research, treatment, administrative, or other purposes. “Diagnosis,” the type of classification that is the focus of this text, refers to a process of classifying an individual as having a particular disease state or set of diseases. Although the diagnostic process dates from antiquity (DuBois, 1965), the modern process of psychiatric diagnosis traces its roots to the work of Emil Kraepelin, who proposed that a system be created for classifying mental illnesses according to their symptoms, causes (i.e., etiologies), and course (i.e., progression of symptomatology) (Kraepelin, 1896). In the medical sciences, conditions such as heart disease and high blood pressure are classified as separate diseases. Analogously, borderline

personality disorder is classified separately from schizophrenia in psychiatric classification. Therefore, diagnosis may be considered a specialized type of classification, one concerned with the categorization of diseases.

In spite of various objections to mental health diagnosis *per se* and its imperfect nature (Frick, Burns, & Kamphaus, 2009), the majority of mental health professionals concur that the basic purposes and inherent advantages of classification support its use and further development (Cantwell, 1996). Related to this assumption, Blashfield (1998) has described five primary purposes for classification in psychopathology that also serve to illustrate its utilitarian properties: (1) creation of a common professional nomenclature; (2) organization of information; (3) clinical description; (4) prediction of outcomes and treatment utility; and (5) the development of concepts upon which theories may be based. These goals, although sound and pragmatic,

have yet to be obtained by any one classification system. The predominant diagnostic classification schemes do attempt to provide a common nomenclature, organize information, and clinically describe syndromes or patterns of behavior. Nevertheless, the reliability and validity of prevailing models have not been adequately demonstrated, supportive evidence varies greatly from one diagnosis to another, nor has a clear line of research established expediency with regard to treatment and theory development (Frick et al., 2009; Edelbrock & Achenbach, 1980).

Worldwide, the diagnosis of child and adolescent psychopathology has traditionally been based on the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) system, now in its fifth edition. Given its status as the premier worldwide standard and its influence on the conduct of research, it is important to know and understand the basic assumptions of this system in particular, along with its limitations. This initial section will discuss widely used classification systems focusing on the DSM, as well as alternative classification approaches, including a dimensional and a person-oriented approach. This section will also address recent research trends and promising future directions that are important for further developing classification systems for child and adolescent behavioral and emotional adjustment, developmental status, competency, and mental health. Specifically, promising research based on cognitive neuroscience and genetics will be presented. In addition, a strength-based approach to mental health will be discussed, which provides a broader perspective on assessing and treating problems in children and adolescents. Lastly, the issue of culture in diagnosis, which has not been as well studied, despite its potential impact on diagnosis, will be given some attention. The field of screening will also be discussed in the latter half of the chapter, as screening can play an integral role in the early steps of classification and diagnosis, and subsequent early intervention.

## **Classification Systems and Approaches**

### **SYSTEMS IN WIDESPREAD USE: THE DSM AND ICD**

The two major sanctioned classification systems of child and adolescent disorders in use at this time are the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the World Health Organization's International Classification of Diseases (ICD). While these classification systems are used in clinical settings, typically outside of public school settings, different

classification systems are often used in school settings (e.g., Individuals with Disabilities Educational Improvement Act, or IDEIA, in the United States). However, psychologists working in schools sometimes still utilize the DSM classification system for case conceptualization and treatment planning. Additionally, practitioners often have opportunities to engage in communication and collaboration across settings as part of their work with child and adolescent populations. Therefore, although this section will primarily focus on a discussion of the DSM system, work with children and adolescents requires knowledge of both the ICD and IDEIA systems.

The DSM has undergone several revisions, with the anticipated publication of its fifth edition this year. When the DSM was first published in 1952, no specific section for child and adolescent disorders existed; instead, childhood and adolescence were considered only as a specific condition for some categories (e.g., "schizophrenic reaction, childhood type"; special symptom reactions such as learning disturbance, enuresis, and somnambulism). DSM-II (American Psychiatric Association, 1968), however, made major progress by adding a new section titled "Behavior Disorders of Childhood and Adolescence." This section including seven disorders, such as hyperkinetic reaction of childhood (or adolescence) and overanxious reaction of childhood (or adolescence), was expanded into "Disorders Usually First Evident in Infancy, Childhood, or Adolescence" in DSM-III (American Psychiatric Association, 1980). Under this title, DSM-III listed nine childhood disorders, including mental retardation, attention-deficit disorder, and conduct disorder; additionally, the DSM-III provided specific developmental disorders, such as reading disorder. The basic structure of the DSM-III was maintained in the subsequent revision of the third edition (DSM-III-R: American Psychiatric Association, 1987). Furthermore, the more recent revisions (DSM-IV and DSM-IV-TR; American Psychiatric Association, 1994, 2000) represented a section named "Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence," under which there are 10 categories of disorders such as learning disorders, communication disorders, and attention-deficit and disruptive behavior disorders. Although the DSM revisions show the continuing development and refinement of child and adolescent disorders, it is important to note that a separate section for childhood and adolescence is provided for convenience of use only, without conceptualizing

child disorders as distinct from adult disorders (American Psychiatric Association, 1994).

The DSM is based on a medical model that posits that disorders reside within an individual child (Frick, Burns, & Kamphaus, 2009). In the DSM diagnostic system, disorders are conceptualized in a dichotomous way: as either present or absent within a child. This categorical premise, however, has not been empirically supported by evidence of cutoff points that can accurately distinguish individuals with a disorder from those without it (Kendell, 2002). The questionable existence of discontinuities in child and adolescent disorders has led to attempts to conceptualize mental disorders as dimensions rather than categories, which will be discussed later in this section. The all-or-nothing conceptualization of disorders also makes it difficult to identify children who present sub-threshold symptoms and may need interventions. From a preventative perspective, the failure to provide mental health services in a timely manner increases the risk for developing disorders. Hence, it is important to have a classification system that helps to assess risk status of individual children and, when necessary, intervene early before problems become severe.

As an alternative to a medical model, a biopsychosocial model has been proposed that encompasses biological, psychological, social, and cultural aspects of child and adolescent disorders. This comprehensive approach has provided a framework on which some of the recent classification systems have been based. For example, the World Health Organization developed The International Classification of Functioning, Disability and Health (World Health Organization, 2001), in which a disability is defined in terms of impairment of structure and function, restriction of activities, and environmental factors that include both facilitators of and barriers to an individual's functioning.

Another important issue pertaining to the concept of mental disorders is that the DSM defines mental disorders with symptoms, not etiology. In fact, for the most part, the causes of mental disorders remain unknown. Moreover, the DSM relies on experts' consensus in developing the concept of specific disorders, though it has moved toward an emphasis on empirical foundations. Due to the provisional nature of DSM disorders, the diagnostic process is affected by a clinician's subjectivity (Jablensky, 1999). Therefore, having balance between clinical judgment and empirical assessment data can be helpful in making a more precise diagnosis (Achenbach, 2001; Doucette, 2002). On another level, it is noted

that, in a sense, DSM disorders are social constructs, as decisions on whether and to what extent a certain behavior or symptom is inappropriate involves making social judgments (Wakefield, 1999).

There are other challenges that remain unresolved by the latest version of the DSM system. The premise that the high levels of comorbidity observed in diagnostic practice reflect true comorbidity is doubtful. The fact that no significant body of evidence supports the DSM disorders as distinct categories (e.g., Meehl, 1995) suggests the possibility that the apparent comorbidity is spurious. For this reason, it has been suggested to replace the term *comorbidity* with *co-occurrence* (Lilienfeld, Waldman, & Israel, 1994). Additionally, the DSM system does not adequately recognize the heterogeneity of children with the same diagnosis (e.g., Hinshaw & Lee, 2003), with some exceptions (e.g., ADHD subtypes and pervasive developmental disorders). A failure to recognize subgroups of a disorder hinders the search for differentiated causes, consequences, and treatments (Quay, 1987).

Lastly, reliability of the DSM diagnoses has improved, while validity evidence is lacking. Although less than the desired diagnostic reliability threshold of .90 (Nunnally, 1978), the reliability of some DSM diagnoses has been improved, in part due to the provision of operational definitions of disorders and the development of structured diagnostic interviews (Kendell, 2002; Schmidt, Kotov, & Joiner, 2004). Hence, the challenge the DSM system faces mostly is the lack of sufficient validity evidence in support of the accuracy of the child and adolescent diagnoses. In studying validity, researchers should give attention to clinical validity in addition to other types of validity. Clinical validity is related to practical issues, one important aspect of which is how much a diagnosis provides guidance on appropriate treatment (Kendell, 2002). As the ultimate purpose of classification of mental disorders lies in treating the identified disorder, the link of diagnosis to intervention is critical for establishing a clinical validity argument (Messick, 1989).

The aforementioned disadvantages of the DSM system have led to proposals for alternative classification approaches in child and adolescent psychopathology. The following section will focus on two of these: dimensional and person-oriented classification systems.

#### *Dimensional Approach*

The relative value of categorical (e.g., the DSM-IV-TR) and dimensional (e.g., Edelbrock & Achenbach, 1980) classification methods has been

frequently debated (Fletcher, 1985). However, an increasing body of literature has described the advantages of dimensional models (LaCombe, Kline, Lachar, Butkus, & Hillman, 1991). For example, Achenbach and McConaughy (1992) noted that the yes/no nature of categorical methods does not necessarily account for children whose problems vary in degree or severity. As a result, the shift between "normalcy" and psychopathology cannot be well understood with categorical methods, since most high-prevalence problem behaviors in children, such as inattention and hyperactivity, are not classifiable when below diagnostic threshold levels. Substantial evidence is emerging to suggest that child behavior problems such as inattention, hyperactivity, depression, and conduct problems, in fact, fall along continua in the population. Therefore, the continuous nature of these child behaviors is more appropriately measured with dimensional scales (Hudziak, Wadsworth, Heath & Achenbach, 1999) rather than with categorical systems (Scalhill, et al., 1999).

In this classification approach, child and adolescent disorders are conceptualized as dimensions, rather than categories, based on the assumption that normality and abnormality range along a continuum. In other words, the difference between persons with a disorder and persons without a disorder is quantitative rather than qualitative. Empirical findings have supported the dimensional nature of childhood disorders for various symptoms, including hyperactivity/impulsivity, inattention, conduct problems, depression, and anxiety (Deater-Deckard, Reiss, Hetherington, & Plomin, 1997; Fergusson & Horwood, 1995; Hudziak et al., 1999; Nease, Volk, & Cass, 1999).

Statistical techniques such as exploratory factor analysis are used to group a number of descriptive variables (e.g., symptoms) into a small number of dimensions (Blashfield, 1998). Put differently, a *dimension* means "a set of correlated descriptive variables" (Blashfield, p. 70). Rating scales, which are frequently used in psychological assessment of children and adolescents, exemplify the dimensional approach. For example, parent ratings of child behavior from the Behavior Assessment System for Children, 2nd edition (BASC-2; Reynolds & Kamphaus, 2004) consist of 15 scales (or dimensions), which are grouped into three composites of internalizing problems (e.g., depression), externalizing problems (e.g., aggression), and adaptive skills (e.g., social skills).

The dimensional classification approach can solve some of the problems inherent within the DSM system. By allowing simultaneous elevations on several

dimensions, this approach addresses the comorbidity or co-occurrence issue in that "diagnoses" are not mutually exclusive. In addition, dimensions may have better predictive power than categories. In a study of adolescents' disruptive behaviors, Fergusson and Horwood (1995) found that dimensions were more predictive of substance abuse, juvenile offending, and school dropout than DSM diagnoses. This is not surprising, however, because categories inevitably cause a loss of information or variability, which, in turn, results in a corresponding loss of predictive power (Kim, Kamphaus, & Baker, 2006).

Despite the possibility of adopting a dimensional approach in future revisions of the DSM for some disorders, especially personality disorders (Widiger & Trull, 2007), the DSM will probably remain categorical, as categories are more effective than dimensions for communication and day-to-day decisions about treatments (Blashfield, 1998; Kendell, 2002). Also, there is an inherent problem associated with dimensions: being variable-oriented, they do not recognize the dynamic nature of human behavior. In addressing those limitations, some have proposed a person-oriented approach that creates categories of persons based on the specific patterns of dimensionally scaled variables (Bergman & Magnusson, 1997). Although the dimensional approach has problems, it is still a useful research tool and can be complementary to the DSM system in clinical practice as well.

### *Person-Oriented Approach*

According to Blashfield (1998), a person-oriented approach that forms groups of persons is simply a specialized type of a categorical classification system. Though the DSM classification is often called a "categorical" approach, this is inaccurate because the categorical approach refers to categories of persons, not disorders (Blashfield). One way to apply this approach to classifying child and adolescent psychopathology is through cluster analysis and related techniques, which create population subgroups based on a configuration of dimensional variables (Bergman, 2000). Cluster or latent class analysis of dimensional scales is a promising classification approach that may best address the issues of comorbidity and sub-threshold symptoms (Cantwell, 1996).

Several attempts have been made to create typologies of childhood psychopathology using clustering procedures (Curry & Thompson, 1985; Edelbrock & Achenbach, 1980; Lessing, Williams, & Gil, 1982). Among these studies, some produced

a comprehensive classification of child behavior using representative national samples. For example, McDermott and Weiss (1995), using the national standardization sample of the Adjustment Scales for Children and Adolescents (ASCA; McDermott, Marston, & Stott, 1993), identified 22 clusters that ranged from the absence of behavior problems to clinically diagnosable problems. In McDermott and Weiss' study, 77% of the sample were classified as well or marginally adjusted, and approximately 21% were at risk or maladjusted. In another study, Kamphaus, Huberty, DiStefano and Petoskey (1997) obtained seven clusters based on teacher ratings of the Behavioral Assessment System for Children (BASC; Reynolds & Kamphaus, 1992): 53% of the national sample were classified as adjusted with no subclinical or clinical problems (i.e., Well-Adapted, Average), 43% in the subclinical range (i.e., Mildly Disruptive, Disruptive Behavior Disorder, Learning Disorder, Physical Complaints, and Worry), and 4% at the clinical level (i.e., Severe Problems). This seven-cluster work has been supported by evidence of internal validity (Huberty, DiStefano, & Kamphaus, 1997) and external validity (DiStefano, Kamphaus, Horne, & Winsor, 2003). It has been also replicated across cultural groups (Kamphaus & DiStefano, 2001) and with at-risk samples of children and adolescents (Distefano et al.; Kim et al., 2006; Kim, Orpinas, Martin, Horne, Sullivan, et al., 2010).

The utility of a cluster analytic classification of child psychopathology should be evaluated with regard to its predictive value. To date, only a few studies have examined and compared the predictive validity of cluster analytic and dimensional classifications of child behavior in schools. Haapasalo, Tremblay, Boulerice, and Vitaro (2000) conducted a cluster analysis of five teacher-rated scales and identified eight clusters. It was found that clusters and dimensions were equally predictive of later outcomes, including delinquency, social withdrawal, and school placement. Furthermore, Kim et al. (2006) created seven clusters based on teacher ratings of 14 dimensions in first grade. They reported that, while both clusters and dimensions significantly predicted a variety of school outcomes in second grade (academic achievement, absenteeism, discipline reports, and pre-referral intervention), the former were more powerful than the latter. These findings provide support for the viability of a cluster analytic classification of child behavior in school settings. Yet continuing research is warranted to accumulate evidence that verifies the predictive validity of clusters, especially in clinical settings.

Future research also needs to examine the stability of clusters over time, using longitudinal data. Given developmental predictability and malleability, it is reasonable to predict both stability and change in cluster membership. Developmental processes are complex as a result of dynamic interactions between persons and environments, and we should always be mindful of unexpected changes. Yet, it is predicted that most individuals, if there is change, would likely move to a cluster similar or adjacent to their previous cluster membership in terms of the phenomenology of their adjustment. Using the clusters identified in the national study of Kamphaus et al. (1997) as examples, children who were initially classified as adjusted would most likely remain members of a relatively healthy cluster, rather than become behaviorally problematic: moving from Well-Adapted to Average, or vice versa. Along with stability and change, it will also be important to understand child and environmental factors that could influence changes in cluster membership over time. This kind of knowledge can be used in planning interventions designed for enhancing adjustment and/or preventing behavioral problems (Kim et al., 2010).

With regard to treatments, clusters may have important utility as a means of designing and evaluating interventions. Although the concept of clusters has been present in the literature for some time, the development of interventions for specific clusters and the evaluation of program effectiveness by cluster have been virtually nonexistent. Traditionally, program developers and researchers select children who are in need of social, academic or behavioral interventions based on a single characteristic. The majority of current intervention efforts evaluate whether the intervention reduces symptoms in relation to a control group. However, clustering may provide a more specific tool by evaluating whether effects differ by child cluster membership (Kim et al., 2010).

Although the person-oriented classification approach appears promising, its direct application to diagnostic practice seems to be limited at the present time, requiring further research. One of the problems that a cluster analytic method has is that clustering is more likely to identify disorders relatively common in children and adolescents, leaving rare disorders unclassifiable by such a framework (Cantwell, 1996).

## ***Recent Trends and Future Directions***

### **HYBRID MODELS**

A rapprochement between DSM, dimensional, and person-oriented methods has been emerging

in the form of “composite” or “hybrid” models of classification, as espoused by Skinner (1981, 1986). According to Skinner, for example, a composite classification system that adopts the strengths from each source system offers considerable potential for the integration of seemingly disparate theories of abnormal behavior; those that emphasize quantitative versus qualitative differences between individuals classified. Composite classification systems, such as the class-quantitative structure, may provide a framework for integrating the distinctive merits of each approach. In Skinner’s words, “Perhaps a real breakthrough in our understanding of psychiatric disorders awaits the skillful use of composite models” (p. 72).

#### COGNITIVE NEUROSCIENCE AND GENETICS

The classification approaches discussed previously, though imperfect, have made substantial progress in defining and measuring symptoms. However, this symptom-oriented approach offers limited knowledge of mental disorders by itself. Thus it is essential to integrate classification with advances in cognitive neuroscience and genetics that have enhanced our understanding of the structures and functions of the human brain associated with disorders. As noted previously, the etiology of most child and adolescent disorders is unknown, and it is hoped that those new areas of research will shed light on etiology in the next decades (Merikangas, 2002).

Neurobiological studies employing functional neuroimaging techniques have shown that specific symptoms are mediated by specific brain regions or circuits (Epstein, Isenberg, Stern, & Silbersweig, 2002). In addition, there is substantial evidence that suggests significance of genetic factors in mental disorders. For example, family studies have demonstrated that family history is the most powerful risk factor for developing most mental disorders (Merikangas & Swendsen, 1997). Although those recent studies offer promising explanations regarding mental disorders, the expression of genes is a complex process, and it is necessary to consider gene-environment interactions (Merikangas, 2002).

Based on the concept of gene-environment interactions, child and adolescent psychopathology should be understood as a result of an intertwined relationship between genes and environments, rather than nature versus nurture (Hudziak, 2008). Longitudinal twin studies conducted in the Netherlands revealed the interplay between genetic factors and the environment, which can vary as a function of problems. Specifically, for internalizing problems, a decrease in the genetic influence and an

increase in the influence of the shared family environment were found from ages three to 12 years. In contrast, the influence of genetic factors increased across childhood for externalizing problems. Lastly, the genetic influence for attention problems remained rather high over time (Boomsma, van Beijsterveldt, Bartels, & Hudziak, 2008).

#### STRENGTH-BASED APPROACHES

A traditional approach to the classification of child and adolescent disorders overemphasizes psychopathology, neglecting the significant role that resilience plays in understanding and treating disorders. Although it is now common practice to evaluate both maladaptive and adaptive behavior of children and adolescents, especially through behavior rating scales (e.g., the ASEBA), the DSM and other official classification systems have not incorporated the assessment of the strengths of an individual child, save for the International Classification of Functioning of the ICD.

Recently, the concept of “mental health” has been broadened to include psychological well-being as well as psychopathology. In other words, mental health is defined as, not only the absence of psychopathology, but also the presence of psychological well-being. This dual-factor model of mental health has been supported by empirical evidence. In a study of middle-school students, Suldo and Shaffer (2008) identified two clinical groups of adolescents who presented high levels of clinical symptoms and yet differed in their level of subjective well-being: The *Troubled* group showed low levels of happiness, whereas the *Symptomatic but Content* group showed high levels of happiness. They also differed from each other in that the symptomatic but content adolescents perceived themselves as having more positive relationships with peers and more social support from adults than did their troubled counterparts. These findings suggest that the two clinical groups, despite the similar level of pathological symptoms, might require different approaches to treatment (Suldo & Shaffer).

As illustrated above, when both the psychopathology and strengths of an individual child are considered together, they provide more comprehensive assessment of the child’s problems, which can purportedly lead to more effective treatment planning. Although the DSM multi-axial diagnostic system allows for assessing psychosocial and environmental aspects of an individual child, especially through Axis IV, it focuses only on symptoms. It may be that Axis IV will be expanded to identify not only

problems but also strengths in psychosocial and environmental aspects of an individual child (Doucette, 2002). Additionally, strength-based approaches appear useful for prevention and enhancement of mental health in children and adolescents (Kim & Esquivel, 2011).

### CULTURE AND DIAGNOSIS

For the most part, the DSM system assumes the universality of mental disorders. In contrast, the relativistic view posits that the culture of an individual defines normality and abnormality of behavior and shapes the expression of symptoms (Mezzich, Kleinman, Fabrega, & Parron, 1996). Unfortunately, there is a lack of empirical evidence to address whether and how culture influences the manifestation and presentation of symptoms for particular child and adolescent disorders (Cuéllar & Paniagua, 2000). However, data so far suggest that neurologically based disorders (e.g., autism, schizophrenia) are more likely to be universal, whereas other disorders (e.g., conduct disorder, oppositional defiant disorder) are more likely to vary across cultures (Canino & Alegría, 2008). Hence, these findings seem to support the combined relativistic and universalistic view (Rutter & Nikapota, 2002).

Compared to the DSM-III-R, the DSM-IV made progress in acknowledging the significance of culture in the diagnosis of mental disorders. Specifically, the DSM-IV provides an outline for cultural formulation and culture-bound syndromes in the Appendix. However, cultural considerations are treated as supplemental to the multi-axial DSM diagnostic system, rather than systematically incorporated (Alarcon, 1995). Despite the lack of formal recognition of culture's role, it is crucial to understand how the dominant cultural norms, a child's culture, and a clinician's culture interact with one another, affecting the diagnostic process. In adult psychopathology, research has demonstrated diagnostic bias associated with ethnicity of patients. For example, despite the similar presentation of symptoms, African Americans and Hispanics are more likely to be diagnosed with schizophrenia, whereas Caucasians are diagnosed with psychotic mood disorder (Garb, 1997). Similarly, the assessment of ethnic and linguistic minority children and adolescents requires cultural sensitivity to avoid misdiagnosis, over-diagnosis, or under-diagnosis. For example, in a prevalence study conducted with a community sample of Puerto Rican children, about half of the sample were found to have significant psychiatric problems when the DSM-III criteria were used

without cultural considerations (Bird et al., 1988). In the assessment of child and adolescent psychopathology, adults such as parents and teachers take an active role in seeking mental health services and reporting problems. Therefore, it is important to understand the cultural meaning and interpretation of symptoms, not only from the child's perspective, but also from the adult's perspective, taking into account the influences of larger social contexts (e.g., school, community; Parron, 1997).

The issue of culture and diagnosis is becoming more important with the increasing diversity of North American and other populations with high immigration rates. At present, there is insufficient evidence that examines the cross-cultural validity of mental disorders, especially for children and adolescents. In advancing our knowledge and understanding of cultural influences on diagnosis, future research needs to address the following questions: Does a particular disorder indeed exist across cultures? Are the diagnostic criteria biased against a certain cultural group? To what extent are gene-environment interactions related to a specific disorder? Do differences in cultural backgrounds and social status between the child and the clinician cause bias? Are assessment tools culturally fair and sensitive? (Canino & Alegría, 2008; Nathan & Langenbucher, 2006).

### Conclusion

This section discussed issues, advances, and future directions related to the classification and diagnosis of child and adolescent psychopathology. Although the field has not reached consensus on how to best classify disorders in children and adolescents, practitioners seem to support the idea that the DSM system should continue to be further refined as it serves several purposes, including facilitating ease of communication and providing a common nomenclature. Specifically, future revisions of the current classification system will need to address several problems such as comorbidity, validity of disorders, and links to treatment. We envision that the study of classification systems is an endeavor in "bootstrapping." This process is iterative in that a new approach is compared to a known imperfect method (the DSM) until the accumulation of evidence for a new approach becomes so compelling that it becomes the new "gold standard." Similarly, a single breakthrough investigation that resolves many issues about the utility of screening, the next topic, is not likely to occur (Schmidt et al., 2004).

## Screening

While psychologists have long viewed classification and diagnosis to be essential components of service delivery, screening has not received the same widespread attention and adoption (VanDeventer & Kamphaus, *in press*). However, due to the renewed attention being given to proactive early identification and intervention for academic, behavioral, and emotional problems, screening, as a component of a multi-tier model of service delivery, has risen to the forefront of considerations for many psychologists and educators. Screening within the educational realm has burgeoned following the 2004 reauthorization of the Individuals with Disabilities Education Act, which emphasized a response-to-intervention (RtI) approach (Ikeda, Neesen, & Witt, 2008). Similarly, screening for mental health problems has received increased attention following reports that the current state of child and adolescent mental health services is a “public health crisis” in part due to the high percentage of children who are both unidentified and untreated for mental, emotional, and behavioral disorders (Campaign for Mental Health Reform, 2005). Both the RtI approach and the public health model consider screening to be an integral step in the process of reducing or eliminating academic and psychological problems. As psychologists and other professionals are examining ways to improve upon the current educational and health care system, screening is now more commonly being advocated as an essential component to identify those in need of services and to provide them with targeted prevention and early intervention services (Glover & Albers, 2007).

The increasing attention paid to the need for universal screening, prevention, and early intervention services across a variety of governmental, research, and educational agencies obviates the need for guidance regarding optimal screening procedures. Thus far, the complexities of diagnosis have been explained, in which the process of giving a diagnosis has been introduced in several ways; including as a continuum of quantitative dimensions of a disorder, or as an interplay of genes, environment, and culture. Since the act of diagnosing is complex, screening, which can act as a preceding or preventative step to diagnosing, is consequently also complex. Although, screening approaches may be complex, and are certainly still being developed and debated, there are several foundational elements to be aware of. Therefore, the following section has two goals: First, it is aimed at providing practitioners with a solid foundation on the central tenets of screening

so that they can better understand and utilize screening as a critical component in a multi-tiered service delivery model; second, it is intended to synthesize research findings and suggest areas of future research that are needed to move the field of screening forward. The primary focus will be on school-based screening, because children and adolescents spend the majority of their time in schools, and schools are often where problems are both identified and addressed (Skalski & Smith, 2006). However, the tenets and issues presented are applicable to screening in a wide range of settings, including primary care clinics and mental health clinics. Toward those ends, definitions of screening will be offered, followed by a discussion of current practices and practical issues to be considered when implementing or evaluating a screening program. Additional research that is needed to further refine the screening process is discussed as well.

## ***Definitions and Background***

### **SCREENING FOR RISK VS. SCREENING FOR DIAGNOSIS**

“Screening” is generally defined as testing or examining for the presence of a problem. The “problem” can be defined as a specific diagnostic disorder, such as depression or post-traumatic stress disorder, or it could be defined as the risk for developing a disorder. For example, a screening can test for cardiovascular disease (i.e., the presence or absence of a heart condition); alternatively, the screening could test for the presence of risk for developing a heart condition. The distinction between screening for risk versus screening for a diagnosis is an important consideration to be made prior to embarking on a screening process.

Screening for risk is a preventative technique that has the intention of establishing early interventions. To screen for the risk of cardiovascular disease, a screener would ask questions about the person’s current body condition and involvement in any activities that are linked to the later development of cardiovascular disease, such as age, body weight, exercise, and diet (Natarajan & Nietert, 2003). Alternatively, a doctor might take a patient’s blood pressure at every appointment. These methods are not informative enough to establish a diagnosis; rather, they are assessing for “red flags” that may lead to later diagnosis. If a patient is found at risk for cardiovascular disease, the doctor will recommend some changes in behavior and lifestyle, which can serve as an early interventions to prevent a later, more serious problem. Screening for risk

usually corresponds with brief and efficient screening methods, which can range from a five-minute pencil and paper rating scale, an informal question from a doctor, or a quick procedure like a reflex test or taking one's temperature. It is not intended to be diagnostic. Identifying and preventing problems before they have already fully developed is a more cost-effective and efficient method of service delivery than focusing solely on diagnosis and treatment (Levitt, Saka, Romanelli, & Hoagwood, 2007).

While screening for risk has numerous benefits, it is not an intention that is agreed upon in the screening literature. Many screeners are designed to assess for diagnosis rather than risk. As discussed earlier in this chapter, *diagnosis* refers to identifying a person as meeting sufficient criteria to be given a specific medical or clinical label, such as attention deficit/hyperactivity disorder or a specific learning disability. In contrast, *risk* is described as the likelihood or vulnerability one has to develop such a diagnosis. Two-hour clinical diagnostic interviews at a mental health clinic, an expensive scan or blood test, or a rating scale with multiple questions ascertaining functioning on each symptom criteria of the DSM-IV are aimed at diagnosis. They are comprehensive procedures that provide enough information to give or inform a diagnosis. This poses the question, when developing a screening process, should the process be designed with the intention of finding and treating incidents of diagnoses? Or should the process be designed to assess for risk, to help inform the clinician what early interventions could prevent the diagnoses from later occurring?

The confusion and controversy over the intention of screening is just one of the many ambiguities and debates related to the purpose and process of screening. Similar to the discussion of different approaches to diagnosis, there is a variety of competing definitions for "screening," and this word is used with reference to various intentions, processes, and contexts. The term "screening" conveys a variety of different meanings (Mills et al., 2006) making consensus difficult and, as a result, some have suggested alternative definitions. Crowell (2005), for example, suggested that, in lieu of the term "screening," the terms "early identification" and "early intervention" should be used. However, this appears to be based on the assumption that one is screening for risk, as opposed to diagnosis, since early identification and intervention are more aligned with the goal of reducing risk. In recognition that the term "screening" is still likely to be widely utilized, it is important for practitioners to recognize that, although the

use of the term varies, the core purpose for screening should be carefully considered and *a priori* decisions about the purpose of screening should be made.

### **UNIVERSAL, SELECTIVE, OR INDICATED SCREENING**

In addition to the lack of correspondence regarding the definitions and purpose of screening, an area that brings forth further confusion is which population will be involved in the screening process. Namely, a decision to conduct screening at the universal, selective, or indicated level must be determined. Based on the public health model of service delivery, a multi-tiered approach provides varying levels of services and support based on the level of documented need. Briefly, *universal* services are provided to all youth; *selected* services are provided to youth who are deemed at-risk; and *indicated* interventions are targeted for youth demonstrating the greatest level of need or impairment (Durlak, 1997). Under a public health approach, a systematic screening would be conducted at a universal level so that all youth have the opportunity to be identified and thus receive follow-up services as needed. However, screenings are often conducted on a population that is decidedly less than universal.

The definitions of universal screening are operationalized in various ways in the literature, making this topic even more blurred and unclear. Universal screening attempts to administer the screener to every person in the relevant population: "the relevant population" meaning every person who has a possible risk of having the problem. For example, men would not be included in the relevant population for screening for breast cancer. However, for mental health screening, the entire population could be considered relevant since there are no groups that are excluded from possible risk of poor mental health; similarly, academic screenings would include all students.

As opposed to a universal screening, a selected screening method would not attempt to screen all individuals in the relevant population but would instead focus on a population that is already deemed to be at risk. For instance, in intimate-partner violence screening, selective screening methods are often used, in which only females who appear injured and/or are perceived as being at high risk for intimate-partner violence are asked about intimate-partner violence (Phelan, 2007). Males or other females are still in the "relevant population," since anyone who has a partner could potentially be a victim of intimate-partner violence, but this is

clearly not a universal approach to screening. The same could be true in mental health clinics, where individuals are not screened for depression until they seek out services, whether it be for depression or for a related problem. Or with knowledge of the link between mental health and educational outcomes, a student may only be screened for emotional or behavioral risk following a referral for reading problems (United States Public Health Service, 2000).

Indicated screening would be conducted with individuals who have already been diagnosed or identified as having a mental health problem, and would probably be a part of a comprehensive clinical assessment (Levitt et al., 2007). The goal would not be early identification of and early intervention with a problem, but rather to identify the particular needs of an individual for treatment planning or the presence of a co-occurring condition, or to prevent the occurrence of more deleterious outcomes associated with the disorder. This level of service is reserved for only the individuals at the highest level of risk and has been suggested to be viewed as a form of treatment (Durlak, 1997).

There is debate in the literature as to which approach—universal, selective or indicated screening—is superior (Levitt et al., 2007). The ultimate decision about which approach to utilize is also likely to depend on the resources available.

### ***Current Practices and Considerations for Implementation***

Following a decision regarding the purpose of screening (risk level or diagnosis) and a decision of who will be screened (universal, selected, or indicated), there are numerous additional decisions to be made and many practical issues to consider. Considerations such as the timing, setting, and administration of implementation, as well as the plan for follow-up with individuals who are screened as being at risk, should be well thought out prior to embarking on a screening program. Overall, psychologists making decisions about screening and the implementation of a screening system should recognize that screening should be a part of a comprehensive service delivery plan and work to develop a team that can be involved throughout the process (Dowdy, Furlong, Eklund, Saeki, & Ritchey, 2010). Without the vision of how screening can ultimately lead to targeted prevention or early intervention services, the result could simply be a list of individuals in need of follow-up. However, if screening is well integrated within a service delivery system, with thoughtful decisions

determined prior to implementation, screening can allow for the early treatment of problems prior to the problems' becoming exacerbated and potentially being more difficult to treat. This section provides readers with information about the current state of screening practices and guides readers through a set of issues to consider when designing or implementing a screening program.

#### **A MULTIPLE-GATING APPROACH**

Currently, screening is often implemented through a *multiple-gating approach*. This approach is consistent with the multi-tiered approach to service delivery advocated by prevention scientists (Weisz, Sandler, Durlak, & Anton, 2005) in that it narrows down the population and only provides more intensive assessment to those identified as being in need of it. In a multiple-gating approach, the first "gate" generally entails all children's being screened, which provides for a universal screening (universal assessment). Then the children who are identified as "at risk" by the first gate screener pass into a second gate, in which an additional assessment is provided (*selected assessment*). The selected assessment strategy often utilizes a more comprehensive, thorough tool such as a full omnibus behavior rating scale, or an additional screener utilizing a different rater or informant. Finally, the children who continue to be identified as having significant risk through the selected assessment strategy are then evaluated with a more comprehensive, individualized assessment as a third gate assessment (*indicated assessment*). This indicated, comprehensive assessment would be more aligned with a full diagnostic assessment and could result in a diagnosis or determine eligibility for services being offered. This multiple-gating approach allows for progressively more precise, specific, and intensive assessments to be provided to students with increased levels of risk. This type of procedure has been shown to increase identification and diagnostic accuracy as well as reduce costs due to inefficient identification (Hill, Lochman, Coie, Greenberg, & The Conduct Problems Prevention Research Group, 2004; Walker & Severson, 1992; Lochman & The Conduct Problems Prevention Research Group, 1995).

One example of a multiple-gating screening procedure is the Systematic Screening for Behavior Disorders (SSBD; Walker & Severson, 1992). The SSBD utilizes a three-stage process including teacher training and rankings (i.e., nomination), teacher ratings of child behavior, and classroom observations. The first stage consists of teachers' rank-ordering all

the students in their classroom on both externalizing and internalizing behavior dimensions. While all students are supposed to be considered, only the top ten students in each dimension (externalizing and internalizing) are nominated and ranked in terms of the severity of their symptoms. Out of the ten students nominated, the top three students in each category proceed through the first gate into the second gate assessment. The second gate assessment requires teachers to complete two rating scales: the Critical Events Index, to discern if the student has engaged in various significantly disruptive activities, such as being physically cruel to animals; and the Combined Frequency Index, to gather information about adaptive and maladaptive behaviors. Students who exceed normative cut points on these two instruments proceed to stage three. The third gate assessment involves systematically observing the students in naturalistic school environments, including assessing for academic engaged time in the classroom and positive social interactions while on the playground. The results from this stage three assessment are used to determine the next level of assessment or intervention that is appropriate, such as a referral for special education testing.

An additional example of a multi-stage screening process involves the use of a multi-disorder screening instrument as a first gate assessment: the Behavioral and Emotional Screening System (BESS; Kamphaus & Reynolds, 2007). The BESS was developed under the awareness that, for a screener to be truly time-efficient and effective, it should assess multiple areas of problems and strengths, including internalizing problems, externalizing problems, school problems, and adaptive skills. The BESS consists of brief screening measures, designed to be completed in five minutes or less with no training required, that can be completed by teachers, parents, and students to identify behavioral and emotional strengths and weaknesses in youth ranging from preschool through high school (Kamphaus & Reynolds). Following the administration of the BESS, children and youth who are identified as "at risk" then proceed to the second gate in which the Behavior Assessment System for Children–Second Edition (BASC-2; Reynolds & Kamphaus, 2004) is given. The BASC-2 is a comprehensive, omnibus rating scale that provides additional information regarding the specific areas that might be problematic for the individual who was screened to be at risk by the BESS. For example, through this second gate assessment, it might become apparent that the student is experiencing significant problems with

anxiety as opposed to hyperactivity. A third gate assessment could entail a more comprehensive, individualized assessment incorporating multiple sources of information to aid in diagnosis and treatment planning.

The number of stages a screening process requires and the amount of personnel time required at each stage highlight the practical limitations of multiple-gating approaches. Practitioners should consider the time and resources that are available prior to implementing a screening system. It is still unknown whether multiple screening gates are, in fact, superior to single stage screenings, and the optimal number of gates to be utilized is still undecided. Multiple factors, only one of which is diagnostic accuracy, should be considered, including the feasibility and cost-effectiveness of multiple gating procedures. In fact, Lane et al. (2009) found the seven-item Student Risk Rating Scale (SRSS; Drummond, 1994) to perform comparably to the three-stage SSBD for the identification of externalizing problems. Therefore, brevity may not denote inferiority. However, a study investigating a two-stage screening process using the BESS and the BASC-2 demonstrated that adding a comprehensive behavior rating scale as the second gate significantly improved their identification accuracy over a single-gate procedure (VanDeventer & Kamphaus, in press). Furthermore, these questions require further research because many screening studies have estimated the effect of using multiple gates rather than implementing a real-world multiple gate screening procedure (VanDeventer & Kamphaus, in press).

## INSTRUMENTATION

The screening instrument to be utilized is a decision that will have an impact on subsequent decisions. When evaluating a screening instrument for potential adoption and use, the instrument should be evaluated for its technical adequacy, including investigation into an instrument's norm adequacy, reliability, and validity. Screening instruments will not be absolutely accurate (i.e., correctly classify every student), and although some error is unavoidable, it is generally recommended that decisions be made in a way that is the least likely to be harmful (Ikeda et al., 2008).

There are four possible outcomes that can result from using a predictor (e.g., screener) to classify individuals according to a criterion (e.g., at risk or not at risk; diagnosed or not diagnosed): true positives, false positives, true negatives, and false negatives. The goal of a screener is to maximize the number of

true positives and negatives and minimize the number of false positives and negatives. However, it is important to realize that when the number of false negatives is reduced, it conversely increases the number of false positives, necessitating a prioritization of which result is more tolerable. In screening, a higher number of false positives is often tolerated in favor of more false negatives. This is because a child classified as a false negative would be “missed” and therefore not have the opportunity to receive further assessment or services. However, under a multi-gating screening approach, children identified as false positives would simply undergo additional assessment to determine which children are identified but do not, in fact, have a disorder or risk of the disorder.

Screening instruments often report their technical adequacy in terms of their sensitivity and specificity. *Sensitivity* refers to the proportion of individuals with the disorder who are correctly identified by the instrument as having the disorder; in other words, true positives. *Specificity* refers to the proportion of individuals without the disorder who are correctly identified as not having the disorder, or true negatives. Additionally, the positive predictive value (PPV) of a screener is often reported, and this is calculated as the proportion of students correctly identified as at risk (true positives) out of all students identified as at risk on the screener. When the PPV is low, a large number of false positives is present, which is tolerated and expected in most screening scenarios (Levitt et al., 2007), given that, when the PPV is optimized, false positives are minimized at the risk of missing true cases. The negative predictive value (NPV) of the instrument is the proportion of students correctly identified as not at risk (true negatives) out of all of the students identified as not at risk on the screener. When the NPV is low, a large number of false negatives results.

It is also recommended to interpret the PPV and NPV in light of information on the base rate of the outcome of interest, as the base rate will significantly affect the PPV and NPV of a screener (Meehl & Rosen, 1955). As Hill and colleagues (2004) explained, “Sensitivity and specificity of tests may sound impressive when reported without reference to PPV, NPV, and base rates. For example, a test with sensitivity of .80 and specificity of .95 has a PPV of about 74% if the base rate is 15%, but the PPV is reduced to 46% if the base rate is 5%” (p. 810). When considering emotional and behavioral problems, for example, prior research suggests that an annual base rate would be around 20% (Campaign for Mental Health Reform, 2005; Friedman,

Katz-Leavy, Manderscheid, & Sondheimer, 1996; Hill et al., 2004), and this base rate will be lower when considering a single disorder.

In addition to technical adequacy, further considerations for evaluating screening instruments have been outlined by Glover and Albers (2007) and include ensuring that the screening instrument is appropriate for the intended use and is practical for use. In regard to practicality, Glover and Albers recommend that the screening instrument be evaluated in terms of the following: (1) cost, (2) feasibility of administration, (3) acceptability to multiple stakeholders, (4) infrastructure for collecting and interpreting screening data, (5) appropriateness of use for entire targeted population, and (6) utility of the information obtained to provide improved treatment decisions.

## SETTINGS

Practitioners will also need to determine where screenings will occur. In this chapter, school-based screening is the primary focus. Schools have been advocated as an ideal setting for the delivery of academic, behavioral, and emotional screening services, not only because children and adolescents spend the majority of their time in schools, but also because schools are often where problems are both identified and addressed (Skalski & Smith, 2006). Although academic screenings seem to be more aligned with the primary mission of schools to educate all children, schools should also be considered as an ideal setting for large-scale, broad-based mental health screening of children and adolescents (Wu et al., 1999) due to the relationship between mental health problems and academic achievement. Recent studies indicate that mental health problems can be significant barriers to learning, and, conversely, positive behavioral and emotional health is associated with academic success (Atkins, Frazier, Adil, & Talbott, 2003; Bradley, Doolittle, & Bartolotta, 2008; Catalano, Haggerty, Oesterle, Fleming, & Hawkins, 2004; United States Public Health Service, 2000; Wagner, Kutash, Duchnowski, & Epstein, 2005).

Additionally, the fact that school-based mental health services are the most commonly accessed services for youth with mental health problems (Burns et al., 1995; Farmer, Burns, Phillips, Angold, & Costello, 2003) suggests that schools might be more ecologically valid, as early intervention should follow early identification. Considering that many children are not seen in primary healthcare settings, in particular children from impoverished backgrounds who are at high risk for poor behavioral outcomes,

schools often become the de facto mental health care system (Kelleher, Moore, Childs, Angelilli, & Comer, 1999). In fact, 20% of all students receive some type of school-supported mental health or social services (Kutash, Duchnowski, & Lynn, 2006). Unfortunately, however, very few schools currently engage in a systematic screening process for emotional or behavioral problems (Romer & McIntosh, 2005). This trend might change with the availability of practical screening instruments and large-scale studies that are currently underway investigating screening within schools (Kamphaus, DiStefano, & Dowdy, 2009).

While schools do appear to be practical and effective settings for screening, the suggestion to conduct screening in schools is not implying that behavior and information drawn from other settings and resources is not valuable. For instance, it is also important to consider home and cultural influences, just as these influences are important aspects of diagnosis. However, conducting screening in schools is an effective starting point, since students are easily accessible and resources are available in the schools for assessment and evaluation.

## INFORMANTS

Even after determining the setting for implementation, practitioners have decisions regarding who within that setting will provide the information to be included in the screening. There are varying opinions and research evidence regarding the number and type of informants who will provide the optimal amount and types of information in a mental health screening system. Although it is often recommended to collect ratings from multiple informants (Frick, Burns, & Kamphaus, 2009), and the “more is always better” stance dominates contemporary thinking (Jensen et al., 1999; Power et al., 1998; Verhulst, Dekker, & van der Ende, 1997), research findings are conflicting. There are several studies that suggest that gathering information from an additional informant adds little variance to the identification process above and beyond what was provided by the first informant (Biederman, Keenan, & Faraone, 1990; Jones, Dodge, Foster, Nix, & Conduct Problems Prevention Research Group, 2002; Lochman and the Conduct Problems Prevention Research Group, 1995). Jones and colleagues found that the effect of combining parent and teacher ratings was equal to or minimally better than that of the teacher-only rating. Mattison, Carlson, Cantwell, and Asarnow (2007) found that teachers rate externalizing and internalizing problems as well as or better than parents. In direct

contrast, Goodman, Ford, Corbin, and Meltzer (2004) found that prediction was best when both caregiver and teacher ratings were combined. As explained above, environment and setting can play an important role in both diagnosis and classification. Similarly, it is also important to consider the relationship between settings and sources when selecting the number and type of informants.

There is often a lack of consistency among raters (Achenbach, McConaughy, & Howell, 1987), suggesting that perhaps different raters provide different, yet still valuable, information. In addition to parents’ and teachers’ being valuable sources of information, there is some evidence that supports the use of child and adolescent self-report measures of externalizing and internalizing symptomatology (Grills & Ollendick, 2003). More research is needed, however, since there is some evidence to suggest that adolescents fail to identify their own risk, at least in one sample of incarcerated males (Vreugdenhil, van den Brink, Ferdinand, Wouters, & Doreleijers, 2006). Self-report screeners, however, have been recommended as instruments of choice for middle, junior, and high school-aged students (Levitt et al., 2007). One must also consider the time and expense incurred to include additional informants. There is no current consensus on the number of informants and the type of informants that should be included in the screening process, and additional research is needed to investigate “the value of different informants at various stages of the assessment process” (Johnston & Murray, 2003).

Academic screenings typically involve students completing brief curriculum-based measures (CBMs; Shinn, 1989). CBMs have been used in universal screenings and, if they are aligned with academic benchmarks, they can be ideal for screenings due to their ease of administration, scoring, and interpretation (Ikeda et al., 2008). For example, the Dynamic Indicators of Basic Early Literacy Skills (DIBELS; Good & Kaminski, 2002) is routinely used to screen for early literacy problems and monitor the development of early literacy skills (Brunsman, 2003). Unlike in behavioral and emotional screenings, students are usually the sole informants. However, teachers can, and frequently do, refer students with academic problems for more intensive assessment and additional academic intervention.

## TIMING

A practitioner interested in screening should also consider when the screener should be administered. For instance, in the context of screening in schools,

a common time-point may be as a student enters a new school, such as before entrance to kindergarten, or as the student transitions to middle school or high school. Stoep and colleagues (2005), for example, targeted students during their transition from elementary to middle school in the Developmental Pathways Screening Program (DPSP), suggesting that this was a critical transitional stage. Preschool screeners are also available, highlighting the need to identify problems early in their developmental trajectories (DiStefano & Kamphaus, 2007; Kamphaus & Reynolds, 2007). Time points involving transitions are also chosen for practical reasons, since often other paperwork or screeners are commonly administered at these times. Additionally, schools can get a sense of the potential problems that the new student body may have at an early stage, so early interventions can be planned accordingly. Research also shows that children may be particularly vulnerable to emotional or behavioral problems when they move to a new school (Csorba et al., 2001; Stoep et al., 2005), which gives sufficient reason to screen for problems at this time.

It is also essential to consider what the screener is designed to look for, to aid the decision of when the screener should be implemented. It is more common to have depression in adolescence when there is an 8% to 12% prevalence rate, versus in childhood when there is a 2% to 3% prevalence rate (California Adolescent Health Collaborative, 2000). Therefore, it might be more sensible to screen for depression in junior high versus elementary school to avoid missing the majority of students who develop depression after elementary school. However, if the screening is designed to assess for the precursors to depression, as opposed to a diagnosis of depression, it might be more sensible to screen earlier so that preventative techniques can be implemented prior to exacerbating symptomatology. Therefore, a variety of factors should be considered when deciding when the screener should be implemented.

## ADMINISTRATION

A logistical choice that needs to be made is in what context the screener should be administered. If the screener requires parental involvement, it can either be administered in person to parents, such as at Back-to-School nights or parent-teacher conferences, or it can be sent home, either by mail or with the student to give to the parents. The response rate tends to be lower when forms are sent home (Esbensen, Melde, Taylor, & Peterson, 2008), and parents may be less likely to consent to it or take the initiative to

ask questions they may have if a screener administrator is not available in person. However, parents may feel more comfortable completing a screener at home, and time will not be taken away from the event the parent is attending at school. For a screener completed by students, the screener can be implemented either by pulling students out of class, be administered within the classroom during a regular school day, or take place alongside state testing. There are advantages and limitations to each approach, and determinations will probably depend on administrative decisions and the amount of buy-in by the community in which the screening will occur.

## INTERPRETATION AND FOLLOW-UP

Prior to implementing a screening program, considerable thought should be given to the process that will occur following an initial screening. As stated previously, screening is not an activity that should be undertaken by one individual or a small group of individuals; rather, it should be a part of an organized effort, with structures in place so that individuals identified as in need of additional services can be promptly attended to. Within a school screening context, school psychologists could oversee a universal screening administration for a variety of problems, including academic, mental health, and harmful behavior problems. For a screener for reading problems, the school psychologist may decide that the results of the screening suggest programmatic, instructional deficiencies due to a wide range of students' performing below benchmarks. Or the school psychologist may determine that there are only a few students who are primarily at risk for developing reading failure. However, the decision-making process has only begun at this point, with further decisions needed regarding the best course of action and the person to be in charge. Who, for example, is the most appropriate person to design an intervention for each of the students: the school psychologist, the teacher, or a reading specialist? Who decides whether all of the at-risk students should be given the same intervention, or whether individualized interventions will ensue? Surely, the number of at-risk students, the number of staff available, and the amount of resources available for intervention affects the answers to these questions. And how will the answers to these questions differ if the problem is mental health-related or drug-use-related? It is important to consider the context of the problem, the knowledge of the staff available, and the practicality of how much time, money, and staff are available.

## LEGAL AND SOCIAL CONSIDERATIONS

In addition to practical implementation considerations, there are some social and legal considerations that deserve mention, including the consent process and the supposed link to medication. First, the process of obtaining parental consent and student assent for screening remains controversial and conflicted, particularly with regard to mental health screening. Informed consent may be either active or passive (Eaton, Lowry, Brener, Grunbaum, & Kann, 2004), and whether to screen is commonly decided by the respective school districts and how they interpret the Protection of Pupil Rights Amendment (PPRA; Chartier et al., 2008). The PPRA “seeks to ensure that schools and contractors obtain written parental consent before minor students are required to participate in any U.S. Department of Education funded survey, analysis, or evaluation that reveals information concerning...” a variety of sensitive behaviors, such as political affiliation and sexual behavior and attitudes. One area included is “mental and psychological problems potentially embarrassing to the student and his/her family” (U.S. Department of Education, 2005). These guidelines can be interpreted in various ways; therefore, it is important to evaluate the differences between active and passive consent for mental health screening. Active consent requires that the written consent form be returned with a signature from the student’s parent. Passive consent requires that the parent return the consent form only if they do *not* want their child to participate in the study; if the consent form is not returned, it is assumed that the parent has given consent. There are benefits and drawbacks for each of these methods.

The explicit parent consent received through active consent provides solid assurance of parent approval. However, while this method appears legally sound, the sometimes lengthy and complicated process of distributing and collecting signed consent forms can introduce an element of bias in the sample, which may undermine the effectiveness of a universal screening approach wherein all individuals have equal opportunity for follow-up and resulting interventions. Active consent processes yield varying return rates from 34% to 67% (Eaton et al.; Esbensen et al., 1996). The decreased sample can be disadvantageous, as students who would benefit from the screener and/or services associated with it may miss out due to the active consent process. While it is important that parents be informed of and have control over what their children are subjected to, consent forms are frequently not returned

for a variety of reasons, and the children might be adversely affected. Chartier et al. (2008) found that, after switching the school-based depression screening process from passive consent to active consent, the participant rate decreased from 85% to 66%. The decrease in participation was not equivalent across subgroups of students, and the percentage of students positively screened for depression was significantly reduced. This illustrates how more stringent consent procedures can potentially reduce the effectiveness of the screener, in which at-risk populations can be less likely to be identified and served. Therefore, this brings up the question that, if the goal of screening is to identify students at risk, in an attempt to provide them help; if active consent is hurting this process, is the “less legally sound” approach of passive consent better?

Mental health screening also frequently comes under scrutiny due to the supposedly direct link to medication. The term “mental health” commonly has a negative connotation, and one of the most frequent ideas associated with “mental health problems” is medication. From the widespread knowledge of the growing practice of prescribing psychostimulants for students with ADHD, or anti-depressants to teenagers who have depressive symptoms, the general population is quick to associate “mental health” with “medication.” It is common for the general population to believe that children are being over-medicated and that the medications have negative long-term effects on development (Pescosolido, Perry, Martin, McLeod, & Jensen, 2007). This controversial issue becomes relevant when people associate mental health screening with a system to aid medicating or over-medication children.

Some organizations express their concerns about the potential over-medication of children as a result of mental health screening funded by psychiatric drug industries (e.g., MindFreedom International, 2005). Therefore, while the practice of mental health screening carries with it some controversial viewpoints, it is important to stress that the sole focus of mental health screening is *not* to medicate individuals. Instead, as stated before, mental health screening is a process for identifying students at risk of developing emotional and behavioral problems so interventions can be set in place to prevent such problems from developing or getting worse. However, it is prudent for those interested in implementing a screening process to be aware of some of the controversies associated with screening so they can work to inform their constituencies.

## Conclusions and Future Directions

Although the field of screening is far from mature, active early screening for emotional, behavioral, and academic problems has intuitive appeal and is generally regarded as a potentially fruitful approach to early identification and prevention (Severson, Walker, Hope-Doolittle, Kratochwill, & Gresham, 2007). The issues highlighted herein provide a critical look at many of the current practice and research considerations regarding screening. However, there are many areas in which additional research is needed regarding both the efficacy and the effectiveness of screening and screening instrumentation (Levitt et al., 2007). Due to the relationship between screening and diagnosis, it is also necessary to consider the potential upcoming changes in approaches to diagnosis to further understand the best approaches to screening. Studies investigating the long-term predictive validity and utility of screening instruments are needed, as previous studies have produced discrepant results regarding the accuracy and validity of screening procedures (Dowdy et al., 2010). Additional studies investigating the cost-effectiveness of screening (Chatterji, Caffray, Crowe, Freeman, & Jensen, 2004) and the practicality of its implementation (Shirk & Jungbluth, 2008) could help bridge the gap between the science of screening and its practical administration. Similar to concerns regarding the “unappreciated paucity of empirical support for RTI and an overly optimistic view of its practical, problematic issues” (Reynolds & Shaywitz, 2009, p. 130), the support for screening is still in its nascent stage. Psychologists interested in screening are encouraged to critically evaluate the emerging screening research and to make determinations regarding implementation based on solid evidence. However, there is enough known now about the value of early identification and intervention that action, as opposed to waiting for further refinement of the screening process, is recommended (Dowdy et al., 2010). In much the same way that the diagnostic systems of DSM and IDEA will continue to benefit from further revision, screening systems will certainly profit and improve due to continued research and refinement.

## Chapter Conclusions and Future Directions

This chapter differs considerably from many other previously published chapters on classification and diagnosis for two reasons. First, up until the last two decades, the chorus of DSM detractors was relatively small, and their concerns were primarily conceptual and theoretical. Now there

is sound empirical evidence, cited throughout this chapter, to suggest that future versions of the DSM will have to respond with a classification system that addresses well-documented problems. Thus, this chapter includes substantial sections on alternative approaches to diagnosis that have some evidence of empirical support.

Second, the timing of this chapter makes mandatory a thorough discussion of classification associated with prevention practice and science via screening. The long-awaited emphasis on prevention and early intervention in child services and schooling requires new classification technologies specifically related to these practices. Consequently, screening dictates the need to change classification and diagnostic systems further, to include classification of various types of “normality” or “typicality,” and classification of risk status.

These two areas of classification science are likely to be the focus of intensive research efforts and conceptual breakthroughs for the foreseeable future. We look forward to the outcomes, for they portend better service to children.

# The ICF-CY: A Universal Taxonomy for Psychological Assessment

Rune J. Simeonsson and Andrea Lee

## Abstract

Assessment is central to psychological practice but has lacked an inclusive framework of health, functioning, and behavior. This chapter advances the International Classification of Functioning, Disability, and Health for Children and Youth—ICF-CY (WHO, 2007) as a new framework for guiding psychological assessment, from conceptualization of needs through documentation of intervention outcomes. In the ICF-CY taxonomy, the components of Body Functions, Body Structures, and Activities/Participation encompass different manifestations of child health and functioning defined in terms of physical, personal, and social dimensions. A unique contribution of the ICF-CY to psychological assessment is inclusion of the component of Environmental Factors for documenting the aspects of the environment that facilitate a child's functioning and participation and those that may serve as barriers. The universal and comprehensive scope of the ICF-CY provides a standard for classifying dimensions of functioning in children with disorders and disabilities complementing diagnostic and etiological information. Assignment of the universal qualifier to codes in the different components of the ICF-CY can indicate the nature and extent of disability or disorder defined in terms of impairments of functioning, activity limitations, or participation restrictions. The use of the ICF-CY is compatible with current psychological assessment methods, tools, and data sources, yielding an efficient profile for summarizing a child's functional status within a child-environment interaction perspective. As a universal tool, the ICF-CY is consistent with perspectives on children's rights and offers a common language for documentation of childhood disability and disorders not only within psychological practice, but also across disciplines and related service systems.

**Key Words:** children's rights, child functioning, assessment, activity, participation, impairment, disability, environmental factors, ICF-CY

## Introduction

Assessment of human functioning is a central activity of the profession of psychology. It is a professional activity that is distinguished from that of other disciplines in that the focus is on assessment of subjective phenomena and their expression. From early methods of observation and interviews to the broad spectrum of standardized tests and inventories of current practice, the purpose of psychological assessment has been to identify the nature and dimensions of an individual's mental, affective,

and behavioral functioning. Such assessment is not carried out for its own sake, but as in medical assessment, serves an end of deriving diagnoses, identifying treatment options, and/or monitoring the progression of a condition or to document treatment outcome.

The aim of this chapter is to advance the practice of comprehensive psychological assessment by presenting a new tool for use. The chapter begins with consideration of the place of psychological assessment, including goals and pitfalls for

psychologists who work with children and youth. The International Classification of Functioning, Disability, and Health for Children and Youth (ICF-CY; WHO, 2007) is presented as a new tool for guiding psychological assessment, from conceptualization of goals through documentation of intervention outcomes. After presenting the ICF-CY and its applicability for assessment, the chapter provides a detailed overview of an assessment approach using the ICF-CY framework, including applied examples of the approach based on vignettes. In its entirety, this chapter provides a systematic overview of how to use the ICF-CY in the practice of comprehensive assessment to document children's abilities and needs in order to enhance their functioning while minimizing the impact or presence of barriers to meaningful participation in the environment.

## Challenges in Psychological Assessment

**David** is a six-year-old boy referred to an outpatient mental health clinic for concerns regarding his delayed language development and "odd behaviors."

**Jane** is a 12-year-old pre-adolescent girl referred to the psychologist at her school for "acting out." Her teachers would like insight into "what's wrong with her" so they can respond to her needs. They tell the psychologist they suspect an emotional or behavioral disorder.

On initial consideration of the vignettes above, the referral questions reflect the need for assessment in the search for a diagnosis for David and the determination of appropriate school services and supports for Jane. In each case we ask, What should be the focus of assessment; what are the measures, approaches, and strategies that should be included in the assessment? A typical approach with David might be to focus on assessment to confirm or rule out a diagnosis of autism spectrum disorder (ASD). For Jane, the approach might be to follow the sequence of steps required to determine her eligibility for special education under a designated diagnostic category. Such assessment, however, would not be sufficient to address the complexity of their presenting problems. These challenges are multiplied given the dramatic increase in the number of children identified with health conditions and disorders (Woliver, 2008). Carrying out assessment with these children in a comprehensive

and developmentally appropriate manner is associated with many significant challenges involving the process of assessment, the scope of assessment measures, and the object of assessment.

In contrast to assessment in medicine, a significant challenge in psychological assessment is that the process of assessing psychological and behavioral characteristics generally requires that the person is alert and responsive. Assessment of mental, affective, and behavioral functioning in most cases requires that the individual not only be alert, but actively cooperate in the assessment. That is, without the willingness of the individual to respond to questions, perform tasks, and engage in observable behaviors, it is difficult to document the normality or deviation of functioning. With children, this challenge is increased in that not only are their verbal and skill repertoires more limited, but so is their motivation to participate in the give-and-take of the typical assessment tasks. This challenge is exacerbated for children whose limitations are more pronounced and more pervasive, but who have the greatest need for valid assessment; that is, children with developmental disabilities or mental disorders. A critical element of this challenge is the need for an approach to assessment that both expands the view of human functioning and fosters an active process of assessment.

A second challenge is diversity in the scope of measures, tools, and procedures available for psychological assessment, described in *Tests in Print* (Murphy, Spies, & Plake, 2006) and *Burros Mental Measurements Yearbook* (Spies, Carlson, & Geisinger, 2010). The most substantial inventory of measures relates to the assessment of cognitive ability, particularly intelligence. This is a domain with well-standardized, robust measures, tracing its developmental history to the early 1900s and work of Binet and Simon. Closely related to the domain of cognitive measures are tools to assess processes such as perception, memory, and language, and the products of cognition in the form of academic achievement and performance tests. Adequate measures are available to assess interpersonal behavior as well as adaptive behavior, although the latter measures have focused more on activities of daily living than on adaptation to physical and social demands and "coping" in a broader sense. Although the domain of affective and intrapersonal functioning is perhaps the one with the greatest need for effective assessment measures, it is the one with a less well-developed inventory of measures. This variability in measures, tools, and procedures reflects a diverse, rather than integrated assessment domain.

A third and related challenge in psychological assessment is the need to expand the object of assessment beyond the child. An underlying premise of psychological theory of human functioning and development is that behavior and personal functioning are the products of ongoing person–environment interaction. However, a systematic analysis and assessment of environmental dimensions is not characteristic of much assessment practice. This is reflected by the fact that there are relatively few measures of the person's physical, social, or psychological environment.

There has been an absence of an inclusive framework for assessment of human functioning in psychology, defining typical and variant functioning and behavior. Practices and measurement in psychological assessment have thus evolved outside a unified and integrated perspective of dimensions of functioning and behavior of children and adults. Instruments and procedures have often emerged in response to meeting a specific need, such as defining the characteristics of a diagnosis or establishing eligibility criteria for intervention and services. Furthermore, when frameworks have been used, these have been based on conceptions of medical pathology in the International Statistical Classification of Diseases and Related Health Problems-ICD-10 (WHO, 1992), or psychiatric disorders in the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition Text Revision-DSM-IV-TR (APA, 2000) and DSM-V (Andrews, Pine, Hobbs, Anderson, & Sunderland, 2012). The limitations of these classifications for comprehensiveness and for developmental sensitivity have resulted in the continued development of yet other classifications of childhood disability and disorders, such as Diagnostic and Statistical Manual–Primary Care (Wolraich, Felice, & Drotar, 1996; Drotar, 2004) for children and youth, and Zero to Three (Wieder, 1994) for very young children. This approach has contributed to use of diagnosed conditions as a way to describe or document child status, a common practice in psychology's past, albeit a practice that has faced criticism over time.

Hobbs (1975) was a prominent voice in describing the stigma of labels, which "often depicted the child in negative terms" (p. 102), conveyed little information, and "suggested only vaguely the kind of help a child may need," (p. 102). As discussed in Florian et al. (2006), there are many problems in approaches utilizing disability status as a primary mechanism for describing a child. Disability labels mask individual differences in functioning, cannot capture the complexity of an individual's varied skills

and needs, and may stigmatize an individual in a way that impairs others' abilities to see a child for who he or she is, and his or her uniqueness (Florian et al., 2006). Leonardi, Bickenbach, Ustun, Kostanjsek, and Chatterji (2006) challenged researchers and practitioners to consider the role of definitions of disability as they advocated for a definition allowing conceptualization of disability as a dynamic interplay between individuals and their environment. In their paper, Leonardi et al. (2006) proposed that *disability* could be conceptualized as "a difficulty in functioning at the body, person, or societal levels, in one or more life domains, as experienced by an individual with a health condition in interactions with contextual factors" (p. 1220). This view is in contrast to the traditional approach to assessment framed within a perspective of intra-individual pathology without adequate recognition of the influence of the environment on ongoing behavior (Simeonsson, 2006).

An inclusive framework of human functioning that integrates the role of the environment could address the challenges noted above and contribute to more comprehensive psychological assessment of children and adults. As a broad framework of human functioning, it would also lend itself to the interdisciplinary nature of efforts to assess children's functional characteristics of relevance for planning intervention and documenting outcomes. The WHO International Classification of Functioning, Disability and Health—ICF (WHO, 2001) and the derived version for children and youth, ICF-CY (WHO, 2007), offer a framework to enhance the practice and instruments of psychological assessment of children (Simeonsson, 2009).

### **ICF-CY: a New Tool for Psychology**

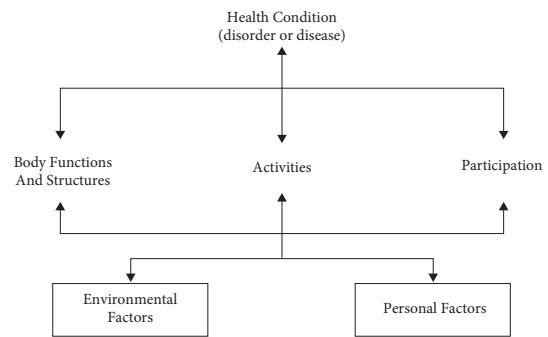

The need for a common conceptualization and language of "disease" was first recognized in the nineteenth century with the introduction of a classification of causes of death (WHO, 1992). More than a century and a half passed before a comparable universal classification of health and functioning was recognized. The World Health Organization first published a taxonomy for documenting individual functioning in 1980, with the publication of a trial version of the International Classification of Impairments, Disabilities, and Handicaps (ICIDH; WHO, 1980). This classification was revised over time, and in 2001, WHO introduced the International Classification of Functioning, Disability, and Health (ICF) as its newest addition to the Family of International Classifications (FIC). The 2001 publication of the

ICF formalized a comprehensive conceptual model and taxonomy to classify health, functioning, and disability as universal human characteristics. The ICF reflected a change in paradigms from a medical model in which disability was viewed as a problem within the person to one in which disability is multidimensional in nature and affected by interactions with the environment. This view is consistent with a biopsychosocial model of health and illness (Engel, 1983, 1992), emphasizing a dynamic, interactive view of health and functioning.

As a taxonomy, the ICF provides comprehensive language to describe individual functioning based on a holistic, integrated framework of health and disability. The ICF allows the documentation of an individual's functioning in interaction with the environment, a marked departure from the use of diagnoses or labels to describe characteristics of a person. The taxonomy utilizes a common language and is sufficiently broad and inclusive to describe functioning across multiple skill domains and domains of living, with multidisciplinary applicability. In addition, the information found within the ICF is applicable across countries, societies, and cultures. The ICF is thus a universal tool for documenting the nature and scope of an individual's functioning.

The ICF provides a framework for documenting the interaction of health dimensions with environmental factors depicted schematically in Figure 10.1. The language of the ICF is important, as it reflects a framework for documenting the person's "functioning," with "disability" defined as an "impairment" or a limitation in the performance of an activity or restriction of participation. In this framework, disability can be seen as a lack of "fit" between the person's functional characteristics and the resources found within the environment to carry out activities or to participate.

There are two parts to the ICF classification. The first conveys functioning and disability; the second, contextual factors. The dimensions of the person are defined by the components of Body Structures, Body Functions, and Activities/ Participation, and the contextual dimensions by the physical, social, and psychological environment. This is reflected in the ICF, in which the term *disability* is an umbrella term that refers to impairments of body functions or structures, activity limitations, and participation restrictions. As illustrated in the conceptual model (Figure 10.1) and reflected in the taxonomical structure, the ICF thus also presents a multidimensional framework and classification of disability.

**Figure 10.1** Interaction Between Components of the ICF-CY.  
(Adapted from WHO, 2007.)

Following its publication in 2001, the value of the ICF has been recognized as a common language for disciplinary and interdisciplinary applications by the health and health-related professions. Recognition of the potential of ICF for psychology and allied health disciplines such as occupational, physical, and speech therapy is evidenced by the development of a practice manual by the American Psychological Association (Reed et al., 2005). Of particular promise has been documentation using ICF codes in assessment measures (Ogonowski, Kronk, Rice, & Feldman, 2004), health records, and patient care in health and health-related settings. At broader policy levels, three of 18 major recommendations have been advanced for the ICF to guide initiatives of U.S. government agencies (National Academy of Sciences, 2007).

Although the content of the four domains of the ICF was extensive and suitable for covering documentation of adult functioning, it was not sufficiently inclusive of functional characteristics of children and their environments. Given that many mental disorders and disabilities have their origin in and are manifested in childhood (DSM-IV TR, 2000), the need for content to classify developmental dimensions of disability was recognized at the time that the revision of the earlier International Classification of Impairments, Disabilities, and Handicaps was underway (Simeonsson et al., 2000). That recognition continued with the publication of the ICF, emphasizing the need for a version that would encompass characteristic of children's functioning in the first two decades of life (Simeonsson et al., 2003). In response to the need for content with sufficient breadth and depth to capture the unique aspects of the developing child, WHO implemented a task force to address these needs, and the group expanded the ICF in scope and content, resulting in the ICF for Children and Youth

ICF-CY. The content of the ICF-CY provided a comprehensive classification of functional characteristics of children from infancy through age 17, as well as content-inclusive codes for precursors of more mature functioning already listed in the ICF.

The ICF-CY was published in 2007 with expanded content and increased specificity of detail reflecting characteristics of the developing child as a “moving target.” Additions to the ICF were made in strong consideration of Bronfenbrenner and Ceci’s (1994) ecological model conceptualizing *adaptation* as an interactive process between a child and the environment over time. The nature and organization of domains and the hierarchical structure of codes within chapters of the ICF-CY was identical to that of the ICF, with expansions taking the form of adding items to unused codes, modifying inclusion and exclusion criteria, and broadening the qualifier to include the concept of developmental delay. In addition to expanding the content to cover developmental aspects of body functions and structures, activities, and participation displayed by infants, toddlers, children, and adolescents, the added content was also suitable to capture levels of functioning of individuals beyond the childhood and adolescent periods. The Activities/Participation domain was most affected by changes made by the task force, with more new codes added in this domain than any other.

### ***ICF-CY Organization and Structure***

As shown earlier in Figure 10.1, the ICF-CY components of Body Functions, Body Structures, and Activities/Participation represent different manifestations of child health and functioning defined in terms of physical, personal, and social dimensions. The component of Environmental Factors defines elements of the physical and social environment and broader services and systems surrounding the child. Contextual factors also include a Personal Factors component, which is referenced in the text and schematic framework, but there is no associated classification of codes. An alphanumeric coding system is used for documentation and coding. Letters represent each of the four components. Body Functions are represented by “b”; Body Structures represented by “s”; Activities/Participation by “d”; and “e” represents Environmental Factors. Throughout the classification, codes within b, Body Functions, describe the physiological functions of body systems, and codes within s, Body Structures, identify parts of the body or anatomical structures. The ICF-CY defines *activity* as the “execution of a task by an individual”

(WHO, 2007, p. 9), and participation as “involvement in a life situation” (WHO, 2007, pp. xvi, 9). Thus, the Activities/Participation domain, d, contains codes describing functioning within society and at an individual level. Environmental Factors are defined as “the physical, social and attitudinal environment in which people live and conduct their lives” (WHO, 2007, pp. xvi, 9).

Each component contains multiple chapters, represented by one-digit numbers and representing relevant information to the domain. The one-level classification of the four domains is presented in Table 10.1. Content encompassing each chapter is defined in taxonomic codes presented in neutral terms. Codes contain three- to five-digit numbers, beginning with the number associated with the chapter and expanded in subcodes reflecting subsections of content. The codes are presented in a hierarchical structure, with major codes defining the central characteristic of function, structure, activities, or participation, followed by subcodes providing additional detail. For example, within component d, Activities/Participation, codes d130 to d159 describe Basic Learning. The construct represented in d131 is Learning Through Actions with Objects, which is further expanded upon with more specific subcodes describing ways in which the child would use objects to learn. Attempts were made to arrange the subcodes in the ICF-CY according to increasing levels of sophistication or toward more mature forms. In the case of use of objects in play, for example, d1310 describes Learning Through Simple Actions with a Single Object (i.e., banging, dropping); while d1314 captures Learning Through Pretend Play (i.e., substituting a novel object; pretending an object is another object). In this example, all of the codes are found within the Activities/Participation component (d), in the first chapter (represented by the initial 1 in the alphanumeric sequence), within the block of codes captured by Learning Through Actions with Objects (d131).

In the listing of codes under the components of Body Function and Activities/Participation, the ICF-CY is a classification of human health and associated environmental factors. When a universal qualifier is applied to codes, the ICF-CY provides a classification of disability documenting the extent of structural or functional problems at the body level, or functional limitations at the person level. It is also a classification of environmental barriers and facilitators when the universal qualifier is applied to document the negative or positive effects,

**Table 10.1 One-Level Classification of Chapters Within ICF-CY Components**

Body Functions	Body Structures
1. Mental functions 2. Sensory functions and pain 3. Voice and speech functions 4. Functions of the cardiovascular, hematological, immunological, and respiratory systems 5. Functions of the digestive, metabolic, and endocrine systems 6. Genitourinary and reproductive functions 7. Neuromusculoskeletal and movement-related functions 8. Functions of the skin and related structures	1. Structures of the nervous system 2. The eye, ear and related structures 3. Structures involved in voice and speech 4. Structures of the cardiovascular, hematological, immunological, and respiratory systems 5. Structures related to the digestive, metabolic, and endocrine systems. 6. Structures related to the genitourinary and reproductive systems 7. Structures related to movement 8. Skin and related structures
Activities and Participation	Environmental Factors
1. Learning and applying knowledge 2. General tasks and demands 3. Communication 4. Mobility 5. Self-care 6. Domestic life 7. Interpersonal interactions and relationships 8. Major life areas 9. Community, social, and civic life	1. Products and technology 2. Natural environment and human-made changes to environment 3. Support and relationships 4. Attitudes 5. Services, systems and policies

respectively, of the environment experienced by the individual. The universal qualifier is central to the use of the ICF-CY in that the “codes are only complete with the presence of a *qualifier*, which denotes a magnitude of the level of health (e.g., severity of the problem; WHO, 2007, p. 20). The universal qualifier is defined by ordinal scale of values; *mild* = 1, *moderate* = 2, *severe* = 3 or *complete* = 4. The qualifier value 0 is typically not documented, as it indicates a typical level of functioning that is the expected default value. The ordinal value is entered following the decimal point in the code to indicate the extent or severity of restriction or limitation of functioning. Application of the universal qualifier requires evidence to support the assignment of a particular scale value. Although clinical judgment can serve as evidence for assigning a qualifier value to a code, standardized scores from tests and measures used in psychological assessment can facilitate matching of derived score from tests with the ordinal scale of the universal qualifier. In another context, we have proposed the matching of clinical and normative data with the ordinal values of the universal qualifier scale (Simeonsson Sauer-Lee, Granlund Björck-Åkesson, 2010).

To illustrate the application of the universal qualifier, if it was established that David had

difficulties with energy and drive functions (b130), significant problems with impulse control (b1304) that could be coded as b1304.2, with the value of “2” reflecting moderate difficulties. Similarly, if evidence was available from records or assessment, Jane’s presenting problems of emotion functions (b152) could be noted as severe, with the value of “3” for the specific code of b1521.3 (Regulation of Emotion). When the universal qualifier is applied to problems of body functions or structures, they are identified as impairments. Coding problems with impulse control and regulation of emotion for David and Jane, respectively, provides a standard language for documenting impairments of their mental functions. As impairments of these mental functions disorders are likely to be associated with difficulties with performing activities or participation, David, for example, may have problems in managing his behavior (d250) documented as moderate “2” with regard to “adapting activity level” (d2504.2). For Jane, impairments of emotional functioning may be likely to affect her complex interactions with others (d720), specifically noted as severe “3” for “regulating behaviors with others” (d7202.3). Problems experienced in these areas are defined as activity limitations and participation restrictions respectively. A major

contribution of the ICF-CY is thus that it offers codes to document how different dimensions of disorders or disabilities are manifested at the level of mental functions as well as in everyday life activities and relationships with others. Of particular significance for children and youth is the conceptualization and classification of participation (Forsyth & Jarvis, 2002).

Given the ICF-CY framework of disability as a product of interactions of the child with a health condition with the environment, the domain of Environmental Factors provides codes to classify the nature and extent of the impact of the environment experienced by a child. In that the nature and severity of mental disorders or disabilities may be impacted or exacerbated by the environment, the ICF-CY provides means to classify the aspects of the environment that may impede or facilitate functioning. For environmental barriers, values of the universal qualifier can be applied following the decimal number of the environmental factor code, to quantify the extent to which environmental factors may affect Body Functions as well as Activities/Participation. For David, with severe impairment of impulse control, for example, existing educational policies (e5852.4) may serve as a barrier to his participation in a regular classroom. To document the facilitating role of the environment, a plus sign would be placed following the decimal point followed by the value of the universal qualifier. Thus, the availability of a special education classroom with appropriate placement for David could be documented as full facilitation (e5853.+4). A significant environmental barrier to participation in school experienced by Jane might be attitudes of rejection by acquaintances and peers (e425.3). For this child, a facilitating environmental factor might be the availability of supportive health services (e5800.+4) to provide therapeutic support.

The universal and comprehensive scope of the ICF-CY provides a standard for classifying dimensions of functioning in children with disorders and disabilities independent of diagnoses or underlying etiology. The ICF-CY can be applied to classify impairments of body structures and body functions, and limitations of the activity and participation of children with various health conditions, as well as defining environmental factors influencing their condition or indicated in their treatment and care. In that the ICF-CY includes developmental indicators, it is well suited to document the onset of disorders in infancy and early childhood as well as their manifestation with maturity (Lollar & Simeonsson,

2005), a feature of value in documenting conditions whose onset is during the developmental period. In addition, the ICF-CY may be particularly useful in meeting the challenge of defining characteristics of functioning in children who are dually diagnosed or identified with comorbid conditions (Jensen, Knapp, & Mrazek, 2006).

## Contributions of the ICF-CY to Psychological Practice

The implications of the ICF have been advanced for psychological practice in clinical settings (Peterson, 2010) and for rehabilitation psychology (Mpofu & Oakland, 2010). An important contribution of the ICF-CY for children with disabilities and chronic conditions is to address current challenges in approaching intervention, treatment, and habilitation. The heterogeneity of developmental disorders and limitations of the existing taxonomies of ICD and DSM to define such disorders have been identified as barriers to effective interdisciplinary practice and research (Reiss, 2009). The comprehensive framework of human function defined by the ICF-CY (WHO 2007) offers a model for specifying the characteristics of the child, the environment and child–environment interaction and a common language for interdisciplinary work. As such, it provides an integrated perspective for assessment of the child's cognitive, communicative, social, and behavioral functioning. The publication of the ICF-CY formalized a comprehensive conceptual model and a common, universal language shared across disciplines and service settings to define children with developmental disabilities and disorders (Colver, 2005). The ICF-CY reflected a change from viewing and classifying disability and disorder as simply a medical problem within the child, to the recognition of disability and disorders as manifestations of child–environment interactions reflected in problems of body functions, activity limitations, and participation restrictions. The applicability and interdisciplinary utility of the ICF and ICF-CY framework and taxonomy of codes have been described in habilitation, early childhood (Björck-Akesson et al., 2010), clinical services (McDougall et al., 2008), and educational settings (DePolo et al., 2009).

In its current form, the ICF-CY is not intended to be the only or exclusive tool for documenting or describing human functioning and disability across all disciplines and all settings. Although the ICF-CY may be used as a primary classification, it may also be used in concert with other WHO-FIC tools, such

as the ICD-10 (WHO, 1992). Diagnoses of disorders or diseases can be appropriately documented using the ICD-10, with the individual's functional characteristics across settings and environments documented using the ICF-CY. The ICF-CY could also be used to complement other classifications like the DSM-IV-TR (American Psychiatric Association, 2000), or related classifications such as the DSM-PC (Wolraich et al., 1996), or Zero to Three (Wieder, 1994). It could also be used with specialty classifications such as that produced by the American Association on Intellectual and Developmental Disabilities to document disorders of development. Although the categorical approach for defining disability in schools in the United States under the Individuals with Disabilities Education Act (IDEA; 2004) is not tied to a specific taxonomy, the ICF-CY holds promise as a tool to document educational disability within school-related eligibility requirement for special education (Simeonsson, Simeonsson, & Hollenweger, 2008).

The introductory section of the ICF-CY describes a number of potential uses, including applications to clinical, administrative, surveillance, policy, research, statistical, and educational sections (WHO, 2007, pp. xviii, 5). The goal of this section is to focus on a framework for utilizing the ICF-CY in psychological assessment of characteristics of children and youth. Such assessment takes into account that the developing child is a "moving target" and that, while a diagnosis remains static, the nature and level of functioning is dynamic, influenced by the child's experiences over time.

This section will focus on the application of the ICF-CY in assessment, from referral through measurement, documentation, and data collection surrounding intervention. The following sections describe using the ICF-CY framework (detailed above) to describe and document human functioning in clinical psychological practice. The dimensional approach of the ICF-CY provides a model for comprehensive assessment of development and psychological functioning and related environmental contexts associated with adaptation of the child. Building on the integrated approach of the ICF-CY, psychological and developmental assessment can help define the focus on the dimensions of functioning unique to children with specific disabilities and disorders. The ICF-CY can serve to provide the common language required to structure an assessment system that has utility in the development of individualized treatment plans and in the design of intervention programs. This integrated approach to

functional assessment provides a common language across disciplines and yields documentation of classification codes relevant for planning and evaluating clinical interventions. It can also yield summary data for administrative records.

In psychological assessment, the ICF-CY can provide a functional base for defining the nature and extent of a disorder and disability, and link this identification with the needed intervention. An added value is that assessment based on the common language of the ICF facilitates interdisciplinary communication and collaboration. The lack of a common language in interdisciplinary child services related to assessment and intervention is evidenced by the unique measures associated with different disciplines (i.e., psychology, education, and allied health and social services), resulting in disparate descriptors of children. A shared framework and language would constitute a clear metric permitting disciplines engaged in services for children and adolescents a shared perspective of functional aspects of behavior and development.

## Applying the ICF-CY in Psychological Assessment

The ICF-CY offers contributions to assessment practice specific to the orientation for assessment, establishment of assessment goals, and uses of assessment data. These contributions are summarized in Table 10.2 and expanded upon in the following sections. A major focus of assessment practice in psychology has been to specify the nature of psychological deficits or psychopathology, rather than forming a holistic view of functioning of the individual. Each of the contributions of the ICF-CY to assessment in psychology noted below emphasizes the value of an integrated view of the individual child in which health and functioning, as well as the nature of impairments and functional impact of problems, are of interest.

To demonstrate the application of the ICF-CY to psychological assessment, the two brief vignettes discussed in the opening to this chapter are used as a platform to illustrate the way the comprehensive framework of human functioning of the ICF-CY can guide psychological services from the time of referral through documentation of outcomes as a result of intervention. The reader will recall that *David* is a six-year-old boy referred to an outpatient mental health clinic for concerns regarding his delayed language development and "odd behaviors." The second vignette involved *Jane*, a 12-year-old pre-adolescent girl referred to the psychologist at

her school for “acting out.” Her teachers would like insight into “what’s wrong with her” so they can respond to her needs. They have told the psychologist they suspect that Jane has an emotional or behavioral disorder.

### ***1. Use of Conceptual Framework to Guide Assessment***

Within the ICF-CY framework, the skills, abilities, and needs of individuals reflect their ongoing interactions with the environment over time. This universal perspective facilitates the assessment and documentation of human functioning without resorting to labels, providing the groundwork for altering practices in making or receiving referrals for psychological assessment. A referral requesting information of a child’s profile of functioning across multiple domains is quite different from a focused referral for an “autism diagnostic” or identification of a diagnosis inclusive of “acting out” behavior. While both referrals may involve common instruments, methods of assessment, and similar areas of development, their difference lies in an integrated

perspective of an individual’s overall functioning, including strengths and challenges, as opposed to confirmation of a diagnostic label that describes only aspects of the individual’s impaired functioning.

How does one transition to such a referral process? In many ways, the transition involves the expansion and reframing of existing practices, as opposed to completely altered processes. In the instance when a clinician questions whether a child meets the diagnostic criteria of an autism spectrum disorder (ASD), the clinician is already considering the multifaceted, multiple-domain nature of an ASD diagnosis (Simeonsson, 2003) and would be considering functioning in communication, social relationships, and behaviors. The conceptual framework illustrated earlier in Figure 10.1 could be applied to identify the nature, focus, and means of psychological and developmental assessment. With reference to the components of the model shown in Figure 10.1, assessment of sensory, mental, or psychosomatic characteristics would relate to the domains of Body Functions and Body Structure. Characteristics related to the child’s physical, social, and psychological adaptation to home, school, and community would be defined by codes in the domain of Activities/Participation. Characteristics of the child’s environment and the extent to which it impedes or facilitates functioning would be covered by Environmental Factors.

As an example, we can return to David and consider the continuation of the referral process and its potential expansion for generating a plan for assessment.

**David:** The psychologists at the outpatient clinic interview David’s parents to understand their perceptions of David, his interests, and how he functions in a typical day. His parents describe David as six years old and full of energy. David’s pediatrician and his parents jointly referred him to the outpatient mental health clinic based on concerns about David’s “language development.” They have “moderate” concerns, as David will speak in only two to three meaning-unit phrases. Further questioning reveals David was a late talker and has always had a tendency to speak louder and in more of a monotone compared to other children. On reflection, his mother confides that David seems to struggle when talking about specific types of human experiences, such as feelings and friendship.

David's parents also note several other behaviors and skills for their son. David can jump, run, and climb as well as his peers, and his ability to use his hands seems age-appropriate. He has full functional use of his body, though his parents remember having great difficulty toilet-training David. He loves trains and building long tracks for the cars. When he is happy to be playing with his trains, David will move his arms and hands very excitedly. If David's play is stopped without warning, he becomes very agitated and will have difficulty transitioning to the next activity. His parents describe him as "shy" and note that he prefers to play alone. He is able to sort colors and shapes but does not name them. He can rote count to 30 and loves numbers. Except for ear infections as a toddler, David has been a healthy child.

Using the ICF-CY as a conceptual framework, the brief interview with David's parents allows the practitioner to expand the focus from a referral for language development and behavioral concerns to an assessment plan based on questions regarding David's overall functioning. As is common practice, caregivers working with David want to know if he perceives the world accurately, and will thus request information regarding his hearing, vision, and sensory processing. It is unclear from the parent interview whether David's cognitive ability is of concern, so additional information will need to be gathered regarding his global mental functions. Several important issues for further exploration are immediately apparent from the referral and David's parents' comments; these include David's limited general communication skills and ability to interact with others. He seems to have emerging pre-academic skills, but the pattern of his skills warrants further exploration as well. David's parents report that he struggled to master toileting skills and responds somewhat atypically to changes in routine. Each of these areas needs to be explored fully by assessing his skills and challenges in self-care and meeting demands in his daily environment. Table 10.3 provides an overview of the process of expanding a referral to questions for assessment of David anchored in the ICF-CY taxonomy.

Thus, translating the ASD diagnostic referral question into an approach consistent with the ICF-CY would involve expansion of the word "autism" to

conceptualizing which ICF-CY domains, chapters, and codes capture salient aspects of the individual's functioning and interaction with the environment. For example, assessment might reveal that relevant codes for capturing the functioning unique to a child such as David, suspected of experiencing difficulties related to autism, would be likely to include codes across Body Functions such as b122 (Global Psychosocial Functions), b1252 (Activity Level) and b163 (Basic Cognitive Functions). In the domain of Activities/Participation, relevant codes are likely to include d175 (Solving Problems), d240 (Handling Stress and Other Psychological Demands), and d335 (Producing Nonverbal Messages). Codes in the Environmental Factors component would probably include facilitators such as e310 (Immediate Family Supports), e410, (Individual Attitudes of Immediate Family Members) and barriers in the form of limited services535 (Communication Services, Systems, and Policies).

The advantage of utilizing ICF-CY codes to help capture the information needed is that the psychologist already knows which pieces of information speak to specific areas of functioning, and which are the same areas to be targeted for intervention, providing a direct link from referral through intervention development. In this way, the ICF-CY framework provides both the framework and the structure for clear, systematic, purposeful documentation throughout the assessment process and into intervention. In many ways, an assessment approach oriented to the ICF-CY as both framework and taxonomy involves the process of expanding the focus beyond conceptualization of disorder to allow for needed documentation of both skills and areas of challenge for later planning of intervention. Using the ICF-CY as a framework, the psychologist explicitly broadens the conceptualization of the child and his or her needs, considering an expansive set of codes important for documenting the child's level of functioning. The link between the nature of assessment and the framework can also be illustrated with a consideration of the referral concerns for Jane.

The psychologist at Jane's school reviewed the referral and realized she knew very little about Jane or her skills. After interviewing Jane's teacher and mother, the psychologist learned that Jane is considered quite bright. Her teachers believe she is capable of higher achievement, but she receives poor grades in school. Jane has difficulty attending in class and often does not complete assignments on time. She has few friends and has difficulties relating to peers or teachers. Jane's teachers indicate that she gets

**Table 10.3 Matching Assessment Questions Within ICF-CY Domains**

Expanding Focus	Step 1: Identify Applicable Domains and Codes	Step 2: Level of Evidence	Step 3: Assessment Approach and Measures
What are the characteristics of David's vision, hearing, and other sensory functioning?	Body Functions, Chapter 2: Sensory functions and pain	Percent problem and clinical judgment Standard scores	Vision and hearing screening Short sensory profile (Dunn, 1999)
How does David understand information compared to other children his age?	Body Functions, Chapter 1: Mental functions	Clinical judgment Standard scores	Observation and interview Wechsler Intelligence Scale for Children–Fourth Edition (WISC-IV; Wechsler, 2003)
How does David communicate? What is his communication style? What is the developmental quality of his speech and language?	Activities/Participation, Chapter 3: Communication	Description Clinical judgment Standard scores	Parent interview Observation in natural setting Clinical Evaluation of Language Fundamentals–4 (CELF-4; Semel, Wiig, & Secord, 2003) Aspects of the Vineland Adaptive Behavior Scales–2nd ed. (VABS-II; Sparrow, Cicchetti, & Balla, 2005)
How does David interact with others? What are his relationships like?	Activities/Participation, Chapter 7: Interpersonal interactions and relationships	Clinical judgment Description Standard scores	Autism Diagnostic Observation Schedule (ADOS; Lord, Rutter, DiLavore, & Risi, 1999) Observations and interview Aspects of the Vineland Adaptive Behavior Scales–2nd ed.
How does David respond and behave in his environment? How does he respond to demands and transition?	Activities/Participation, Chapter 2: General tasks and demands	Description and clinical judgment Standard scores	Observations and interview Aspects of the Vineland Adaptive Behavior Scales–2nd Edition
How does David learn? What are the characteristics of his learning style?	Activities/Participation, Chapter 1: Learning and applying knowledge	Descriptive terms Standard scores	Classroom artifacts and teacher interview Woodcock Johnson Tests of Achievement–3 <sup>rd</sup> ed. (WJ-III; Woodcock, McGrew, & Mather, 2001)
What level of support does David need in regards to adaptive functioning?	Activities/Participation, Chapter 5: Self-care	Clinical judgment Standard scores	Observation and interview Vineland Adaptive Behavior Scales–2nd ed.

upset easily and acts out, with the result that she often finds herself in trouble at school.

Interviewing Jane, the psychologist finds out that she complains of not having an appetite and experiences difficulty sleeping. She has missed school many days in the last several years for a variety of physical complaints. At home, her mother reports that Jane acts out when asked to help with routine household tasks.

The psychologist using the ICF-CY as a framework would be able to capture the complex set of difficulties reported by this youngster in direct assessment (Young, Yoshida, Williams, Bobardier, & Wright, 1995) documenting areas of her functioning, and in consideration of the environmental context. Based on the interviews conducted, the psychologist may plan an evaluation protocol

based on functioning related to the domain of Body Functions, such as codes for b1251 (Responsivity), b1261 (Agreeableness), b1521 (Regulating Emotion), b1302 (Appetite), b134 (Sleep Functions) and b1644 (Insight). In the domain of Activities/Participation, relevant codes defining Jane's difficulties are likely to include d2501 (Responding to Demands), d2502 (Approaching Persons or Situations), d7104 (Social Cues in Relationships), and d 7202 (Regulating Behaviors within Relationships). Negative attitudes of people in positions of authority (e430) and peers and others (e425) in school and community toward Jane may be barriers to her social functioning, whereas professional support (e355) and social support from friends (e320) could serve facilitating roles. In the development of an assessment plan, the practitioner may choose to frame concerns in a question format. Aligning the questions to ICF-CY chapters or codes will help organize the process and allow for systematic documentation of skills and needs throughout the assessment process.

## ***2. Identifying Evidence Needed to Document Codes Within ICF-CY Domains***

Beginning the assessment approach with a careful review of all information needed, and how to collect this information for the purpose of documentation of functioning, is an important step facilitated by use of the ICF-CY framework. After identifying a set of codes that are likely to describe an individual and his or her needs, the psychologist must identify sources of evidence to document their functioning and consider how this functioning will be quantified or captured for the purposes of interpretation. This process is particularly important for the later process of utilizing assessment data to design specific, individualized interventions that enhance the individual's functioning.

As a central purpose of assessment is to document an individual's functioning in terms of both their strengths and needs, it is important to select measures that allow for documentation of the severity (including possible absence) of any disorder or disability, utilizing the ICF-CY universal qualifier. As previously described, the universal qualifier can be assigned to document impairment, limitation, or restriction of functioning with values ranging from 0, "no impairment/limitation," to 4, "complete impairment/limitation." Values of 2 and 3 represent "moderate" and "severe impairment/limitation of functioning" respectively. If standardized tools are used in assessment of a

child's functioning, assigning values for the qualifier to document severity of limitation or impairment can be done with standard scores, scaled scores, T-scores, standard deviations, and percentile ranks (Simeonsson, et al., 2010). It is possible to document clinical judgment utilizing the universal qualifier as well, with the same advantages and limitations to the reliability and validity of the documentation as are inherent whenever clinical judgment is used as a primary mechanism for evaluating functioning. The important point is to systematically decide how the data resulting from the assessment approach will be applied to the activity of documenting the child's functioning and characteristics, and to do so during the process of selecting measures to ensure that the highest-quality data possible are collected during the assessment process. Here, it will be important to consider whether eligibility determination is a goal of the assessment process. If so, the psychologist must recognize the importance of matching the level of evidence required for eligibility to the level of evidence selected for the assessment. For example, eligibility criteria may require a child to demonstrate a discrepancy of a certain number of standard deviations or standard score points between areas of functioning measured, so it would be necessary to incorporate that knowledge into planning for assessment.

Returning to David's vignette, the psychologist designing an assessment approach and battery will need to consider the ultimate goal of the assessment process. David is of school age and attends a school system that provides free school-based services for children with disabilities, as long as the child meets specific eligibility criteria. The criteria are defined, in large part, by differences in a child's scores on standardized measures from those of other same-age children, or large intra-individual discrepancies on areas of functioning. Large discrepancies are typically characterized by a specific number of standard deviations or standard score points, and as such, there is a heavy reliance on standardized measures in assessment. As all assessments incorporate clinical judgment, and some skill sets are not easily measured by formal tests, the psychologist will need to identify which areas of functioning can be captured by standard scores and which will be based on clinical judgment of the child's functioning supplementing evidence for tests. The psychologist's choice of level of evidence for each area of functioning can be seen in Table 10.3 for David.

### ***3. Identifying Measures Corresponding to Desired Level of Evidence for Use with ICF-CY***

With the referral question expanded and described using a set of ICF-CY codes capturing children's functioning across domains and in interaction with the environment, along with the identification of level of evidence required of the assessment data, the next step is to select the actual measures that will be used to capture estimates of a child's skills and needs. This third step presents a central challenge in the field of psychology, in that tools themselves have served as the standard for describing phenomena difficult to observe directly. That is, the goal of many tools is to elicit responses from a child assumed to measure constructs such as intelligence, but the items that compose such measures may lack a conceptual framework integrating domains of functioning. A related concern is that measurement is often focused on performance of specific tasks rather than aspects of functioning such as attending, learning, and problem-solving that underlie such achievement and are prerequisites for developmental and academic readiness. Another issue pertains to the fact that although child–environment interaction is a central tenet of developmental theory and research, systematic attention to the child in context is limited in screening and assessment measures. This is a limitation in that understanding the child–environment interaction forms the foundation for the provision of required support and intervention (Sameroff & Fiese, 2000). These and other limitations are consistent with recommendations advanced to address the need for improved measurement of young children's functioning and development. It is important for psychologists to be cognizant of the limitations of their own tools, particularly when these tools are used to "measure" a child's skills to determine their eligibility for services and design interventions to meet their "measured" needs. Also note that there are many resources available to help guide psychologists' tasks of reviewing the reliability, validity, and general adequacy of a particular instrument to capture information regarding a specific individual, given factors such as his or her age, gender, education, sociocultural background, and the presence and/or relative severity of particular impairments. These resources include the *Mental Measurements Yearbooks* (Buros, by year) and the *Standards for Educational and Psychological Testing* (AERA, APA, & NCME, 1999).

In practice, then, the third step involves the careful and thoughtful selection of existing tools and informal measures that can best and most accurately capture a child's functioning for the later purpose of noting the level of limitation/impairment for designing individualized interventions matched to the child's unique pattern of skills and needs (Lollar, Simeonsson, & Nanda, 2000). These measures must not only capture the area of functioning in question, but they must also result in the level of evidence selected during Step 2. As most assessment tools were not developed with reference to the ICF-CY component framework, sources identifying tests or measures covering specific component content are available (see, for example, selected measures capturing emotional functioning by Lee, 2012) and will probably continue to emerge.

For assessment of cognitive, social, and affective functioning, a psychologist would need to carefully consider which available tools would be appropriate for a child of a particular age and background, which are designed to estimate levels of functioning in a particular area, and which will meet the pre-identified level of evidence. The psychologist would also need to consider if any measure could capture functioning in multiple areas, so as to limit the number of measures to administer in consideration of cost, time, and fatigue. In reference to David's case described in this chapter, the psychologist selected the Vineland Adaptive Behavior Scales—Second Edition (VABS-II; Sparrow, Cicchetti, & Balla, 2005) because of its utility in capturing estimates of functioning from parent and teacher reports in multiple areas of functioning, including communication skills, interpersonal or social skills, adaptability to changes in the environment or routine, and general self-care skills. The Strengths and Difficulties Questionnaire, a recently normed measure in the United States (Bourdon et al., 2005) and a number of other countries (Obel et al., 2004) may offer an efficient way for parents and teachers to report aspects of child functioning that correspond with some content under Mental Functions and Activities and Participation domains in the ICF-CY.

### ***4. Identifying Environmental Factors Influencing Child Functioning***

A unique contribution of the ICF-CY to assessment is inclusion of the Environmental Factors classification allowing documentation of the aspects of the environment that facilitate a child's functioning and participation and those that may serve as

barriers. Until the introduction of the ICF, there was no standard way to document the role of environmental factors in a systematic, clear manner that would be understandable to caregivers and professionals involved with the child.

Two central aspects of the environment that are important to document during assessment are *barriers* and *facilitators*. In the process of planning interventions, psychologists readily recognize that it is as important to know what resources, services, and aspects of the environment are available for enhancing a child's functioning and participation as it is to know which aspects of environment serve as barriers to the child's ability to live and function as meaningfully as possible. Indeed, a central theme in designing interventions involves consideration of what can be altered in the environment, what can be added in, and what can be removed. However, recognition of the role of environmental influences on child functioning has probably been based more on informal observations by the psychologist than on assessment using specific tools.

The importance of documenting both the child's skills as well as characteristics of the environment is exemplified by considering a child in a resource-impoverished environment. A child may have the foundational abilities necessary to read but is not developing reading skills, given limited access to formal schooling (ICF-CY, Chapter 5 of Environmental Factors) and the lack of books and reading materials (ICF-CY, Chapter 1 of Environmental Factors) in the home environment. In this context, it is important not only to assess the child's limited reading skills, but also to assess factors in the child's environment that restrict or provide opportunities for learning, while documenting the skills the child does have that create the groundwork for later skill development.

Just how does one measure environmental factors? Person–environment interaction (Bronfenbrenner & Ceci, 1994) has been central to psychological assessment as a concept, but a standard approach to measurement of the environment and associated tools to capture physical and social qualities of the environment has been limited. This is in contrast to the measures that have been developed to assess specific aspects of interaction with the environment, such as child–teacher interaction, classroom environment, or parent–child interaction within the home. When considering how to best measure and describe facilitators, psychologists should consider not only if an aspect of the environment is available, but also if it is accessible, reasonable in terms of cost

and time, and if it would be acceptable to the child and family. The quality is also important—including issues such as structural integrity, dependability, and a general sense of whether the quality is poor or good. Barriers, on the other hand, may affect a child because of either their presence or their absence. Other important issues to consider in relation to barriers include how frequently they hinder the individual, when they occur, if they can be avoided, and the relative strength of the barrier in terms of its impact on the child. Drawing on chapters of the Environmental Factors domain of the ICF-CY, a psychologist may identify barriers and/or facilitators involving products and technology (Chapter 1), natural environment and human-made changes to the environment (Chapter 2), support and relationships (Chapter 3), attitudes (Chapter 4), and services, systems, and policies (Chapter 5). These environmental factors can be summarized as relating to physical aspects (Chapters 1–2), social supports and attitudes (Chapters 3–4), or infrastructures and systems (Chapter 5) in the environment.

Compared to the wide array of psychometric tools for measuring cognitive, social, psycho-educational, and neuropsychological functioning, a significant problem is that there are relatively few measures for systematically assessing the environments of children. In a recent review of 43 measures commonly used to assess children with acquired brain injury, Ehrenfors, Borell, and Hemmingson (2009) found that 30 measures addressed the ICF domain of Body Functions, 13 addressed the domain of Activities and Participation, but none related to Environmental Factors domain. Measures that do exist are typically focused on documenting physical dimensions of children's environments, such as home, day care, and kindergarten settings (Bradley et al., 2001), or measurement of the school environment (Trickett, Leone, Fink & Braaten 1993). Interest in assessment of environments is increasing with the development of tools measuring children's activity environments (Hume, Ball, & Salmon, 2006) with content that may be mapped to some items in the Environmental Factors domain of the ICF-CY. It may also be important to assess needs related to specific assistive or augmentative devices of children with physical or motor impairments. As the latter may be unfamiliar to psychologists, they may want to team with an occupational or physical therapist or another professional trained in the use of such devices to determine how to identify which environmental factors are important for planning interventions.

While more tools to measure the environment corresponding to the ICF-CY classifications are a priority, psychologists do have skills in informal assessment that can be helpful in documenting environmental factors. These skills include objective observation and interviewing. Careful and thorough observation of a child in his or her environments, across many settings and contexts, cannot be overvalued in terms of its contribution to identify and describe environmental factors that can serve as barriers or facilitators. Interviewing the child, caregivers, and peers is also very important, particularly given the significance of attitudes of those working and living with the child and how they may facilitate or inhibit the child's participation and functioning. Returning to David and his story, Table 10.4 illustrates how a psychologist could (on his or her own) identify and document salient facilitators and barriers pertinent to David's life and functioning.

### 5. Generating Profiles of Functioning

The classification of codes and qualifiers is the essential contribution of the ICF-CY, offering for the first time a universal language for communication, not only within psychological practice, but also across disciplines, service systems, and countries. Implementation of this universal language of functioning, disability, and health in practice takes the form of assigning ICF-CY codes to assessment results for a child. The assessment of the child to address questions and concerns defined in Table 10.3

will yield results documenting characteristics of the child's functioning and environment. Those results then serve as evidence for assigning ICF-CY codes and qualifiers corresponding to the nature and extent of impairments of body functions, activity limitations, and restrictions of participation characterizing the child. The array of resulting ICF-CY codes constitutes a profile of functioning unique to that child at that point of time. The profile should also include codes documenting environmental factors influencing such functioning. In each case, the profiles should reflect the nature and severity of functional problems unique to David and Jane in their respective environments and at specific developmental stages.

The profile of codes does not take the place of test results and clinical data, but provides a common language to profile the functional status of the child and corresponding needs for intervention or support. Furthermore, in that it is based on description rather than diagnosis, it is in keeping with a holistic and non-stigmatizing approach to defining disorder and disability. The utility of functional profiles based on the ICF has been demonstrated in the documentation of school inclusion of students with disabilities in a regional study in Italy (Fusaro, Maspoli, & Vellar, 2009). Beyond an efficient description of the individual child, the code profiles can be aggregated across children to summarize the characteristics of children served by a clinic, school system, agency, or larger entity. In addition, the systematic use of codes

**Table 10.4 Identifying Environmental Barriers and Facilitators**

ICF-CY Environmental Factors Code	Data Source	Facilitator (+) or Barrier (-) and Level Using Qualifier
Chapter 1: Products and Technology	Observations and interviews	e11521+2: access to specialized/adapted play materials e1251+2: access to assistive communication devices, such as communication boards e1301.1: few assistive educational products available to child e310+3: very supportive immediate family prepared to adapt environment
Chapter 3: Support and Relationships	Observations and interviews	e355: health professionals are available to the child through the school system if he qualifies for services
Chapter 4: Attitudes	Observations and interviews	e410+3: immediate family members are supportive and understanding of child's needs e460.1: family impacted by negative societal stereotypes of mental health
Chapter 5: Services, Systems, and Policies	Observations and interviews	E5854: special education and training services available to child if he qualifies for services

can also be useful in studies of disability prevalence (Mudrick, 2002) and in national surveys (McDougall & Miller, 2003). For these kinds of applications, it would be important to establish a uniform list or set of codes that would portray the distribution of problems in the population. An example of a minimal list of codes has been proposed in Annex 9 of the ICF-CY for surveys and information systems. As the ICF-CY is implemented, code sets will be designed for documentation of developmental characteristics (Ellingsen & Simeonsson, 2010) or applications for specific settings such as clinics or schools.

## ***6. Confirming Functional Criteria for Eligibility***

Codes in the ICF-CY document disability when the universal qualifier is assigned to indicate the extent of disability or disorder, defined in terms of impairments of functioning, activity limitations, or participation restrictions. In contexts specifying criteria for a child's eligibility for intervention, receipt of specialized services, or referral for care, documentation has typically been based on a medical model encompassing etiological or diagnostic indicators derived from ICD-10 or DSM-IV-TR. In early-childhood intervention in the United States for example, a young child's eligibility under Part C of IDEA for early intervention is based on evaluation results that meet the criteria for assigning the child to one of three categories: "manifested developmental delay," "established medical condition," and the status of "at risk for delay" (U.S.C. §1432, as amended by IDEA, 2004). As it is problems of functioning that identify children in need of intervention and support, the ICF-CY may be particularly useful in shifting the focus of eligibility criteria from a medical to a biopsychosocial framework. Thus, whether eligibility is to be determined for receipt of assistive technology, special education, or therapy, the basis for defining criteria would be reframed in terms of activity limitations and participation restrictions. In the case of young children with development delays, applicable codes could be found in the Activities/Participation domain of learning (Chapter 1) communication (Chapter 3), mobility (Chapter 4), personal care (Chapter 5), interpersonal relationships (Chapter 7), and major life areas (Chapter 8).

## ***7. Providing a Base for Intervention/Treatment Planning***

An assessment approach organized with ICF-CY facilitates the process of using assessment to specify interventions. The assessment itself allows

identification of the nature and extent of problems and delays in functional performance. In contrast to documentation of underlying impairments, assessment on the basis of functional limitations provides a correspondence with the nature of the needed interventions. Within the framework of the ICF-CY, the identification of functional limitations can serve as the basis for the development of individualized interventions. Such interventions recognize the child's interaction with the environment as the unit for assessment, and the design of programs of supports and treatments based on the child's profile of functioning defined by Activities/Participation (Simeonsson, Leonardi et al., 2003; Simeonsson, Pereira et al., 2003). In other words, intervention planning subsequent to assessment organized by the ICF-CY can focus on increasing skills in completing activities and participating in important life situations and experiences.

The focus on functioning, as opposed to diagnosis, is a distinct advantage of using the ICF-CY to frame assessment. Too often, interventions are selected from a list because they are thought to address the diagnosis describing the child's impairments. While common, this approach often is not followed with efforts to individualize the intervention to meet the child's specific needs while capitalizing on the child's specific strengths. For example, selecting "an intervention for children with autism" utilizing a schedule of verbal activities would be inappropriate for a nonverbal child or a child who does not read. Concern regarding the lack of individualized assessment and individualized intervention has been expressed for decades, including remarks made by Donald Campbell in 1969 as he addressed fellow psychologists of the American Psychological Association, and in the special-education literature in the United States, which has encouraged use of a problem-solving assessment model to facilitate the implementation of individualized interventions based on data gathered on each individual child (see, for example, Deno, 1989, 2002). The ICF-CY-based approach to assessment provides the practitioner with functional information as well as identification of factors in the environment that play a role in the interventions or that must be intervened upon.

In David's example, his parents are important environmental resources and supports and may provide more individualized support than the school system, should he not qualify for services at school. Therefore, interventions focused on enhancing parental knowledge of David's unique patterns of skills and needs and providing them with training

on intervention techniques helpful to David would be a prudent approach to providing intervention. The focus of intervention will depend on the results from his assessment. Areas of primary focus may include the areas of David's profile reflecting significant limitations, with the goal of decreasing the relative severity of his impairment and/or improving his actual level of functioning.

## **8. Monitoring Intervention Implementation and Outcomes**

Interventions should be monitored frequently and over time in order to ensure that the intervention is implemented correctly and adjusting the nature or process of the intervention if necessary to ensure optimal outcomes for the child. Monitoring interventions by documenting outcomes with the ICF-CY qualifier or codes should be an ongoing process (Loe & Feldman, 2007). Changes attributed to intervention can be documented with the ICF-CY by noting either a change in qualifier or a change in functioning as denoted by a change in actual code. A change in the qualifier would denote a reduction in the severity level of impairment or limitation within an area of functioning as captured by the code. For example, if the universal qualifier decreases from 3 (i.e., b1342.3), describing *severe impairment*, to 1 (i.e., b1342.1), describing *mild impairment*, then there is documentation of the severity of impairment decreasing over time. There may also be a change in functioning that could be documented based on noting a shift in the hierarchy of the codes, from a lower- to higher-level code. For example, a child may improve from walking short distances with moderate impairment (d4500.2) to walking long distances with moderate impairment (d4501.2), representing an increase in functioning but no notable decrease in the severity of impairment.

In this way, data monitoring becomes part of the child's record, and documentation with the ICF-CY allows ongoing evidence of progress to be included in the child's educational, health, social services, medical, or other files. If continued systematically, documentation within the child's files would provide measurement of outcomes, including clear documentation of the child's needs for services (as identified at the beginning of the intervention process) through documentation of the impact of interventions that were identified to meet the child's individual's needs based on clear identification of impairments or limitations in functioning clearly documented in the child's profile of functioning.

In David's case, let us consider the scenario where he had moderate impairments in comprehending

simple spoken messages (d3101.2). Interventions were designed to help David increase his ability to communicate with others. More specifically, David's parents minimized the number of meaning units ("David, sit" instead of "David, you need to sit down") in their own communication with him to provide David greater opportunity to understand their meaning. After three months, David was responding to their requests, and assessment results indicated that he understood simple spoken messages with only mild impairment (d3101.1). After one year, he could understand simple spoken messages with no impairment (d3101.0), and his parents were guided to increase the number of meaning units in their communication with him. Over the course of his elementary school years, David still had moderate impairments with understanding complex spoken language (d3102.2), but he had advanced in his receptive communication abilities. David's teachers maintained a log of codes with qualifiers describing his progress in comprehending spoken messages. This provided documentation of his progress, which could be traced back to the original assessment that estimated his level of communication functioning. Table 10.5 below provides an example of ongoing documentation of interventions for David and functional outcomes defined by changes in qualifier level and shifting of codes.

## **Conclusions**

Although the health, functioning, and well-being of the individual are central to the practice of psychology, a corresponding classification of these domains has not been available to the profession prior to the publication of the ICF in 2001. As the two primary members of the WHO family of classifications, the ICD-10 and the ICF contribute complementary classification of disease and health, respectively. With the publication of the ICF-CY, it contributes a universal language defining elements of health, functioning, and well-being essential for all children and youth. In this context, the ICF-CY can be seen as a reference for defining these elements as children's rights, complementing the United Nations Convention on the Rights of the Child (United Nations General Assembly, 1989). Drawing on the principles of equality of opportunity, participation, and independence, the Convention articulates rights of children, such as the right to be heard; to have access to care, education, and support; and to be secure from harm, neglect, and exploitation (Corker & Davis, 2000; Dalton, 2002; Lansdown, 2000). It can also serve

**Table 10.5 Documenting Intervention Implementation and Outcomes**

Date	Description of Intervention	David's Level of Functioning	Description of Progress
March 2012	Use two meaning-unit phrases when speaking to David	D3101.2	Initial assessment
June 2012	Use two to three meaning-units phrases when speaking to David	D3101.1	Decrease in severity of impairment
March 2013	Use two simple sentences (three to five meaning units) to communicate with David	(D3101.0) D3102.3	Decrease in severity of impairment Shift in hierarchy of codes/increase in spoken message complexity
June 2013	Use two or more simple sentences (three to five meaning units) to communicate with David	D3102.2	Decrease in severity of impairment

as a reference for related documentation of rights and standards for equality of opportunity (United Nations General Assembly, 1993).

To the extent that psychology and related disciplines are committed to insuring that these rights are met for children (Simeonsson, Björck-Åkesson, & Bairrao, 2006), the ICF-CY extends beyond existing diagnostic classifications by providing a structure for practice, interdisciplinary collaboration, and communication (Lollar & Simeonsson, 2005). This chapter has advanced the framework and the taxonomy of the ICF-CY as an approach to enhance the assessment of physical, social, and personal functioning of children and youth. The use of the ICF-CY is compatible with current assessment methods, tools, and data sources, yielding an efficient profile summarizing a child's functional status within a child–environment interaction perspective. In this way, the ICF-CY can facilitate synergistic efforts to match children's needs with environmental supports through a common interdisciplinary language.

## Future Directions

Since their respective publications, the growth of interest in the implementation of the ICF (2001) and the ICF-CY (2007) has been substantial, reflected in a wide range of clinical, policy, and research applications. As that interest continues to grow, several priorities can be identified for research and development with particular reference to implementation of the ICF-CY in psychological services for children and youth.

1. As the development of most existing assessment tools was often purpose-specific and not referenced to a comprehensive framework of human

functioning, implementation of the ICF-CY has required “back-coding” of instruments, that is, examining the extent to which their content can be matched to ICF-CY codes. Instruments are being developed based on the ICF-CY framework (Saigal et al., 2005; Wells & Hogan, 2003), but there is a need for more measures that yield evidence corresponding directly to ICF-CY codes.

2. The Environmental Factors domain of the ICF-CY represents an essential focus for assessment, but it is a domain that is largely lacking coherent conceptualization as an area for assessment as well as valid measurement tools. To this end, there is a priority for the development of tools to assess the physical, social, and infrastructure environments that are compatible with the ICF-CY taxonomy.

3. Current diagnostic practice with children is problematic in that there are issues of instability and fluidity of diagnoses and comorbidity and practices are discipline-specific, for example the use of DSM-IV TR in mental health and IDEA categories in special education in the United States. A particular limitation of diagnostic approaches with children is that signs and symptoms are collapsed into a single diagnosis, masking intra- and inter-individual differences. An area for further work is the application of the ICF-CY separately or in combination with other classification systems to complement diagnostic data with profiles of the child's functioning and the environmental factors that may influence such functioning.

# Responsible Use of Psychological Tests: Ethical and Professional Practice Concerns

Jonathan W. Gould, David A. Martindale, and James R. Flens

## Abstract

Psychologists bring to the task of assessing children and adolescents their knowledge of psychometrics and their skills in psychological testing. Ethical standards and professional practice guidelines admonish psychologists to select psychological assessment techniques that are reliable and valid as well as suitable for use with the population being assessed. In this chapter, we argue that when selecting psychological tests to be administered in an evaluation, psychologists must employ, not set aside, their knowledge of psychometrics: unreliable projective techniques should be eliminated from consideration.

**Key Words:** projective tests, projective techniques, psychological testing, ethical standards, *Daubert*, rules of evidence

Among the most important distinctions between clinical psychology practice and other forms of mental health practice is the use of formal assessment using psychometrically sound assessment techniques. Historically, clinical psychologists have employed projective techniques as part of a comprehensive approach to diagnostic assessments, and these techniques have been considered particularly useful in the comprehensive assessment of children (Chandler, 2003). McClure, Kubiszyn, and Kaslow (2002) suggest that “less well-validated assessment techniques, including projectives...can provide rich data about the older child’s internal life and inform the clinician more fully about developmental, relational, cultural, and contextual variables” (p. 131).

On the other hand, the use of projective techniques in the assessment of children has come under fire. In response to McClure et al., Lee and Hunsley (2003) comment that the recommendation to use projective techniques as part of an evidence-based assessment model for the evaluation of children is “particularly troubling” (p. 112) because many of

the projective techniques recommended for use in child assessments “have consistently failed to meet scientific standards for psychological tests” (p. 112).

Over the past several decades, there has been a decline in the use of “time-intensive, clinician administered instruments that have historically defined personality practice” (Meyer, Finn, Eyde, Kay, Moreland, Dies, et al., 2001, p. 128). Despite this decline, the use of projective techniques, which are of questionable reliability and validity, continues to be widespread (Chandler, 2003). For example, the second edition of this volume contained an entire section, comprising six chapters, describing various projective techniques, including projective story telling, projective drawings, sentence completion, and the Holtzman Inkblot Technique.

The theoretical foundation upon which the use of projective techniques rests is the projective hypothesis (Chandler, 2003; Martindale, 2008). Important elements of the projective hypothesis have never been supported by empirical examination, however.

As Chandler (2003), a supporter of the use of projective techniques in children's assessment, reminds us: "Until there is some agreement as to what constitutes an appropriate outcome when projective techniques are used in clinical assessment, validity problems will remain, and projective techniques will continue to be poorly understood" (p. 56).

### **Why *Daubert v. Merrell* Is Important to Clinicians As Well As to Forensic Practitioners**

Our approach to the selection of psychological tests is influenced by our work in the forensic arena. When conducting an evaluation for the courts, psychologists need to select psychological tests that are grounded in the methods and procedures of science, with appropriate validation. As discussed in the next section, on ethical standards, we argue that the selection of psychological tests must be grounded in the methods and procedures of science, such as the emphasis on reliable and valid techniques discussed in Ethical Standard 9.01 (a) addressing assessment (APA, 2002).

Although we have identified no research examining the selection, administration, scoring, and interpretation of psychological tests used in child assessment, we have observed that psychologists often base their test selections on the frequency with which various tests are used, on the basis of what tests were used during their graduate education and training, and on the frequency with which various tests are alluded to in journals articles or books (Bow, Gould, Flens, & Greenhut, 2006). That is, psychologists seem to select tests for use in a psychological assessment based on their familiarity or popularity rather than on their reliability and validity.

The criteria articulated in the Supreme Court's decision in *Daubert* (*Daubert v. Merrell Dow Pharmaceuticals Inc.* 509 US 579 [1993]) to assist judges in determining the admissibility of scientific evidence are, in our judgment, useful criteria to consider when choosing psychological tests to be used in clinical psychological assessments as well as in forensic psychological assessments.

The first criterion to be considered is whether the underlying theory upon which the test has been developed has been subjected to testing examining its falsifiability [*Daubert* at 580]. As applied to the selection of psychological tests in child assessment, the first issue to consider is whether the underlying theory upon which the test rests has been subjected to empirical examination through rigorous challenge.

The second criterion articulated in *Daubert* is whether the underlying theory has been subjected to critical peer review and publication [*Daubert* at 580]. When examining the degree to which a test has received support, one might consult independent peer review publications such as the *Buros Mental Measurement Yearbook's* "Test Reviews Online."

Not all peer review procedures are equal (see for example, Dickersin, 1990; Dickersin, Chan, Chalmers, Sacks, & Smith, 1987; Kerr, 1998; Rosenthal, 1979). It is our position that, in the process of establishing expertise, professionals whose publications have appeared in peer-reviewed journals or in texts that have included a peer review element in the editorial procedure are quick to point this out. In doing so, they indirectly suggest that peer review is a procedure that yields scholarly contributions and eliminates foolishness. It turns out that this is true only if one's peers are scholars and not fools. The right of fools to publish their foolishness is protected by our Constitution. We delude ourselves when we think of peer-reviewed journals as scholarly periodicals requiring that each article submitted for publication be judged by an independent panel of scholarly or scientifically minded peers, who will reject submitted articles that are lacking in scholarship. Though the process of peer review (sometimes referred to as "refereeing") subjects authors' work to examination by others, when fools examine the work of their colleagues, we cannot expect foolish work to be eliminated in the screening process. The purpose of peer review is to require that authors meet the standards of their respective disciplines; but what if those who run a particular journal and those who submit articles are all members of a generally unrecognized discipline? Won't contributors to the *Journal of Unsupported Theories*, the *Journal of Sophistry & Silliness*, and the *Journal of the Wildly Whimsical* all assert that their published works have been peer-reviewed? Members of the editorial boards of journals are ordinarily well-respected members of their respective fields of study; however, not all fields of study are worthy of respect.

The third criterion articulated in the *Daubert* decision is whether the theory has a known or potential error rate [*Daubert* at 580]. To date, there has been little case law regarding addressing error rate. In two federal appellate cases it was suggested that the error rate involved the error in classification based on the scientific methodology, such as a false positive or false negative classification (*United States v. Smith*, 869 F.2d 348 [U.S. App. Dist. 7, 1989]; *United*

*States v. Williams*, 583 F.2d 1194 [U.S. App. Dist. CA2 1978]). Both of these federal cases predated the *Daubert* opinion, but they offer some understanding of how error rate might be applied to psychological testing; specifically, whether a test score can accurately classify an individual, and what the rate of error might be in that classification attempt. In the reporting of intelligence and achievement test performance, it is common to see scores combined with confidence intervals. The psychometrically savvy reader will recall that the calculation of psychological test scores involves the assumption of error in the score, whether it is in the form of standard deviation, standard error of measurement, or confidence intervals. All of these methods involve the use of a score's anticipated error. A reported test score is actually an estimate of an individual's true score on a particular scale. By reporting confidence intervals along with scores, evaluators provide to the readers of their reports information concerning the likely range of accuracy for any given reported score.

The fourth criterion is whether there are standards controlling the technique's operation [*Daubert* at 580]. Does the test have a manual with standard instructions for administration and scoring? Some practitioners who use the Thematic Apperception Test (TAT), for example, tend to administer the technique using a personally developed set of ideas about which cards are most likely to elicit useful responses, sometimes administering different sets of cards to different people, depending upon the issues being assessed (Ackerman & Kane, 2002; Dana, 1996). It has been our experience in the forensic setting that, often, practitioners do not own the most current edition of the manuals for tests that they are using, or they have not read test manuals prior to administering tests. Some practitioners develop their own set of administration procedures, deliberately ignoring the procedures prescribed in manuals (Ackerman & Kane, 2002; Gould, Martindale, & Flens, 2009).

The fifth criterion is whether the theory is generally accepted in the field in which it is being offered for use [*Daubert* at 580]. General acceptance is often reflected in favorable reviews in respected, peer-reviewed journals. Elsewhere, we (Martindale & Gould, 2008) and others (Zeedyk & Raitt, 1998) have suggested that, generally, acceptance is not as useful a criterion as it might appear to be.

Although these criteria were developed for use by judges so that they might more effectively rule on the admissibility of proffered scientific evidence, the quality of assessments conducted by psychologists would increase if psychologists were to consider

these criteria when selecting and administering psychological tests.

## **Ethical Standards**

Important companions to the criteria identified above are the ethical standards guiding the work of psychologists drawn from the American Psychological Association's Ethical Code of Conduct. Competence is the first stepping-stone in developing an ethical framework for the psychological assessment of children.

### ***Competence***

Those familiar with Federal and State Rules of Evidence will note that the psychological ethical standard defining *competence* is similar to the definition used in Federal Rule 702 regarding qualifying expert witnesses. In both psychology and law, a list of the defining characteristics of expertise begins with education, training, supervised experience, consultation, and study.

Though the foregoing characteristics are necessary, they are not sufficient when the expertise at issue involves psychological testing. Psychologists are responsible for demonstrating the reliability and validity of methodology used to generate data upon which psychologists base their opinions. “[S]ocial scientists will be called upon to demonstrate the validity of the premises that lie behind their testimony” (Faigman, Kaye, Saks, & Sanders, 2002, p. 52).

Again, we stress a dominant theme of this chapter: The law requires scientists to be good scientists first and good expert witnesses second (Faigman et al., 2002). Just as the task of an expert witness is to regulate the supply of facts to a jury or judge in a manner that “states a preference for science as the preeminent method for discovering facts” (Faigman et al., 2002, p. 47), it is our contention that psychologists engaged in psychological assessment have a parallel responsibility to their clients. Treating practitioners must regulate the supply of facts to clients in a manner that gives evidence of a preference for scientific rigor and integrity as the preeminent method for discovering useful psychological information.

In a 2006 study, Bow, Flens, Gould, and Greenhut (2006) found that child custody evaluators who administered psychological tests were often unfamiliar with important elements of the tests. For example, almost half of the Bow et al. sample of forensic practitioners underestimated the required reading level for the Minnesota Multiphasic Personality Inventory 2 (MMPI-2) and Millon Clinical Multiphasic Inventory 3rd Edition (MCMI III); 25 percent of respondents

allowed examinees to take the tests in the lobby of their offices; only a slight majority of respondents were aware of the MCMI III cutoff for the presence and prominence of a trait/syndrome; and 42 percent of respondents interpreted subscale scores whether or not the parent scales were elevated.

To the best of our knowledge, no similar study has been undertaken investigating psychologists' use of psychological tests in child assessment. We presume, however, that forensic practitioners are more likely than clinical practitioners to be aware that their work product may be critically reviewed by others and, as a result, may be more likely to be familiar with the tests they use in forensic assessment.

We foresee as an increased need for those practicing in the forensic arena to be well versed in psychological testing. Bow et al. (2006) wrote:

[W]e believe there will be increased legal scrutiny about the use of psychological testing in child custody evaluations. Consequently, psychologists will need to be well versed in the properties of psychological testing in such evaluations, along with the legal issues that may arise from a *Daubert* challenge. (p. 26)

#### **ETHICAL STANDARD 2.01 (C)**

Psychologists planning to provide services, teach, or conduct research involving populations, areas, techniques, or technologies new to them undertake relevant education, training, supervised experience, consultation, or study.

We have observed, on clinical and forensic online listservs in which we participate, that mental health colleagues often accept assignments to conduct evaluations and then post queries about test selection and test administration relating to assessment devices they are unfamiliar with and that they have never used. It is clear from their inquiries that their endeavor to interpret the data from these tools will be their first.

Psychologists asked to conduct evaluations that will involve the use of psychological tests or techniques they are unfamiliar with should consider the APA Ethical Standard 2.01 (c), which admonishes psychologists to undertake relevant education, training, supervised experience, consultation, or study. With specific reference to consultation, we recommend developing a formal consultative relationship with a colleague who is more knowledgeable and experienced and who can offer assistance in the selection of appropriate instruments and the interpretation of assessment data.

#### **2.03: MAINTAINING COMPETENCE**

Psychologists should undertake ongoing efforts to develop and maintain their competence.

Maintaining competence in psychological assessment and keeping up with current empirical research and professional practice in the use of psychological tests enables psychologists to base their work on established scientific principles and the professional knowledge of the discipline.

Ethical Standard 2.04 admonishes psychologists to base their work on established scientific principles and on the professional knowledge of the discipline. There is a parallel between the criteria established in the *Daubert* decision and Ethical Standard 2.04, in which both the legal rule and the psychological standard focus attention on the need for psychological opinions to be based upon established scientific principles and on the professional knowledge of the discipline.

Psychologists have an ethical obligation to know about the laws governing their work, including state and federal laws about the creation of records, retention of records, release of records, confidentiality, and other relevant areas that affect clinical practice. Psychologists working in the forensic arena are admonished to be reasonably familiar with the judicial or administrative rules governing their roles.

Once competence has been developed, Ethical Standard 2.03 directs psychologists to maintain competence. Often, we have been witness to depositions or trials in which aggressive cross examination of clinicians who conducted psycho-educational or psychological evaluations of children revealed that the evaluators under scrutiny had not kept up with research and practice in the use of the psychological tests administered as part of their evaluations, had not attended continuing education courses aimed at maintaining competence in the tests administered, and had not sought peer supervision or peer consultation relating to tests they utilized. These evaluators appear to have taken the position that once psychological tests have been learned in graduate school, there is no reason to engage in ongoing efforts to maintain their competence in relevant areas of psychological assessment.

#### **Multiple Relationships**

Whether one works in the clinical or forensic arena, it is important that psychologists be transparent in all aspects of their professional evaluative work. The 1992 APA ethics code contained

an ethical standard emphasizing the importance of transparency in record keeping. Standard 1.23 (b) read as follows:

When psychologists have reason to believe that records of their professional services will be used in legal proceedings involving recipients of or participants in their work, they have a responsibility to create and maintain documentation in the kind of detail and quality that would be consistent with reasonable scrutiny in an adjudicative forum.

Although no similar admonition appears in the 2002 ethics code, it is our position that records of all aspects of psychological evaluations should be created in reasonable detail, should be legible, should be stored in a manner that makes expeditious production possible, and should be made available in a timely manner to those with the legal authority to inspect them or possess copies of them. (The foregoing wording has been adapted from Model Standard 3.2 (b) of the Association of Family and Conciliation Courts' *Model Standards for Child Custody Evaluation* [AFCC, 2007]).

Ethical Standard 6.01: Documentation of Professional and Scientific Work and Maintenance of Records Psychologists create, and to the extent the records are under their control, maintain, disseminate, store, retain, and dispose of records and data relating to their professional and scientific work in order to:

- facilitate provision of services later by them or by other professionals;
- allow for replication of research design and analyses;
- meet institutional requirements;
- ensure accuracy of billing and payments;
- ensure compliance with law.

Whether an evaluation of a child is conducted at the request of a parent, is the result of government-mandated programs, or is conducted as the result of a court order, the integrity of the evaluative process is dependent upon transparency and the degree to which actions by the evaluator is subject to scrutiny. Unless otherwise informed by the court or mandated by the government, evaluators should presume that everything in their files is subject to disclosure. Withholding or destroying components of our files undermines our work.

Transparency is an essential element of our system of justice. Courts, not psychologists, decide what is and what is not discoverable. The willingness of the public to view us and our work products as trustworthy is dependent upon the transparency that characterizes our work.

The term *transparency*, as used in this chapter, is intended to describe a philosophy from which a pattern of professional behavior logically follows. The philosophy guides us in our roles as evaluators and, subsequently, in our roles as consulting psychologists to families and as testifying experts to courts.

(1) *As evaluators*, in order to gather information helpful to triers of fact and to the families being assessed, psychologists must be unencumbered by personal or philosophical agendas; must be committed to a balanced approach in their work; and, must be alert to phenomena that adversely affect decision making.

(2) *As consultants to families or as testifying experts to the court*, in order to be effective, psychologists must be credible; must recognize that credibility is earned and that complete openness is one means by which an expert establishes credibility; and, must respect the rights of those wishing to question a consultant's or expert's opinions and the manner in which they were formulated. The pattern of behavior that flows from the stated philosophy includes: (a) prior to commencing an evaluation, actively disclosing any prior or current relationships with the participants; (b) being diligent in the creation and maintenance of one's records; and (c) producing, in response to a legally permissible request, the complete contents of one's file in the matter being litigated to those who are the legal authority to review the file.

### ***The Initial Contact***

In any type of psychological evaluation, a file should be created at the time of the initial contact. Ideally, messages left by those seeking an evaluator's services should be noted and responded to quickly. If one is engaged in a psychological evaluation for the courts, it may be wise to have a member of the office staff respond to messages. When this is not possible, only the most basic information should be taken during an initial phone contact, but all information should be recorded with care. If an evaluation is litigation-related, it is important to maintain precise records of all contacts. It is not uncommon (nor is it unreasonable) for a cross-examining

attorney to inquire concerning all contacts that litigants, collateral sources, and others have had with an evaluator.

An evaluator's records should indicate when and by whom the initial contact was made and what information was provided. Before agreeing to accept an assignment, an evaluator should determine who the participants will be and disclose prior involvements with any of them and with individuals with significant ties to them. From our perspective, disclosure is a no-lose endeavor. Keeping track of contacts is relatively easy (but not a topic for this chapter); making such contacts known sets the stage for an open process; and, pre-evaluation disclosure eliminates one of the more unpleasant avenues of cross-examination. We also encourage those engaged in clinical (as contrasted to forensic) work to maintain a similar set of records.

### ***Information Gathering***

A discussion of the types of information likely to be useful to an evaluator and the means by which to gather such information is beyond the scope of this chapter. It must be emphasized, however, that under no circumstances whatsoever should an evaluator take possession of information offered without first having made it clear to the provider(s) of the information that it will be shared with others. All information accepted by an evaluator must be open for discussion with the person for whom or organization for which the evaluation is being conducted, whether that is a parent, a school district, or a court. Exceptions are rare, and evaluators must be familiar with any state laws that prohibit or place specific limitations on disclosure. Particularly when parents or school administrators have had previous involvements with mental health professionals, they should be reminded that the principles of confidentiality that may have applied in earlier interactions with mental health professionals are not applicable in contexts such as those in which forensic evaluations are conducted.

### ***Preservation of Records***

With the exceptions of dishonesty and displays of ignorance, there is no greater threat to a psychologist's credibility than the appearance that s/he has endeavored to shield from scrutiny any aspect of the manner in which s/he has conducted her/his professional activities.

The American Psychological Association's Record Keeping Guidelines (Committee on

Professional Practice and Standards, American Psychological Association, 2007, p. 995) remind psychologists that they have "a professional and ethical responsibility to develop and maintain their records."

It is our view that the most useful guidance concerning the creation, maintenance, and release of records is to be found in the previously referenced AFCC *Model Standards*. Though the document was developed for custody evaluators, there is no element of the AFCC's guidance relating to records that is not equally helpful to mental health professionals performing other types of evaluations, including evaluations performed in a health service context.

Model Standard 3.2 admonishes evaluators to create all records expeditiously and to presume that their records are created, maintained, and preserved in anticipation of their review by others who are legally entitled to possess them and/or to review them. Model Standard 3.2 (b) declares that records should be created in reasonable detail, should be legible, should be stored in a manner that makes expeditious production possible, and should be made available in a timely manner to those with the legal authority to inspect them or possess copies of them.

It is important to recognize that distinctions often made in clinical contexts between progress notes and process notes or between a client's file and a treating practitioner's personal file are distinctions that are not recognized in forensic mental health evaluations. Mental health professionals whose previous evaluative tasks have been conducted within a treatment context should recognize that, in a litigation context, several ground rules are different. For example, regardless of the form in which information is presented, once evaluators take possession of an item, it must be retained, and reasonable care must be taken to prevent its loss or destruction. More often than not, evaluators who offer testimony are required to produce items that were considered by them in the course of their evaluations, even if, after having considered certain items, decisions were made not to rely upon them. For those conducting clinical evaluations, maintaining information in the file that was influential in forming their opinions is also important.

The responsibilities alluded to above are all tied to the concept of transparency. Evaluators cannot be effectively cross-examined if appropriate records have not been created; if handwritten documents are illegible; or if records that might form the basis of

cross-examination have been concealed, destroyed, or returned to the litigants or others. Federal Rule of Evidence #705 reminds expert witnesses of the obligation to disclose the facts or data that form the basis for their opinions.

Though psychologists who have conducted their evaluations in forensic contexts are called upon to explain and defend their findings and the opinions formulated on the basis of those findings, treatment providers should not presume that they will never have to shoulder the burden of justifying their methods. All providers of liability coverage for health professionals stress the importance of creating reasonably detailed records and preserving those records. It is foolhardy for clinicians to embrace the flawed notion that whatever records they create are created and maintained only for their own use and, for that reason, do not have to be created with the possibility of their inspection by others in mind.

### ***The Full Monty***

Without access to evaluators' complete files, those wishing to challenge our data or question our interpretations of those data are put at a significant disadvantage in their endeavors to shed light on deficiencies in our work. When evaluators' alteration, concealment, or destruction of portions of the file inhibits or interferes with a thorough exploration of their methods and procedures, there is an increased risk that errors will go undetected.

Those who conduct psychological evaluations in forensic contexts implicitly accept several responsibilities. Among them is the responsibility to familiarize ourselves with the ways in which ineradicable biases and the lacunae in psychology's knowledge base limit the precision of our assessments. Education and training make us aware of the sources of bias, and various professional guidelines urge us to reduce the effects of these biases by seeking corroboration of information relied upon and to generate and explore alternative hypotheses. We must, however, be mindful of the fact that our best efforts may bring our biases to an irreducible level, but education, training, and significant effort do not eliminate them.

### **Protecting Privacy**

We have reviewed clinical evaluations and forensic evaluations that contain information that has no relevance to matters under investigation. Standard 4.04 of our Ethics Code (American Psychological

Association, 2002) instructs us to minimize intrusions on privacy. "Psychologists include in written and oral reports and consultations, only information germane to the purpose of which the communication is made." Psychologists may elect to exclude from their reports information reasonably viewed as not germane to the matter at hand. Though evaluators have the authority to omit information not deemed pertinent from their reports, all information must be preserved, and, when the evaluator is asked for it, its existence must be made known.

There are times when mental health professionals are reasonably expected to protect their records (or portions of their records) from disclosure in order to prevent unwarranted intrusions into the privacy of others who are owed a duty of care. When psychologists are in possession of material that they reasonably believe should be protected from disclosure, their concerns should be raised with the proper authorities. In a forensic context, this may mean making application to the court and respecting the court's decision-making authority. For forensic practitioners, though it is likely that the procedures to be followed vary somewhat from state to state, the process is outlined in the Federal Rules of Civil Procedure [specifically, Fed. R. Civ. P. 26(b)(5)(C), 2001, p. 33], the language of which has been adopted by many of the states. For clinical psychologists,

There may be times when you are faced with the need to protect your records to prevent unwarranted intrusions into the privacy of others to whom you owe a duty of care. When a psychologist is in possession of material that she reasonably believes should be protected from disclosure, she may raise such a concern with the proper authorities. In a clinical context, the proper authorities whom one may need to consult include attorneys representing organizations in which evaluations have been conducted.

### **Staying Within What We Know**

Among the most common errors we have observed among the reports we have reviewed is the offering of opinions based on insufficient information or based on psychological assessment techniques with little or no evidence of reliability and/or validity. Psychology is a social science, and, as such, is presumed to have developed a foundation of knowledge derived from empirical research. The methods and procedures developed for use in empirical research are presumed to have psychometric integrity; that is, the assessment techniques used in empirical research are expected to have demonstrated reasonable reliability and validity.

Shuman and Sales (1998) identified four types of expert testimony, and we believe that these four types of expert testimony are useful categories to use when examining the presentation of psychological testing results both inside and outside of a court context. The first type of expert opinion is based on clinical judgment because there is no scientific research available. We propose that offering such an opinion is inconsistent with psychologists' code of ethical conduct. Psychologists have an ethical responsibility to offer professional opinions for which there is sufficient support from reliable and valid scientific research. This is discussed more fully below.

The second type of expert opinion is based on clinical judgments where there is research evidence available on the issue that is contrary to the clinical judgment. Similar to the concern voiced above, we believe that offering of such an opinion is inconsistent with psychologists' code of ethical conduct.

The third type of expert opinion is based on presentation of results of scientific research and includes opinions based on clinical judgments that go beyond the results of current research. Psychologists have an ethical responsibility not to over-interpret—or under-interpret—psychological findings.

The fourth type of expert opinion is based on the results of scientific research (Shuman & Sales, 1998, p. 1230). Opinions based on results of scientific research reflect the spirit and intention of psychologists' code of ethical conduct.

### **Bases for Assessment**

Ethical Standard 9.01 (a) addresses the need for psychologists to "base the opinions contained in their recommendations, reports, and diagnostic or evaluative statements, including forensic testimony, on information and techniques sufficient to substantiate their findings." A foundation of contemporary psychology is the development of reliable and valid procedures to assess human behavior. When psychologists are engaged to conduct psychological evaluations of children, it is presumed is that they will employ psychological assessment procedures that are scientifically based; that the data generated from those assessment procedures are reliable and valid; and that the interpretations of these reliable and valid data are sufficient to support the opinions that will subsequently be expressed by the evaluators.

In reviewing the work of psychologists who have been appointed or retained to conduct psychological assessments of children, we often encounter evidence of inattentiveness to Ethical Standard 9.01

(b) and offer opinions about people who they have neither met nor evaluated. Specifically, reports are prepared in which psychologists offer opinions on the matter of a child's psychological best interests when they have failed to evaluate both parents. In such reports, it is not uncommon to find very specific statements about the psychological characteristics of individuals who have not been evaluated.

Psychologists have traditionally been trained in service models derived from clinical treatment. Psychotherapy has been conceived as a process initiated by the client, on the basis of the client's own perception of a need to make changes in his or her life. The psychotherapist-patient privilege is presumed to facilitate open communication by decreasing the risk that a client's thoughts, feelings, or behavior will be revealed to others without the client's permission. Implicit in the psychotherapy process is the assumption that the client will be motivated to provide as much *accurate* information to the therapist as possible, so that the therapist's ability to assist the client will be maximized (Greenberg, Martindale, Gould, & Gould-Saltman, 2004).

Greenberg et al. (2004) argued that many psychotherapists adopt a mindset that leads to the uncritical acceptance of information provided by their clients—adults and children alike. Therapists are often trained to accept, support, and advocate for the needs of their clients. This orientation may lead to a reluctance to challenge a client's assumptions, interpretations, or dysfunctional behavior. Therapists who adopt this perspective may also underestimate the level of bias in information they receive from their clients.

When a psychologist is appointed or retained to conduct a psychological evaluation of a child whose parents are involved in conflict over custodial placement, the assumptions underlying clinical assessment and treatment become inapplicable. Particularly in high-conflict cases, parents may become consumed with their desire to prevail in the custody conflict to such a degree that it impairs their ability to perceive situations accurately and support their children's independent needs. Constructive motives ordinarily encountered in the psychotherapy process, such as the desire to be candid in the reporting of information, may be subordinated to the parent's desire to prevail in the litigation. This issue is complicated by the fact that in high-conflict disputes, the litigating parents often believe that the parenting arrangement that they seek is the arrangement that best serves the child's interests. Quite often the arrangement is one in which the role of the other parent is dramatically

minimized. Thus, even where a particular parent has been the one to seek an evaluation, the parent is motivated by a desire to prevail in the legal matter. The desire to identify and alter problematic attitudes and behaviors—the desire ordinarily present in a psychotherapy context—is not present. In such situations, even when parents engage in efforts to improve their parenting skills or address emotional issues identified by evaluators or the court, it appears that they are often motivated by a wish to be perceived more favorably.

Adults who are intent on achieving a particular outcome may (intentionally or otherwise) alter, or may teach their children to alter, their interaction with mental health professionals in order to achieve their overall goals. While even young children are capable of reporting events accurately if they are not exposed to suggestive questioning (Ceci, Kulkofsky, Klemfuss, Sweeney, & Bruck, 2007), children at the center of a custody conflict are often exposed to significant adults (including parents) whose perceptions and interpretations of events have been distorted by bias. Children often respond to biased questioning, or to an interviewer with a strong opinion or emotional agenda, by producing the information the adult is seeking (Martindale, 2005a).

Where litigation is involved, all of these factors must be considered as decisions are made concerning what weight should be attached to children's reported perceptions, behaviors, and statements either to evaluators or to therapists. Opinions expressed by evaluators that are based on children's stated perceptions of parents who have never been evaluated are likely to have been formulated based on unreliable information or upon information whose reliability has not been ascertained.

Ethical Standard 9.01 (c): When psychologists conduct a record review or provide consultation or supervision, and an individual examination is not warranted or necessary for the opinion, psychologists explain this and the sources of information on which they base their conclusions and recommendations.

Most psychological assessment techniques that have been developed for psycho-educational assessment tend to have manuals that contain useful information about the reliability and validity of the instrument. As discussed above, our survey data suggest that a minority of psychologists do not administer tests in a manner consistent with

the instructions in the manual. In general, however, we have observed that assessments examining psycho-educational functioning appear to have fewer problems than assessments examining psychological and emotional functioning.

Among the commonly used assessment procedures of many child and clinical psychologists are projective techniques. Many of those who utilize these techniques attach to them a misleading aura of precision by identifying them as psychological "tests." *Standards for Educational and Psychological Testing* (American Psychological Association, American Educational Research Association, & National Council on Measurement in Education, 1999), in the introductory section, offers a definition of "test": "A test is an evaluative device or procedure in which a sample of an examinee's behavior in a specified domain is obtained and subsequently evaluated and scored using a standardized process" (p. 3).

Chapters in previous editions of this text have supported the use of projective techniques in the psychological assessment of children (e.g., Chandler, 2003; Knoff, 2003). It is our position that consumers of our professional services are being misled when projective techniques are identified as psychological tests. As discussed extensively below, there is no support in current research for the notion that projective techniques constitute a scientifically informed psychological assessment procedure.

Chandler and Knoff are not the only colleagues who encourage the use of projective techniques in the psychological assessment of children. McClure, Kubiszyn, and Kaslow (2002) have argued that there is an urgent need for empirical validation of techniques used in the psychological assessment of children and point to a number of articles that they believe support such a use of projective techniques. Most of the articles they refer to, however, focus on the Rorschach test (see Hilsenroth, Fowler, & Padawer, 1998; Meyer et al., 2001), rather than more commonly used projective techniques.

It should be noted that, in commenting on the use of the Rorschach with children, Exner (1980, p. 569) has stated: "It would be very erroneous to assume that test findings developed from a record of a younger child can be used as indicators of 'things to come.'" Exner, Thomas, and Mason (1985, pp. 17 & 18) stated: "The magnitude of the many changes [that take place in children] argues against the decision to make long-term *predictive descriptions* [emphasis in original] concerning a child from a Rorschach taken prior to age 14." In addition, there are concerns about the Comprehensive System's

normative data for children. The Comprehensive System's existing normative data, for example, may overpathologize psychologically healthy children (see for example, Shaffer, Erdberg, & Meyer, 2007).

Chapters in the previous edition of this volume describe the projective hypothesis as the theoretical foundation for projective techniques (e.g., Chandler, 2003); various projective techniques such as storytelling (Dupree & Prevatt, 2003); drawings (Knoff, 2003); sentence completion (Haak, 2003); the Rorschach, and, in particular, the Exner Comprehensive System, with children (Allen & Hollifield, 2003); and the Holtzman Inkblot Technique with children (Holtzman & Swartz, 2003). Writing about the use of the TAT, Dupree and Prevatt (2003) declare, "Despite the fact that there appears to be no consistently used, psychometrically sound scoring system for it, the TAT continues to enjoy widespread usage in academic training programs, internships, and clinical practice" (p. 71).

Reviews of research on the psychometric integrity of projective drawings reveal concerns that are similar to those that have been alluded to by Dupree and Prevatt with respect to the TAT. Knoff (2003) reported that any analysis of the usefulness of projective drawings is virtually impossible because of the multitude of methodologies used in such studies. He concludes that "these studies provide such widely differing methodological details that one cannot assume that results are clinically accurate and socially valid without additional validation and replication" (p. 101). Knoff concludes that interpretations of projective drawings are characterized by poor test-retest reliability and poor internal consistency. Citing a review of the psychometric literature on the Kinetic Family Drawing Technique (Handler & Habenicht, 1994), Knoff concludes that "few, if any, recent studies have specifically evaluated the reliability of projective drawings" (p. 101). In light of the fact that psychologists with favorable views of projective techniques acknowledge their psychometric deficiencies, we are perplexed by their continued use and by the frequent labeling of these techniques as psychological tests. Knoff (2003) suggests that projective drawing techniques (a) be used only for the generation of social, emotional, or behavioral hypotheses; (b) never be used as a sole basis of clinical diagnoses; and (c) never be used as the sole basis for conclusions.

The distinction between a "psychological test" and an "interview aid" is significant, and it is one that psychologists should take great care to make.

When the writer of a report identifies an assessment procedure or device as a "psychological test," readers of the report are likely to assume that the procedure or device rests on a scientific foundation. Projective techniques are based on the projective hypothesis, which has never been validated. With the possible exception of the Rorschach, scored using the Exner system and the recently developed Rorschach Performance Assessment System<sup>1</sup> (Meyer, Viglione, Mihura, Erard, & Erdberg, 2011), not one of the projective techniques currently in use has been shown to have psychometric integrity. Therefore, we believe it is inappropriate to include such techniques on the lists of psychological tests that customarily appear in the opening sections of reports outlining the findings of comprehensive psychological assessments. It is our contention that, with the possible exception of the Exner-scored Rorschach and the newer Rorschach Performance Assessment System, no projective techniques have demonstrated reliability and validity sufficient to justify their use as anything other than interview aids (see, e.g., Mihura, Meyer, Dumitrascu, & Bombel, 2012). When we reflect on the reports we have reviewed over the years, it is our impression that only a small percentage of the evaluators who employ projective techniques describe the strengths and limitations of the interpretations they have generated.

More often than not, the readers of reports that have been prepared in a clinical context are not informed of the limitations of interpretations based on psychometrically unsound assessment techniques. In our judgment, the failure to include a discussion of the limitations of projective techniques violates both the letter and the spirit of the ethical code.

Ethical Standard 9.02 (b): Psychologists use assessment instruments whose validity and reliability have been established for use with members of the population tested. When such validity or reliability has not been established, psychologists describe the strengths and limitations of test results and interpretation.

When parents are in the process of choosing pediatricians, the parents are entitled to know whether the pediatricians practice conventional, mainstream medicine that includes administering scientifically developed medical tests, or use holistic or Far Eastern approaches to maintaining health. When pediatricians use unconventional treatment

methods that do not enjoy scientific support in the medical literature yet find support in holistic, alternative treatment literature, parents are entitled to the information that will enable them to make informed decisions in selecting health care practitioners for their children.

In 2006, Trubitt, recognizing the unreliability of assessments of children that rely on interpretations of the children's drawings or play, nevertheless advised play therapists to "continue to use play therapy methods" (Trubitt, 2006, p. 5). She opined: "We do not have to mention [our] use [of these methods]" (p. 5). Our perspective contrasts sharply with Trubitt's. In our view, when psychologists use projective techniques and utilize interpretations of responses to projective stimuli in diagnosing children, the psychologists have an ethical responsibility to inform parents of the known psychometric deficiencies in projective assessment techniques. Standard 9.03 (a) of the Psychologists' Ethics Code admonishes psychologists to "obtain informed consent for assessments, evaluations, or diagnostic services...." One cannot give informed consent to any procedure (including an assessment procedure) without first having been provided with all pertinent information. In particular, psychologists should disclose the risks known to be associated with their favored assessment procedures and should discuss alternative assessment methods.

We have found evaluators who believe children's drawings can be helpful even though they lack psychometric integrity. For example, the following was taken from a report reviewed by one of the authors:

The House-Tree-Person test is based on the premise that unconscious aspects of the personality are exposed through the person's drawings of familiar items. Children who are in stressful situations are often hesitant to respond to direct questioning about this experience. Researchers have studied the H-T-P to determine if these children produce discrete indicators of their situation, however the test's validity and reliability have not been proven. Despite this lack of psychometric support, the test can be very valuable in providing general information about a child's personality.

Such an approach is consistent with the "broken clock" approach to psychometric integrity: Even a broken clock is accurate twice a day.

Many of our psychodynamically oriented colleagues believe strongly in the usefulness of psychodynamic concepts and believe that projective

techniques shed light on unconscious processes, filling a void that is created by the use of self-report inventories. Our position, quite simply, is that when using assessment procedures that lack an empirically supportable theoretical foundation and lack demonstrable reliability and validity, psychologists have a responsibility under Ethical Standard 9.03 (a) to provide full information concerning the techniques, so that those with decision-making authority (parents, school administrators, courts) are able to make informed decisions.

It is our position that if one fully understands the concept of projection, one is more likely than not to conclude that drawings cannot possibly be viewed as a reliable source of information concerning children's perceptions of themselves, their families, the dynamics within their families, or anything else. Even if it could be demonstrated that the dynamic of projection consistently operates as children produce these drawings, there would still be no basis for conceptualizing interpretations of drawings as a reliable data source. The early proponents of projective techniques made it clear that we cannot be certain what perceptions, attitudes, fears, or wishes are being projected.

Practitioners who request that children "draw a person" are generally in agreement that the same-sex figure should be conceptualized as a "self" figure. Even if we presume that drawings "tell" us something about the psychology of children who have produced drawings, it must be recognized that the "self" figure may represent a child's perception of himself or herself (with emphasis either on physical or psychological attributes); may represent what s/he wishes himself or herself to be (again, with emphasis either on physical or psychological attributes); or, to complicate things further, the drawing may symbolically portray physical or psychological impairment, compensation for a real or perceived shortcoming, or a combination of these factors.

If these cautionary statements are applied to family drawings, it follows that if a child produces a drawing in which she places herself close to her father, this may represent a projection of her perception of her relationship with her father, but it may also represent a wish rather than a perception. The child with a father who is either physically absent or emotionally distant might draw the father close to the child. An older child whose drawing skills are somewhat better might draw himself being cared for by a parent who, in reality, provides deficient care.

Other complicating factors must also be considered. Even if children's family drawings reflected

the children's perceptions of family relationships as accurately as thermometers measure temperature, there is no basis whatsoever for presuming that such perceptions are stable over time. How a particular child views his parents and his relationship with each of them today may be dramatically different from how he will view his parents and his relationship with them six months from today. Finally, even if we could presume that it is always a perception (as opposed to a wish) that is being projected, and even if we could presume that such perceptions are reasonably stable over time, there is no basis for presuming that children's perceptions of family dynamics are accurate. Neither is there a basis for presuming that if children's perceptions are inaccurate, it does not matter, because it is only their perceptions that are of concern to us. Reality matters.

There are no data demonstrating that children's drawings display temporal stability (test/retest reliability) and there is no evidence that different experts viewing the same drawing will formulate the same opinions concerning the information provided by the drawing. Though some of those who wish to employ drawings in their assessments have endeavored to create standardized processes, there is no evidence to suggest that any of the systems designed to date demonstrate acceptable inter-judge reliability.

The standardized processes alluded to above involve utilization of what is known as the "sign approach" to figure-drawing interpretation, in which certain features in the drawings are viewed as signs (indicators) of various life experiences or personality characteristics. In commenting on the sign approach, several well-respected writers have concluded that the advocates of the sign method often disagree among themselves concerning what a particular feature indicates (Lally, 2001).

Richard Dana (1996), a psychologist who has written extensively on projective techniques, has called attention to the fact that interpretations of responses to projective stimuli are vulnerable to *eisegesis*—distortion stemming from projection by the examiner (as opposed to the examinee) deriving from the examiner's theoretical biases, emotional investment in certain hypotheses, etc. The late Anne Anastasi (Anastasi & Urbina, 1997), one of psychology's leaders in the field of assessment, opined that the interpretation of responses to projective stimuli "may reveal more about the theoretical orientation, favorite hypotheses, and personality idiosyncrasies of the examiner than it does about the examinee's personality dynamics."

Though no published data are available for reference, it is our impression that more often than not, practitioners who rely upon drawings as an assessment technique offer no statements in their reports that might alert readers to the deficiencies in the technique. In the 1999 edition of *Standards for Educational and Psychological Testing* (APA et al., 1999), the following admonition appears: "Professionals are expected to make every effort to be aware of evidence of validity and reliability that supports or does not support their inferences and to place appropriate limits on the opinions rendered." In reviews of drawing techniques prepared for The Buros Institute and published in the *Mental Measurements Yearbook*, reviewers have consistently concluded that there are no empirical data to support the use of drawings.

Some clinicians and forensic evaluators have utilized drawings produced by a child for the purpose of identifying the child as a member of a specific group (for example, sexually abused children). There are no data to support the notion that interpretations of drawings can be effectively used for the purpose of discriminating between two classes of examinees. Research has repeatedly shown drawings to be lacking in discriminant validity. Even if there were research findings supporting the contention that a certain feature is often observed in drawings produced by abused children, detection of this feature would be useful only if research also demonstrated that the specified feature is observed exclusively in the drawings of abused children and is not observed in the drawings of non-abused children.

The methods employed both by treatment providers and by evaluators in gathering information from children differ dramatically from the methods employed in gathering information from adults. Statements made by individuals of any age are viewed as a data source, and mental health professionals interviewing children often find that play, building tasks, drawing tasks, and similar activities facilitate constructive oral interaction. When drawings are utilized as a stimulus for conversation and where it is the statements made that are conceptualized as the data source, it is unlikely that any harm is created by the use of drawings. We contend, however, that significant risk of harm is created when no inquiry is conducted and when the drawings themselves and the mental health professional's interpretations of those drawings are viewed as a data source.

The psychologists' Ethical Standard 9.02 (a) reads: "Psychologists administer, adapt, score,

interpret, or use assessment techniques, interviews, tests, or instruments in a manner and for purposes that are appropriate *in light of the research on or evidence of the usefulness and proper application of the techniques* [emphasis added].” Section (b) reads, in pertinent part: “Psychologists use assessment instruments whose validity and reliability have been established [emphasis added] for use with members of the population tested.” It is our position that projective assessment techniques do not meet the criteria alluded to in the ethics code.

## Notes

1. The Rorschach Research Council began in 1997 with the goal to improve the research of the Comprehensive System. Following Exner’s death in 2006, several members of the original Rorschach Research Council developed the Rorschach Performance Assessment System, also known as the R-PAS. The goal of this group was to expand on the evidence-based scoring and interpretation of the Comprehensive System. The R-PAS group developed a more structured administration procedure, a detailed scoring system and kept only those scores and indices with solid research foundations. Their work relied heavily on a meta-analytic review of the Comprehensive System’s variables (Mihura, Meyer, Dumitrascu, & Bombel, 2012). At this point, the R-PAS has an extensive manual, a computer-assisted scoring system that utilizes an extensive international reference group, and uses research-based interpretive strategies.

# Cognitive Assessment: Progress in Psychometric Theories of Intelligence, the Structure of Cognitive Ability Tests, and Interpretive Approaches to Cognitive Test Performance

Dawn P. Flanagan, Vincent C. Alfonso, Samuel O. Ortiz, and Agnieszka M. Dynda

## Abstract

This chapter highlights the progress that has been made in theories of intelligence (particularly psychometric theories), the structure of cognitive ability batteries, and methods of cognitive ability test interpretation over the past century. Early theories of intelligence revolved around notions of a single general factor, or *g*, but steadily advanced into two-factor models (e.g., original *Gf-Gc*), early multiple-factor models (e.g., Thurstone's Primary Mental Abilities), and eventually to current, multiple-factor models (e.g., Cattell-Horn-Carroll [CHC] theory). Also discussed is the fact that cognitive batteries seldom kept pace with developments in theory, but they nevertheless have shown significant growth and development overall, particular within the last decade. The latter half of the chapter provides a discussion of refinements to CHC theory at both the broad and narrow ability levels, application of CHC theory to academic outcomes research, integration of CHC and neuropsychological theories, and greater emphasis on flexible battery approaches. We conclude that contemporary cognitive assessment allows for sufficient illustration of the links between abilities (e.g., cognitive and academic) and neuropsychological processes such that avenues for instruction, intervention, and treatment of individuals who struggle to learn will not only be clear, but also empirically supported.

**Key Words:** psychometric theories, CHC theory, cognitive assessment, cross-battery, flexible battery, intelligence, neuropsychological assessment

## Introduction

As the measurement of cognitive abilities with standardized, norm-referenced tests passes its first century of practice, it seems appropriate to write about the progress that has been made in psychometric theories of intelligence, the structure of cognitive ability tests, and interpretive approaches to cognitive test performance. Indeed much has changed since the days of Spearman's general intelligence or *g* factor and the Stanford-Binet Intelligence Scale (Terman, 1916). Although progress in psychometric

theories of intelligence was steady and proceeded gradually over a period of decades, measurement and interpretation of cognitive abilities did not keep pace. Despite 100 years of psychological assessment, the most significant changes in the practice of the measurement and interpretation of cognitive abilities occurred recently and over an astonishingly short period of time.

In a review of the state of the art in cognitive assessment prior to 2000, Flanagan and colleagues (Flanagan, Ortiz, Alfonso, & Dynda, 2008) pointed

out a number of major concerns with cognitive assessment that existed at the time. For example, they noted that nearly all intelligence (or cognitive) batteries available prior to 2000 were mainly “based on either outdated (psychometric) theory or no theory at all” (p. 633). Historically, psychological testing was more concerned with practical issues than theoretical ones, apart from vague notions of Spearman’s *g* (see Wasserman, 2012). Thus, even up to the brink of the twenty-first century, practitioners were routinely using intelligence tests that were not, in fact, based on the most current and credible scientific evidence (Carroll, 1993a; Flanagan & Ortiz, 2001; Horn, 1991; Kamphaus, 1993; McGrew & Flanagan, 1998; Shaw, Swerdlik, & Laurent, 1993).

Flanagan and colleagues (2008) also pointed out that the major contribution of intelligence tests was the intelligence quotient itself (or Full Scale IQ [FSIQ] as defined by the popular Wechsler scales) (e.g., Flanagan, McGrew, & Ortiz, 2000). The term *IQ* worked its way into the common vernacular quickly and, since the publication of the Wechsler-Bellevue in 1939, became central and critical to virtually all clinical, educational, and neuropsychological conclusions, diagnoses, and decisions (Kamphaus, Winsor, Rowe, & Kim, 2005, 2012). Despite the prominence and ubiquity of IQ, many researchers questioned whether such a reputation was deserved and whether IQ had significant relevance for differential diagnosis and treatment (e.g., Carroll, 1993a; Flanagan et al., 2000; Lezak, 1995; Reschly & Grimes, 1995; Sternberg, 1993). By the 1990s, there was considerable debate regarding the utility of IQ in psychological evaluations, with one camp arguing its superiority over analysis of lower-order composites and subtests (e.g., McDermott, Fantuzzo, & Glutting, 1990) and the other camp arguing that IQ should be de-emphasized or replaced with an evaluation of multiple, theory-based ability composites (e.g., Horn & Blankson, 2005; Keith, Kranzler, & Flanagan, 2001; McGrew, Flanagan, Keith, & Vanderwood, 1997). While both camps have continued this debate (see Canivez, this volume; and Reynolds, Keith, Flanagan, & Alfonso, in press), current intelligence tests (now more popularly known as “cognitive” tests) are, nevertheless, on the whole more firmly grounded in contemporary psychometric theory and research than their predecessors.

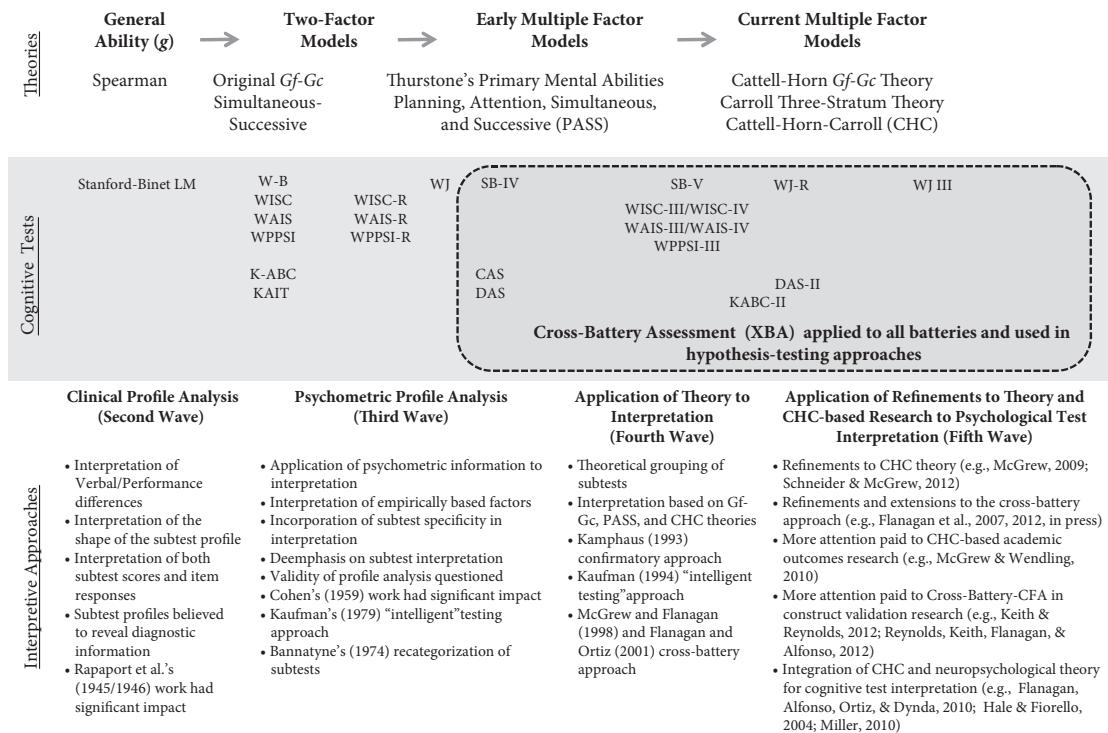

The purpose of this chapter is to describe the progress that has been made in: (a) psychometric theories of intelligence or the structure of cognitive abilities; (b) the structure of cognitive ability tests;

and (c) interpretive approaches to cognitive test performance. Figure 12.1 highlights the progress that has been made in each of these areas via three continua. It is important to recognize that the three continua presented in Figure 12.1 do not represent linear timelines; rather, they portray developments in the three broad categories of theories, tests, and interpretive approaches. Also noteworthy is the fact that the specific theories, tests, and interpretive approaches listed in Figure 12.1 are examples and, therefore, the figure does not contain a complete list in any of the three continua. This chapter discusses each continuum and concludes with a description of the current state-of-the-art of cognitive assessment.

### ***Progress in Psychometric Theories of Intelligence***

There is perhaps only one irrefutable law or truth in psychology—the law of individual differences (cf. McGrew & Flanagan, 1998). Accordingly, “individuals differ from one another in their ability to understand complex ideas, to adapt effectively to the environment, to learn from experience, to engage in various forms of reasoning, to overcome obstacles by taking thought” (Neisser et al., 1996, p. 77). The construct of *intelligence* has been offered to explain and clarify this particular constellation of abilities, and tests were developed to account for individual differences among them.

Attempts to define the construct of intelligence and to explain individual differences in intellectual functioning have been characterized by much variability over the period of several decades (e.g., Carroll, 1993b; Gustafsson & Undheim, 1996; Horn, 1991; McGrew, 1997, 2005; Schneider & McGrew, 2012; Taylor, 1994; Thorndike, 1997). The significant differences between theories of intelligence are exemplified by the various multiple intelligences models that have been offered and revised recently to explain the structure of intelligence; namely, the Cattell-Horn Fluid-Crystallized (*Gf-Gc*) theory (Horn & Blankson, 2005), Carroll’s three-stratum theory of cognitive abilities (Carroll, 1993b, 1997), Gardner’s Theory of Multiple Intelligences (Chen & Gardner, 2012), the Luria-Das model of information processing (Naglieri, Das, & Goldstein, 2012), Sternberg’s Triarchic Theory of Intelligence (Sternberg, 2012), and the Cattell-Horn-Carroll (CHC) theory of cognitive abilities (McGrew, 2005; Schneider & McGrew, 2012). Each of these theories provides a framework for understanding the

**Figure 12.1** Progress in psychometric theories of intelligence, the structure of cognitive ability tests, and interpretive approaches to cognitive test performance.

*Note:* This figure is an adaptation and extension of Woodcock's (1994) "Continuum of Progress in Theories of Multiple Intelligences" and Flanagan, McGrew, and Ortiz's (2000) "Progress in Psychometric Theories and Applied Measures of Intelligence." The second, third, and fourth waves of interpretation included in this figure were described by Kamphaus, Petoskey, and Morgan (1997). The first wave of interpretation (quantification of general level) is omitted from this figure due to space limitations.

multi-differentiated structure of cognitive abilities and the interrelationships among them. For a comprehensive description of these theories, the reader is referred to Flanagan and Harrison (2005, 2012). This chapter will focus specifically on the *psychometric* or structural approach to understanding individual differences.

The psychometric approach "attempts to measure performance along dimensions which are purported to constitute the fundamental structure of the psychological domain" (Taylor, 1994, p. 185). The psychometric approach relies on psychological tests that yield scores on qualitative scales that may be analyzed by correlative and factor-analytic methods to identify ability dimensions that form the structure of individual differences in cognitive ability (Gustafsson & Undheim, 1996; Keith, 2005; Keith & Reynolds, 2010, 2012; McGrew, 1997, 2005). As compared to other theoretical and research traditions (e.g., information processing, cognitive modifiability; see Taylor, 1994, for an overview), the psychometric approach is the oldest,

most research-based and best established (Daniel, 1997; Gustafsson & Undheim). Additionally, the psychometric approach led to the most economically efficient and practical tests for measuring intelligence in applied settings (Neisser et al., 1996). Space limitations preclude the presentation of a detailed summary of the history and evolution of the dominant psychometric theories of intelligence (see Wasserman, 2012, for more information). Instead, we provide here a general description of the progress in psychometric approaches, as depicted in the top portion of Figure 12.1.

## Spearman's *g*-Factor Theory

The genesis of the psychometric research tradition, by and large, is considered to have begun with Spearman's (1904, 1927) development of factor analytic techniques with which he offered a *general* or *g*-factor that became synonymous with the concept of general intelligence. Although Spearman's model refers rightly to a two-factor theory (i.e., *g*, the general factor to which all tests contribute,

and  $s$ , the specific information provided by each test), the general factor was always considered to be preeminent and  $s$  factors were always subordinate, so that the theory was seen largely as a single-factor model of intelligence. His application of factor analytic methods to general mental ability measures provided the basis for defining both the substance of general intelligence and the tests that were developed to measure it (Jensen, 1998). Spearman's  $g$  is thus a theory of general intelligence, a single factor that accounts for the performance of individuals on nearly all types of cognitive tasks.

Despite the view that Spearman's  $g$  represents a single-factor theory, Spearman himself did not entirely let go of the possible significance of the  $s$  factors, which he believed could represent independent and unique factors apart from the group factor known as  $g$ . In fact, together with Karl Holzinger, he developed a "bi-factor" model that may have been the beginning of a recognition of  $s$  factors as being more than merely subordinate to general ability but perhaps important in their own right. According to Carroll (1993b), if Spearman had lived beyond 1945, he most likely would have converged on a multiple-abilities model similar to the ones proposed by other researchers (e.g., Thurstone's [1938] "primary mental abilities"), although unlike Thurstone and others, he would have probably retained the notion of  $g$  as a measure of general intelligence.

## Two-Factor Theories and Models

The demise of Spearman's general factor and bi-factor models might have begun as early as 1909, primarily as a result of the evidence presented by Sir Cyril Burt in favor of *group factors*. According to Jensen (1998), by 1911, Burt's data had convinced most psychologists that it was more reasonable to accept the existence and importance of independent group factors,  $s$ , in addition to  $g$ . The evidence for factors beyond  $g$  resulted in a variety of attempts to develop theories and measures of independent vs. general group factor abilities. The recognition that a complete understanding of intelligence required the measurement and interpretation of abilities beyond  $g$  set the stage for the eventual development and interpretation of new intelligence tests. It is important to note, however, that Burt did not deny the existence of a general ability factor nor its cardinal position among factors, because it was necessary for support of the prevailing hereditarian views on intelligence. Burt suggested only that there did appear to be some significance to the lesser, but

independent factors, of which there appeared to be at least two promising candidates—verbal and quantitative abilities.

One of the early factor models of intelligence that did not involve a pyramidal hierarchy was developed by Raymond Cattell (1941, 1957) and included a framework that identified two independent but equally important abilities, which he named *fluid (Gf)* and *crystallized (Gc)*. Cattell, who earned his doctoral degree under Spearman, believed his data suggested that  $g$  was not a unitary or general trait at all, but rather a composite of two different types of specific factors or abilities representing novel problem-solving ( $Gf$ ) and consolidated knowledge ( $Gc$ ) (Jensen, 1998). His model became known simply as *Gf-Gc* theory, and it formed the foundation for advancements in intelligence theory that still underlie research in the present day, despite not providing support for a single, supreme general ability factor (i.e.,  $g$ ).

Another framework that relied on a similar two-factor view of intelligence was later offered by Russian neuropsychologist A. R. Luria (1966, 1970, 1973, 1980), who utilized the prevailing information processing theory in the development of a "simultaneous-successive" processing model. According to Luria, *simultaneous* processing is involved in the integration or synthesis of stimuli into groups when the individual components of the stimuli are interrelated, and is primarily associated with the right hemisphere (Kaufman, 1994; Naglieri, 1997). In contrast, *successive* processing is involved when the individual stimuli are processed in a serial order and there is no point in time at which the stimuli are interrelated. This type of processing is typically associated with left-hemisphere functioning. Luria's model became and remains heavily influential as the guiding paradigm in the neuropsychological assessment arena, and like Cattell's model, it does not rely on any notion of general intelligence or  $g$ .

## Early Multiple Intelligences Theories

Early investigations of the concept of intelligence were not limited to only two independent factors. As stated above, Thurstone, for example, proposed a factor analytic-based theory composed of seven *primary mental abilities* (PMAs; Thurstone, 1938; Thurstone & Thurstone, 1941). Thurstone's PMA theory suggested that, rather than being a function of  $g$ , performance on psychometric tests of cognitive ability was due to a number of primary mental abilities or faculties, such as spatial visualization (S),

perceptual speed (P), number (N, computational), verbal comprehension (V), word fluency (W), associative memory (M), and inductive reasoning (R) (Gould, 1996; Kamphaus, 1993). Because of its complexity and range at the time, Thurstone's PMA model was not directly operationalized by any particular battery of tests. Nevertheless, whether by intention or not, many modern-day tests are constructed in a manner that is similar to that which Thurstone proposed (Taylor, 1994). Other examples of factor-analytically based models are seen in the works of Burt (1949), although, unlike Thurstone, who saw abilities as independent in an egalitarian manner, Burt continued to insist that secondary abilities beyond  $g$  were subordinate to it. Other models were later proposed by French, Eckstrom, and Price (1963), and Vernon (1961), but did not receive much attention. Given the benefit of hindsight, the generation of "multiple" intelligences theories described thus far are seen as relatively "limited" (Flanagan et al., 2008; McGrew & Flanagan, 1998).

As depicted in Figure 12.1, even the simultaneous/sequential processing model ultimately evolved into four constructs and became known as the Planning, Attention, Simultaneous, and Successive model (PASS; Das & Naglieri, 1997; Naglieri, Das, & Goldstein, 2012). Planning is one of a number of activity-related executive functions used to identify and organize steps required to achieve a goal or carry out an intention. It is characterized by "forward thinking," the generation of alternatives, the weighing and making of choices, and the development of a framework or structure that provides direction in the completion of a plan (Lezak, 1995). Planning is associated with the prefrontal lobe region of the brain. Attention involves the processes that allow individuals to focus and respond to a particular stimulus while concurrently ignoring "competing" stimuli (Naglieri, 1997) and is associated with the brainstem region.

### Current Multiple Intelligences Theories

Psychometric intelligence theories converged in recent years on a more complete multiple intelligences taxonomy, reflecting syntheses of factor-analytic research conducted over the past 60 to 70 years. The most recent representation of this taxonomy is reflected by the Cattell-Horn-Carroll theory of the structure of cognitive abilities. CHC theory is an integration of Horn's *Gf-Gc* and Carroll's three-stratum theories of intelligence.

### Original *Gf-Gc* Theory and the Cattell-Horn Expanded *Gf-Gc* Theory: First Precursors to CHC Theory

The original concept of intelligence developed by Cattell in the early 1940s, *Gf-Gc* theory, was essentially a dichotomous view of human cognitive ability. Cattell based his theory on his own factor-analytic work as well as that of Thurstone, conducted in the 1930s. Cattell believed that fluid intelligence (*Gf*) included inductive and deductive reasoning abilities that were influenced by biological and neurological factors, as well as incidental learning through interaction with the environment. He postulated further that crystallized intelligence (*Gc*) consisted primarily of acquired knowledge abilities that reflected, to a large extent, the influences of acculturation (Cattell, 1957, 1971).

In 1965, Cattell's student John Horn reanalyzed Cattell's data and expanded the dichotomous *Gf-Gc* model to include four additional abilities; namely, visual perception or processing (*Gu*), short-term memory (short-term acquisition and retrieval—SAR or *Gsm*), long-term storage and retrieval (tertiary storage and retrieval—TSR or *Glr*), and speed of processing (*Gs*). Later Horn also added auditory processing ability (*Ga*) to the theoretical model and refined the definitions of *Gu*, *Gs*, and *Glr* (Horn, 1968; Horn & Stankov, 1982). By the early 1990s, Horn had added a factor representing an individual's quickness in reacting (reaction time) and making decisions (decision speed). The decision speed factor was labeled *Gt* (Horn, 1991). Finally, factors for quantitative ability (*Gq*) and broad reading/writing ability (*Grw*) were added to the model, based on the research of Horn (1991) and Woodcock (1994), respectively. As a result of the work of Horn and his colleagues, *Gf-Gc* theory expanded into an 10-factor model that became known as the Cattell-Horn *Gf-Gc* theory, or sometimes as *modern Gf-Gc theory* (Horn, 1991; Horn & Blankson, 2005; Horn & Noll, 1997).

### Carroll's Three-Stratum Theory: Second Precursor to CHC Theory

In his seminal review of the world's literature on human cognitive abilities, Carroll (1993b) proposed that the structure of cognitive abilities could be understood best via three strata that differ in breadth and generality. The broadest and most general level of ability is represented by stratum III. According to Carroll, stratum III represents a general factor consistent with Spearman's (1927) concept of *g* and subsumes both broad (stratum II) and

narrow (stratum I) abilities. The various broad (stratum II) abilities are denoted with an uppercase *g* followed by a lowercase letter(s), much as they had been written by Cattell and Horn (e.g., *Gf* and *Gc*). The eight broad abilities included in Carroll's theory subsume a large number of narrow (stratum I) abilities (Carroll, 1993b; see also Carroll, 1997).

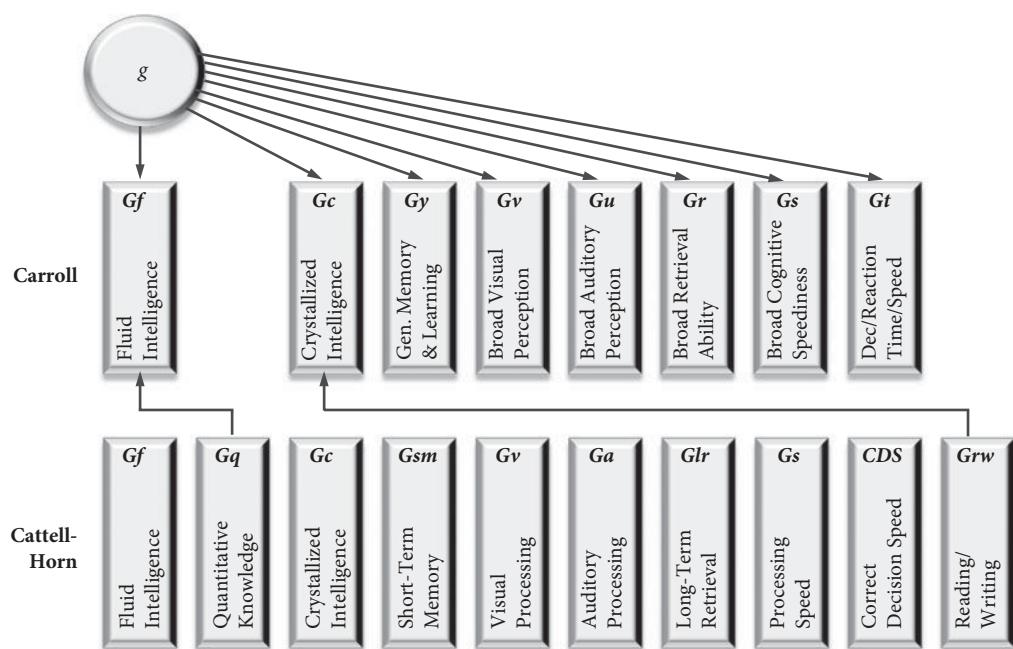

### The Cattell–Horn and Carroll Theories: Similarities and Differences

Figure 12.2 provides a comparison of the Cattell–Horn *Gf*–*Gc* theory and Carroll's three-stratum theory (with only broad abilities shown). These theories are presented together in order to highlight the most salient similarities and differences between them. It is readily evident that the theories have much in common, as each posits multiple broad (stratum II) abilities that, for the most part, have names and abbreviations that are either similar or identical. But there are at least four major structural differences between the two models that bear noting. First, Carroll's theory includes a general ability factor (stratum III) whereas the Cattell–Horn theory does not (see Schneider & McGrew, 2012, for a more detailed discussion regarding *g* in this context). Second, the Cattell–Horn theory includes quantitative reasoning as a distinct broad ability (i.e., *Gq*), whereas Carroll's theory includes

quantitative reasoning as a narrow ability subsumed by *Gf*. Third, the Cattell–Horn theory includes a distinct, broad reading/writing (*Grw*) factor. Carroll's theory includes reading and writing as narrow abilities subsumed by *Gc*. And fourth, Carroll's theory includes short-term memory with other memory abilities, such as associative memory, meaningful memory, and free-recall memory, under *Gy*, whereas the Cattell–Horn theory separates short-term memory (*Gsm*) from associative memory, meaningful memory, and free-recall memory, because the latter abilities are purported to measure long-term retrieval (*Glr* in Figure 12.2). Notwithstanding these differences, Carroll (1993b) concluded that the Cattell–Horn *Gf*–*Gc* theory represents the most comprehensive and reasonable approach to understanding the structure of cognitive abilities currently available.

### A Decade of CHC Theory (2001–2011)

In the late 1990s, McGrew (1997) attempted to resolve some of the differences between the Cattell–Horn and Carroll models. On the basis of his research, McGrew proposed an “integrated” *Gf*–*Gc* theory, and he and his colleagues used this model as a framework for interpreting the Wechsler scales (Flanagan et al., 2000). This integrated theory became known as the “CHC theory of cognitive

**Figure 12.2** Comparison of the Cattell–Horn and Carroll theoretical models.

*Note:* This figure was reproduced with permission from the authors, Flanagan, McGrew, and Ortiz (2000). All rights reserved.

abilities” shortly thereafter (see McGrew, 2005), and the Woodcock-Johnson III Tests of Cognitive Abilities (WJ III COG; Woodcock, McGrew, & Mather, 2001) was the first cognitive battery to be based on this theory. The components of CHC theory are depicted in Figure 12.3. This figure shows that CHC theory consists of 10 broad cognitive abilities and more than 70 narrow abilities.

The CHC theory presented in Figure 12.3 omits a *g* or general ability factor, primarily because the utility of the theory (as it is employed in assessment-related disciplines) is in clarifying individual cognitive and academic strengths and weaknesses, which are understood best through the operationalization of broad (stratum II) and narrow (stratum I) abilities (Flanagan, Ortiz, & Alfonso, 2007, 2013). Others, however, believe that *g* is the most important ability to assess because it predicts the lion’s share of the variance in multiple outcomes, both academic and occupational (e.g., Canivez & Watkins, 2010; Glutting, Watkins, & Youngstrom, 2003). Notwithstanding one’s position on the importance of *g* in understanding various outcomes (particularly academic), there is considerable evidence that both broad and narrow CHC cognitive abilities explain a significant portion of variance in specific academic abilities, over and above the variance accounted for by *g* (e.g., Floyd, McGrew, & Evans, 2008; McGrew et al., 1997; Vanderwood, McGrew, Flanagan, & Keith, 2002).

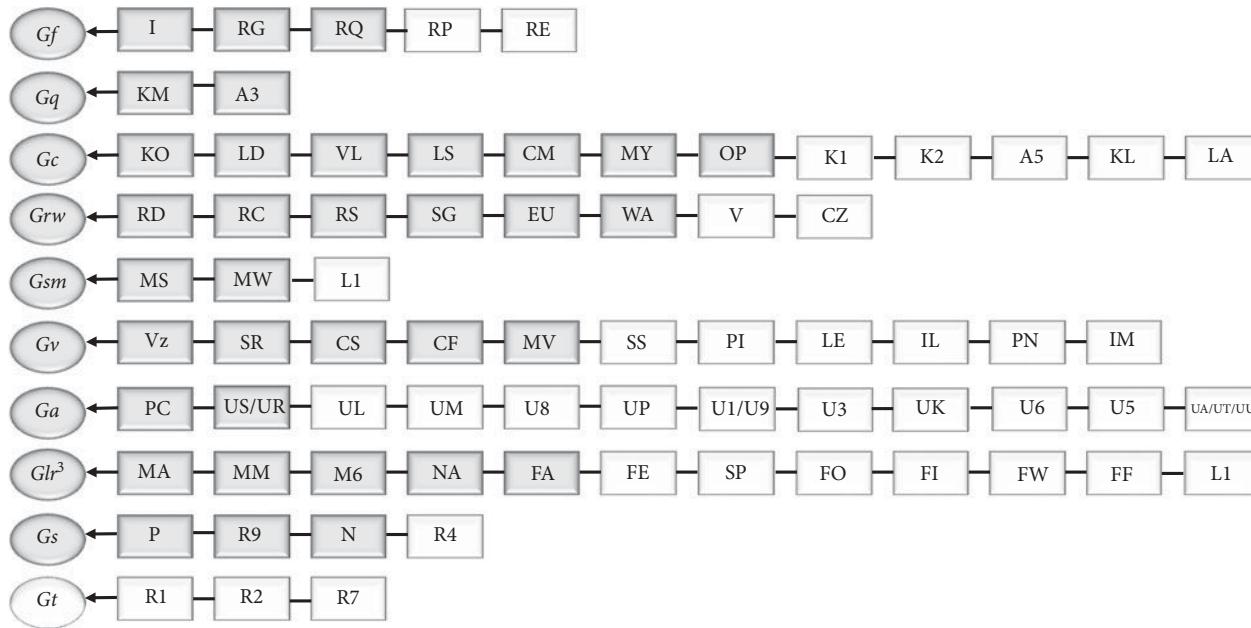

The various revisions of and refinements to the original theory of fluid and crystallized intelligence over the past several decades, along with its mounting network of validity evidence, only began to influence intelligence test development relatively recently—that is, in the middle to late 1980s (see Schneider & McGrew, 2012). In the past decade, however, nearly every intelligence test developer and author acknowledged the importance of CHC theory in defining and interpreting cognitive ability constructs, and most have used this theory to guide directly the development of their cognitive tests. The increased importance given to CHC theory in intelligence test development is summarized next.

### ***Progress in the Structure of Cognitive Ability Batteries***

The middle portion of Figure 12.1 highlights progress in the structure of intelligence and cognitive ability batteries. Although there was substantial evidence supporting at least eight or nine broad cognitive CHC abilities by the late 1980s,

intelligence tests of that era did not reflect this diversity in measurement. As such, there was a notable theory-practice gap in assessment practice (Flanagan & McGrew, 1997). For example, Table 12.1 shows that, from a CHC theoretical perspective, the popular ability tests such as the Wechsler Preschool and Primary Scale of Intelligence – Revised (WPPSI-R), Kaufman Assessment Battery for Children (KABC), Kaufman Adolescent and Adult Intelligence Test (KAIT), Wechsler Adult Intelligence Scale – Revised (WAIS-R), and Cognitive Assessment System (CAS) only measured two or three broad abilities adequately (Alfonso, Flanagan, & Radwan, 2005). The WPPSI-R primarily measured *Gv* and *Gc*. The K-ABC primarily measured *Gv* and *Gsm*, and to a much lesser extent, *Gf*; while the KAIT primarily measured *Gc* and *Glr*, and to a much lesser extent, *Gf* and *Gv*. The CAS measured *Gs*, *Gsm*, and *Gv*. Finally, while later tests, such as the Differential Ability Scales (DAS), Stanford-Binet Intelligence Scales – Fourth Edition (SB:FE), and Wechsler Intelligence Scale for Children –Third Edition (WISC-III) also failed to provide sufficient coverage of abilities to narrow the gap between contemporary theory and practice, their comprehensive measurement of approximately four CHC abilities was nonetheless an improvement over the aforementioned batteries. Table 12.1 shows that even as the new millennium dawned, only the Woodcock-Johnson Psycho-educational Battery – Revised (WJ-R) included tests that measured nearly all of the broad cognitive abilities depicted in Figure 12.3 (i.e., 9 out of 10) as compared to the other batteries available at that time, which measured far fewer broad abilities adequately (i.e., between 2 and 4; Alfonso et al., 2005; McGrew & Flanagan, 1998).

In general, Table 12.1 highlights the fact that many CHC abilities, namely *Gf*, *Gsm*, *Glr*, *Ga*, and *Gs*, were not measured well by the majority of intelligence and cognitive ability tests published prior to 2000. Therefore, it is clear that test authors did not make routine use of contemporary psychometric theories of the structure of cognitive abilities to guide the development of their tests. As such, the theory-practice gap continued; that is, theories of the structure of cognitive abilities were far in advance of the instruments used to operationalize them. In fact, prior to the mid 1980s, theory seldom played a fundamental role in intelligence test development. The numerous dashes in Table 12.1 exemplify the “theory-practice gap” that existed in the field of psychological assessment at that time (i.e., prior to

**Figure 12.3** The Cattell-Horn-Carroll (CHC) model of cognitive abilities that guided intelligence test construction in the first decade of the millennium.

Note: Broad abilities appear as ovals and narrow abilities appear as rectangles in this figure. The shaded broad and narrow abilities are those that are measured most consistently on current and widely used cognitive and achievement tests.  $G_f$  = Fluid Intelligence;  $G_q$  = Quantitative Knowledge;  $G_c$  = Crystallized Intelligence;  $G_{rw}$  = Reading/Writing Ability;  $G_{sm}$  = Short-Term Memory;  $G_v$  = Visual Processing;  $G_a$  = Auditory Processing;  $G_{lr^3}$  = Long-Term Storage and Retrieval;  $G_s$  = Processing Speed;  $G_t$  = Decision Speed/Reaction Time. 2000; Alfonso et al., 2005; Flanagan & McGrew, 1997).

Despite the persistent gap between theory and practice, much has changed in the past decade to narrow the gap. Particularly, CHC theory had a significant impact on the revision of nearly all cognitive tests that were revised in the 2000's. There are likely various reasons for this "collective psychometric epiphany" (Flanagan et al., 2008) in the field of psychological assessment, such as the wealth of research supporting CHC theory and the well-established relationships among its component parts and various outcomes (e.g., academic). In addition, advances in training standards, better operationalization and definitions of learning disabilities, and the rise in popularity of systematic, theoretically, and psychometrically defensible interpretive approaches (e.g., the cross-battery approach [XBA]; Flanagan et al., 2001, 2007, 2013; McGrew & Flanagan, 1998; this method of assessment is discussed in the last section of this chapter) facilitated the field's convergence on CHC theory to guide practice. As a result, a wider range of broad and narrow abilities is now represented on current intelligence batteries than that which was represented on any and all previous editions of these tests. Table 12.2 provides several salient examples of the impact that CHC theory and the XBA CHC classifications have had on intelligence test development in recent years. In addition, Table 12.2 lists the major intelligence tests in the order in which they were revised, beginning with those tests with the greatest number of years between revisions (i.e., K-ABC) and ending with newly revised tests (i.e., WPPSI-IV). As is obvious from a review of Table 12.2, CHC theory and the CHC XBA classifications have had a significant impact on recent test development (Alfonso et al., 2005).

Of the seven intelligence batteries that were published since 2000, the test authors of four explicitly used CHC theory and the CHC XBA classifications as the foundation upon which to guide test construction and development (i.e., WJ III, SB5, KABC-II, and DAS-II). Only in the case of the Wechsler Scales (i.e., WPPSI-III, WPPSI-IV, WISC-IV, WAIS-IV) is there no direct reference as to whether CHC theory was used as a guide for revision. Nevertheless, the authors of the Wechsler Scales do acknowledge the research of Cattell, Horn, and Carroll in their most recent manuals (Wechsler, 2002, 2003, 2008, 2012) and it would appear that CHC theory played an important role in shaping the final versions of each test whether so stated or not. The information

contained in Table 12.2 demonstrates that all intelligence and cognitive tests in current use with some regularity subscribe either explicitly or implicitly to CHC theory (Alfonso et al., 2005; Flanagan et al., 2007, 2012).

Additional information and data regarding the convergence of recent intelligence and cognitive ability tests toward the incorporation of CHC theory is presented in Table 12.3. This table is similar to Table 12.1, except that it includes all the major intelligence and cognitive ability tests published after 2000, including the revisions of many of the tests from Table 12.1. This table also includes the *narrow* CHC abilities that are measured by the subtests within each of the batteries. A comparison of Tables 12.1 and 12.3 shows that many of the gaps in measurement of *broad* cognitive abilities have now been filled. Specifically, the majority of tests published after 2000 now measure four to five broad cognitive abilities and do so adequately (see Table 12.3), as compared to measuring only two to four (see Table 12.1) and not always in adequate fashion. Specifically, Table 12.3 shows that the WISC-IV, WAIS-IV, WPPSI-III, KABC-II, and SB5 measure four to five broad CHC abilities. The WISC-IV and WAIS-IV measure *Gf*, *Gc*, *Gv*, *Gsm*, and *Gs*, while the KABC-II measures *Gf*, *Gc*, and *Gv* adequately, and to a lesser extent *Gsm* and *Glr*. The WPPSI-III measures *Gc*, *Gv*, and *Gs* adequately, and to a lesser extent *Gf*. The DAS-II measures *Gf*, *Gc*, *Gv*, *Gsm*, and *Glr* adequately, and to a lesser extent *Gs* and *Ga*. Finally, the SB5 measures four CHC broad abilities adequately (i.e., *Gf*, *Gc*, *Gv*, *Gsm*; Alfonso et al., 2005). Table 12.3 also shows that the WJ III measures seven broad cognitive abilities adequately.

In addition, comparison of Tables 12.1 and 12.3 indicates that two broad abilities not measured by many intelligence and cognitive ability tests prior to 2000 are now measured by the majority of these tests available today; that is, *Gf* and *Gsm*. It seems likely that these broad abilities may be better represented on current intelligence and cognitive ability batteries because of the accumulating research evidence regarding their importance in overall academic success (see Flanagan, Alfonso, & Mascolo, 2011; Flanagan, Ortiz, Alfonso, & Mascolo, 2006; McGrew & Wendling, 2010). Finally, despite the significant improvements in the number of abilities measured and the increased adequacy of construct representation, Table 12.3 reveals that intelligence and cognitive ability batteries continue to fall short in their measurement of three CHC broad abilities;

**Table 12.2 Impact of CHC Theory and XBA CHC Classifications on Intelligence Test Development**

Test (Year of Publication) CHC and XBA Impact	Revision (Year of Publication) CHC and XBA Impact
<b>K-ABC (1983)</b> No obvious impact.	<b>KABC-II (2004)</b> Provided a second global score that includes fluid and crystallized abilities; Included several new subtests measuring reasoning; Interpretation of test performance may be based on CHC theory or Luria's theory; Provided assessment of five CHC broad abilities.
<b>SB:FE (1986)</b> Used a three-level hierarchical model of the structure of cognitive abilities to guide construction of the test: the top level included general reasoning factor or "g"; the middle level included three broad factors called crystallized abilities, fluid-analytic abilities, and short-term memory; the third level included more specific factors including verbal reasoning, quantitative reasoning, and abstract/visual reasoning.	<b>SB5 (2003)</b> Used CHC theory to guide test development; Increased the number of broad factors from 4 to 5; Included a Working Memory Factor based on research indicating its importance for academic success.
<b>WPPSI-R (1989)</b> No obvious impact.	<b>WPPSI-III (2002)</b> Incorporated measures of Processing Speed that yielded a Processing Speed Quotient based on recent research indicating the importance of processing speed for early academic success; Enhanced the measurement of fluid reasoning by adding the Matrix Reasoning and Picture Concepts subtests.
<b>WJ-R (1989)</b> Used modern <i>Gf-Gc</i> theory as the cognitive model for test development; Included two measures of each of eight broad abilities.	<b>WJ III (2001; Normative Update, 2007)</b> Used CHC theory as a "blueprint" for test development; Included two or three qualitatively different narrow abilities for each broad ability; The combined cognitive and achievement batteries of the WJ III include 9 of the 10 broad abilities subsumed in CHC theory.
<b>WISC-III (1991)</b> No obvious impact.	<b>WISC-IV (2003)</b> Eliminated Verbal and Performance IQs; Replaced the Freedom from Distractibility Index with the Working Memory Index; Replaced the Perceptual Organization Index with the Perceptual Reasoning Index; Enhanced the measurement of fluid reasoning by adding Matrix Reasoning and Picture Concepts; Enhanced measurement of Processing Speed with the Cancellation subtest.
<b>DAS (1990)</b> No obvious impact.	<b>DAS-II (2007)</b> CHC broad abilities are represented in the DAS-II subtests and composites
<b>WAIS-III (1997)</b> No obvious impact.	<b>WAIS-IV (2008)</b> Eliminated Verbal and Performance IQs; Replaced the Perceptual Organization Index with the Perceptual Reasoning Index; Enhanced the measurement of fluid reasoning by adding the Figure Weights and Visual Puzzles subtests; Enhanced measurement of Processing Speed with the Cancellation subtest. Enhanced measurement of memory with the Working Memory Index.
<b>WPPSI-III (2002)</b> Incorporated measures of Processing Speed that yielded a Processing Speed Quotient based on recent research indicating the importance of processing speed for early academic success; Enhanced the measurement of fluid reasoning by adding the Matrix Reasoning and Picture Concepts subtests.	<b>WPPSI-IV (2012)</b> Eliminated Verbal and Performance IQs; Enhanced measures of visual memory, processing speed and inhibitory control.

*Note:* CHC classifications are based on the literature and primary sources such as Carroll (1993); Flanagan & Ortiz (2001); Flanagan, Ortiz, & Alfonso (2007, 2012); Flanagan, Ortiz, Alfonso, & Mascolo (2006); Horn (1991); Keith, Fine, Taub, Reynolds, & Kranzler (2006); McGrew (1997); and McGrew & Flanagan (1998). WISC-IV = Wechsler Intelligence Scale for Children–Fourth Edition (Wechsler, 2003); WAIS-IV = Wechsler Adult Intelligence Scale–Fourth Edition (Wechsler, 2008); WPSSI-III = Wechsler Preschool and Primary Scale of Intelligence–Third Edition (Wechsler, 2002); KABC-II = Kaufman Assessment Battery for Children–Second Edition (Kaufman & Kaufman, 2004); WJ III = Woodcock-Johnson III Normative Update Tests of Cognitive Abilities (Woodcock, McGrew, & Mather, 2001, 2007); SB5 = Stanford-Binet Intelligence Scales–Fifth Edition (Roid, 2003); DAS-II = Differential Ability Scales–Second Edition (Elliot, 2007). *Gf* = Fluid Intelligence; *Gc* = Crystallized Intelligence; *Gv* = Visual Processing; *Gsm* = Short-Term Memory; *Glr* = Long-Term Storage and Retrieval; *Ga* = Auditory Processing; *Gs* = Processing Speed; *Gq* = Quantitative Knowledge; RQ = Quantitative Reasoning; I = Induction; RG = General Sequential Reasoning; VL = Lexical Knowledge; K0 = General (verbal) Knowledge; LS = Listening Ability; MV = Visual Memory; Vz = Visualization; SS = Spatial Scanning; CF = Flexibility of Closure; CS = Closure Speed; MW = Working Memory; MS = Memory Span; MA = Associative Memory; FI = Ideational Fluency; NA = Naming Facility; M6 = Free Recall Memory; PC = Phonetic Coding; UR = Resistance to Auditory Stimulus Distortion; P = Perceptual Speed; R9 = Rate-of-Test-Taking; KM = Math Knowledge; A3 = Math Achievement.

<sup>1</sup>Pattern Reasoning appears to be a measure of *Gv*-Vz only at ages 5–6 years.

<sup>2</sup>*Gc*-K0 appears to be the primary ability measured by Story Completion at ages 5–6 years. At older ages (i.e., ages 7+), the primary ability measured by Story Completion appears to be *Gf*-RG.

<sup>3</sup>Elliot (2007) places Rapid Naming under the construct *Gs* based on the results of factor analysis. The current authors place this test under the construct *Glr* based on theory.

specifically,  $G_{lr}$ ,  $G_a$ , and  $G_s$ . Moreover, current intelligence and cognitive ability tests do not provide adequate measurement of most specific or narrow CHC abilities—many of which are important in predicting academic achievement (Flanagan et al., 2007, 2012; McGrew & Wendling). Thus, although there is greater coverage and better adequacy in measurement of CHC broad abilities now than there was just a few years ago, practitioners interested in measuring the full range of cognitive abilities will probably need to supplement testing in some manner (e.g., use of the XBA approach), since a significant number of narrow abilities remains inadequately measured by current intelligence tests (Alfonso et al., 2005; Flanagan et al., 2012, 2013).

### **Progress in Approaches to Interpreting Cognitive Test Performance**

Kamphaus and colleagues (1997, 2005, 2012) provided a detailed historical account of the major approaches that have been used to interpret an individual's performance on intelligence and cognitive ability tests since their inception. These authors describe the history of intelligence test interpretation in terms of four “waves”: (1) quantification of general level; (2) clinical profile analysis; (3) psychometric profile analysis; and (4) application of theory to intelligence test interpretation. Kamphaus and colleagues' organizational framework is used here to illustrate the evolution of test interpretation (see bottom portion of Figure 12.1), which was based largely on the Wechsler scales and efforts to derive meaning without the aid of theory. In addition, we offer a discussion on what we believe to be the current, fifth wave of interpretation—application of refinements to theory and CHC-based research to psychological test interpretation.

### **The First Wave: Quantification of General Level**

Intelligence tests, particularly the “gold standard” Stanford-Binet, as proclaimed by Lewis Terman, garnered widespread use in psychology and a variety of other applied fields, largely because they appeared to offer an objective method of differentiating and rank ordering individuals on the basis of their general intelligence. According to Kamphaus and colleagues (2012), this was the first wave of intelligence test interpretation and was driven by practical considerations regarding the need to classify individuals into distinct groups that shared the same level of this attribute (e.g., mentally retarded, now called intellectual disability).

During the first wave, the omnibus IQ (so named after the original mental age score was replaced by a ratio quotient) was the focus of intelligence test interpretation. The prevalent influence of Spearman's  $g$  theory of intelligence and the age-based Stanford-Binet scale, coupled with the fact that budding factor-analytic and other psychometric methods were not yet widely available for investigating multiple cognitive abilities, contributed to the almost exclusive use of global IQ for classification purposes. Hence, a number of classification systems were proposed for organizing individuals according to their global IQs.

Early classification systems included labels that had already entered into the medical and legal lexicon, including “idiot,” “imbecile,” and “moron” (Levine & Marks, 1928). Although the Wechsler scales did not contribute to the early classification efforts during most of the first wave of test interpretation, David Wechsler eventually made his contribution by proposing a classification system that relied less on evaluative labels (although it still contained the terms “defective” and “borderline,” presumably “borderline moron”) and more on meaningful deviations from the mean as specified by the deviation IQ, which he believed more accurately reflected the “prevalence of certain intelligence levels in the country at that time” (Kamphaus et al., 1997, p. 35). With some refinements over the years, interpretation of intelligence tests continue to be based largely on the deviation IQ metric and similar descriptive classification systems that rely on characterizations of performance relative to others in general. That is, distinctions are still made between individuals who are intellectually disabled versus average, or those who are intellectually gifted versus average, for example. But the difference in intelligence between individuals in one of these groups versus those in another is more precisely described by a score (IQ) that is based on the individual's relative standing in the general population as determined by the normal probability distribution. As such, current classification categories are quite different from earlier ones, as may be seen in Table 12.4.

His pioneering of the deviation IQ aside, it appears that Wechsler accepted the prevailing ideas regarding  $g$  and the conceptualization of intelligence as a global entity, consistent with those already put forth by Terman, Binet, Spearman, and others (Reynolds & Kaufman, 1990). This is evident in the definition of intelligence he offered as underlying his own scales. According to Wechsler (1939), *intelligence* is “the aggregate or global capacity of the

**Table 12.4 Comparison of Selected Historical and Current Test Score Classification Systems**

Levine & Marks (1928) Classifications			Wechsler Scales (1944) IQ Classifications			Flanagan, Ortiz, & Alfonso (2007) XBA Classifications		
Normative Classification	Standard Score Range	Percentile Range	Normative Classification	Standard Score Range	Percentile Range	Normative Classification	Standard Score Range	Percentile Range
Idiot	0–24	<.02						
Imbecile	25–49	.02nd to .04th						
Moron	50–74	.05th to 4th	Defective	≤ 65	≤ 1st	Lower Extreme	< 70	<2nd
Borderline	75–84	5th to 14th	Borderline	66–79	1st to 8th	Below Average – Normative Weakness	70–84	2nd to 14th
Dull	85–94	16th to 35th	Dull Normal	80–90	9th to 25th	Low Average	85–89	16th to 23rd
Average	95–104	38th to 62nd	Average	91–110	27th to 75th	Average	90–110	25th to 75th
Bright	105–114	65th to 83rd	Bright Normal	111–119	77th to 89th	High Average	111–115	77th to 84th
Very Bright	115–124	84th to 95th	Superior	120–127	91st to 97th	Above Average – Normative Strength	116–129	86th to 97th
Superior	125–149	95th to 99.94th	Very Superior	≥ 128	≥ 97th	Upper Extreme	>130	≥98th
Very Superior	150–174	99.95th to 99.99th						
Precocious	>175	>99.99						

individual to act purposefully, to think rationally and to deal effectively with his environment" (p. 3). He concluded that this definition "avoids singling out any ability, however esteemed (e.g., abstract reasoning), as crucial or overwhelmingly important" (p. 3) and implied that any one intelligence subtest is readily interchangeable with another. In this way, Wechsler was also minimizing the importance of the manner in which he had constructed his tests; that is, subtests that were categorized as either "verbal" or "performance." Given his experiences during World War I with the Army Mental Tests (Alpha and Beta) as well as his interactions with Yerkes, Terman, Brigham, and others, Wechsler recognized the importance of attempts to measure intelligence in various modalities, but it seems clear that, at least initially, he did not see the Verbal IQ (VIQ) or Performance IQ (PIQ) as constructs unto themselves or as scores that merited individual interpretation. Nevertheless, the clinical need for assigning meaning to test results eventually led to subsequent interpretive methods that included use of both the VIQ and PIQ, particularly the difference between them.

### **The Second Wave: Clinical Profile Analysis**

Kamphaus and colleagues (1997, 2005, 2012) identified the second wave of interpretation as *clinical profile analysis* and stated that the publication of the Wechsler-Bellevue (W-B; Wechsler, 1939) was pivotal in spawning this approach to interpretation. Clinical profile analysis was a method designed to go beyond global IQ and interpret more specific aspects of an individual's cognitive capabilities through the analysis of patterns of subtest scaled scores.

The Wechsler-Bellevue Intelligence Scale, Form I (W-B I), published in 1939 (an alternate form, the W-B II, was published in 1946), represented an approach to intellectual assessment in adults that was clearly differentiated from other instruments available at that time (e.g., the Binet scales). The W-B was composed of 11 separate subtests, namely Information, Comprehension, Arithmetic, Digit Span, Similarities, Vocabulary, Picture Completion, Picture Arrangement, Block Design, Digit Symbol, and Coding. (The Vocabulary subtest was an alternate for W-B I.)

As stated previously, perhaps the most notable feature introduced with the W-B, which advanced interpretation beyond classification of global IQ, was the grouping of subtests into Verbal and Performance composites. The Verbal-Performance dichotomy represented an organizational structure

that was based on the notion that intelligence could be expressed and measured through both verbal and nonverbal communication modalities. To clarify the Verbal-Performance distinction, Wechsler asserted that this dichotomy "does not imply that these are the only abilities involved in the tests. Nor does it presume that there are different kinds of intelligence (e.g., verbal, manipulative). It merely implies that these are different ways in which intelligence may manifest itself," again, a lesson probably learned from his experiences with the Army Alpha and Army Beta tests (Wechsler, 1958, p. 64, cf. Flanagan & Kaufman, 2009).

Another important feature pioneered in the W-B revolved around the construction and organization of subtests. At that time, the Stanford-Binet scale was ordered and administered sequentially according to developmental age, irrespective of the task. In contrast, Wechsler utilized only 11 subtests, each scored by points rather than age, and each with sufficient range of item difficulties to encompass the entire age range of the scale.

In his later writings, Wechsler often shifted between conceptualizing intelligence as either a singular entity (the first wave) or possibly as a collection of specific mental abilities (the second wave). At times he appeared to encourage the practice of subtest-level interpretation, suggesting that each subtest measured a relatively distinct cognitive ability (McDermott et al., 1990). To many, this position appeared to contradict his prior attempts not to equate general intelligence with the sum of separate cognitive or intellectual abilities. This shift in viewpoint may have been responsible, in part, for the development of interpretive methods that characterize the second and third waves, notably profile analysis (Flanagan, 2000).

Without a doubt, the innovations found in the W-B were impressive, practical, and in many ways, superior, to other intelligence tests available in 1939. More importantly, the structure and organization of the W-B scale provided the impetus for Rapaport, Gill, and Schafer's (1945-1946) approaches to test interpretation, which included an attempt to understand the meaning behind the shape of a person's profile of scores. This notion may have been prompted in part by the manner in which the 11 tests on the W-B were organized on the scoring protocol (6 verbal vs. 5 performance). By grouping the verbal and performance tests relatively independently, it tended to suggest that the VIQ and PIQ were distinct constructs in their own right. Likewise, the scoring protocol provided a

graph wherein the arrangement explicitly encouraged practitioners to connect the obtained subtest scaled scores via lines that effectively produced a visual “profile.” Whatever its original intent, the ubiquitous visual profile available on every scored W-B protocol easily supported and facilitated the search for enduring and similar “patterns” of test score performance that would be associated with specific pathologies or diagnoses. According to Kamphaus and colleagues (1997, 2005, 2012), a new method of test interpretation had been developed under the assumption that “patterns of high and low subtest scores could presumably reveal diagnostic and psychotherapeutic considerations” (Kamphaus et al., 1997, p. 36). Thus, during the second wave of intelligence test interpretation, the W-B (1939) was the focal point from which a variety of clinical interpretations were developed for deriving diagnostic and prescriptive meaning from the shape of subtest profiles and the difference between Verbal and Performance IQs.

In addition to the scope of Rapaport and colleagues’ (1945–1946) diagnostic suggestions, their approach to understanding profile shape led to a flurry of investigations that sought to identify the psychological functions underlying an essentially infinite number of profile patterns and their relationships to each other. Perhaps as a consequence of the clinical appeal of Rapaport and colleagues’ approach, the availability of the W-B (and its later incarnation, WAIS, and siblings WISC and WPPSI) helped relegate general-level assessment to the back burner while increasing the heat on clinical profile analysis (Flanagan & Kaufman, 2009).

Although the search for diagnostic meaning in subtest profiles and IQ differences was a more sophisticated approach to intelligence test interpretation as compared to the interpretive method of the first wave, it also created methodological problems. For example, with enough practice, just about any astute clinician could provide a seemingly rational interpretation of an obtained profile to fit the known functional and dysfunctional patterns of the examinee. Not surprisingly, analysis of profile shape and IQ differences never actually resulted in any increased diagnostic validity for the WISC (e.g., Glutting, McDermott, & Konold, 1997; Watkins, Glutting & Youngstrom, 2005). Despite its failings, the next wave in intelligence test interpretation sought to address the methodological flaws in the clinical-profile analysis method in hopes of still advancing it as a viable and valid interpretive method (Kamphaus et al., 2012).

### The Third Wave: Psychometric Profile Analysis

In 1955, the original W-B was revised and updated, and its new name, Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955), was aligned with the existing child version (i.e., WISC) which had been created by Wechsler in 1949. Major changes and revisions included (1) incorporating Forms I and II of the W-B into a single scale with a broader range of item difficulties; (2) realigning the target age range to include ages 16 years and older (which eliminated overlap with the WISC, creating a larger and more representative norm sample); and (3) refining the subtests to improve reliability (Flanagan & Kaufman, 2004, 2009).

Within this general time period, eventual technological developments in the form of computers and statistical software to assist with intelligence test interpretation provided the impetus for what Kamphaus and colleagues (1997, 2005, 2012) called the “third wave” of interpretation—*psychometric profile analysis*. The work of Cohen (1959), which was based primarily on the WISC and the WAIS, sharply criticized the clinical-profile analysis tradition that had defined the second wave. For example, Cohen’s factor-analytic procedures revealed a viable three-factor solution for the WAIS that challenged the prevailing dichotomous verbal-performance model and remained the *de facto* standard for the Wechsler scales for decades. The labels used by Cohen for the three Wechsler factors that emerged in his factor analysis of the WISC subtests (i.e., Verbal Comprehension, Perceptual Organization, and Freedom from Distractibility) were the names of the Indexes on two subsequent editions of this test (WISC-R and WISC-III), spanning more than two decades (Flanagan & Kaufman, 2009).

By examining and removing the variance shared between subtests, Cohen demonstrated that the majority of Wechsler subtests had very poor *specificity* (i.e., reliable, specific variance). Thus, the frequent clinical practice of interpreting individual subtests as reliable measures of a *presumed* construct was not supported. Kamphaus and colleagues (1997, 2005, 2012) summarize Cohen’s significant contributions, which largely defined the third wave of test interpretation, as threefold: (1) empirical support for the FSIQ based on analysis of shared variance between subtests; (2) development of the three-factor solution for interpretation of the Wechsler scales; and (3) revelation of limited subtest specificity, questioning individual subtest interpretation.

The most vigorous and elegant application of psychometric profile analysis to intelligence test interpretation occurred with the revision of the venerable WISC as the Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler, 1974). Briefly, the WISC-R utilized a larger, more representative norm sample than its predecessor; included more contemporary-looking graphics and updated items; eliminated some content that was differentially familiar to specific groups; and included improved scoring and administration procedures. "Armed with the WISC-R, Kaufman (1979) articulated the essence of the psychometric profile approach to intelligence test interpretation in his seminal book, *Intelligent Testing with the WISC-R* (which was superseded by *Intelligent Testing with the WISC-III*; Kaufman, 1994)" (Flanagan et al., 2000, p. 6). Kaufman had been Wechsler's primary collaborator on the revision of the WISC and as such had a great deal of insight into the test as well as into potential methods for appropriate interpretation.

Kaufman emphasized flexibility in interpretation and provided a logical and systematic approach that utilized principles from measurement theory. He applied these principles to clinical profile analysis and thereby provided the very name for this third wave of interpretation—psychometric profile analysis. His approach was more complex than previous ones and required the examiner to have a greater level of psychometric expertise than might ordinarily be possessed by the average psychologist (Flanagan et al., 2000). Anastasi (1988) lauded this and recognized that "the basic approach described by Kaufman undoubtedly represents a major contribution to the clinical use of intelligence tests. Nevertheless, it should be recognized that its implementation requires a sophisticated clinician who is well informed in several fields of psychology" (p. 484).

In some respects, publication of Kaufman's work can be viewed as an indictment against the poorly reasoned and unsubstantiated interpretation of the Wechsler scales that had sprung up in the second wave (clinical profile analysis; Flanagan et al., 2000). Kaufman's ultimate message centered on the notion that interpretation of Wechsler intelligence test performance must be conducted with a higher than usual degree of psychometric precision and based on credible and dependable evidence, rather than merely the clinical lore that surrounded earlier interpretive methods (Anastasi, 1988; Flanagan & Kaufman, 2009; Flanagan et al., 2000).

Despite the enormous body of clinical, case study, and anecdotal literature that has mounted

steadily over the years arguing in support of the use of profile analysis with the Wechsler scales, this form of interpretation, even when upgraded with the rigor of psychometrics, has been regarded as a perilous endeavor primarily because it lacks empirical support and is not grounded in a well-validated theory of intelligence. With over 75 different profile types discussed in a variety of areas, including neuropsychology, personality, learning disabilities, and juvenile delinquency (McDermott et al., 1990), there is considerable temptation to believe that the findings of this type of analysis alone are reliable. Nevertheless, many studies (e.g., Hale, 1979; Hale & Landino, 1981; Hale & Saxe, 1983) demonstrated consistently that "profile and scatter analysis is not defensible" (Kavale & Forness, 1984, p. 136; also see Glutting, McDermott, Watkins, Kush, & Konold, 1997).

In a meta-analysis of 119 studies of the WISC-R subtest data, Mueller, Dennis, and Short (1986) concluded that using profile analysis with the WISC-R in an attempt to differentiate various diagnostic groups is clearly not warranted. Subsequent evaluations regarding the merits of psychometric profile analysis produced similar results (e.g., Glutting, McDermott, Watkins, et al., 1997; Kamphaus, 1993; McDermott, Fantuzzo, Glutting, Watkins, & Baggaley, 1992; Watkins et al., 2005; Watkins & Kush, 1994).

### **The Fourth Wave: Application of Theory to Interpretation**

Although the third wave of intelligence test interpretation did not meet with any real degree of success in terms of establishing validity evidence for profile analysis, the psychometric approach provided the foundation necessary to catapult the field into the fourth wave of intelligence test interpretation. This wave is described generally by Kamphaus and colleagues (1997, 2005, 2012) as "application of theory." Although the need to integrate theory and research into the intelligence test interpretation process appeared obvious to those involved in theory development, it was not until Kaufman's book *Intelligent Testing with the WISC-R* was published in 1979 that practitioners began to understand the need for this connection. Specifically, Kaufman observed that problems with intelligence test interpretation went beyond psychometric deficiencies and could be attributed largely to the lack of a specific theoretical base to guide interpretive practices. He suggested that it was possible to enhance interpretation significantly by reorganizing subtests into

clusters specified by a particular theory. In fact, Kaufman's test, the K-ABC (Kaufman & Kaufman, 1983), was the first cognitive battery to be based on theory (i.e., Luria's Simultaneous-Successive theory of information processing; Luria, 1973). The WJ-R (Woodcock & Johnson, 1989) is also a good example of a test that was explicitly designed to yield clusters that represented theoretical constructs—in this case, constructs specified by the Cattell-Horn *Gf-Gc* theory. In essence, the end of the third wave of intelligence test interpretation and the beginning of the fourth wave was marked by Kaufman's pleas for practitioners to ground their interpretations in theory, as well as by his efforts to demonstrate the importance of linking intellectual measurement tools to empirically supported and well-established conceptualizations of human cognitive abilities (Flanagan & Kaufman, 2004, 2009; Flanagan et al., 2000; Woodcock, Werder & McGrew, 1991).

In response to Kaufman's calls to narrow the theory-practice gap in intelligence test development and interpretation by applying theory, Flanagan and colleagues (Flanagan & Ortiz, 2001; Flanagan et al., 2000; McGrew & Flanagan, 1998) developed a method for measurement and interpretation called the "cross-battery approach" (XBA) and applied it to the Wechsler scales and other major intelligence and cognitive ability tests available at that time (i.e., the late 1990s). This method was intentionally grounded in *Gf-Gc* (and later CHC) theory and provided a series of systematic steps and rigorous guidelines that were designed to ensure that science and practice are closely linked in the measurement and interpretation of cognitive abilities. According to McGrew (2005), the cross-battery approach "infused CHC theory into the minds of assessment practitioners and university training programs, regardless of their choice of favorite intelligence battery...." (p. 149). Kaufman's (2000) description of the cross-battery approach as an interpretive method that (1) has "research as its foundation," (2) "adds theory to psychometrics," and (3) "improves the quality of the psychometric assessment of intelligence" (p. xiii) is consistent with Kamphaus and colleagues' fourth wave of intelligence test interpretation.

In comparison to prior waves, where the strong need and desire for assigning meaning to scores meant relatively quick and easy acceptance of "new" interpretive schemes, theory-driven interpretive approaches (e.g., XBA) did not fare especially well early on. Despite their availability and applicability for interpreting the most popular intelligence and cognitive ability tests available (including the

WISC-III), the inertia of tradition remained strong, and practitioners largely continued using interpretive methods based on the second and third waves (Flanagan & Kaufman, 2004). This is not to say that there was no recognition of problems with or concern about the theoretical structure, or lack thereof, of many tests. For example, evaluations of the WISC-III upon its publication were anything but positive, and the conclusions offered by a wide range of reviewers were remarkably similar—the newly published WISC-III was *outdated*. According to Kamphaus (1993), "The WISC-III's history is also its greatest liability. Much has been learned about children's cognitive development since the conceptualization of the Wechsler scales, and yet few of these findings have been incorporated into revisions" (p. 99). Similarly, Shaw, Swerdlik, and Laurent (1993) concluded, "Despite more than 50 years of advancement of theories of intelligence, the Wechsler philosophy of intelligence...written in 1939, remains the guiding principle of the WISC-III....[T]he latest incarnation of David Wechsler's test may be nothing more than a new and improved dinosaur" (p. 163).

Eventually the message seemed to get through—practitioners slowly began to recognize the theoretical and psychometric limitations of measurement tools and interpretive approaches, which probably made them more receptive to alternatives (e.g., XBA; Flanagan & Ortiz, 2001; Flanagan et al., 2007). Whatever the reasons, and there were no doubt many, the advent of the twenty-first century was accompanied by a dramatic rise in the popularity of CHC theory (and the tests and interpretive methods based on it). Apart perhaps from Spearman's *g*, never before in the history of intelligence testing had any theory played so prominent a role in test development and interpretation. Amidst the publication of CHC-based instruments was the latest revision of the Wechsler scales—the WISC-IV—which, although not explicitly based on CHC theory, nevertheless represented the most sweeping structural revision of any Wechsler scale in the history of the Wechsler lineage, due primarily to its closer alliance with theory.

As noted previously, CHC theory became the foundation for the revision of most major cognitive ability tests, the majority of which were published after 2000. At the same time, measurement and interpretive methods, such as XBA, have also gained considerable popularity among practitioners, particularly school psychologists. Whether the former promoted the latter or vice versa, it is clear that

there has been a significant change in the manner in which measurement and interpretation of cognitive abilities are conducted (see Flanagan & Harrison, 2012; Sotelo-Dynega & Cuskley, 2011).

### **The Fifth Wave: Application of Refinements in Theory and CHC-based Research to Psychological Test Interpretation**

As the fourth wave continues to unfold, it is our belief that the beginnings of the next wave have already begun to emerge. Indeed, specific programs of research in cognitive psychology, neuropsychology, neuroscience, and learning disabilities, for example, will converge in the next decade, resulting in more defensible and clinically meaningful interpretations of cognitive test performance. It is beyond the scope of this chapter to discuss the range of research programs that will lead to better test interpretation in the future. The interested reader is referred to the work of Keith and Reynolds (2010, 2012) for information on their rigorous program of research on factorial invariance within the CHC taxonomy, as their work will continue to shed light on the construct validity of cognitive batteries and lead to refinements of theories on the structure of cognitive abilities. Also, the ongoing work of Berninger and colleagues (see Berninger, 2011) and Fletcher and colleagues (e.g., Fletcher, Lyon, Fuchs, & Barnes, 2007) will continue to demonstrate how converging research programs (including their own) enhance test interpretation and, therefore, should be followed closely. For the purpose of this chapter, we limit our discussion of the fifth wave of intelligence and cognitive ability test interpretation to the following areas: (a) refinements and extensions to CHC theory; (b) CHC theory applied to academic outcomes research; (c) integrating CHC and neuropsychological theories to enhance test interpretation; and (d) greater emphasis on flexible battery approaches to assessment and interpretation.

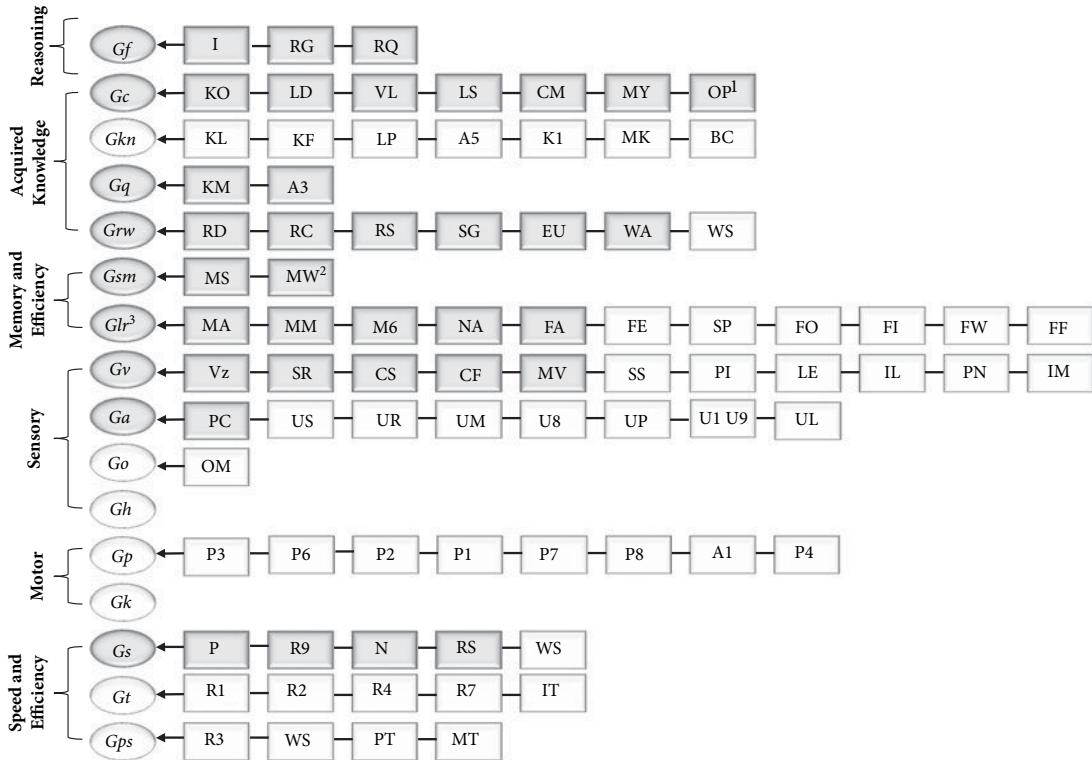

### **Refinements and Extensions to CHC theory**

Recently, Schneider and McGrew (2012) reviewed CHC-related research and provided a summary of the CHC abilities (broad and narrow) that have the most evidence to support them. In their attempt to provide a CHC overarching framework that incorporates the best-supported cognitive abilities, they articulated a 16-factor model containing over 80 narrow abilities (see Figure 12.4). Because of the greater number of abilities represented by CHC theory now, compared to past CHC models (e.g., Figure 12.3), the broad abilities in Figure 12.4

have been grouped conceptually into six broad categories, in a manner similar to those suggested by Schneider and McGrew, to enhance comprehensibility (i.e., Reasoning, Acquired Knowledge, Memory and Efficiency, Sensory, Motor, and Speed and Efficiency). Space limitations preclude a discussion of all the ways in which CHC theory has evolved and the reasons why certain refinements and changes have been made (see Schneider & McGrew for a discussion). However, to assist the reader in transitioning from the 10-factor CHC model (Figure 12.3) to the 16-factor CHC model (Figure 12.4), the following brief explanations are offered.

Of the 10 CHC factors depicted in Figure 12.3, all were refined by Schneider and McGrew (2012), except *Gq*. First, with regard to *Gf*, Piagetian Reasoning (RP) and Reasoning Speed (RE) were de-emphasized (and, therefore, are not included in Figure 12.4), primarily because there is little evidence that they are distinct factors. Second, four narrow abilities (Foreign Language Proficiency [KL], Geography Achievement [A5], General Science Information [K1], and Information about Culture [K2]) were moved to a different CHC broad ability, called Domain-Specific Knowledge (*Gkn*; defined below). Also, within the area of *Gc*, Foreign Language Aptitude (LA) was dropped, as it is a combination of abilities designed for the purpose of predicting one's success in learning foreign languages, and, as such, is not considered a distinct ability. The final refinement to *Gc* involved dropping the narrow ability of Oral Production and Fluency (OP) because it is difficult to distinguish it from the narrow ability of Communication Ability (CM). Nevertheless, OP continues to be represented in Figure 12.4 because several tests and subtests have been classified as OP in existing resources (e.g., Flanagan et al., 2007; Flanagan, Ortiz, Alfonso, & Mascolo, 2006).

Third, in the area of *Grw*, Verbal (Printed) Language Comprehension (V) was dropped because it appears to represent a number of different abilities (e.g., reading decoding, reading comprehension, reading speed) and, therefore, is not a distinct ability. Likewise, Cloze Ability (CZ) was dropped from *Grw* because it is not meaningfully distinct from reading comprehension. Rather, CZ appears to be a specific method of measuring reading comprehension. As such, tests like those formally classified as CZ (e.g., WJ III Passage Comprehension) should be classified (or reclassified) as "RC" or Reading Comprehension. The final refinement to *Grw*

**Figure 12.4** Current Cattell-Horn-Carroll (CHC) model of cognitive abilities.

**Note:** The current CHC model depicted in this figure contains 16 broad abilities and over 80 narrow abilities as specified by Schneider and McGrew (2012). Abilities encompassing the domains of “Reasoning,” “Acquired Knowledge,” “Memory and Efficiency,” “Speed and Efficiency,” and “Motor” are grouped according to function and “Sensory” abilities are grouped conceptually, following the logic of Schneider and McGrew. Broad and narrow abilities represented by gray shaded ovals and rectangles, respectively are those most commonly measured by contemporary cognitive and achievement batteries.

<sup>1</sup>The narrow ability of Oral Production and Fluency (OP) is difficult to distinguish from the narrow ability of Communication Ability (CM). Therefore, Schneider and McGrew recommended that OP be dropped from the CHC model. However, OP continues to be represented in this model because several tests and subtests have been classified as OP in existing resources (e.g., Flanagan, Ortiz, & Alfonso, 2007; Flanagan, Ortiz, Alfonso, & McGrew, 2006).

<sup>2</sup>Working Memory is now called Working Memory Capacity.

<sup>3</sup>The narrow abilities comprised by  $G_{lr}$  may be divided into two categories—Learning Efficiency (MA, MM, M6) and Retrieval Fluency (which includes the remaining narrow  $G_{lr}$  abilities listed in this figure). Note that Figural Flexibility (FX) was not listed in this figure due to space limitations.

$G_f$  = Fluid Intelligence;  $G_c$  = Crystallized Intelligence;  $G_{kn}$  = General (Domain-Specific) Knowledge Ability;  $G_q$  = Quantitative Knowledge  $G_{rw}$  = Reading/Writing Ability;  $G_{sm}$  = Short-Term Memory;  $G_{lr}$  = Long-Term Storage and Retrieval;  $G_v$  = Visual Processing;  $G_a$  = Auditory Processing;  $G_o$  = Olfactory Abilities;  $G_h$  = Tactile Abilities;  $G_p$  = Psychomotor Abilities;  $G_k$  = Kinesthetic Abilities;  $G_s$  = Processing Speed;  $G_t$  = Decision Speed/Reaction Time;  $G_{ps}$  = Psychomotor Speed; I = Induction; RG = General Sequential Reasoning; RQ = Quantitative Reasoning; K0 = General (verbal) Knowledge; LD = Language Development; VL = Lexical Knowledge; LS = Listening Ability; CM = Communication Ability; MY = Grammatical Sensitivity; OP = Oral Production and Fluency; KL = Foreign Language Proficiency; KF = Knowledge of Signing; LP = Skill in Lip-reading; A5 = Geography Achievement; K1 = General Science Information; MK = Mechanical Knowledge; BC = Knowledge of Behavioral Content; KM = Math Knowledge; A3 = Math Achievement; RD = Reading Decoding; RC = Reading Comprehension; RS = Reading Speed; SG = Spelling Ability; EU = English Usage Knowledge; WA = Writing Ability; WS = Writing Speed; MS = Memory Span; MW = Working Memory Capacity; MA = Associative Memory; MM = Meaningful Memory; M6 = Free Recall Memory; NA = Naming Facility; FA = Associational Fluency; FE = Expressional Fluency; SP = Sensitivity Problems; FO = Originality/Creativity; FI = Ideational Fluency; FW = Word Fluency; FF = Figural Fluency; FX = Figural Flexibility; Vz = Visualization; SR = Speeded Rotation; CS = Closure Speed; CF = Flexibility of Closure; MV = Visual Memory; SS = Spatial Scanning; PI = Serial Perceptual Integration; LE = Length Estimation; IL = Perceptual Illusions; PN = Perceptual Alternations; IM = Imagery; PC = Phonetic Coding; US = Maintaining and Judging Rhythm; UR = Resistance to Auditory Stimulus Distortion; UM = Memory for Sound Patterns; U8 = Speech Sound Discrimination; UP = Absolute Pitch; U1U9 = Musical Discrimination and Judgment; UL = Sound Localization; OM = Olfactory Memory; P3 = Static Strength; P6 = Multilimb Coordination; P2 = Finger Dexterity; P1 = Manual Dexterity; P7 = Arm-hand Steadiness; P8 = Control Precision; A1 = Aiming; P4 = Gross Body Equilibrium; P = Perceptual Speed; R9 = Rate-of-Test-Taking; N = Number Facility; RS = Reading Speed; WS = Writing Speed; R1 = Simple Reaction Time; R2 = Choice Reaction Time; R4 = Semantic Processing Speed; R7 = Mental Comparison Speed; IT = Inspection Time; R3 = Speed of Limb Movement; WS = Writing Speed; PT = Speed of Articulation; MT = Movement Time.

involved adding the narrow ability of Writing Speed (WS), as this ability appears to cut across more than one broad ability (see Schneider & McGrew, 2012).

Fourth, several refinements were made to the broad memory abilities of *Glr* and *Gsm*. Learning Abilities (L1) was dropped from both *Glr* and *Gsm*. It appears that Carroll conceived of L1 as a superordinate category consisting of different kinds of long-term learning abilities. Schneider and McGrew (2012) referred to this category (i.e., L1) as “*Glr*-Learning Efficiency,” which includes the narrow abilities of Free Recall Memory, Associative Memory, and Meaningful Memory. The remaining *Glr* narrow abilities are referred to as “Retrieval Fluency” abilities (see Figure 12.4). In the area of *Gsm*, the name of the Working Memory (MW) narrow ability was changed to *Working Memory Capacity*, as Schneider and McGrew believe the latter term is more descriptive of the types of tasks that are used most frequently to measure MW (e.g., Wechsler Letter-Number Sequencing).

Fifth, in the area of *Gv*, one refinement was made. That is, the narrow ability name Spatial Relations (SR) was changed to “Speeded Rotation” (also “SR”) to more accurately describe this ability. Speeded Rotation is the *ability to solve problems quickly using mental rotation of simple images* (Schneider & McGrew, 2012, p. 129). This ability is similar to visualization because it involves rotating mental images, but it is distinct because it has more to do with the speed at which mental rotation tasks can be completed (Lohman, 1996; Schneider & McGrew; Lohman, 1996). Also, Speeded Rotation tasks typically involve fairly simple images. It is likely that the majority of tests that were classified as Spatial Relations in the past should have been classified as measures of *Vz* *only* (rather than SR, *Vz*) (see Flanagan et al., 2013).

Sixth, in the area of *Ga*, Temporal Tracking (UK) tasks are thought to measure Attentional Control within working memory. As such, UK was dropped as a narrow ability comprising *Ga*. In addition, six *Ga* narrow abilities (General Sound Discrimination [U3], Sound-Intensity/Duration Discrimination [U6], Sound-Frequency Discrimination [U5], and Hearing and Speech Threshold [UA, UT, UU]) were considered to represent sensory acuity factors, which fall outside the scope of CHC theory and, therefore, were dropped (Schneider & McGrew, 2012).

Seventh, in the area of *Gs*, Reading Speed (RS) and Writing Speed (WS) were added. Although tasks that measure these abilities clearly fall under

the broad ability of *Grw*, they demand quick, accurate performance and are, therefore, also measures of *Gs*. The narrow *Gs* ability of Semantic Processing Speed (R4) was moved to *Gt*. Also, the narrow ability of Inspection Time (IT) was added to the broad ability of *Gt* (see Schneider & McGrew, 2012, for details).

In addition to the within-factor refinements just mentioned, the CHC model has been expanded to include six additional broad abilities, namely General (Domain-Specific) Knowledge (*Gkn*), Olfactory Abilities (*Go*), Tactile Abilities (*Gh*), Psychomotor Abilities (*Gp*), Kinesthetic Abilities (*Gk*) and Psychomotor Speed (*Gps*). A brief description of these broad abilities is found in a subsequent section of this chapter. Noteworthy is the fact that the major intelligence tests do not measure most (or any) of these additional factors directly. The reason for this is probably related to the fact that these abilities (with the possible exception of *Gkn*) do not contribute much to the prediction of achievement, which is a major purpose of intelligence and cognitive ability tests. However, many of these factors appear to be assessed by neuropsychological instruments because these tests are intended, in part, to understand the sensory and motor manifestations of typical and atypical fine and gross motor development, traumatic brain injury, and other neurological disorders. For example, several tasks of the Dean-Woodcock Neuropsychological Battery (Dean & Woodcock, 2003) appear to measure *Gh* (e.g., tactile examination: finger identification; tactile examination: object identification; tactile examination: palm writing; tactile identification: simultaneous localization; see Flanagan et al., 2013, for additional examples). Also noteworthy is the fact that, with rare exceptions, there do not appear to be any commercially published and commonly used intelligence or neuropsychological batteries that measure *Go*, *Gt*, or *Gps*.

In sum, despite the number of refinements and extensions that have been made to CHC theory recently, approximately nine broad cognitive abilities and 35–40 narrow abilities are measured consistently by popular cognitive and achievement tests. These commonly measured abilities are shaded gray in Figures 12.3 and 12.4. Researchers have already begun classifying tests according to the CHC extensions discussed by McGrew (2005; e.g., Flanagan et al., 2010). Without question, our next generation of psychological tests and CHC test classifications will correspond more closely to current CHC theory as it is depicted in Figure 12.4 (e.g., Flanagan et al., 2013).

## CHC Theory Applied to Academic Outcomes Research

Because practitioners often use intelligence and cognitive ability tests to gain insight into the underlying causes of learning difficulty and academic failure, it is important to understand the cognitive correlates to specific academic skills. Research on the relations between cognitive abilities, cognitive processes, and academic outcomes has mounted over the years (see Flanagan, et al., 2006; Fletcher et al., 2007; and McGrew & Wendling, 2010 for summaries). Much of the recent research on cognitive-academic relationships has been interpreted within the context of CHC theory (e.g., Flanagan, Alfonso, & Mascolo, 2011). In addition, statistical analyses, such as structural equation modeling, has been used to understand the extent to which specific cognitive abilities explain variance in academic skills above and beyond the variance accounted for by  $g$  (e.g., Floyd et al., 2008; McGrew et al., 1997; Vanderwood, McGrew, Keith, & Flanagan, 2002). Finally, many valuable resources summarize the research on cognitive and neurobiological processes associated with specific academic skill deficits (e.g., Fletcher et al., 2007; Miller, 2010; Fletcher-Janzen & Reynold, 2008).

The research summarized in this section is limited to the relations among the various CHC cognitive abilities and processes and the major areas of achievement—namely, reading, math, and writing. Tables 12.5 and 12.6 provide two sets of findings from two different literature reviews (i.e., Flanagan et al., 2006; and McGrew & Wendling, 2010). Because the literature reviews yielded some differences with regard to which abilities and processes are most relevant to academic achievement, these tables include a “Comments” section that offers some possible explanations for the differences. Likewise, Table 12.7 provides a summary of the literature on the relations between CHC cognitive abilities and processes and writing achievement (Flanagan et al., 2006). The information in Tables 12.5—12.7 is discussed below.

### Cognitive Abilities and Reading Achievement

A review of the literature suggests a number of conclusions regarding the relations between CHC abilities and reading achievement (see Table 12.5). First, narrow abilities subsumed by  $Ga$ ,  $Gc$ ,  $Glr$ ,  $Gsm$ , and  $Gs$  displayed the most consistent significant relations with reading achievement. Measures

of phonological processing or awareness (e.g., Phonetic Coding [PC], which is subsumed by  $Ga$ ) showed strong and consistent relations with reading achievement across many studies, especially during the early elementary school years.  $Gc$  abilities, which were typically represented by measures of Lexical Knowledge (VL), Listening Ability (LS), Language Development (LD), and General Information (KO), were also significantly related to reading achievement. As reported in some studies (e.g., Evans, Floyd, McGrew, & Leforgee, 2001; Garcia & Stafford, 2000; McGrew, 1993; McGrew et al., 1997), the significant effects of  $Ga$  and  $Gc$  on reading were present even after the powerful effect of  $g$  was accounted for in the analyses. That is, specific CHC abilities contributed significantly to the explanation of reading above and beyond the significant and large effect of  $g$ .

Many studies that included  $Gsm$  indicated that  $Gsm$  most likely contributes to reading achievement through working memory processes. Nevertheless, significant relationships between Memory Span and reading achievement have also been documented (see McGrew & Wendling, 2010). Taken as a whole, independent, comprehensive reviews of the reading achievement literature suggest that  $Gsm$ , including working memory and memory span, contributes significantly to the prediction of reading achievement (e.g., Flanagan et al., 2006; Feifer, 2011; McGrew & Wendling).

The relationship between  $Glr$  and reading achievement is consistent across most of the school age range (e.g., 6–13 years). Associative Memory and Naming Facility are important during the elementary years; Meaningful Memory is important at ages 9–13 years, particularly for reading comprehension (McGrew & Wendling, 2010). In addition, several studies found a strong relation between Perceptual Speed (P), a narrow  $Gs$  ability, and reading achievement across the school age range (6–19 years) (e.g., McGrew, 1993; McGrew et al., 1997). The effect of  $Gs$  was present even after the effect of  $g$  on reading achievement was accounted for in the McGrew and colleagues' (1997) study. This finding was replicated by Evans et al. (2001) who found  $Gs$  to be significantly related to both basic reading skills and reading comprehension in the early years. Thus, as with  $Ga$  and  $Gc$  abilities,  $Gs$  abilities (viz., perceptual speed) explain significant variance in reading achievement above and beyond the variance explained by  $g$ .

It appears that  $Gf$  and  $Gv$  abilities are less related to reading achievement as compared to  $Gc$ ,  $Ga$ ,

**Table 12.5 Important Findings on Relations Between CHC Abilities and Reading Achievement**

CHC Ability	Flanagan, Mascolo, Alfonso, & Ortiz (2006) General Reading Review (116 independent studies)	McGrew & Wendling (2010) Basic Reading Skills and Reading Comprehension Findings <sup>1</sup> (19 CHC/WJ studies)	Comments
<i>Gf</i>	Inductive (I) and General Sequential Reasoning (RG) abilities play a moderate role in reading comprehension.	Quantitative Reasoning (RQ) is tentative/speculative at ages 6–8 and 14–19 years for Basic Reading Skills (BRS). <sup>2</sup> Broad <i>Gf</i> is tentative/speculative at ages 14–19 years for Reading Comprehension (RC).	The lack of a relationship between <i>Gf</i> abilities and reading in the McGrew and Wendling summary may be related to the nature of the dependent measures. For example, RC was represented by the WJ Passage Comprehension and Reading Vocabulary tests, both of which draw minimally on reasoning (e.g., they do not require an individual to draw inferences or make predictions).
<i>Gc</i>	<b>Language Development (LD), Lexical Knowledge (VL), and Listening Abilities (LS) are important. These abilities become increasingly important with age.</b>	LS is moderately consistent at ages 6–8 years for BRS. LS is highly consistent at ages 6–19 years for RC. General Fund of Information (KO) is consistent at ages 6–8 and moderately consistent at ages 9–19 years for BRS. KO is highly consistent at ages 6–19 years for RC. Broad <i>Gc</i> is moderately consistent at ages 6–13 and highly consistent at ages 14–19 years for BRS. Broad <i>Gc</i> is highly consistent at ages 6–19 years for RC.	The findings across the Flanagan et al., and McGrew and Wendling summaries are quite similar given that Broad <i>Gc</i> in the McGrew and Wendling summary is defined primarily by the narrow abilities of LD and VL. However, Flanagan et al. did not find a consistent relationship between the narrow ability of KO and reading, as KO was not well represented in the studies they reviewed.
<i>Gsm</i>	Memory Span (MS) is important especially when evaluated <b>within the context of working memory</b> .	Working Memory (MW) is moderately consistent at ages 6–19 years for BRS and highly consistent for RC at ages 6–19 years. MS is tentative/speculative at ages 6–8 and moderately consistent at ages 9–19 years for BRS. MS is consistent at ages 6–13 and moderately consistent at ages 14–19 years for RC. Broad <i>Gsm</i> is consistent at ages 6–8 and highly consistent at ages 9–19 years for BRS. Broad <i>Gsm</i> is consistent at ages 6–8 and 14–19 years for RC.	Both the Flanagan et al. and McGrew and Wendling summaries highlight the importance of <i>Gsm</i> for reading.

<i>Gv</i>	Orthographic processing	Visual Memory (MV) is moderately consistent at ages 14–19 years for RC. Broad <i>Gv</i> is not consistently related to BRS or RC.	One possible explanation for the lack of a <i>Gv</i> relationship with BRS in the McGrew and Wendling summary is that the types of tasks used to measure visual processing in the studies they reviewed (e.g., spatial relations) do not measure the visual aspects of reading (e.g., orthographic processing). Orthographic processing or awareness (the ability to rapidly map graphemes to phonemes) may be more related to the perceptual speed tasks found on cognitive tests (e.g., Symbol Search on the Wechsler scales).
<i>Ga</i>	<b>Phonetic Coding (PC) or phonological awareness/processing is very important during the elementary school years.</b>	PC is moderately consistent at ages 6–13 and consistent at ages 14–19 years for BRS. PC is consistent at ages 6–8 and 14–19 years; tentative/speculative at ages 9–13 years for RC. Speech Sound Discrimination and Resistance to Auditory Stimulus Distortion (US/UR) are consistent at ages 9–19 years for BRS. Broad <i>Ga</i> is not consistently related to BRS. Broad <i>Ga</i> is moderately related at ages 6–8 years for RC.	Interestingly, and in contrast to Flanagan et al.'s summary, McGrew and Wendling's summary does not show a strong relationship between PC/phonological processing and reading at any age level. Given the wealth of research on the relations between PC/phonological processing and reading coupled with the neuroimaging research showing normalization of brain function in response to effective interventions for PC/phonological processing deficits, a reasonable assumption is that PC/phonological processing plays an important role in reading development during the early elementary school years. The relationship between PC/phonological processing and reading may be more prominent in students with reading difficulties, a population not included in the McGrew and Wendling samples.

(continued)

Table 12.5 (Continued)

CHC Ability	Flanagan, Mascolo, Alfonso, & Ortiz (2006) General Reading Review (116 independent studies)	McGrew & Wendling (2010) Basic Reading Skills and Reading Comprehension Findings <sup>1</sup> (19 CHC/WJ studies)	Comments
<i>Glr</i>	<b>Naming Facility (NA) or <i>rapid automatic naming</i> is very important during the elementary school years.</b> Associative Memory (MA) was also found to be related to reading at young ages (e.g., age 6 years).	MA is consistent at ages 6–8 years for BRS. Meaningful Memory (MM) is highly consistent at ages 9–19 years for RC. NA is consistent at ages 14–19 and moderately consistent at ages 9–13 years for RC. Broad <i>Glr</i> is consistent at ages 6–8 years for BRS. Broad <i>Glr</i> is consistent at ages 9–13 years for RC.	The lack of a significant relation between NA and BRS in the early elementary school years (ages 6–8 years) in the McGrew and Wendling summary is surprising, as rapid automatized naming or rate has always been implicated in young children who struggle with reading achievement, particularly reading fluency. However, the outcome measures in the studies reviewed by McGrew and Wendling may not have measured reading fluency well or at all.
<i>Gs</i>	<b>Perceptual speed (P) is important during all school years, particularly the elementary school years.</b>	P is consistent at ages 6–8 and 14–19 years and moderately consistent at ages 9–13 years for BRS. P is consistent at ages 14–19 and moderately consistent at ages 6–13 years for RC.	Flanagan et al.'s summary shows a stronger relationship between <i>Gs</i> and reading than McGrew and Wendling's summary. Nevertheless, the findings of both investigations show that <i>Gs</i> and P, in particular, are important for reading.

*Note:* For a discussion of the limitations of the findings reported in this table, see McGrew and Wendling (2010).

<sup>1</sup> Qualitative descriptors of *consistency* for McGrew and Wendling (2010) analyses were coded as follows: The label “highly consistent” means that a significant finding was noted in 80% or more of the studies reviewed; “moderately consistent” means that a significant finding was noted in 50% to 79% of the studies reviewed; and “consistent” means that a significant finding was noted in 30% to 49% of the studies reviewed.

<sup>2</sup> *Tentative/ speculative* results were those that were: (a) between 20%–29% in consistency, (b) based on a very small number of analyses (e.g.,  $n = 2$ ), and/or (c) based only on McGrew's (2007) exploratory multiple regression analysis of manifest WJ III variables at the individual IV test level (McGrew & Wendling, 2010).

**Table 12.6 Important Findings on Relations Between CHC Abilities and Mathematics Achievement**

CHC Ability	Flanagan, Mascolo, Alfonso, & Ortiz (2006) General Math Review <sup>1</sup> (32 independent studies)	McGrew & Wendling (2010) Basic Math Skills and Math Reasoning Findings <sup>2</sup> (10 CHC/WJ studies)	Comments
<i>Gf</i>	<b>Inductive (I) and general sequential (RG) reasoning abilities are consistently related to math achievement at all ages.</b>	Quantitative Reasoning (RQ) highly consistent at ages 6–19 years. RG highly consistent at ages 14–19 years for Math Reasoning (MR) and consistent at ages 6–19 years for Basic Math Skills (BMS).	Broad <i>Gf</i> is highly consistent at ages 6–13 and moderately consistent at ages 14–19 years for MR and moderately consistent at ages 6–19 years for BMS. In McGrew & Wendling's analyses, Induction was part of the RQ tasks and also was subsumed by <i>Gf</i> .
<i>Gc</i>	<b>Language development (LD), lexical knowledge (VL), and listening abilities (LS) are important. These abilities become increasingly more important with age.</b>	LD and VL are consistent at ages 9–13 and highly consistent at ages 14–19 years for BMS. LD and VL are consistent at ages 6–8 years, moderately consistent at ages 9–13 and highly consistent at ages 14–19 years for MR. LS is consistent at ages 6–8 and highly consistent at ages 9–19 years for MR. LS is highly consistent for BMS at ages 6–19 years. K0 is moderately consistent up to age 13 and highly consistent at ages 14–19 years for MR only.	The lack of a relationship between LD/VL and BMS at ages 6–8 years in McGrew and Wendling is surprising, as elementary math contains several language concepts (e.g., less than, greater than, sum, in all, together). This finding is likely related to the nature of the math tasks used in the studies reviewed. General Fund of Information (K0) was either not represented or did not demonstrate a consistent relationship with math achievement in the Flanagan et al. review. Broad <i>Gc</i> is moderately consistent at ages 9–19 years for BMS. Broad <i>Gc</i> is consistent at ages 6–8 years, moderately consistent at ages 9–13 and highly consistent at ages 14–19 years for MR.
<i>Gsm</i>	Memory span (MS) is important especially when evaluated <b>within the context of working memory</b> .	Working Memory (MW) is highly consistent at ages 6–19 years. MS is consistent at ages 6–8 years for MR only.	Broad <i>Gsm</i> is consistent at ages 14–19 years for MR only.
<i>Gv</i>	May be important primarily for higher level or advanced mathematics (e.g., geometry, calculus).	Spatial Scanning (SS) is consistent at ages 6–8 years for BMS only.	<i>Gv</i> abilities related to math achievement are either not measured or not measured adequately by current intelligence batteries. Alternatively, the importance of an adequately measured <i>Gv</i> ability may be masked by the presence of other important variables (e.g., <i>Gc</i> , <i>Gsm</i> ) included in the analyses (McGrew & Wendling).

**Table 12.6 (Continued)**

CHC Ability	Flanagan, Mascolo, Alfonso, & Ortiz (2006) General Math Review <sup>1</sup> (32 independent studies)	McGrew & Wendling (2010) Basic Math Skills and Math Reasoning Findings <sup>2</sup> (10 CHC/WJ studies)	Comments
<i>Ga</i>		<p>Phonetic Coding (PC) is consistent at ages 6–13 years for BMS. PC is moderately consistent at ages 6–8 and consistent at ages 9–19 years for MR.</p> <p>Speech Sound Discrimination and Resistance to Auditory Stimulus Distortion (US/UR) are moderately consistent at ages 9–13 years for MR only.</p>	The relationship in the McGrew and Wendling study between PC and BMS reflects the use of Sound Blending as the PC indicator. Memory span is necessary for optimal performance on Sound Blending, which may account for the presence of the relationship.
<i>Glr</i>		<p>Meaningful Memory (MM) is moderately consistent at ages 14–19 years for MR.</p> <p>MM is moderately consistent at ages 9–13 years for BMS.</p> <p>Associative Memory (MA) is consistent at ages 6–8 years for BMS.</p> <p>NA is consistent at ages 6–19 years for BMS only.</p>	<p>MM and MA was either not represented or did not demonstrate a consistent relationship with math achievement in the Flanagan et al. review.</p> <p>The relationship between Naming Facility (NA) and BMS would likely be more robust if the cognitive task stimuli involved the rapid naming of numbers rather than pictures.</p>
<i>Gs</i>	<b>Speed of Processing (Gs) and, more specifically, Perceptual Speed (P) is important during all school years, particularly during elementary school.</b>	<p>Broad <i>Gs</i> is moderately consistent at ages 6–13 and consistent at ages 14–19 years for BMS.</p> <p>Broad <i>Gs</i> is consistent at ages 6–8 and moderately consistent at ages 9–13 years for MR.</p> <p>AC/EF is consistent at ages 6–8 years for BMS.</p> <p>AC/EF is highly consistent for ages 9–13 and consistent for ages 14–19 years for BMS.</p> <p>P is highly consistent at ages 6–19 years for BMS and moderately consistent at ages 6–19 years for MR.</p>	<p>In McGrew and Wendling's summary of the relations between <i>Gs</i> and math, P is also described as Attention-Concentration/Executive Functioning (AC/EF).</p>

*Note:* For a discussion of the limitations of the findings reported in this table, see McGrew and Wendling (2010).

<sup>1</sup> The absence of comments for a particular CHC ability and achievement area (e.g., *Ga* and mathematics) in the Flanagan et al. review indicates that the research reviewed either did not report any significant relationships between the respective CHC ability and the achievement area, or if significant findings were reported, they were only for a limited number of studies. Comments in bold represent the CHC abilities that demonstrated the strongest and most consistent relationship to mathematics achievement.

<sup>2</sup> Qualitative descriptors of *consistency* for McGrew & Wendling (2010) analyses were coded as follows: The label "highly consistent" denotes that a significant finding was noted in 80% or more of the studies reviewed; "moderately consistent" denotes that a significant finding was noted in 50% to 79% of the studies reviewed; and "consistent" denotes that a significant finding was noted in 30% to 49% of the studies reviewed.

**Table 12.7 Important Findings on Relations Between CHC Abilities and Writing Achievement**

CHC Ability	Writing Achievement
<i>Gf</i>	Inductive (I) and general sequential reasoning abilities are related to basic writing skills primarily during the elementary school years (e.g., 6–13) and consistently related to written expression at all ages.
<i>Gc</i>	<b>Language development (LD), lexical knowledge (VL), and general information (KO)<sup>1</sup> are important primarily after age 7. These abilities become increasingly more important with age.</b>
<i>Gsm</i>	<b>Memory span (MS) is important to writing, especially spelling skills whereas working memory has shown relations with advanced writing skills (e.g., written expression).</b>
<i>Gv</i>	Orthographic Processing
<i>Ga</i>	<b>Phonetic coding (PC) or “phonological awareness/processing” is very important during the elementary school years for both basic writing skills and written expression (primarily before age 11).</b>
<i>Glr</i>	Naming facility (NA) or “rapid automatic naming” has demonstrated relations with written expression, primarily the fluency aspect of writing. Associative Memory.
<i>Gs</i>	<b>Perceptual Speed (P) is important during all school years for basic writing and related to all ages for written expression.</b>

*Note:* Comments in bold represent the CHC abilities that showed the strongest and most consistent relation to writing achievement. Information in this table was reproduced from Flanagan, Ortiz, Alfonso, & Mascolo (2006) with permission from John Wiley and Sons. All rights reserved.

<sup>1</sup>Includes orthographic knowledge and knowledge of morphology, which contribute to spelling and written expression.

*Glr*, *Gsm*, and *Gs* abilities. The significant and most consistent *Gf* findings were between inductive and deductive reasoning and reading comprehension (e.g., see Flanagan et al., 2006, for a discussion). This suggests that the comprehension of text may draw on an individual's reasoning abilities, depending on the demands of the comprehension task (e.g., tasks that require drawing inferences and making predictions).

Very few studies reported a significant relation between *Gv* and reading achievement, although McGrew and Wendling (2010) reported a consistent relationship between Visual Memory and reading comprehension at ages 14–19 years. Overall it appears that *Gv* abilities do not play a significant role in reading achievement. This does not mean that visual processing abilities are not involved during reading. The lack of significant *Gv*/reading research findings indicates that the contribution of *Gv* abilities (as measured by the major intelligence batteries) to the explanation and prediction of reading achievement is so small that, when compared to other abilities (e.g., *Ga*), it is of little practical significance. However, it is important not to over generalize this conclusion to all visual abilities. As pointed out by Berninger (1990), visual perceptual abilities should not be confused with abilities that are related to the coding of visual

information in printed words (i.e., orthographic code processing)—visual processes thought to be important during reading. Indeed, Flanagan and her colleagues (2006) found in their review of the literature a consistent relationship between orthographic processing and reading achievement (i.e., basic reading skills).

In summary, narrow abilities in seven broad CHC domains appear to be related significantly to reading achievement. The findings of two independent, comprehensive literature reviews (i.e., Flanagan et al., 2006; McGrew & Wendling, 2010) suggest that abilities subsumed by *Gc* (Language Development, Lexical Knowledge, Listening Ability, General Information), *Gsm* (Memory Span, Working Memory), *Ga* (Phonetic Coding), *Glr* (Associative Memory, Naming Facility, Meaningful Memory), and *Gs* (Perceptual Speed) are related significantly to reading achievement. Furthermore, developmental results suggest that the *Ga*, *Gs*, and *Glr* relations with reading are strongest during the early elementary school years, after which they systematically decrease in strength (e.g., Flanagan et al.; McGrew, 1993). In contrast, the strength of the relations between *Gc* abilities and reading achievement increases with age. The *Gv* abilities of orthographic processing and visual memory are related to reading achievement. Finally, *Gf* abilities

appear related primarily to reading comprehension from childhood to young adulthood.

### Cognitive Abilities and Math Achievement

Similar to reading, both literature reviews (i.e., Flanagan et al., 2006; McGrew & Wendling, 2010) found that *Gc*, *Gsm* (particularly working memory), and *Gs* are related significantly to math achievement. In contrast to reading, stronger evidence of the relations between *Gf* and *Gv* abilities and math achievement was found.

In some of the more comprehensive studies of the relations between CHC abilities and math achievement (e.g., McGrew & Hessler, 1995), *Gf*, *Gc*, and *Gs* abilities correlated consistently and significantly with basic math skills and math problem-solving. However, there were developmental differences. The *Gc* relation with mathematics achievement increased monotonically with age, whereas the *Gs* relation was strongest during the elementary school years, after which it decreased (although the relationship remained significant well into adulthood). *Gf* was related consistently to mathematics achievement at levels higher than all other CHC abilities (except *Gc*) across all ages. As in the reading achievement research just mentioned, certain specific abilities (*Gf*, *Gs*, *Gc*) were found to be related significantly to mathematics achievement above and beyond the contribution of *g* (e.g., McGrew et al., 1997).

With one exception (i.e., a consistent relation between Spatial Scanning and basic math skills), no significant relations between *Gv* and mathematics achievement were found. Likewise, very few studies reported a significant relationship between *Glr* and mathematics achievement (Floyd et al., 2003; Geary, 1993; Geary, Hoard, & Bailey, 2011). According to McGrew and Wendling (2010), the *Glr* narrow ability of Meaningful Memory is related to basic math skills at ages 9–13 years and math reasoning at ages 14–19 years; Associative Memory and Naming Facility are related to basic math skills at ages 6–8 years and 6–19 years, respectively. Moreover, Swanson and Beebe-Frankenberger (2004) found that long-term memory is important in predicting mathematical problem-solving solution accuracy beyond that predicted by other abilities (e.g., *Gsm*, *Gs*).

### Cognitive Abilities and Writing Achievement

A review of Table 12.7 demonstrates that several CHC domains are related to writing achievement. Specifically, researchers have documented relations

between cognitive abilities and writing achievement across the seven CHC domains listed in Table 12.7 (*Gf*, *Gc*, *Gsm*, *Gv*, *Ga*, *Glr*, and *Gs*). However, the limited number of studies in certain CHC domains clearly suggests that the consistency of relations differs markedly across areas. For instance, only one study demonstrated a relation between *Gf* abilities and writing achievement. Specifically, McGrew and Knopik (1993) found that fluid reasoning abilities (i.e., induction and general sequential reasoning) were related significantly to basic writing skills primarily during the elementary school years (i.e., ages 6 to 13) and significantly related to written expression across all ages.

Similarly, the study by McGrew and Knopik (1993) provided evidence for the role of *Gs* abilities in writing. More specifically, this study demonstrated that the *Gs* cluster (comprised of measures of perceptual speed) “was significantly related to Basic Writing Skills during the school years . . . after which it decreased in strength of association” (p. 690) with age. The relations between *Gs* and written expression were more consistent in strength across ages. As explained by McGrew and Knopik, “Given the timed nature of the [WJ-R] Writing Fluency tests that comprises one-half of the [WJ-R] Written Expression cluster, the finding of consistently significant associations between Processing Speed and this writing achievement criterion was not surprising” (p. 692). This finding is also not surprising in light of the recent refinements to CHC theory, particularly the addition of Writing Speed (WS) as a narrow *Gs* ability (see Figure 12.4).

Similar to McGrew and Knopik’s (1993) findings, Floyd and colleagues (2008) and Williams and colleagues (1993) also reported significant relations between *Gs* and writing abilities. For example, the latter study demonstrated relations between the WISC-III Coding subtest (a measure of Rate of Test Taking) and the WJ-R Writing Fluency test. Likewise, Hargrave (2005) found that, in addition to other CHC broad abilities, *Gs* significantly predicted performance on the WJ III ACH Broad Written Language Cluster. Given these findings, it seems likely that processing speed is important in terms of writing automaticity as well as more general writing ability. Although only a few studies found a relation between *Gs* and writing achievement, the strength of the *Gs* effects demonstrated in the aforementioned studies is significant and warrants continued attention and investigation (Floyd et al., 2008).

Research on the relations between *Gv* and writing achievement is sparse, suggesting the need for continued study (see Berninger, 1999). Because only one study in Flanagan and colleagues' (2006) review reported a significant relation between *Gv* and writing achievement (Aaron, 1995), it may be that *Gv* abilities as assessed by the major intelligence batteries do not play a significant role in writing achievement. This is not to say that *Gv* abilities are unimportant for writing. In fact, orthographic processing, is particularly influential in basic writing tasks (e.g., spelling; see Berninger, 2009). As defined by Aaron (1995), orthography refers to the visual patterns of the written language. However, "orthographic processing ability is not the same as visual memory even though visual memory may play a role in it" (Aaron, p. 347). Specifically, some researchers have indicated that a certain type of memory for orthographic units may play a role in spelling words that cannot be accurately spelled using the rules of pronunciation alone (see Kreiner & Gough, 1990, for a more in-depth discussion). Despite the role that orthographic knowledge plays in basic writing tasks, this relationship is not evident in Table 12.7, primarily because CHC theory does not currently have a narrow ability category corresponding to this type of processing. Many of the existing *Gv* abilities that comprise CHC theory (e.g., visualization, spatial relations; closure speed) appear to be minimally related to writing achievement. It is likely that *Gv*-type abilities, such as orthographic processing, that are related to writing (and reading) achievement will be incorporated within the CHC theoretical framework in the near future, particularly as this research base mounts (Flanagan et al., 2006).

The research on the relations between *Glr* and *Gc* and writing achievement is also sparse. The fact that only a handful of studies have documented a significant relation between *Glr* and writing to date suggests that either *Glr* abilities are of limited importance to the writing process or the importance of *Glr* in writing ability has not been investigated thoroughly. Nevertheless, the narrow ability of Associative Memory (MA) appears to be involved in mapping sounds to their corresponding letters (e.g., Mather & Wendling, 2011). In terms of *Gc*, McGrew and Knopik (1993) and Floyd et al. (2008) found significant relations among language development (LD), lexical knowledge (VL), general information (K0), and writing abilities (i.e., basic writing skills and written expression). Although the *Gc* research is also limited, there are certainly stores of knowledge (*Gc*) that are necessary for successful

writing. For example, knowledge of orthography and morphology as well as lexical knowledge contribute to spelling and written expression (Mather & Wendling).

Despite the limited research on the relations between CHC abilities and writing achievement, Table 12.7 shows that *Gc* and *Gsm* displayed the most consistent significant relations with overall writing achievement. Additionally, Phonetic Coding, a narrow *Ga* ability, and Perceptual Speed, a narrow *Gs* ability, were found to have strong and consistent relations with writing achievement across many studies, especially during the early elementary school years (e.g., Berninger et al., 1994; Johnson, 1993; Joshi, 1995; McGrew & Knopik, 1993). Finally, the majority of studies that found a relationship between *Gsm* and writing achievement suggested that memory span is an important predictor of early writing achievement.

Overall, several CHC abilities are related significantly to writing achievement. Among these, the most consistent relations appear to be with *Ga* (phonetic coding), *Gsm* (memory span), *Gs* (perceptual speed), and *Gc* (lexical knowledge, language development, and general information, the latter of which includes orthographic knowledge and knowledge of morphology). The relatively limited research on the relations between cognitive abilities and writing achievement may be related, in part, to the fact that writing research has taken a tertiary position to reading and math research. That is, although the early pioneering literature on learning disabilities emphasized both writing and reading disabilities, the subsequent learning disabilities literature has given more attention to reading than writing (Berninger, 1997, 2011). Given the importance of writing throughout one's educational (and often, professional) careers, the field would benefit from additional research within this domain.

In summary, Tables 12.5, 12.6, and 12.7 presented the available literature on the relations between cognitive abilities (and processes) and reading, math, and writing achievement, respectively, based largely on two independent, comprehensive reviews of the literature (Flanagan et al., 2006; McGrew & Wendling, 2010). Narrow abilities subsumed by *Gc* (lexical knowledge, language development, listening ability, general information), *Gsm* (memory span, working memory), *Ga* (phonetic coding), *Glr* (associative memory, meaningful memory, naming facility), and *Gs* (perceptual speed) were found to be significantly and most consistently related to reading achievement. Similarly, narrow abilities within

these same broad abilities were found to be related to writing achievement. Narrow abilities within the areas of *Gf*, *Gc*, *Gsm*, *Glr*, and *Gs* were found to relate significantly to math achievement, with *Gf* (induction and general sequential reasoning) showing a stronger relation to this academic area than either reading or writing.

## Integrating CHC and Neuropsychological Theories to Enhance Test Interpretation<sup>1</sup>

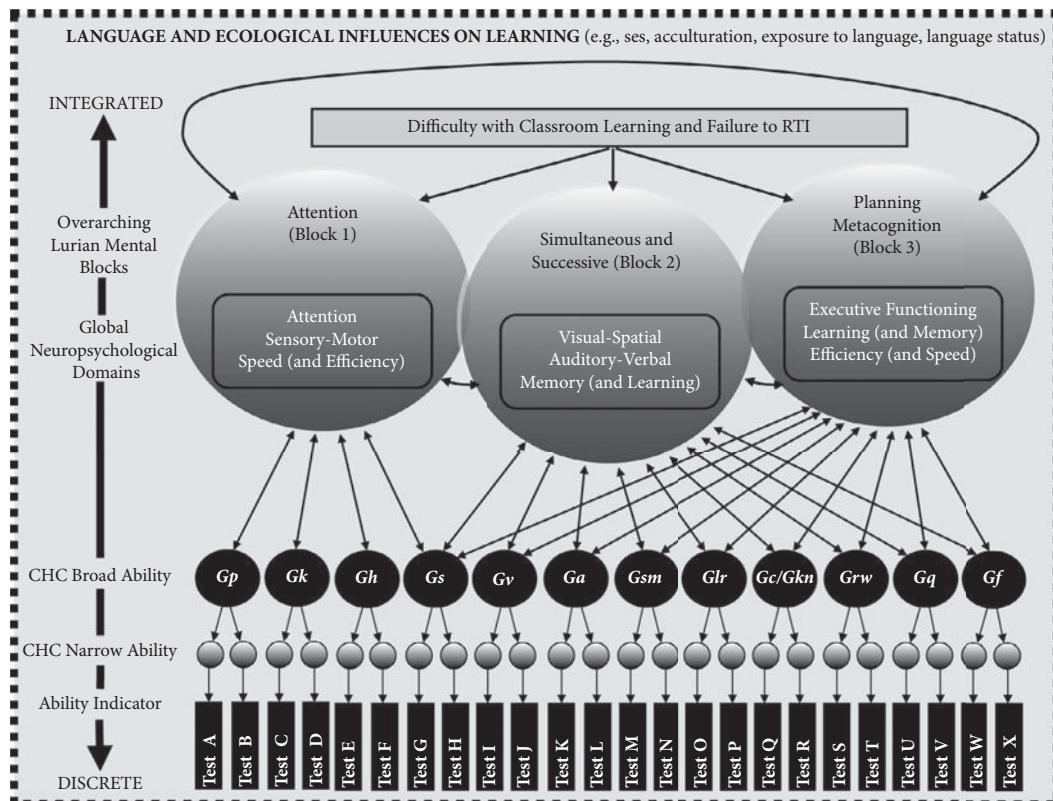

With the emergence of the field of school neuropsychology (e.g., Fletcher-Janzen & Reynolds, 2008; Hale & Fiorello, 2004; Miller, 2007, 2010) came the desire to link CHC theory and neuropsychological theories. Understanding how CHC theory and neuropsychological theories relate to one another will expand the options available for interpreting cognitive test performance in particular and will improve the quality and clarity of test interpretation in general, as a much wider research base will be available to inform practice.

Although scientific understanding of the manner in which the brain functions and how mental activity is expressed on psychometric tasks has increased dramatically in recent years, there is still much to be learned. All efforts to create a framework that guides test interpretation benefit from diverse points of view. For example, according to Fiorello et al. (2008), “the compatibility of the neuropsychological and psychometric approaches to cognitive functioning suggests converging lines of evidence from separate lines of inquiry, a validity dimension essential to the study of individual differences in how children think and learn” (p. 232). Their analysis of the links between the neuropsychological and psychometric approaches not only provides validity for both, but also suggests that each approach may benefit from knowledge of the other. As such, a framework that incorporates the neuropsychological and psychometric approaches to cognitive functioning holds the promise of increasing knowledge about the etiology and nature of a variety of disorders (e.g., specific learning disability) and the manner in which such disorders are treated. This type of framework should not only connect the elements and components of both assessment approaches, but it should also allow interpretation of data within the context of either model. In other words, the framework should serve as a “translation” of the concepts, nomenclature, and principles of one approach into their similar counterparts in the other. A brief discussion of one such framework, developed by Flanagan, Alfonso, Ortiz, and Dynda

(2010), is presented in the following section. This framework is illustrated in Figure 12.5 and represents an integration based on psychometric, neuropsychological, and Lurian perspectives.

The interpretive framework shown in Figure 12.5 draws upon prior research and sources, most notably Dehn (2006); Fiorello et al. (2007); Fletcher-Janzen and Reynolds (2008); Miller (2007); and Strauss, Sherman, and Spreen (2006). In understanding the manner in which Luria's blocks, the neuropsychological domains, and CHC broad abilities may be linked to inform test interpretation and mutual understanding among assessment professionals, Flanagan and colleagues pointed out four important observations that deserve mention. First, there is a hierarchical structure among the three theoretical conceptualizations. Second, the hierarchical structure parallels a continuum of interpretive complexity, spanning the broadest levels of cognitive functioning, where mental activities are “integrated,” to the narrowest level of cognitive functioning where mental activity is reduced to more “discrete” abilities and processes (see far left side of Figure 12.5). Third, all mental activity takes place within a given ecological and societal context and is heavily influenced by language as well as other factors external to the individual. As such, the dotted line surrounding Figure 12.5 represents “language and ecological influences on learning,” which includes factors such as exposure to language, language status (English learner vs. English speaker), opportunity to learn, and socioeconomic status (SES). Fourth, because the administration of cognitive and neuropsychological tests should not typically be conducted in the schools (for students suspected of having a learning disability) unless a student fails to respond as expected to evidence-based instruction and intervention, a rectangle is included at the top of Figure 12.5 that is labeled, “Difficulty with Classroom Learning and Failure to RTI.” Thus, the framework in Figure 12.5 is a representation of the cognitive constructs that may be measured and the manner in which they relate to one another.

According to Flanagan and colleagues (2010), arrows leading from the “Difficulty with Classroom Learning and Failure to RTI” rectangle to Luria's three functional units of the brain (represented as large circles in Figure 12.5) demonstrate the beginning of a school-based hypothesis-generation, testing, and interpretation process. Luria's functional units are depicted in Figure 12.5 as overarching cognitive concepts. The interaction between, and the interconnectedness among, the functional units

**Figure 12.5** An integrative framework based on psychometric, neuropsychological, and Lurian perspectives.

*Note:* Reproduced with permission from Wiley. Copyright 2010. All rights reserved.

are represented by double-headed arrows. Because Luria's functional units are primarily descriptive concepts designed to guide applied clinical evaluation practices, neuropsychologists have had considerable independence in the manner in which they align their assessments with these concepts (Flanagan et al., 2010).

Although a few psychoeducational batteries have been developed to operationalize one or more of Luria's functional units, for the most part, neuropsychologists have couched Luria's blocks within clinical and neuropsychological domains. In doing so, the Lurian blocks have been transformed somewhat from overarching concepts to domains with more specificity (Flanagan et al., 2010). These domains are listed in rectangles within each of the three functional units (large circles) in Figure 12.5. For example, the neuropsychological domains include: *attention, sensory-motor, and speed (and efficiency)*, corresponding to Block 1; *visual-spatial, auditory-verbal, memory (and learning)*, corresponding to Block 2; and *executive functioning, learning (and memory), and efficiency (and speed)*

corresponding to Block 3. Noteworthy is the fact that the memory and learning domain spans Blocks 2 and 3, and its placement and use of parentheses is intended to convey that memory may be associated primarily with Block 2 (simultaneous/successive) whereas the learning component of this domain is probably more closely associated with Block 3 (planning/metacognition). Likewise, speed and efficiency spans Blocks 1 and 3, and its placement and use of parentheses denote that speed may be associated more with Block 1 (i.e., attention) whereas efficiency seems to be associated more with Block 3 (Flanagan et al., 2010).

Perhaps the most critical juncture of Flanagan and colleagues' (2010) integrative framework is the distinction between functioning at the neuropsychological domain level and functioning at the broad CHC level. As compared to the neuropsychological domains, CHC theory allows for greater specificity of cognitive constructs. Because of structural differences in the conceptualization of neuropsychological domains and CHC broad abilities vis-à-vis factorial complexity, it is not possible

to provide a precise, one-to-one correspondence between these conceptual levels. This is neither a problem nor an obstacle, but simply the reality of differences in perspective among these two lines of inquiry.

As compared to the neuropsychological domains, CHC constructs within the psychometric tradition tend to be relatively distinct because the intent is to measure a single broad ability as purely and independently as possible. This is not to say, however, that the psychometric tradition has completely ignored shared task characteristics in favor of a focus on precision in measuring relatively distinct cognitive constructs. For example, Kaufman provided a “shared characteristic” approach to individual test performance for several intelligence tests including the KABC-II (Kaufman & Kaufman, 2004) and the various Wechsler scales (Kaufman, 1979; see also McCloskey, 2009, McGrew & Flanagan, 1998 and Sattler, 1998). This practice has often provided insight into the underlying cause(s) of learning difficulties, and astute practitioners continue to make use of it. Despite the fact that standardized, norm-referenced tests of CHC abilities were designed primarily to provide information about relatively discrete constructs, performance on these tests can still be viewed within the context of the broader neuropsychological domains. That is, when evaluated within the context of an entire battery, characteristics that are shared among groups of tests on which a student performed either high or low, for example, often provide the type of information necessary to assist in further understanding the nature of an individual’s underlying cognitive function or dysfunction, conceptualized as neuropsychological domains (Flanagan et al., 2010).

The double-headed arrows between neuropsychological domains and CHC abilities in Figure 12.5 demonstrate that the relationship between these constructs is bidirectional. That is, one can conceive of the neuropsychological domains as global entities that are composed of various CHC abilities, just as one can conceive of a particular CHC ability as involving aspects of more than one neuropsychological domain. Flanagan and colleagues’ (2010) conceptualization of the relations between the neuropsychological domains and the CHC broad abilities follows. For the purpose of parsimony the neuropsychological domains are grouped according to their relationship with the Lurian blocks and thus, these domains are discussed as clusters, rather than discussed separately.

### ***Correspondence Between the Neuropsychological Domains and CHC Broad Abilities***

According to Flanagan and colleagues (2010), at least six CHC broad abilities compose the *Attention/Sensory-Motor/Speed (and Efficiency)* neuropsychological cluster, including Psychomotor Abilities (*Gp*), Tactile Abilities (*Gh*), Kinesthetic Abilities (*Gk*), Decision/Reaction Time or Speed (*Gt*)<sup>2</sup>, Processing Speed (*Gs*), and Olfactory Abilities (*Go*)<sup>3</sup>. *Gp* involves the ability to perform body movements with precision, coordination, or strength. *Gh* involves the sensory receptors of the tactile (touch) system, such as the ability to detect and make fine discriminations of pressure on the surface of the skin. *Gk* includes abilities that depend on sensory receptors that detect bodily position, weight, or movement of the muscles, tendons, and joints. Because *Gk* includes sensitivity in the detection, awareness, or movement of the body or body parts and the ability to recognize a path the body previously explored without the aid of visual input (e.g., blindfolded), it may involve some visual-spatial processes, but the input remains sensory-based and thus better aligned with the sensory-motor domain. *Gt* involves the ability to react and/or make decisions quickly in response to simple stimuli, typically measured by chronometric measures of reaction time or inspection time. *Gs* is the ability to automatically and fluently perform relatively easy or overlearned cognitive tasks, especially when high mental efficiency is required. As measured by current intelligence tests (e.g., WISC-IV Coding, Symbol Search, and Cancellation), *Gs* seems to capture the essence of both speed and efficiency, which is why there are double headed arrows from *Gs* to Block 1 (where *Speed* is emphasized) and Block 3 (where *Efficiency* is emphasized) in Figure 12.5. *Go* involves abilities that depend on sensory receptors of the main olfactory system (nasal chambers). Many of the CHC abilities comprising the *Attention/Sensory-Motor/Speed (and efficiency)* cluster are measured by neuropsychological tests (e.g., Dean-Woodcock; Flanagan et al., 2010).

Prior research suggests that virtually all broad CHC abilities may be subsumed by the *Visual-Spatial/Auditory-Verbal/Memory (and Learning)* neuropsychological cluster. That is, the vast majority of tasks on neuropsychological, intelligence, and cognitive ability tests require either visual-spatial or auditory-verbal input. Apart from tests that relate more to discrete sensory-motor functioning and

that utilize sensory input along the kinesthetic, tactile, or olfactory systems, all other tests will necessarily rely either on visual-spatial or auditory-verbal stimuli. Certainly, visual ( $Gv$ ) and auditory ( $Ga$ ) processing are measured well on neuropsychological and cognitive instruments. Furthermore, tests of Short-Term Memory ( $Gsm$ ) and Long-Term Storage and Retrieval ( $Glr$ ) typically rely on visual (e.g., pictures) or verbal (digits or words) information for input. Tasks that involve reasoning ( $Gf$ ), stores of acquired knowledge (viz.,  $Gc$ ), and even speed ( $Gs$ ) also use either visual-spatial and/or auditory-verbal channels for input. Furthermore, it is likely that such input will be processed in one of two possible ways—simultaneously or successively (Flanagan et al., 2010).

And last, Flanagan and colleagues (2010) believe that prior research suggests that the *Executive Functioning/Learning (and Memory)/Efficiency (and Speed)* neuropsychological cluster is thought to correspond well with perhaps eight broad CHC abilities, including Fluid Intelligence ( $Gf$ ), Crystallized Intelligence ( $Gc$ ), General (Domain-Specific) Knowledge Ability ( $Gkn$ ), Quantitative Knowledge ( $Gq$ ), Broad Reading and Writing Ability ( $Grw$ ), Processing Speed ( $Gs$ ), Short-Term Memory ( $Gsm$ ), and Long-Term Storage and Retrieval ( $Glr$ ).  $Gf$  generally involves the ability to solve novel problems using inductive, deductive, and/or quantitative reasoning and, therefore, is most closely associated with executive functioning.  $Gc$  represents one's stores of acquired knowledge (e.g., vocabulary, general information) or "learned" information and is entirely dependent on language, the ability that Luria believed was necessary to mediate all aspects of learning. In addition, Domain-Specific Knowledge ( $Gkn$ ), together with knowledge of Reading/Writing ( $Grw$ ) and Math ( $Gq$ ), reflect the *learning* component of "memory and learning." Therefore,  $Gc$ ,  $Gkn$ ,  $Grw$ , and  $Gq$  are included as part of this cluster.  $Gsm$ , especially working memory, and  $Glr$  appear to require executive functions, such as planning and organizing.

As may be seen in Figure 12.5, Flanagan and colleagues (2010) have placed the CHC *narrow* abilities at the *discrete* end of the integrated-discrete continuum. Noteworthy is the fact that narrow ability deficits tend to be more amenable to remediation, accommodation, or compensatory strategy interventions as compared to broad and more overarching abilities. For example, poor memory span, a narrow ability subsumed by the broad ability,  $Gsm$ , can often be compensated for effectively via the use

of strategies such as writing things down or recording them in some manner for later reference. In contrast, when test performance suggests more pervasive dysfunction, as may be indicated by deficits in one or more global neuropsychological domains, for example, the greater the likelihood that intervention will need to be broader, perhaps focusing on the type of instruction being provided to the student and how the curriculum ought to be modified and delivered to improve the student's learning (Flanagan et al., 2011; Fiorello et al., 2008). An example of the applicability of this framework may be seen in Table 12.8, which includes an example of how the WISC-IV was classified via the framework depicted in Figure 12.5 (Flanagan, Alfonso, Mascolo, & Hale, 2011; for classifications of other intelligence and neuropsychological batteries, see Flanagan et al., 2010).

### Greater Emphasis on Flexible Battery Approaches

As our understanding of cognitive abilities continues to unfold and as we begin to gain a greater understanding of how school neuropsychology will influence the practice of intelligence and cognitive ability test interpretation, it seems clear that the breadth and depth of information we can garner from our tests is ever increasing. In light of the recent expansion of CHC theory and the integration of this theory with neuropsychological theories, it will remain unlikely that an individual intelligence, cognitive ability, or neuropsychological battery will provide adequate coverage of the full range of abilities and processes that may be relevant to any given evaluation purpose or referral concern. The development of a battery that fully operationalizes CHC theory, for example, is likely to be extremely labor-intensive and prohibitively expensive for the average practitioner, school district, clinic, or university training program. Therefore, flexible battery approaches are likely to remain essential within the repertoire of practice for most professionals. By definition, flexible battery approaches offer an efficient and practical method by which practitioners may evaluate a broad range of human cognitive abilities and processes. In this section, we summarize one such flexible battery approach, XBA, because it is grounded in CHC theory and is based on sound psychometric principles and procedures.

The XBA was introduced by Flanagan and her colleagues about 15 years ago (Flanagan & McGrew, 1997; Flanagan, McGrew, & Ortiz, 2000;

Note:  $Gf$  = Fluid Intelligence;  $Gc$  = Crystallized Intelligence;  $Gsm$  = Short-Term Memory;  $Gv$  = Visual Processing;  $Gs$  = Processing Speed. RQ = Quantitative Reasoning; MW = Working Memory; SR = Spatial Relations; Vz = Visualization; P = Perceptual Speed; R9 = Rate-of-Test-Taking; K0 = General (verbal) Knowledge; MS = Memory Span; I = Induction; RG = General Sequential Reasoning; CF = Flexibility of Closure; VL = Lexical Knowledge. The following Cattell-Horn-Carroll (CHC) broad abilities are omitted from this table because none is a primary ability measured by the WISC-IV:  $Gh$  (Tactile Abilities);  $Gk$  (Kinesthetic Abilities);  $Gp$  (Psychomotor Abilities);  $Gkn$  (General [domain-specific] Knowledge);  $Gq$  (Quantitative Knowledge);  $Glr$  (Long-Term Storage and Retrieval);  $Ga$  (Auditory Processing);  $Gt$  = (Decision/Reaction Time or Speed);  $Grw$  (Reading and Writing Ability);  $Go$  (Olfactory Abilities); and  $Gps$  (Psychomotor Speed). Most CHC test classifications are from *Essentials of Cross-Battery Assessment, 2nd edition* (Flanagan, Ortiz, & Alfonso, 2007). Classifications according to neuropsychological domains were based on the authors' readings of neuropsychological texts (e.g., Fletcher-Janzen & Reynolds, 2008; Hale & Fiorello, 2004; Lezak, 1995; Miller, 2007).

Flanagan & Ortiz, 2001; McGrew & Flanagan, 1998). It provides practitioners with the means to make systematic, reliable, and theory-based interpretations of cognitive batteries and to augment them with other cognitive ability subtests, including subtests from academic and neuropsychological instruments, to gain a more complete understanding of an individual's strengths and weaknesses (Flanagan et al., 2007, 2013). Moving beyond the boundaries of a single cognitive, achievement, or neuropsychological battery by adopting the theoretically and psychometrically defensible XBA principles and procedures allows practitioners the flexibility necessary to measure the cognitive constructs and neurodevelopmental functions that are most germane to referral concerns (e.g., Carroll, 1998; Decker, 2008; Kaufman, 2000; Wilson, 1992).

According to Carroll (1997), the CHC taxonomy of human cognitive abilities "appears to prescribe that individuals should be assessed with respect to the total range of abilities the theory specifies" (p. 129). However, because Carroll recognized that "any such prescription would of course create enormous problems," he indicated that "[r]esearch is needed to spell out how the assessor can select what abilities need to be tested in particular cases" (p. 129). Flanagan and colleagues' XBA approach was developed specifically to "spell out" how practitioners can conduct assessments that approximate the total range of cognitive and academic abilities and neuropsychological processes more adequately than what is possible with any collection of co-normed tests.

In a review of the XBA approach, Carroll (1998) stated that it "can be used to develop the most appropriate information about an individual in a given testing situation" (p. xi). More recently, Decker (2008) stated that the XBA approach "may improve school psychology assessment practice and facilitate the integration of neuropsychological methodology in school-based assessments...[because it] shift[s] assessment practice from IQ composites to neurodevelopmental functions" (p. 804).

Noteworthy is the fact that assessment professionals "crossed" batteries well before Woodcock (1990) recognized the need to do so and before Flanagan and her colleagues introduced the XBA approach in the late 1990s, following his suggestion. Neuropsychological assessment has long adopted the practice of crossing various standardized tests in an attempt to measure a broader range of brain functions than that offered by any single

instrument (Lezak, 1976, 1995; Lezak, Howieson, & Loring, 2004; also see Wilson, 1992 for a review). Nevertheless, several problems with crossing batteries plagued assessment-related fields for years. Many of these problems have been circumvented by Flanagan and colleagues' XBA approach (see Table 12.9 for examples). But unlike the XBA model, the various so-called cross-battery techniques applied within the field of neuropsychological assessment, for example, are not typically grounded in a systematic approach that is theoretically and psychometrically sound. Thus, as Wilson (1992) cogently pointed out, the field of neuropsychological assessment was in need of an approach that would guide practitioners through the selection of measures that would result in more specific and delineated patterns of function and dysfunction—an approach that provided more clinically useful information than one that was "wedded to the utilization of subscale scores and IQs" (p. 382). Indeed, all fields involved in the assessment of cognitive and neuropsychological functioning have some need for an approach that would aid practitioners in their attempt to "touch all of the major cognitive areas, with emphasis on those most suspect on the basis of history, observation, and on-going test findings" (Wilson, 1992, p. 382). The XBA approach has met this need. A brief definition of and rationale for XBA is presented next.

### ***Definition of the XBA Approach***

The XBA approach is a method of assessing cognitive and academic abilities and neuropsychological processes that is grounded mainly in CHC theory and research. It allows practitioners to measure reliably a wider range (or a more in depth but selective range) of ability constructs than that represented by any given stand-alone assessment battery. The XBA approach is based on three foundational sources of information (Flanagan et al., 2007, 2013) that together provide the knowledge base necessary to organize theory-driven, comprehensive assessments of cognitive, achievement, and neuropsychological constructs.

### ***The Foundation of the XBA Approach***

The foundation of the XBA approach rests on contemporary CHC theory and the broad and narrow CHC ability classifications of all subtests that comprise current cognitive, achievement, and selected neuropsychological batteries. Because CHC theory was described previously, we will focus here on the classifications of tests.

**Table 12.9 Parallel Needs in Cognitive Assessment–Related Fields Addressed by the XBA Approach**

Need Within Assessment-Related Fields <sup>1</sup>	Need Addressed by the XBA Approach
School psychology, clinical psychology, and neuropsychology have lagged in the development of conceptual models of the assessment of individuals. There is a need for the development of contemporary models.	The XBA approach provides a contemporary model for measurement and interpretation of cognitive and academic abilities and neuropsychological processes.
It is likely that there is a need for events external to a field of endeavor to give impetus to new developments and real advances in that field.	Carroll and Horn's <i>Fluid-Crystallized</i> theoretical models (and more recently, Schneider and McGrew's CHC model) and research in cognitive psychology and neuropsychology provided the impetus for and continued refinements to the XBA approach and led to the development of better assessment instruments and interpretive procedures.
There is a need to utilize a conceptual framework to direct any approach to assessment. This would aid in both the selection of instruments and methods, and in the interpretation of test findings.	The XBA approach to assessment is based mainly on CHC theory, but also neuropsychological theory. Since the XBA approach links all the major intelligence and achievement batteries as well as selected neuropsychological instruments to CHC theory, in particular, both selection of tests and interpretation of test findings are made easier.
It is necessary that the conceptual framework or model underlying assessment incorporates various aspects of neuropsychological and cognitive ability function that can be described in terms of constructs which are recognized in the neuropsychological and cognitive psychology literature.	The XBA approach incorporates various aspects of neuropsychological and cognitive ability functions that are described in terms of constructs that are recognized in the literature. In fact, a consistent set of terms and definitions within the CHC literature (e.g., Schneider & McGrew, 2012) and the neuropsychology literature (e.g., Miller, in press) underlie the XBA approach.
There is a need to adopt a conceptual framework that allows for the measurement of the full range of behavioral functions subserved by the brain. Unfortunately, in neuropsychological assessment there is no inclusive set of measures that is standardized on a single normative population.	XBA assessment allows for the measurement of a wide range of broad and narrow cognitive abilities specified in CHC theory and neuropsychological processes specified by neuropsychology theory and research. Although an XBA norm group does not exist, the crossing of batteries and the interpretation of assessment results are based on sound psychometric principles and procedures.
Because there are no truly unidimensional measures in psychological assessment, there is a need to select subtests from standardized instruments that appear to reflect the neurocognitive function of interest. In neuropsychological assessment, the aim, therefore, is to select those measures that, on the basis of careful task analysis, appear mainly to tap a given construct.	The XBA approach is defined, in part, by a CHC classification system. The majority of subtests from the major intelligence and achievement batteries as well as selected neuropsychological instruments were classified empirically as measures of broad and narrow CHC constructs (either via CHC within- or cross-battery factor analysis or expert consensus, or both). In addition, the subtests of intelligence and neuropsychological batteries were classified according to several neuropsychological domains (e.g., attention, visual-spatial, auditory-verbal, speed and efficiency, executive). Use of evidence-based classifications allows practitioners to be reasonably confident that a given test taps a given construct.
It is clear that an eclectic approach is needed in the selection of measures, preferably subtests rather than the omnibus IQs, in order to gain more specificity in the delineation of patterns of function and dysfunction.	The XBA approach ensures that two or more relatively pure, but qualitatively different, indicators of each <i>broad</i> cognitive ability are represented in a complete assessment. Two or more qualitatively similar indicators are necessary to make inferences about specific or <i>narrow</i> CHC abilities. This process is eclectic in its selection of measures.
There is a need to solve the potential problems that can arise from crossing normative groups as well as sets of measures that vary in reliability.	In the XBA approach, one can typically achieve baseline data in cognitive functioning across seven to nine CHC broad abilities through the use of only two well-standardized batteries, which minimizes the effects of error due to norming differences. Also, since interpretation of both broad and narrow CHC abilities is made at the cluster (rather than subtest) level, issues related to low reliability are less problematic in this approach. Finally, because cross-battery clusters are generated using estimated median reliabilities and intercorrelations, the data yielded by this approach are psychometrically sound.

1. Information obtained, in part, from Wilson, B.C. (1992). The neuropsychological assessment of the preschool child: A branching model. In I. Rapin & S. I. Segalowitz (Eds.), *Handbook of neuropsychology: Child neuropsychology* (Vol. 6) (pp. 377–394).

## **CHC BROAD (STRATUM II) CLASSIFICATIONS OF COGNITIVE, ACHIEVEMENT, AND NEUROPSYCHOLOGICAL TESTS**

Based on the results of a series of cross-battery confirmatory factor analysis studies of the major intelligence batteries (see Keith & Reynolds, 2010, for a review) and the task analyses of many cognitive test experts, Flanagan and colleagues classified all the subtests of the major cognitive and achievement batteries, as well as selected neuropsychological batteries according to the particular CHC broad abilities they measured (e.g., Flanagan et al., 2006, 2007, 2013; McGrew, 1997; McGrew & Flanagan, 1998; Reynolds, Keith, Flanagan, & Alfonso, in press). To date, more than 100 batteries and 700 subtests have been classified according to the CHC broad and narrow abilities they measure, based in part on the results of these studies (see Flanagan et al., 2013). The CHC classifications of cognitive, achievement, and neuropsychological batteries assist practitioners in identifying measures that assess the various broad and narrow abilities represented in CHC theory.

Classification of tests at the broad ability level is necessary to improve the validity of cognitive assessment and interpretation. Specifically, broad ability classifications ensure that the CHC constructs that underlie assessments are minimally affected by *construct-irrelevant variance* (Messick, 1989, 1995). In other words, knowing which tests measure what abilities enables clinicians to organize tests into *construct-relevant* clusters—clusters that contain only measures that are *relevant to* the construct or ability of interest (McGrew & Flanagan, 1998).

To clarify, *construct-irrelevant variance* is present when an “assessment is too broad, containing excess reliable variance associated with other distinct constructs...that affects responses in a manner irrelevant to the interpreted constructs” (Messick, 1995, p. 742). For example, the WISC-IV Perceptual Reasoning Index (PRI) contains construct-irrelevant variance because, in addition to its two indicators of *Gf* (i.e., Picture Concepts, Matrix Reasoning), it has an indicator of *Gv* (i.e., Block Design). Therefore, the PRI is a *mixed* measure of two relatively distinct, broad CHC abilities (*Gf* and *Gv*); it contains reliable variance (associated with *Gv*) that is irrelevant to the interpreted construct of *Gf*. Through CHC-driven confirmatory factor analysis (CFA), Keith et al. (2006) showed that a five-factor model that included *Gf* and *Gv* (in lieu of PRI) fit the WISC-IV standardization data well. As a result of their analysis, *Gf* and *Gv* composites for the WISC-IV were provided in Flanagan and Kaufman (2004, 2009) and are

recommended in the XBA approach because they contain only construct-*relevant* variance (Flanagan et al., 2013). The ongoing cross-battery CFAs conducted by Keith and colleagues will continue to lead to improvements in how cognitive subtests are classified in general, and organized within the context of XBA in particular (e.g., Reynolds et al., in press).

## **CHC NARROW (STRATUM I) CLASSIFICATIONS OF COGNITIVE, ACADEMIC AND NEUROPSYCHOLOGICAL TESTS**

Narrow ability classifications were originally reported in McGrew (1997), then later reported in McGrew and Flanagan (1998) and Flanagan, McGrew, and Ortiz (2000) following minor modifications. Flanagan and her colleagues continued to gather content validity data on cognitive ability tests and expanded their analyses to include tests of academic achievement (Flanagan et al., 2002; 2006) and more recently tests of neuropsychological processes (Flanagan et al., 2010, 2013). Classifications of cognitive ability tests according to content, format, and task demand at the narrow (stratum I) ability level were necessary to improve further upon the validity of intellectual assessment and interpretation (see Messick, 1989). Specifically, these narrow ability classifications were necessary to ensure that the CHC constructs that underlie assessments are well represented (McGrew & Flanagan). According to Messick (1995), *construct underrepresentation* is present when an “assessment is too narrow and fails to include important dimensions or facets of the construct” (p. 742).

Interpreting the WJ III Concept Formation (CF) test as a measure of Fluid Intelligence (i.e., the broad *Gf* ability) is an example of construct underrepresentation. This is because CF measures *one* narrow aspect of *Gf* (viz., Inductive Reasoning). At least one other *Gf* measure (i.e., subtest) that is qualitatively different from Inductive Reasoning is necessary to include in an assessment to ensure adequate representation of the *Gf* construct (e.g., a measure of General Sequential [or Deductive] Reasoning). Two or more qualitatively different indicators (i.e., measures of two or more narrow abilities subsumed by the broad ability) are needed for adequate construct representation (Comrey, 1988; Keith & Reynolds, 2012; Messick, 1989, 1995). The aggregate of CF (a measure of Inductive Reasoning at the narrow ability level) and the WJ III Analysis-Synthesis test (a measure of Deductive Reasoning at the narrow ability level), for example, would provide an adequate estimate of the broad *Gf* ability because these

tests are strong measures of  $Gf$  and represent qualitatively different aspects of this broad ability (see Flanagan et al., 2013 for additional examples).

In short, the classifications of tests at the broad and narrow ability levels of CHC theory guard against two ubiquitous sources of invalidity in assessment: construct-irrelevant variance and construct underrepresentation. In addition, these classifications augment the validity of test performance interpretation. Taken together, the CHC classifications of tests that underlie the XBA approach provide the necessary foundation upon which to organize assessments and interpret assessment results in a manner that is comprehensive and supported by theory and research.

### ***Application of the XBA Approach***

#### **GUIDING PRINCIPLES**

In order to ensure that XBA procedures are theoretically and psychometrically sound, it is recommended that practitioners adhere to several guiding principles (McGrew & Flanagan, 1998). First, select a comprehensive ability battery as your core battery in assessment. It is expected that the battery of choice will be one that is deemed most responsive to referral concerns. These batteries may include, but are certainly not limited to, the major intelligence, cognitive, academic, and neuropsychological batteries. It is important to note that the use of co-normed tests, such as the WJ III tests of cognitive ability and tests of achievement and the KABC-II and KTEA-II, may allow for the widest coverage of broad and narrow CHC abilities and processes.

Second, use subtests and *clusters/composites* from a single battery whenever possible, to represent broad CHC abilities. In other words, best practices involve using actual norms whenever they are available, in lieu of various other methods of aggregating scores (e.g., averaging, use of formulae). Because the development of current intelligence and cognitive ability batteries benefited greatly from CHC theory and research, the practice of averaging scores or using formulae to create cross-battery composites is seldom necessary at the *broad ability level*. However, aggregating scores across batteries continues to be necessary at the narrow ability level and when testing hypotheses about aberrant performance within broad ability domains. In these circumstances, Flanagan and colleagues provide a psychometrically defensible method for aggregating scores from different batteries that is based on formulae that incorporate test reliability and test intercorrelations (see Flanagan et al., 2013, for details).

Third, when constructing CHC broad and narrow ability clusters, select tests that have been classified through an acceptable method, such as through CHC theory-driven within-battery or preferably cross-battery factor analyses and/or expert consensus content validity studies. All test classifications included in the works of Flanagan and colleagues have been classified through these methods (Flanagan et al., 2007, 2013). Furthermore, to ensure appropriate construct representation when constructing broad (stratum II) ability composites, *two or more qualitatively different*, narrow (stratum I) ability indicators should be included to represent each domain. Of course, it seems likely that the more broadly an ability is represented (i.e., through the derivation of composites based on *multiple* qualitatively different, narrow ability indicators), the more confidence one would have in drawing inferences about the broad ability underlying a composite. A minimum of two qualitatively different indicators per CHC broad ability is recommended in the XBA approach mainly for practical reasons (i.e., time-efficient assessment). Noteworthy is the fact that most commonly used intelligence tests include at least two qualitatively different indicators (subtests) to represent broad abilities, which is why constructing broad ability clusters in the XBA approach is seldom necessary.

Fourth, when at least two qualitatively different indicators of a broad ability of interest are not available on the core battery, then supplement the core battery with at least two qualitatively different indicators of that broad ability from another battery. In other words, if an evaluator is interested in measuring Auditory Processing ( $Ga$ ), and the core battery includes only one or no  $Ga$  subtests, then select a  $Ga$  *cluster* from another battery to supplement the core battery. This practice ensures that actual norms are used when interpreting broad ability performance.

Fifth, when crossing batteries (e.g., augmenting a core battery with relevant CHC clusters from another battery) or when constructing CHC broad or narrow ability clusters using tests from different batteries, select tests that were developed and normed within a few years of one another to minimize the effect of spurious differences between test scores that may be attributable to the “Flynn effect” (Flynn, 1984; Kaufman & Weiss, 2010). The tests that have been recommended by Flanagan and her colleagues in their most recent XBA books include only those that were normed within 10 years of one another (Flanagan et al., 2006, 2007, 2012).

Sixth, select tests from the smallest number of batteries to minimize the effect of spurious differences between test scores that may be attributable to differences in the characteristics of independent norm samples (McGrew, 1994). In many cases, using selected tests from one battery to augment the constructs measured by any other comprehensive ability battery is sufficient to represent a significant breadth of broad cognitive abilities adequately (i.e., about seven broad abilities), as well as to allow for at least three qualitatively different narrow ability indicators of the broad abilities (Flanagan et al., 2007).

Seventh, establish ecological validity for any and all test performances that are suggestive of normative weaknesses or deficits. The finding of a cognitive weakness or deficit is largely meaningless without evidence of how the weakness is manifested in activities of daily living, including academic achievement (Flanagan et al., 2011, 2013). The validity of test findings is bolstered when clear connections are made between the cognitive dysfunction (as measured by standardized tests) and the educational impact of that dysfunction; for example, as observed in classroom performance and as may be gleaned from a student's work samples.

When the XBA guiding principles are implemented systematically and the recommendations for development, use, and interpretation of clusters are adhered to, the potential error introduced through the crossing of norm groups is negligible (Flanagan et al., 2007). Additionally, the authors of *Essentials of Cross-Battery Assessment* (2nd and 3rd editions) included software with their books to facilitate the implementation of the XBA method and aid in the interpretation of cross-battery data (see Flanagan et al., 2007, 2013).

### ***The XBA Approach in Perspective***

The XBA approach is a method that allows practitioners to augment or supplement any ability battery to ensure measurement of a wider range of cognitive and academic abilities, and neuropsychological processes, in a manner consistent with contemporary theory and research. The foundational sources of information upon which the XBA approach was built (e.g., the classifications of ability batteries according to CHC theory) along with its guiding principles and steps provide a way to systematically construct a theoretically driven, comprehensive, and valid assessment of abilities and processes. For example, when the XBA approach is applied to the Wechsler Intelligence Scales, it is possible to measure important abilities and processes

that would otherwise go unassessed (e.g., *Ga*, *Glr*, *orthographic processing*, *executive functions*)—abilities and processes that are important in understanding acquisition of certain basic academic skills and school learning (e.g., Flanagan et al., 2013).

The XBA approach allows the measurement of the major cognitive areas specified in CHC theory with emphasis on those considered most critical on the basis of history, observation, and available data sources. The CHC classifications of a multitude of ability tests bring stronger content and construct validity evidence to the evaluation and interpretation process. As test development continues to evolve and becomes increasingly more sophisticated (psychometrically and theoretically), batteries of the future will undoubtedly possess stronger content and construct validity. Notwithstanding, it is unrealistic from an economic and practical standpoint to develop a battery that operationalizes contemporary CHC theory fully (Carroll, 1998; Flanagan et al., 2007, 2013). Therefore, it is likely that the XBA approach will become increasingly useful as the empirical support for CHC theory mounts (Reynolds et al., in press).

### **Summary**

The purpose of this chapter was to highlight the progress that has been made in theories of intelligence (particularly psychometric theories), the structure of cognitive ability batteries, and methods of cognitive ability test-interpretation over the past century. The initial part of this chapter traced such influences in each of these areas back to Galton, Burt, Spearman, and others. Early theories of intelligence revolved around notions of a single general factor, or *g*, but steadily advanced into two-factor models (e.g., original *Gf-Gc*), early multiple-factor models (e.g., Thurstone's PMAs), and eventually to current multiple-factor models (e.g., CHC theory).

Cognitive batteries have seldom kept pace with developments in theory, but they nevertheless have shown significant growth and development overall, particularly within the last decade. Whereas the original Stanford-Binet was the first test designed to measure general intelligence or *g*, other tests such as the Wechsler-Bellevue and subsequent Wechsler scales, K-ABC and KACB-II, CAS, DAS and DAS-II, and WJ-R and WJ III continued to expand the range of options available to practitioners in their quest to measure abilities and processes beyond general intelligence.

Not surprisingly, as cognitive batteries expanded and incorporated contemporary theory, methods of interpretation advanced accordingly. It was

discussed that test interpretation began with evaluation of a single factor (*g*) because that was all that was offered by the Stanford-Binet. But as new batteries were developed and later expanded, methods of interpretation followed suit and shifted toward clinical profile analysis, followed by psychometric profile analysis, and on to the present wave, where current theory and its related research base are applied to the understanding of test results.

The latter half of the chapter provided a discussion of what we believe to be an emerging interpretive wave—the fifth wave—which includes refinements to CHC theory at both the broad and narrow ability levels, application of CHC theory to academic outcomes research, integration of CHC and neuropsychological theories, and greater emphasis on flexible battery approaches. The fifth wave is likely to lead to a clearer “road map” for assessment that will allow practitioners to either expand or selectively focus their evaluations as may be necessary and appropriate in the search for underlying causal explanations for learning problems and neurodevelopmental disorders, difficulties in academic skill development, and application of academic skills to acquire content knowledge. But the major result of the fifth wave is likely to be a growing body of research related to outcomes that are predictable and explainable via empirically related abilities and processes. That is, contemporary cognitive assessment within this wave should allow for sufficient illustration of the links between abilities (e.g., cognitive and academic) and neuropsychological processes such that avenues for instruction, intervention, and treatment of individuals who struggle to learn will not only be clear, but also empirically supported.

## Notes

1. This section of the chapter was adapted from Flanagan, Alfonso, Ortiz, and Dynda (2010) with permission from Wiley. 2010. All rights reserved.

2. *Gt* is omitted from Figure 12.5 because commonly used intelligence and neuropsychological batteries do not measure this ability.

3. *Go* is omitted from Figure 12.5 because commonly used intelligence and neuropsychological batteries do not measure this ability and the cognitive and perceptual aspects of this ability have not been studied extensively (McGrew, 2005).

# Principles of Assessment of Aptitude and Achievement

W. Joel Schneider

## Abstract

An idiosyncratic account of the assessment of achievement and aptitudes is presented. Major theories of cognitive abilities are reviewed briefly, with emphasis on the Cattell-Horn-Carroll theory of cognitive abilities. Procedures for combining scores in a statistically and theoretically sound manner are shown. The use of multiple regression applied to individuals is explained. Recommendations about psychological report writing are offered.

**Key Words:** aptitude, achievement, cognitive abilities, psychological assessment, psychological reports

The principles of assessment are like a set of unruly and loosely affiliated wandering tribes. There is no established hierarchy of rules, no “Prince of Principles,” and no royal family. There is no Senate, no Supreme Court, no United Nations. Yet, some members are esteemed by all. Others play partisan politics. Some are pompous windbags, others meek speakers of truth. Some are brilliant but impractical, others practical but limited. Some go unnoticed because they are subtle, others because they are so obvious. Some are widely misunderstood and some have outlived their usefulness. Some appear to be senselessly confining but actually protect us from our own excesses and foibles.

This review will not be a comprehensive account of the principles of assessment of aptitudes and achievement. Were it even feasible, such an account would be too large and detailed to be useful to anyone. Instead, I have focused on essential, practical, or curious aspects of assessment that may have been underemphasized, oversimplified, or simply omitted by the instructor of an introductory cognitive assessment course (or under-appreciated, misunderstood, or dimly remembered if not forgotten by

the students!). I will make a good faith effort in this idiosyncratic account to be candid when I am aware that my opinions may not be widely held.

## Aptitudes and Achievement: Definitions, Distinctions, and Difficulties

“Achievement” typically refers to knowledge and skills that are formally taught in academic settings. However, this definition of achievement can be broadened to include any ability that is valued and taught in a particular cultural setting (e.g., hunting, dancing, or computer programming). “Aptitude” refers to an individual’s characteristics that indicate the potential to develop a culturally valued ability, given the right circumstances. The difference between aptitudes and achievement at the definitional level is reasonably clear. However, at the measurement level, the distinction becomes rather murky.

Potential, which is latent within a person, is impossible to observe directly. It must be inferred by measuring characteristics that either are typically associated with an ability or are predictive of the future development of the ability. Most of

the time, aptitude is assessed by measuring abilities that are considered to be necessary precursors of achievement. For example, children who understand speech have greater aptitude for reading comprehension than do children who do not understand speech. Such precursors may themselves be a form of achievement. For example, it is possible for researchers to consider students' knowledge of history as an outcome variable that is intrinsically valuable. However, some researchers may measure knowledge of history as a predictor of being able to construct a well-reasoned essay on politics. Thus, aptitude and achievement tests are not distinguished by their content, but by how they are used. If we use a test to measure current mastery of a culturally valued ability, it is an achievement test. If we use a test to explain or forecast mastery of a culturally valued ability, it is an aptitude test.

IQ tests are primarily used as aptitude tests. However, an inspection of the contents of most IQ tests reveals that many test items could be repurposed as items in an achievement test (e.g., vocabulary, general knowledge, and mental arithmetic items). Sometimes the normal roles of reading tests and IQ tests are reversed, such as when neuropsychologists estimate loss of function following a brain injury by comparing current IQ to performance on a word-reading test.

A simple method to distinguish between aptitude and achievement is to ask, "Do I care about whether a child has the ability measured by this test because it is inherently valuable or because it is associated with some other ability (the one that I actually care about)?" Most people want children to be able to comprehend what they read. Thus, reading tests are typically achievement tests. Most people are not particularly concerned about how well children can reorder numbers and letters in their heads. Thus, the WISC-IV Number-Letter Sequencing subtest is typically used as an aptitude test, presumably because the ability it measures is a necessary component of being able to master algebra, program computers, follow the chain of logic presented by debating candidates, and other skills that people in our culture care about.

### Mean-spirited Mono-*g*-ists vs. Muddleheaded Poly-*G*-ists

*I hate the impudence of a claim that in fifty minutes you can judge and classify a human being's predestined fitness in life. I hate the pretentiousness of the claim. I hate the abuse of scientific method which it involves.*

*I hate the sense of superiority which it creates, and the sense of inferiority which it imposes.*

—Walter Lippmann, in a 1923 essay on Lewis Terman and the IQ testers

*Most of us have uncritically taken it for granted that children who attend school eight or ten years without passing the fourth grade or surmounting long division are probably stupider than children who lead their classes into high school at twelve years and into college at sixteen. Mr. Lippmann contends that we can't tell anything about how intelligent either one of these children is until he has lived out his life. Therefore, for a lifetime at least, Mr. Lippmann considers his position impregnable!*

—Lewis Terman, in response to Walter Lippmann

Spearman's (1904, 1927) little *g* caused a big stir when it was first proposed, and it has, for over a century now, been disrupting the natural state of harmony that would otherwise prevail amongst academics. Many a collegial tie has been severed, many a friendship has soured, perhaps even engagements broken off and marriages turned into dismal, loveless unions because of the rancor this topic provokes. I have seen otherwise mild-mannered professors in tweed jackets come to blows in bars over disagreements about *g*.<sup>1</sup>

It all began when Spearman observed that mental abilities that he measured were all positively correlated. This observation has been replicated by thousands of studies. No one who is familiar with this gigantic body of evidence doubts that essentially all cognitive abilities are positively correlated. This statistical regularity is typically referred to as the *positive manifold*.<sup>2</sup> You could become an academic superstar (i.e., admired by six or seven other academics) if you were to find a pair of cognitive abilities that are negatively correlated with each other. So far, no one has.<sup>3</sup> Thus, everyone in the know agrees with Spearman on this point. What some people hate is his explanation for it.

Spearman believed (and invented some very fancy statistical procedures to support his argument)<sup>4</sup> that abilities are correlated because all abilities are influenced by a common cause, *g* (general intelligence). Spearman was careful to note that he did not know for certain what *g* was but was not shy about speculating about its nature. He thought that it might be a kind of mental energy, and that some people had a lot of it and some had very little.

The essential points of contention in the Byzantine quarrels between Spearmanian mono-*g*-ists and anti-Spearmanian poly-*G*-ists<sup>5</sup>

have not changed much over the decades. There is some diversity within both groups, but the lines between them are fairly clear. Not only do the mono-*g*-ists insist that *g* be acknowledged as an ability, but they believe that it should be esteemed above all others. Some appear to believe that no ability other than *g* even matters. Some poly-*G*-ists will grant that *g* exists but deem it inconsequential compared to the myriad other abilities that influence the course of a human life. Other poly-*G*-ists deny that *g* exists and are disgusted by the very idea of it.

It turns out that these two groups are not merely on opposite sides of an intellectual debate—they are members of different tribes. They speak different dialects, vote for different candidates, and pray to different gods. Their heroic tales emphasize different virtues, and their foundation myths offer radically different but still internally consistent explanations of how the world works. If you think that the matter will be settled by accumulating more data, you have not been paying attention for the last hundred years.

Poly-*G*-ists do not merely believe that mono-*g*-ists are mistaken but that they are mean-spirited, perhaps evil, or at the very least, Republicans. In their view, the course of human history can be summed up in this manner:

*Since the dawn of time up to the beginning of the twentieth century, humans lived in a paradise of loving harmony and high self-esteem. Then Spearman invented *g* and ruined everything. Previously, Live White Males (for back then they were not yet dead) had been content to be equal to everyone else and were really rather decent fellows. However, many of them were corrupted by Spearman's flattery and convinced themselves they had more *g* than other people. The deceived began to call themselves Fascists and went around disempowering people with nasty labels. Though eventually defeated by George Lincoln King, Jr., in the Civil Liberties War, Fascists still wield influence via college aptitude tests. If we rid the world of all standardized tests, people will no longer label one another, low self-esteem will be eradicated, and a new Utopia will be established.*

On the other side, mono-*g*-ists know that poly-*G*-ists have seen the same data and read the same studies as they have. They believe that the poly-*G*-ists are simply too muddle-headed to understand the data, too blinded by their ideological wishes to see the world as it is, or too fearful of social consequences to proclaim publicly that the emperor has no clothes. In the short epic tragedy

*The Spearmaniad*, mono-*g*-ists find this account of how things came to be:

*In the dark mists of prehistory, life was nasty, brutish, and short. Worse, it was almost impossible to tell the common folk from their betters, and some very mediocre presidents were elected. When the goddess of mathematics looked upon the chaos of the world, she cried crystal tears of pure correlation coefficients. Now Spearman was a mighty statistician, and he gathered the correlations up and arranged them in matrices. From these matrices, he invented factor analysis, from which flowed new knowledge: first IQ tests, then writing, then the wheel. All that was done with factor analysis was beautiful, virtuous, and true. But the brief flowering of civilization that followed was ended when a cabal of ignorant do-gooders objected to the use of IQ tests, presumably because they (or their ugly, talentless children) performed poorly on them. We now stand on the brink of disaster. Giving up IQ tests will be followed immediately by a rapid descent into barbarism. College aptitude tests may postpone or soften the impact of this catastrophe for a little while but cannot avert it entirely.*

The theoretical status of *g* will not cease to be controversial until something extraordinary happens to the field. I do not pretend to know what this might be. Maybe a breakthrough from biology will resolve the matter. Maybe divine intervention. Until then, I feel no need to join either tribe. I will remain agnostic and I will not get too excited the next time really smart people eagerly announce that finally, once and for all, they have proof that the other side is wrong. This has happened too many times before.

## How to Assess Aptitudes If You Are a Mono-*g*-ist

For the mono-*g*-ist, the assessment of aptitudes is rather simple: measure *g* and be done with it. Other abilities may have a little predictive validity beyond *g*, but not enough to make it worth all the additional effort needed (Glutting, Watkins, Konold, & McDermott, 2006). This advice is simple enough, but how does one measure *g* well?

The first step is to select a set of highly *g*-loaded tests. The term *highly g-loaded* simply means “to correlate strongly with statistical *g*.” This raises an important question. If the existence of *g* is in doubt, how can we know if a test correlates with it? To the poly-*G*-ist, this might sound like studying the environmental impact of unicorn overpopulation. The problem is resolved by distinguishing between two different meanings of *g*. First, there is theoretical *g*,

a hypothetical entity thought to have causal relationships with many aspects of daily functioning. This is the *g* that many doubt exists. Second, there is statistical *g*, which is not in question. It is typically defined by a statistical procedure called *factor analysis* (or a closely related procedure called *principal components analysis*). All scholars agree that statistical *g* can be extracted from a correlation matrix and that virtually all cognitive tests correlate positively with it to some degree. Thus, a *g*-hating poly-*G*-ist can talk about a *g*-loaded test without fear of self-contradiction. A highly *g*-loaded test simply has a strong correlation with statistical *g*. A highly *g*-loaded test, then, is by definition highly correlated with many other tests. This means that it is probably a good predictor of academic achievement tests, which are, for the most part, also highly *g*-loaded. A cognitive test with a low *g*-loading (e.g., WJ III Planning or WISC-IV Cancellation) does not correlate with much of anything except itself. Mono-*g*-ists avoid such tests whenever possible (but Poly-*g*-ists love them—if they can be found to be uniquely predictive of an important outcome).

The second step to estimate *g* is to make sure that the highly *g*-loaded tests you have selected are as different from each other as possible in terms of item content and response format. To select highly similar tests (e.g., more than one vocabulary test) will contaminate the estimate of *g* with the influence of narrow abilities, which, to the mono-*g*-ist, are unimportant.

Fortunately, cognitive ability test publishers have saved us much trouble and have assembled such collections of subtests to create composite scales that can be used to estimate *g*. Such composite scores go by many different names,<sup>6</sup> but I will refer to them as IQ scores. These operational measures of *g* tend to correlate strongly with one another, mostly in the range of 0.70 to 0.80 but sometimes as low as 0.60 or as high as 0.90 (Kamphaus, 2005). Even so, they are not perfectly interchangeable. If both tests have the traditional mean of 100 and standard deviation of 15, the probability that the two scores will be within a certain range of each other can be found in Table 13.1.<sup>7</sup> For example, for a person who takes two IQ tests that are correlated at 0.80, there is a 29% chance that the IQ scores will differ by 10 points or more.

If a person has two or more IQ scores that differ by a wide margin, it does not necessarily mean that something is wrong. To insist on perfect correlations between IQ tests is not realistic and not fair.<sup>8</sup> However, when a child has taken two IQ tests

**Table 13.1 What Is The Probability That a Person's Scores on Two IQ Tests Will Differ by the Specified Amount or More?**

Difference	Probability if the IQ tests correlate at $r =$			
	0.60	0.70	0.80	0.90
> 5	0.71	0.67	0.60	0.46
> 10	0.46	0.39	0.29	0.14
> 15	0.26	0.20	0.11	0.03
> 20	0.14	0.09	0.03	0.003
> 25	0.06	0.03	0.01	0.0002

recently and the scores are different, it raises the question of which IQ is more accurate.

### Can't Decide Which IQ Is Best? Make a Composite Score<sup>9</sup>

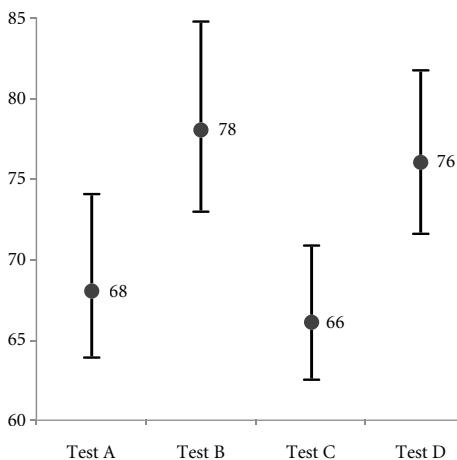

*A man with a watch knows what time it is. A man with two watches is never sure.*

—Segal's Law

Suppose you have been asked to settle a matter with important implications for an evaluatee. A young girl was diagnosed with mental retardation three years ago. Along with low adaptive functioning, her Full Scale IQ was a 68, two points under the traditional line used to diagnose mental retardation. Upon re-evaluation two months ago, her IQ, derived from a different test, was now 78. Worried that their daughter would no longer qualify for services, the family paid out of pocket to have their daughter evaluated by another psychologist, and the IQ came out as 66. Because of your reputation for being fair-minded and knowledgeable, you have been asked to decide which, if any, is the real IQ. Of course, there is no such thing as a "real IQ," but you understand what the referral question is.

You give a different battery of tests, and the girl scores a 76. Now what should be done? It would be tempting to assume that "other psychologists are sloppy, whereas my results are free of error." However, you are fair-minded. You know that all scores have measurement error, and you plot the scores and their 95% confidence intervals as seen in Figure 13.1.

It is clear that Test C's confidence interval does not overlap with those of Tests B and D. Is this kind of variability in scores unusual?<sup>10</sup> There are two tests that indicate an IQ in the high 60s

**Figure 13.1** Recent IQ Scores and Their 95% Confidence Intervals from the Same Individual.

and two tests that indicate an IQ in the high 70s. Which pair of tests is correct? Should the poor girl be subjected to yet another test that might act as a tie breaker?

Perhaps the fairest solution is to treat each IQ test as a subtest of a much larger “Mega-IQ Test.” That is, perhaps the best that can be done is to combine the four IQ scores into a single score and then construct a confidence interval around it.

Where should the confidence interval be centered? Intuitively, it might seem reasonable to simply average all four IQ results and say that the IQ is 72. However, this is not quite right. Averaging scores gives a rough approximation of a composite score, but it is less accurate for low and high scorers than it is for scorers near the mean. An individual’s composite score is further away from the population mean than the average of the individual’s subtest scores. About 3.1% of people score a 72 or lower on a single IQ test (assuming perfect normality). However, if we were to imagine a population of people who took all four IQ tests in question, only 1.9% of them would have an average score of 72 or lower. That is, it is more unusual to have a mean IQ of 72 than it is to score a 72 IQ on any particular IQ test. It is unusual to score 72 on one IQ test, but it is even more unusual to score that low on more than one test on average. Another way to think about this issue is to recognize that the mean score cannot be interpreted as an IQ score, because it has a smaller standard deviation than IQ scores have. To make it comparable to IQ, it needs to be rescaled so that it has a “standard” standard deviation of 15.

Here is a good method for computing a composite score and its accompanying 95% confidence interval. It is not nearly so complicated as it might seem at first glance. This method assumes that you know the reliability coefficients of all the scores and you know all the correlations between the scores. All scores must be index scores ( $\mu = 100$ ,  $\sigma = 15$ ). If they are not, they can be converted using this formula:

$$\text{Index Score} = 15 \left( \frac{X - \mu}{\sigma} \right) + 100$$

### ***Computing a Composite Score***

Step 1: Add up all of the scores.  
In this case,

$$68 + 78 + 66 + 76 = 288$$

Step 2: Subtract the number of tests times 100.  
In this case there are 4 tests. Thus,

$$288 - 4 * 100 = 288 - 400 = -112$$

Step 3: Divide by the square root of the sum of all the elements in the correlation matrix.

In this case, suppose that the four tests are correlated as follows:

	Test A	Test B	Test C	Test D
Test A	1	0.80	0.75	0.85
Test B	0.80	1	0.70	0.71
Test C	0.75	0.70	1	0.78
Test D	0.85	0.71	0.78	1

The sum of all 16 elements, including the ones in the diagonal, is 13.18. The square root of 13.18 is about 3.63. Thus,

$$-112 / 3.63 = -30.85$$

Step 4: Complete the computation of the composite score by adding 100.

In this case,

$$-30.82 + 100 = 69.18$$

Given the four IQ scores available, assuming that there is no reason to favor one above the others, the best estimate is that her IQ is 69. Most of the time,

there is no need for further calculation. However, we might like to know how precise this estimate is by constructing a 95% confidence interval around this score.

### Confidence Intervals of Composite Scores

Calculating a 95% confidence interval is more complicated than the calculations above, but not overly so.

Step 1: Calculate the composite reliability.

Step 1a: Subtract the number of tests from the sum of the correlation matrix.

In this case, there are 4 tests. Therefore,

$$13.18 - 4 = 9.18$$

Step 1b: Add in all the test reliability coefficients.

In this case, suppose that the four reliability coefficients are 0.97, 0.96, 0.98, and 0.97. Therefore,

$$9.18 + 0.97 + 0.96 + 0.98 + 0.97 = 13.06.$$

Step 1c: Divide by the original sum of the correlation matrix.

In this case,

$$13.06 / 13.18 \approx 0.9909$$

Therefore, in this case, the reliability coefficient of the composite score is higher than that of any single IQ score. This makes sense: given that we have four scores, we should know what her IQ is with greater precision than we would if we only had one score.

Step 2: Calculate the standard error of the estimate by subtracting the reliability coefficient squared from the reliability coefficient and taking the square root. Then, multiply by the standard deviation, 15.

In this case,

$$15\sqrt{0.9909 - 0.9909^2} \approx 1.4247$$

Step 3: Calculate the 95% margin of error by multiplying the standard error of the estimate by 1.96.

In this case,

$$1.96 * 1.4247 \approx 2.79$$

The value 1.96 is the approximate z-score associated with the 95% confidence interval. If you want the z-score associated with a different margin of

error, then use the following Excel formula. Shown here is the calculation of the z-score for a 99% confidence interval:

$$=NORMSINV(1-(1-0.99)/2)$$

Step 4: Calculate the estimated true score by subtracting 100 from the composite score, multiplying the reliability coefficient, and adding 100. That is,

$$\text{Estimated True Score} = \text{Reliability Coefficient} * (\text{Composite} - 100) + 100$$

In this case,

$$0.9909 * (69.18 - 100) + 100 = 69.46$$

Step 5: Calculate the upper and lower bounds of the 95% confidence interval by starting with the estimated true score and then adding and subtracting the margin of error.

In this case,

$$69.46 \pm 2.79 = 66.67 \text{ to } 72.25$$

This means that we are 95% sure that her IQ is between about 67 and 72. Assuming that other criteria for mental retardation are met, this is in the range to qualify for services in most states. It should be noted that this procedure can be used for any kind of composite score, not just for IQ tests.

### Potential Misconceptions about Potential

If you are a mono-*g*-ist, you can use the estimate of *g* (IQ) to get an idea of what is the typical range of achievement scores for a child with that IQ. Not every child with the same IQ will have the same achievement scores.<sup>11</sup> Not even mono-*g*-ists believe that. Also, it is simply not true that achievement cannot be higher than IQ. Equally false is the assumption that if achievement is higher than IQ, then the IQ is wrong. These misconceptions are based on two premises: one true, the other false. If potential is the range of all possible outcomes, it is logically true that people cannot exceed their potentials. The false premise is that IQ and achievement tests are measured on the “potential scale.” By analogy, if I say, “This thermometer reads -10 degrees. I know from my understanding of physics that Brownian motion never stops and thus no temperature dips below zero. Therefore, this thermometer is incorrect.” My premise is true, if the thermometer is on the Kelvin scale. However, it is on the Celsius scale, so there is no reason to believe that something is

amiss. IQ and achievement simply are not measured on the “potential scale.” They are measured with standard scores, which are transformed deviations from a population mean. Because of this, about half of all people have academic achievement scores that are higher than their own IQ. There is nothing wrong with this.

## Predicted Achievement Using Simple Linear Regression

There are two ways to make an estimate of a person’s abilities. A *point estimate* (a single number) is precise but usually wrong, whereas an *interval estimate* (a range of numbers) is usually right but can be so wide that it is nearly useless. Confidence intervals combine both types of estimates in order to balance the weaknesses of one type of estimate with the strengths of the other. If I say that Suzie’s expected reading comprehension is  $85 \pm 11$ , the 85 is the point estimate (also known as the “expected score,” or the “predicted score,” or just “ $\hat{Y}$ ”). The  $\pm 11$  is called the *margin of error*. If the confidence level is left unspecified, by convention we mean the 95% margin of error. If I add 11 and subtract 11 to get a range from 74 to 96, I have the respective lower and upper bounds of the 95% confidence interval.

## Calculating the Predicted Achievement Score

I will assume that both the IQ and achievement scores are index scores ( $\mu = 100$ ,  $\sigma = 15$ ) to make things simple. The predicted achievement score is a point estimate. It represents the best guess we can make in the absence of other information. The equation below is called a *regression equation*.

$$\hat{Y} = \sigma_Y r_{XY} \frac{X - \mu_X}{\sigma_X} + \mu_Y$$

If  $X$  is IQ,  $\hat{Y}$  is the predicted Achievement score, and both scores are index scores ( $\mu = 100$ ,  $\sigma = 15$ ), the regression equation simplifies to:

$$\text{Predicted achievement} = (\text{Correlation between IQ and Achievement}) (IQ - 100) + 100$$

## Calculating the Confidence Interval for the Predicted Achievement Score

Whenever you make a prediction using regression, your estimate is not exactly right very often. It is expected to differ from the actual achievement score by a certain amount (on average). This amount is called the *standard error of the estimate*. It

is the standard deviation of all the prediction errors. Thus, it is the *standard* to which all the *errors* in your *estimates* are compared. When both scores are index scores, the formula is:

Standard error of the estimate

$$= 15\sqrt{1 - \text{Correlation}^2}$$

To calculate the margin of error, multiply the standard error of the estimate by the z-score that corresponds to the degree of confidence desired. In Microsoft Excel, the formula for the z-score corresponding to the 95% confidence interval is:

$$= \text{NORMSINV}(1 - (1 - 0.95)/2) \\ \approx 1.96$$

For the 95% confidence interval, multiply the standard error of the estimate by 1.96. The 95% confidence interval’s formula is:

$$95\% \text{ Confidence Interval} = \text{Predicted Achievement} \\ \pm 1.96 * \text{Standard Error of the Estimate}$$

This interval estimates the achievement score for 95% of people with the same IQ as the child. About 2.5% will score lower than this estimate, and 2.5% will score higher.

You can use Excel to estimate how unusual it is for an observed achievement score to differ from a predicted achievement score in a particular direction by using this formula,

$$= \text{NORMSDIST}(-1 * \text{ABS}(\text{Observed} - \text{Predicted}) / \\ (\text{Standard error of the estimate}))$$

If a child’s observed achievement score is unusually low, it does not automatically mean that the child has a learning disorder. Many other things need to be checked before that diagnosis can be considered valid. However, it does mean that an explanation for the unusually low achievement score should be sought.

## Aptitude Assessment Using CHC Theory

There is much more to talk about once you have decided that you are interested in more than just g. First, you have to decide which abilities are relevant to the assessment question. In order to do that, you have to decide, at least tentatively, which abilities even exist. There are many models of the structure of cognitive abilities, but most are historical relics with no living supporters. For example, in the end, even Spearman rejected his Two-Factor Theory (Horn & Blankson, 2005). There are a few theories

that are still alive in the sense that they are taken seriously by active researchers. Chief among them is the Cattell-Horn-Carroll theory of cognitive abilities (CHC theory; McGrew, 2005; Schneider & McGrew, 2012).

CHC theory is the child of two titans, Carroll's (1993) lumbering leviathan, the Three-Stratum Theory of Cognitive Abilities, and Cattell and Horn's two-headed giant, *Gf-Gc* Theory (Horn & Cattell, 1966). Given that Horn was as staunchly anti-*g* as they come (Horn & Blankson, 2005) and that Carroll was a dedicated *g*-man (though not of the *g*-and-only-*g* variety; Carroll, 2003), it is surprising that these theories even had a courtship, much less a marriage. From 1986 to the late 1990s, in a series of encounters initiated and chaperoned by test developer Richard Woodcock, Horn and Carroll discussed the intersections of their theories and eventually consented to have their names yoked under a single framework (McGrew, 2005). Although the interfaith ceremony was officiated by Woodcock, the product of their union was midwifed primarily by McGrew (1997). Woodcock, McGrew, and colleagues' ecumenical approach has created a space in which mono-*g*-ists and poly-*G*-ists can engage in civil dialogue, or at least ignore one another politely. CHC theory puts *g* atop a three-stratum hierarchy of cognitive abilities, but *g*'s role in the theory is such that poly-*G*-ists can ignore it to the degree that they see fit. By 2005, it was clear that revisions to almost all of the major cognitive tests batteries were being influenced, partially

if not primarily, by the development of CHC theory (Alfonso, Flanagan, & Radwan, 2005). In the intervening years, this trend has not changed.

## Broad Overview of CHC Theory

Performance on cognitive ability tests is influenced by many cognitive functions operating simultaneously. If performance on two tests is influenced by more or less the same subset of cognitive functions, the scores on the two tests will be highly correlated. If test performance on the two tests is influenced by only a few cognitive functions in common, the correlation between the tests is likely to be low.

CHC theory distinguishes among abilities at three levels: Stratum I (narrow abilities), Stratum II (broad abilities), and Stratum III (*g*). The words *broad* and *narrow* are so versatile that it is easy to forget that they are being used as metaphors in this case. What is meant by the distinction between broad and narrow is not typically made explicit, but there are at least two interpretations that can be considered. Of course, these interpretations are not mutually exclusive.

## Broad vs. Narrow: Different Levels of Generality

The distinction between broad and narrow that is implied by Figure 13.2 is that broad abilities are cognitive functions that influence performance in a wide variety of tasks. Narrow abilities are functions that influence performance in a smaller subset

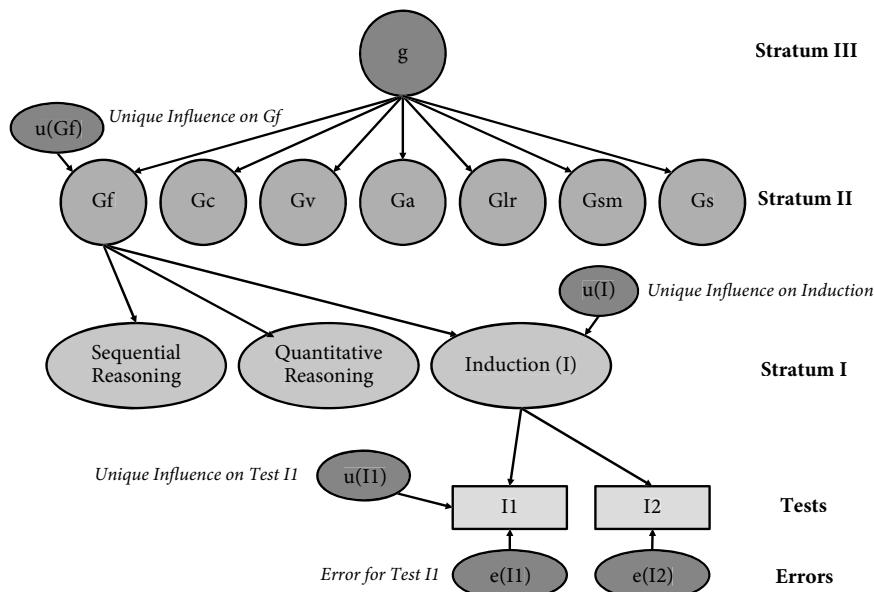

Figure 13.2 Influences on Test Performance Operate at Different Levels of Generality.

of tasks. Thus, from this perspective, broad abilities (including the broadest of abilities,  $g$ ) are not fundamentally different from narrow abilities. They are all abilities in the same sense. They simply differ in their generality.

Consider the difference between two physical abilities, the ability to walk and the ability to hurl a shot in shot put. They are both learned, they require practice, and some people are better at them than are others. However, walking is an ability that can be used to achieve a much larger set of goals than can throwing the shot. In this sense, walking is a broad ability and throwing the shot is a narrow one. If you cannot walk, many other activities are difficult. If you cannot throw the shot very far but are otherwise healthy, the consequences for you are slight.

In Figure 13.2, it is clear that there are multiple ways in which people might obtain the same level of performance on the hypothetical measure of inductive reasoning, Test  $I1$ . Performance on Test  $I1$  could be described as

$$I1 = g + u(Gf) + u(I) + u(I1) + e(I1)$$

Where

$$I1 = \text{Score on Test } I1$$

$g$  = The sum of all factors that influence all test scores

$u(Gf)$  = The sum of all factors that influence all  $Gf$  tests, controlling for  $g$

$u(I)$  = The sum of all factors that influence all Induction tests, controlling for  $g$  and  $u(Gf)$

$u(I1)$  = The sum of all stable influences on Test  $I1$ , controlling for  $g$ ,  $u(Gf)$ , and  $u(I)$

$e(I1)$  = The sum of all unstable influences on Test  $I1$

A person might score well on  $I1$  because of luck (a form of error), previous exposure to very similar tasks (a kind of unique influence on  $I1$ ), specific training in inductive reasoning (a unique influence on the narrow ability of inductive reasoning), cultural emphasis on abstract reasoning (a unique influence on the broad ability of fluid intelligence), or a lifetime of having been fed well and protected from large brain injuries and exposure to neurotoxins (different kinds of influences that would affect the functioning of the whole brain and thus would affect  $g$ ).

### ***Broad vs. Narrow: Different Levels of Abstraction<sup>12</sup>***

A second meaning of the distinction between broad abilities and narrow abilities is that we can

conceive of abilities as existing at different levels of abstraction. Certain tasks are inherently complex in that they require the coordinated actions of multiple cognitive functions simultaneously or in sequence. To use another example involving track and field events, performing well on the 100-meter hurdles requires, among other things, sprinting and jumping in a well-timed alternating sequence. We could measure sprinting speed by having people sprint for 100 meters. We could measure jumping by having people stand still and then jump over the hurdle. However, it is hard to argue that this is the same kind of jumping (and an argument could be made that it is not same kind of sprinting if one is not expected to hurdle). Thus, running the 100-meter hurdles requires an ability that is not merely the sum of sprinting and jumping abilities, but a non-additive combination of the skills.

That hurdling requires sprinting and jumping is obvious, because we are able to observe athletes as they run and jump. When people perform cognitive tasks, it is not always so obvious which cognitive functions contribute to performance. Thus, the components of performance must be inferred statistically.

In Figure 13.3, a hypothetical set of tests that are intended to measure different facets of ability are shown. Although it was the intention of the hypothetical researchers to measure the five narrow abilities in the figure with two tests each, it is impossible to measure one and only one ability at a time, and there is considerable overlap. For example, a General Information test inherently requires language development. Furthermore, fluid reasoning plays a role in acquiring knowledge because most of what we know is not explicitly taught. For example, if I notice that a word is used only by snobby people, I might use inductive reasoning to infer that using the word makes one sound snobby. Because I know that there are no settlements on the moon, I can deduce that there are no fast food restaurants there...yet!

What is being illustrated in Figure 13.3 is that  $g$ ,  $Gf$ , and inductive reasoning are not distinct abilities that differ in terms of their generality. Rather, they exist at different levels of abstraction.  $Gf$  is a legitimate category because a certain subset of narrow abilities is bundled together in ways that are difficult, if not impossible, to separate. In a sense,  $Gf$  is not really an ability at all. One can see this clearly by an analogy to vision. It is perfectly acceptable to talk about "the ability to see." However, a moment's reflection will reveal that *seeing* is not a single ability but many abilities (to list but a few: the ability to distinguish light and dark, color vision, the ability

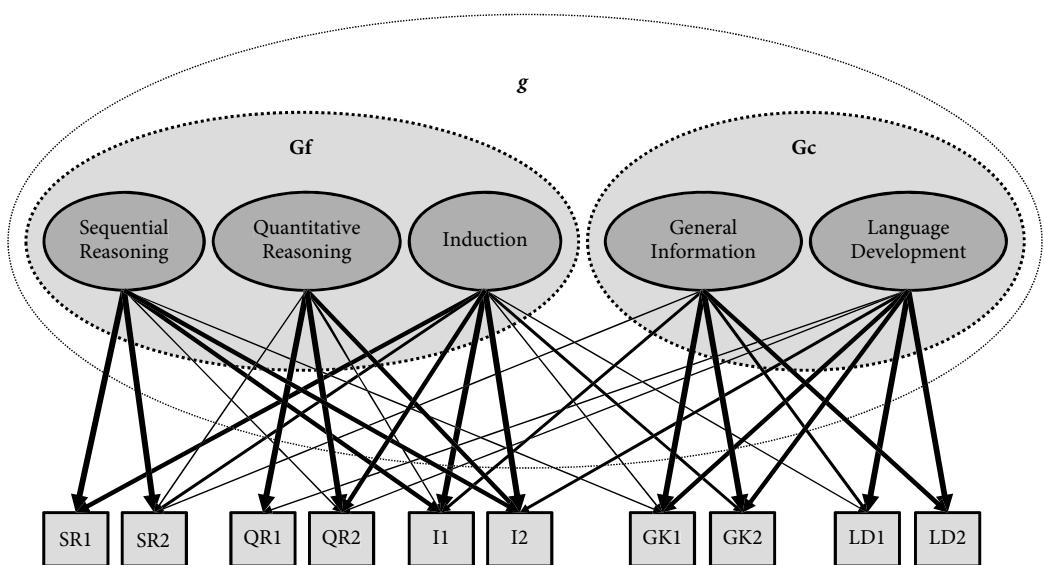

Figure 13.3 Abilities Conceptualized at Different Levels of Abstraction.

to focus, the ability to move one's eyes to follow an object, the ability to see distinct stimuli as forming a gestalt, and so forth<sup>13</sup>). What makes it legitimate to talk about vision as an ability is that the various sub-abilities work together as a functional unit. In the same sense, fluid intelligence ( $G_f$ ) is an ability (and so too, possibly, is the dreaded  $g$ ).

### Fluid Intelligence ( $G_f$ )

Mentioning fluid intelligence at cocktail parties as if it were a perfectly ordinary topic of conversation carries with it a certain kind of cachet that is hard to describe unless you have experienced it for yourself. Part of  $G_f$ 's mystique can be attributed to Cattell's (1987) assertions that  $G_f$  is linked to rather grand concepts such as innate ability, genetic potential, biological intelligence, mass action, and the overall integrity of the whole brain.<sup>14</sup> Heady stuff indeed!

At the measurement level,  $G_f$  tests require reasoning with abstract symbols such as figures and numbers.<sup>15</sup> Good measures of  $G_f$  are novel problems that require mental effort and controlled attention to solve. If a child can solve the problem without much thought, the child is probably making use of prior experience. Thus, even though a test is considered a measure of fluid intelligence, it does not measure fluid intelligence to the same degree for all children. Some children have been exposed to matrix tasks and number series in school or in games. Fluid intelligence is about novel problem-solving and, as Kaufman (1994, p. 31) noted, wryly pointing out the obvious, a test is only novel once.

The second time a child takes the same fluid intelligence test, performance typically improves (by about 5 points or 1/3 standard deviation, Kaufman & Lichtenberger, 2006). This is why reports that fluid intelligence can be improved with training (Jaeggi, Buschkuhl, Jonides, & Perrig, 2008) cannot be taken at face value.<sup>16</sup> Just because performance has improved on “ $G_f$  tests” because of training does not mean that  $G_f$  is the ability that has improved.

At the core of  $G_f$  is the narrow ability of *induction*. Inductive reasoning is the ability to figure out an abstract rule from a limited set of data. In a sense, inductive reasoning represents a person's capacity to acquire new knowledge without explicit instruction. Inductive reasoning allows a person to profit from experience. That is, information and experiences are abstracted so that they can be generalized to similar situations. *Deductive* reasoning is the ability to apply a rule in a logically valid manner to generate a novel solution. In CHC theory, deductive reasoning is called “general sequential reasoning.” Although logicians have exquisitely nuanced vocabularies for talking about the various sub-categories of inductive and deductive reasoning, it will suffice to say that everyday problem-solving typically requires a complex mix of the two.

Inductive and deductive reasoning can be found in multiple places in CHC theory. Whenever inductive and deductive reasoning are applied to quantitative content, they are called “quantitative reasoning.” For mysterious reasons, inductive and deductive reasoning with quantitative stimuli tend

to cluster together in factor analyses. Inductive and deductive reasoning also make an appearance in  $G_c$ . Whenever inductive and deductive reasoning tasks rely primarily on past experience and previous knowledge, they are classified as measures of crystallized intelligence. Many researchers have supposed that the Similarities subtest in the Wechsler tests contains an element of fluid reasoning because inductive reasoning is used to figure out how two things or concepts are alike. If the question is something like, “How are a dog and a cat alike?” then it is very unlikely that a child arrives at the correct answer by reasoning things out for the first time. Instead, the child makes an association immediately based on prior knowledge.

Researchers are not satisfied with accepting  $G_f$  as a given. They wish to know the origins of  $G_f$  and to understand why some people are so much more adept at abstract reasoning than other people are (Conway, Cowan, Bunting, Therriault, & Minkoff, 2002). One hypothesis that is still being explored is that fluid reasoning has a special relationship with working memory. *Working memory* is the ability to hold information in mind while using controlled attention to transform it in some way (e.g., rearranging the order of things or applying a computational algorithm). Many researchers have noted that tests of fluid reasoning, particularly matrix tasks (e.g., WISC-IV Matrix Reasoning), can be made more difficult by increasing the working memory load required to solve the problem. Kyllonen and Christal (1990) published the provocative finding that individual differences in  $G_f$  could be explained entirely by individual differences in working memory. Many studies have attempted to replicate these findings but have failed. Most studies find that  $G_f$  and working memory are strongly correlated (about 0.6) but are far from identical (Kane, Hambrick, Tuholski, Wilhelm, Payne, & Engle, 2004).

Just as we have distinguished between statistical  $g$  and theoretical  $g$ , it is important to note that there is a difference between the  $G_f$  that is measured by  $G_f$  tests and the  $G_f$  that is written about by theorists. Some of Cattell's hypotheses about  $G_f$  have stood the test of time, whereas others have not held up very well. For example, the heritability of  $G_f$  is not higher than that of  $G_c$ , as Cattell's theory predicts. I mention this because it is probably not justified to claim that because a child scores well on  $G_f$  tests, the child has high innate talent or that the child's biological intelligence is high.

**Table 13.2 Measures in the  $G_f$  Domain**

General Sequential Reasoning	KAIT Logical Steps WJ III Analysis-Synthesis
Quantitative Reasoning	DAS-II Sequential & Quantitative Reasoning SB5 Nonverbal Quantitative Reasoning SB5 Verbal Quantitative Reasoning WAIS-IV Figure Weights WJ III Number Matrices WJ III Number Series

Most of the effects of  $G_f$  on academic achievement are mediated by  $G_c$  (i.e., better reasoning leads to more knowledge, which leads to higher achievement). However,  $G_f$  seems to have a special relationship with complex problem-solving in mathematics. Because  $G_f$  tests measure abstract reasoning, it is unsurprising that they would predict performance in an abstract domain such as mathematics (Floyd, Evans, & McGrew, 2003).

Examples of tests that measure narrow abilities in the  $G_f$  domain can be found in Table 13.2.

### **Crystallized Intelligence ( $G_c$ )**

*Sir, the man who has vigour, may walk to the east, just as well as to the west, if he happens to turn his head that way.*

—Samuel Johnson, arguing that Edmund Burke would have achieved greatness in any field

Broadly speaking, *crystallized intelligence* refers to the ability to use culturally sanctioned knowledge and problem-solving methods to achieve culturally sanctioned goals (Hunt, 2000). In Cattell's (1941) original theory, there were two general factors of intelligence,  $g_f$  and  $g_c$ .<sup>17</sup> General fluid intelligence ( $g_f$ ) represented potential, whereas crystallized intelligence ( $g_c$ ) represented the realization of potential. In what came to be known as *investment theory*, Cattell observed that children with more potential

to learn tend to acquire more knowledge. Thus, Cattell called statistical  $g$  “historical  $g_f$ ” because it represents the aggregate effects of  $g_f$  on  $g_c$  over a person’s lifetime (“...this year’s crystallized ability level is a function of last year’s fluid ability level...”; Cattell, 1987, pp. 139). This may be the reason that  $g_f$  is indistinguishable from  $g$  in some samples (Gustafsson & Undheim, 1996).

Fortunately for people with low  $g_f$ , it is possible for differences in learning to occur that have nothing to do with  $g_f$ . Cattell called any intentional effort to enhance  $g_c$  “investment.” That is,  $g_c$  is “invested” in activities that enhance  $g_c$ . Investment takes many forms, including parental investment of time and energy to teach children, societal investment to educate the next generation with public schooling and special programs to help children with intellectual gifts or deficits, and personal investment to educate oneself via the personality traits of conscientiousness (some children learn more because they are more obedient in school), ambition (some children learn more because they hope to accomplish more), and intellectual curiosity (some children learn more because they enjoy learning more). This theory predicts that, to the degree a society provides equal opportunity to all its citizens,  $g_f$  and  $g_c$  will be more correlated and harder to distinguish.

Cattell (1987) invoked the metaphor of the fluid/crystallized distinction to suggest that talent was inchoate, whereas knowledge had definite form resulting from specific experiences.<sup>18</sup> In later years, Horn de-emphasized the conceptualization of fluid intelligence as potential and saw it more as a person’s current capacity for abstract thought. Thus, he believed that not only did fluid intelligence affect the growth of crystallized intelligence but also that education and other forms of experience might affect one’s capacity for abstraction (Horn & Blankson, 2005).

In my experience, a kind of sincere but misguided egalitarianism leads many graduate students to esteem  $G_f$  and to disdain  $G_c$ . In their minds,  $G_f$  is *real* intelligence, whereas  $G_c$  is merely the result of opportunity. Thus, contemplating a person whose opportunities to learn have been limited, students wish to ignore the person’s lack of knowledge and focus instead on things that “actually matter,” like potential. Although this position is not entirely wrong, it turns out that knowledge matters quite a bit. Almost all of IQ’s predictive validity in the workplace is mediated by specific job knowledge. That is, although bright people learn faster, more efficiently, and more deeply, it is the job knowledge itself that primarily determines competence (Gottfredson,

1997).<sup>19</sup> Students assume that if a child has high fluid ability but low crystallized intelligence, the child will be fine (eventually), either because raw talent will carry the day or because the child’s high  $G_f$  will cause accelerated knowledge acquisition in the future. The question they fail to ask is, “Why hasn’t this happened already?” There may be hidden factors at work, and these knowledge-inhibiting factors are not likely to change unless the right intervention is implemented.

Crystallized intelligence is the best Stratum II predictor of every kind of academic achievement (Benson, 2008; Evans, Floyd, McGrew, & Leforgee, 2002; Floyd, Evans, & McGrew, 2003). The exact nature of the relationship between the narrow facets of  $G_c$  and mathematics is not clear. For example, it is doubtful that knowing the capital of Australia (Canberra!) helps children with long division. It is unlikely that knowing about oxymorons will unlock the secrets of geometry. Nevertheless,  $G_c$  predicts mastery of mathematics even after controlling for all other abilities, probably because the link between calculation and quantitative reasoning is typically mediated via language. Verbal concepts (e.g., integers, perfect squares, right triangles) are just as much a part of mathematics as they are of any other academic domain. There is no reason to suppose that learning them is radically different from learning other verbal concepts. Thus,  $G_c$  is an essential precursor ability to mathematics achievement.

What constitutes adequate measurement of  $G_c$  in practice is not entirely settled; it seems best to discuss only the aspects that are widely accepted as belonging in this domain and are measured clearly by the major cognitive test batteries.

### **Lexical Knowledge**

If *lexical knowledge* is simply memorizing the definitions of fancy words, then, at best, it is a trivial ability valued by academics, pedants, and fuddy-duddies. At worst, its elevation by elitists is a tool of oppression. There is some truth to these views of lexical knowledge, but they are myopic. I will argue that vocabulary tests are rightfully at the center of most assessments of language and crystallized intelligence. Some words have the power to open up new vistas of human experience. For example, when I was thirteen, learning the word “ambivalence” clarified many aspects of interpersonal relationships that were previously baffling.

A word is an abstraction. The need for labels of simple categories is perfectly clear. Knowing the word “anger” (or its equivalent in any other

language) frees us from having to treat each encounter with the emotion as a unique experience. Being able to communicate with others about this abstract category of experience facilitates self-awareness and the understanding of interpersonal relations. We can build up a knowledge base of the sorts of things that typically make people angry and the kinds of reactions to expect from angry people.

It is less obvious why “anger” has so many synonyms and near-synonyms, some of which are a bit obscure (e.g., *iracund*, *furibund*, and *zowerswopped!*). Would it not be easier to communicate if there were just one word for every concept? It is worthwhile to consider the question of why words are invented. At some point in the history of a language, a person thought that it would be important to distinguish one category of experience from others, and that this distinction merited its own word. Although most neologisms are outlived even by their inventors, a few of them are so useful that they catch on and are used by enough people for enough time that they are considered “official words” and are then taken for granted as if they had always existed.<sup>20</sup> That is, people do not adopt new words with the primary goal of impressing one another. They do it because the word succinctly captures an idea or a distinction that would otherwise be difficult or tiresome to describe indirectly. Rather than saying, “Because Shelly became suddenly angry, her sympathetic nervous system directed her blood away from her extremities toward her large muscles. One highly visible consequence of this redirection of blood flow was that her face turned white for a moment and then became discolored with splotches of red.” It is simply more economical to say that “Shelly was livid with rage.” By convention, the use of the word “livid” signals that Shelly is probably not thinking too clearly at the moment, and that the next thing that Shelly says or does is probably going to be impulsive and possibly hurtful.

Using near-synonyms interchangeably is not merely offensive to word nerds and the grammar police. It reflects, and possibly leads to, an impoverishment of thought and a less nuanced understanding of the world. For example, *jealousy* is often used as a substitute for *envy*. They are clearly related words, but they are not at all the same. In fact, in a sense, they tend to be experienced by people on opposite sides of a conflicted relationship. Envy is the painful, angry awareness that someone else enjoys some (probably undeserved) advantage that we covet. Jealousy is the angry, often vigilant, suspicion we may lose our beloved to a rival.

Unaware of this distinction, it would be difficult to benefit from or even make sense of the wisdom of Rochefoucauld’s observation that “Jealousy is born with love, but does not die with it.”

Lexical knowledge is obviously important for decoding words while reading. If you are familiar with a word, it is easier to decode. It is also obviously important for reading comprehension. If you know what a word means, it is easier to comprehend the sentences in which it appears. It is probably the case that reading comprehension also influences lexical knowledge. Children who comprehend what they read are more likely to enjoy reading and thus read more. Children who read more expose themselves to words that rarely occur in casual speech but whose meaning can be inferred from how they are used in the text. Finally, lexical knowledge is important for writing. Children with a rich understanding of the distinctions between words will not only be able to express what they mean more precisely, but their knowledge of certain words will enable them to express thoughts that they might not otherwise have had. For example, it seems to me unlikely that a student unfamiliar with the word “paradox” would be able to write an essay about two ideas that appear to be contradictory at first glance but at a deeper level are consistent with each other.

### ***Language Development***

*Time flies like an arrow; fruit flies like a banana.*

—Groucho Marx

*While he was declaring the ardour of his passion in such terms, as but too often make vehemence pass for sincerity, Adeline, to whom this declaration, if honourable, was distressing, and if dishonourable, was shocking, interrupted him and thanked him for the offer of a distinction, which, with a modest, but determined air, she said she must refuse.*

—Ann Radcliffe, in *Romance of the Forest* (1791), describing the heroine’s response to an unwelcome sexual advance

*Language development* refers to the complexity of one’s understanding and use of language. Without a deep understanding of language, neither of the above quotes can be understood, much less admired for their genius. There is no sharp distinction between lexical knowledge and language development. Indeed, Carroll (1993) considered “lexical knowledge” to be a subcomponent of “language development.” In their initial application of CHC theory to major test batteries, McGrew and Flanagan (1998) labeled many subtests from

major cognitive ability batteries (e.g., WISC-III Comprehension) as primarily measures of language development. More recently, almost all of these subtests have been reclassified to other areas (primarily to General Information and to Lexical Knowledge). However, the secondary loading to language development is still noted on the most recent cross-battery worksheets (Flanagan, Ortiz, & Alfonso, 2007). Specialized measures of syntax (e.g., CELF-4 Sentence Assembly) and nonliteral language comprehension (e.g., CASL Nonliteral Language) are more direct measures of language development. McGrew and I (Schneider & McGrew, 2012) have drawn attention to Carroll's original conception of language development as an intermediate category between *Gc* and narrow language abilities such as lexical knowledge, grammatical sensitivity, listening ability, and oral production.

### **General Verbal Information**

*There is much pleasure to be gained from useless knowledge.*

—Bertrand Russell

When critics look through the items in a general verbal information test, they, with some justification, sometimes sneer at the usefulness of the content. Is there any money in being able to reel off the names of the planets? Can I oppose injustice, armed with my knowledge of state capitals? Will any babies be saved because I know who Julian the Apostate was? Probably not. Many (most?) facts I have learned are unlikely to ever be of practical use. If I knew which ones they were, I might happily surrender them to forgetfulness. However, because it is impossible to know what might be useful in the future, I will hang onto my useless and pointless knowledge for a little while longer, thank you very much.

When Francis Bacon wrote parenthetically that "knowledge itself is a power..." in the context of an argument attempting to discredit the theological beliefs of certain religious sects, he probably did not mean the phrase in the sense that it is invoked today (i.e., that knowledge *confers* power). However, the phrase "knowledge is power" has survived because it resonates with our experience and pithily expresses something that is increasingly true in an age that gives increasing returns to those who can profit from information.

Good items in a General Information test should not be about random facts. Easy items should not be *merely* easy (e.g., "What is the color of the sky?").

Rather, they should test for knowledge of information considered essential for living independently in our culture. A person who does not understand why dishes should be washed is not ready to live unsupervised. More difficult items should not be *merely* difficult (e.g., "What is the largest city in Svalbard?" "How many teeth does an orca whale have?"). Rather, they should measure knowledge that is relevant to what are considered core aspects of our culture (e.g., "Why do banks loan people money?" "Why do people still learn Latin and ancient Greek?" "Who was Isaac Newton?" "What is the purpose of the United Nations?").

Just as language development consists of many narrow abilities, there are many sub-categories in general information. Typically these sub-categories consist of academic domains such as knowledge of the humanities and knowledge of the sciences. These categories have further subdivisions (e.g., physics, chemistry, biology, and so forth)—and each of these, in turn, has further subdivisions.

*General information* consists of knowledge that each person in a culture is expected to be familiar with (or would be admired for if he or she knew). However, much (if not most) of a person's knowledge is not of this sort. For example, although it is expected that everyone in this culture should know what airplanes are, only pilots are expected to know how to fly them. In CHC theory, knowledge that is expected to be known only to members of a particular profession or enthusiasts of a particular hobby, sport, or other activity is classified as Domain-Specific Knowledge (*Gkn*). Most subject-specific academic achievement tests (e.g., European history, geology, contemporary American literature) would be considered measures of *Gkn*, not *Gc*. That is, typically (but not always), achievement measures are the relevant outcomes we wish to explain, not explanatory aptitudes. In contrast, measures of general information (e.g., WISC-IV Information) are intended to be estimates of the body of knowledge from which a person can draw to solve a wide range of problems.

Like lexical knowledge, general information has a bi-directional relationship with reading comprehension. Very little of what is written is fully self-contained; authors presume that readers have considerable background knowledge and often do not bother to explain themselves. Drout (2006) describes how difficult and amusing it is to explain to non-native speakers of English what newspaper headlines such as "Under Fire from G.O.P.,

White House Hunkers Down” mean.<sup>21</sup> Children who know more understand more of what they read. Understanding more makes reading more enjoyable. Reading more exposes children to more knowledge, much of which is inaccessible via oral culture.

Examples of tests that measure narrow abilities in the Gc domain can be found in Table 13.3.

### Visual-Spatial Processing (Gv)

Gv and Ga (auditory processing) are two broad abilities linked to specific sensory modalities. There are efforts to expand CHC theory to include abilities linked to other senses (olfactory, gustatory, tactile, and kinesthetic) but it is not yet clear what the abilities are and how distinct they are from other abilities already included in CHC theory (Danhiir, Roberts, Pallier, & Stankov, 2001; Stankov, Seizova-Cajic, & Roberts, 2001). It is confusing to parents to talk about visual-spatial processing (or about auditory processing) because we are not used to thinking

about visual-spatial processes divorced from the sensory experience of vision. I like to explain the difference between vision and visual-spatial processing like this:

Vision is the ability to see something, and visual-spatial processing helps you make sense of what you see. Vision is the ability to see what is there. Visual-spatial processing is the ability to see what is not there, too, in a sense. With good vision you can see what something looks like; with good visual-spatial processing you can imagine what something would look like if you turned it around or if you were standing somewhere else, or if something else was covering part of it. With good vision, you can see objects; with good visual-spatial processing, you can see how they might fit together. With good vision, you can see a bunch of lines and splotches of colors; with good visual-spatial processing, you can see how those lines and splotches of color form meaningful patterns. This is the ability that sculptors, painters, designers, engineers, and architects need. It comes in pretty handy for the rest of us, too.

**Table 13.3 Measures in the Gc Domain**

Narrow Abilities	Measures

Within the domain of Gv, there are many narrow abilities. Few of them are well understood, and they seem to be defined more by the kind of test used to measure them than by the underlying psychological processes needed to perform on the tests. Most of them are not measured directly by the major cognitive test batteries and thus they have been omitted from this discussion.

### Spatial Relations and Visualization

In Carroll's (1993) theory, *spatial relations* and *visualization* were distinguished from each other in the following manner. “Spatial relations” was defined by tests in which participants had to answer as many questions as possible as quickly as possible by mentally rotating simple visual figures in order to deduce the correct answer.<sup>22</sup> The “visualization” factor was defined by tests in which time pressure was less of an issue and the spatial reasoning tasks were more complex. Visualization tests require children to imagine what something might look like from a different angle, to manipulate a visual image in the mind's eye, and to assemble objects to fit them together. Visualization tests tend to be more *g*-loaded and, in the minds of many theorists and test developers, good markers of *Gf* (more accurately, of Cattell's original fluid intelligence factor *g<sub>f</sub>*). Although the theoretical distinction between spatial relations and visualization may be important, there are no commercially available test batteries designed

to help clinicians to distinguish between these factors. Specifically, no commercially available subtest resembles the highly speeded mental rotation tasks that define the Spatial Relations factor as described originally by Carroll.<sup>23</sup> Although McGrew and Flanagan (1998) tentatively speculated that some subtests from major test batteries might be influenced by spatial relations to some degree, they were always clear that all such tests at least had a strong secondary loading on visualization. To my knowledge, no evidence exists that would make the distinction between spatial relations and visualization clinically vital for any purpose. It is therefore my recommendation not to worry about the distinction. Instead, I recommend selecting measures of spatial relations/visualization that have differing formats to minimize the effects of format-specific factors.

After controlling for  $g$ , this factor of ability does not typically have substantial relationships with achievement tests (Floyd, Evans, & McGrew, 2003). One of the reasons for this is that most academic achievement tests de-emphasize aspects of learning that require visual-spatial reasoning. It is quite possible that achievement tests could be devised that draw on this ability, but few test developers do so. At any rate, there is ample reason to suspect that visual-spatial reasoning is an important predictor of success in certain fields. For example, visual-spatial ability (primarily visualization) measured in childhood was a strong predictor of educational and occupational outcomes for mathematically precocious students (Shea, Lubinski, & Benbow, 2001). In particular, strong visual-spatial ability predicted choosing careers in the physical sciences and mathematics. These effects were important even after controlling for verbal and quantitative ability.

### ***Closure Speed***

In *closure speed* tasks, a child is given a distorted picture of a real object and must guess what it is. It is not exactly clear to me where speediness factors into Closure Speed tasks unless bonus points are awarded for faster responses.<sup>24</sup> It seems that French's (1951) term *Gestalt perception* would be a better name for what is being measured.

In both commercially available tests of closure speed (KABC-II Gestalt Closure and WJ III Visual Closure), the test  $g$ -loadings are low. In addition, closure speed tests often have low correlations with other  $Gv$  tests and can have substantial loadings on  $Gc$  (Reynolds, Keith, Fine, Fisher, & Low, 2007; Woodcock, McGrew, Schrank, & Mather, N., 2007). Presumably, closure speed tasks load

on  $Gc$  because the distorted image is compared to images stored in long-term memory to see if there is a match. To my knowledge, no study has ever identified any clinically relevant outcome that is better predicted by closure speed than by some other narrow ability.

### ***Visual Memory***

It is obvious that such a thing as “visual memory” exists. However, it is unclear how distinct the visual memory factor is from other abilities. One of the problems with the measurement of visual memory is that people employ a wide variety of strategies on visual memory tasks, and these strategies alter which abilities are employed. In most visual memory tasks, children are shown a complex visual stimulus and are asked to reproduce the stimulus from memory or to recognize it from an array of similar pictures.<sup>25</sup> Many children verbalize what they see (“Three circles inside a square”), converting the task into a verbal memory test. Some children encode the stimulus analytically (part by part), whereas others encode it holistically. The more children can encode the stimulus as broken into larger units, the lower the load on memory, and the higher the load on visual-spatial ability. Carroll was unsure about the theoretical status of this factor. Furthermore, he was not aware of any research on the usefulness of visual memory tasks in predicting educational or occupational success (Carroll, 1993, p. 184). In the intervening years, no study I am aware of has shown the usefulness of this factor.

Examples of tests that measure narrow abilities in the  $Gv$  domain can be found in Table 13.4.

### ***Auditory Processing (Ga)***

*ME: Tell me about why you decided to be evaluated.*

*ADULT CLIENT: I think I might have HDHD and dalexia.*

*ME (unsure): You think you might have ADHD and dyslexia?*

*ADULT CLIENT (embarrassed): Right, ADHD... but I think I have dalexia, too.*

Auditory processing problems are among the hardest problems to explain. If you were to give parents a simple, technically correct definition of *auditory processing* (e.g., the ability to perceive patterns in sound), you are likely to be misunderstood. Parents know that “auditory” has something to do with hearing and are likely to think that their child has a hearing problem or has difficulty understanding

**Table 13.4 Measures in the *Gv* Domain**

speech. “Auditory processing” is the ability that I spend the most time explaining so that I do not cause confusion. If a child has auditory processing problems, I say something like this to the parents:

Auditory Processing is not the ability to hear. Your daughter can hear just fine. The problem that she has is difficult to explain, so I am going to start by comparing her problem to vision problems (She does not have a vision problem, either. I am just comparing the two problems.) Nearsighted people are not blind. Up close, they see well. Things that are far away, however, are blurry. Making lights brighter does not help; nearsighted people need glasses. In the same way that someone who is nearsighted is not blind, your daughter is not deaf; she is not even hard of hearing. However, for her, speech sounds are a little blurry for her. It is as if she needs glasses for her ears, to make sounds clearer. Unfortunately, no such thing exists. A hearing aid would not help because it is not the volume of the sound that is the problem.

The problem is that the sounds in words are hard for her to distinguish. I’ll explain what I mean. Words are made of different sounds blended together. We usually think of the word “cat” as one big blob of sound—/cat/. However, whenever we need to, we can break “cat” into three separate sounds—/c/ /a/ /t/. With a word like *cat*, this is easy to do, and even your daughter does not have much trouble with it. However, when she hears a long word or a word

with a lot of consonants bunched together, it is hard for her to break the word into individual sounds. For example, the word “strength” has only one syllable but it has six sounds—/s/ /t/ /r/ /e/ /ŋ/ /θ/. With “cat” there are three letters, one for each sound. With “strength” it gets complicated because the *n* and the *g* form a single sound /ŋ/ and the *t* and the *h* make the sound /θ/. If I pronounce both the *n* and the *g* separately—/stren/ /g/ /θ/—it sounds strange. With a word like “strength,” your daughter can hear the first sound and the last sound but gets lost in the middle and starts leaving sounds out or guessing wrong sounds.

Now, if you say the word “strength” out loud, she can hear it and she understands it. She is not confused. She can even pronounce the word correctly. Why? I’ll make another comparison to vision. When you are driving and you see a road sign from far away, you might not be able to see every letter on the sign distinctly. However, you might be able to make out the shape of the word, and because you know what different signs are likely to say, you can tell someone what the word on the sign is. This is sort of like what you daughter can do. She hears the word and can say what it is based on the overall features of the word. However, she has difficulty hearing each of the sounds as distinct from each other.

If the only thing that were wrong was that she could not split words into different sounds, there would be no cause for concern. However, it turns out that this ability to hear the sounds in words as distinct rather than as big blobs of sound is really important to learning to read. If you can hear the different sounds in words, you can hear why the words are spelled as they are (if they are words with regular spelling). If you are reading and you come across a new word, you can sound it out like they do on *Sesame Street*.

Children who have difficulty hearing speech sounds distinctly often have trouble learning to spell and to read. Most children learn their letters and the sounds they make and then can figure out how to read and spell most words (at least the ones with regular spelling). Without the ability to sound out a word, learning to read and spell depends mostly on memorizing each word one by one. New words have to be taught explicitly to the child. Some children with this problem figure out how to work around it; some have help. When children with this problem fall behind in their ability to read, we call the problem *dyslexia*.

I want to be clear what *dyslexia* is and what it is not. You may have heard that *dyslexia* is when

children see words backwards. This is not true. I have been doing this for a long time, and I have seen many children with dyslexia. Not one of those children saw anything backwards. However, many of them jumble their letters and, like younger children, sometimes they write their letters backwards. This is not due to *seeing* things backwards. Instead, these mistakes are due to ordinary memory errors. If you give me a long list of groceries to buy, I might remember most of the items on the list, but I might not remember them in the right order. When children with dyslexia learn a new word, they might remember which letters were in the word but might forget their order. They will probably remember the first and last letters but might mix up the middle letters. If they could sound out the words, they would be able to see that the order was wrong, but that does not happen as often as it otherwise would.

The reason that young children often write letters backward is that letters are very unusual. Most things have the same name no matter what angle we view them from [*I demonstrate with a pen, rotating it and turning it*]. This pen is called a *pen* no matter what I do with it. Letters are not like that. The letter *b* changes its name, depending on how it is rotated or flipped. It can be a *d*, a *p*, or even a *q*. A backwards *j* does not even have a name. This is weird for children, and it takes a while for them to get the hang of it. Children with dyslexia have a bit of a problem remembering which sounds go with which letters, and thus continue making these sorts of errors longer than do most children. The problem is blurry sounds, not backwards vision.

There are many narrow abilities within the auditory processing domain. They include abilities that are important for achievement in music (e.g., judging differences in volume, pitch, and rhythm). Other abilities have to do with tracking the temporal sequencing of sound, localizing sound, and deciphering sound under distorted conditions (e.g., understanding a conversation in a noisy room, recorded with a bad microphone). The most important predictor of academic achievement in this domain is *phonetic coding* (also known as *phonological processing* and *phonemic awareness*). Sometimes (e.g., Flanagan, Ortiz, Alfonso, & Mascolo, 2006) phonetic coding is divided into *analytic phonetic coding* (the ability to hear a word and distinguish among its phonemes) and *synthetic phonetic coding* (the ability to hear disconnected phonemes and assemble them into a pronounceable word). This distinction is primarily useful in selecting tests that have differing task demands. To my knowledge,

there is no clinical utility in knowing which ability is higher.

Phonetic coding is clearly relevant to the acquisition of reading decoding skills. Its predictive validity is most evident in children who are just learning to read (Evans, Floyd, McGrew, & Leforgee, 2002). It is likely that there is something of a threshold effect at work. To learn to decode words, it is advantageous to have a certain level of phonological processing ability. However, there is probably little to be gained by reading decoding and reading comprehension once a person has passed that threshold. Imagine that, at age six, only the bottom 10% of children have phonetic decoding problems that are severe enough to hamper reading decoding skills. By age 10, almost all of those children have reached the threshold at which they have surpassed the bottom 10% of six-year-olds (Woodcock, McGrew, Schrank, & Mather, 2007). If children are still poor readers by age 10, it is probably for reasons other than their current phonological processing. This may be hard for clinicians to accept because they have been trained to view phonological processing problems as the primary cause of reading problems. Try this thought experiment: If a child has a WJ III Comprehension-Knowledge (Gc) score of 100 and a WJ III Phonemic Awareness score of 70, what is the likeliest score on Basic Reading Skills? What is the probability that the child's Basic Reading Skills score is poor (< 85), given that, among all children, about 16% have scores this low or lower? These questions can be answered approximately using the correlations from the WJ III NU manual (Woodcock, McGrew, Schrank, & Mather, 2007), and creating a multiple regression equations for different age groups.<sup>26</sup> Until I worked out the calculations myself, my estimates would have been wildly off from the answers presented in Table 13.4. I would never have guessed that only 24% of children aged six to eight with those predictor scores would have Basic Reading Skills scores less than 85, and that half of them would score over 94.

I was prompted to run these estimates when I tested a teenager with extremely low Gc but with average Gc and reading skills. I remember explaining to his mother, "It is as if he has a dyslexic's brain, but without the dyslexia." I wondered how common this was and ran some estimates. I was shocked. I wondered why I had not seen more children like this before. A moment's reflection revealed the answer: I probably had. If the initial interview

does not suggest that reading is a problem, I typically skip measuring  $G_a$  and therefore do not see this pattern as often as it occurs in the population. In addition, good readers with poor  $G_a$  are less likely to be evaluated in the first place.

The main point of Table 13.5 is that the adequate Gc/low  $G_a$  pattern associated with phonological dyslexia does not doom a person to having poor reading skills. Most people with reasonable Gc but low  $G_a$  actually do learn to read. However, the risk of reading decoding problems increases substantially if  $G_a$  is low.

Examples of tests that measure narrow abilities in the  $G_a$  domain can be found in Table 13.6.

## Memory

*If any one faculty of our nature may be called more wonderful than the rest, I do think it is memory. There seems something more speakingly incomprehensible in the powers, the failures, the inequalities of memory, than in any other of our intelligences. The memory is sometimes so retentive, so serviceable, so obedient: at*

**Table 13.6 Measures in the  $G_a$  Domain**

*others, so bewildered and so weak; and at others again, so tyrannic, so beyond control! We are, to be sure, a miracle every way—but our powers of recollecting and of forgetting do seem peculiarly past finding out.*

—Jane Austen, *Mansfield Park*

It is clear that there are individual differences in abilities related to memory. It is also clear that there are many different kinds of memory. If you have had a recent course in cognitive psychology or have kept abreast of developments in the study of memory, you might be surprised at how little overlap cognitive psychology and CHC theory have in terms of theoretical constructs. There are several reasons for this. Cognitive psychologists are typically not interested in the individual differences of memory. They wish to understand how memory works in general. They are less interested in why some individuals have better memory than others, unless such differences shed light on how memory works in general. By analogy, engineers who design automobiles and mechanics who repair them have much knowledge in common. However, mechanics have a specialized knowledge of the parts of the car that tend to break down and how to replace them, whereas engineers may have an exquisite understanding of how those parts work (but may not be competent at diagnosing your car's problem). Psychologists who diagnose memory problems use tests that are sensitive to those problems. They are not typically designed to measure all of the complex processes that cognitive psychologists study. It is possible that memory assessment will become increasingly aligned with the field of cognitive psychology, but for now, the borrowings are meager and crude. This is not a criticism of our field. It is extremely difficult to measure many aspects of memory, and in many cases it is not yet clear if it would be worth the effort even if we could.

Of all the Stratum II abilities in CHC theory, the two memory abilities are the least settled. It is

not clear how separate they should be considered to be, and it is not yet clear where some narrow factors belong. In Carroll's (1993) theory, the fundamental distinction was between learning and the fluency of recall. Short-term memory and long-term memory (learning) were grouped together in a factor called General Memory and Learning. Carroll also named a factor "Broad Retrieval Ability." In Gf-Gc Theory, the distinction is between short-term and long-term retrieval. What is meant by *long-term* is a period of hours or more (Horn & Blankson, 2005).

In CHC theory, the two broad memory factors have varied considerably from the source theories. The distinction between short- and long-term memory is maintained, but "long-term" seems to mean any amount of time in which the information is no longer expected to be maintained in one's immediate awareness (less than 15–30 seconds). This means that *associative memory*, *free recall memory*, and *meaningful memory* had to be relocated to the long-term factor, even though tests measuring such abilities require children to answer immediately after the stimuli are presented. The reasons for the differences in theory reflect, I believe, some of the inherent difficulties in distinguishing between memory processes that typically work as a functional whole. Information must have been retained over the short term in order for it to be retained over the long term. Thus, even if the short-term/long-term distinction is valid, short- and long-term memory processes are inherently intertwined on any memory test. There does seem to be an important distinction, too, between the amount of information one can retain and the fluency with which it can be retrieved. This is one manifestation of the speed/power distinction that is pervasive in intelligence research. Both Cattell (1987) and Carroll (1993) agreed that there is a sense in which speed is an important aspect of all of the broad abilities, but they were unclear about how speed should be integrated into the theory.

## **Short-Term Memory (Gsm)**

### **Memory Span**

*Memory span* refers to the ability to hold information in mind just long enough to use it. For example, looking up a telephone number and holding it in mind until it has been dialed is an example of the use of memory span. Memory span can be compared to a computer's random-access memory (RAM) because it is a temporary holding space for information that can be accessed rapidly. Unlike RAM, however, information in short-term memory is very fragile. Unless you engage in deliberate mental

rehearsal, the information is lost quickly. Typically, information in short-term memory decays spontaneously within 15 to 30 seconds. If your concentration is disrupted, the information in short-term memory is likely to be lost much sooner.

The size of a person's memory span is the number of elements that can be held in short-term memory. This is not really a fixed number. It varies considerably depending on a person's state of mind; fatigue, worry, intoxication, and many other disruptive influences shorten memory span considerably. Aspects of the stimuli in memory matter as well. People perform on tests with real words better than pseudo-words (e.g., gub, ril, stad); monosyllabic words better than polysyllabic words (longer articulation times impede performance); phonologically dissimilar lists (e.g., bed, puck, cup, fill) better than phonologically similar lists (e.g., bid, bet, but, bit, bed, bud); and semantically related words (e.g., bed, pillow, blanket) better than semantically unrelated words (e.g., bell, willow, ticket; Baddeley, 2006).

Memory span tests can be constructed so that they have very low *g*-loadings. In fact, Spearman believed that rote-memory tasks had little to do with intelligence (Carroll, 1993, p. 249). It is not uncommon for children with mental retardation to have memory spans approaching the average range (Conners, Carr, & Willis, 1998). Likewise, children with very high IQs often have memory spans that are much lower than the rest of their abilities (Wilkinson, 1993).

However, much can be done to increase the *g*-loadings of memory span tests. This is desirable if the goal is to measure *g*, but not if the goal is to measure memory span. To make a measure that is a purer measure of memory span, it is necessary to reduce the influence of previously learned information. There are two ways of doing this: to use stimuli that are equally familiar to all (simple words, numbers, or letters) or to use stimuli that are equally unfamiliar to all (pseudo-words or simple visual stimuli). Children with high *Gc* or *Gf* will have an advantage on memory span tasks if it occurs to them to group stimuli in easily remembered *chunks* (yes, this is the technical term for it!). This advantage can be minimized by ensuring that the test stimuli do not have obvious relationships. For example, it is much easier to remember "table chair kitten puppy" than "kitten table pink candy." However, subtle relationships may be found by some children. Using the last example, many children may visualize a kitten on a table with pink candy. Simply reordering the words can make such visualizations harder (e.g., "table kitten candy

pink"). Even with digits, subtle effects can happen. I once lived in a city in which the telephone area code matched the first three digits in a difficult item on the WISC-III. For children who recognized this, the item was much easier than it was intended to be. Some children will enhance their performance via mental rehearsal. Minimizing the effects of  $G_c$  and  $G_f$  (or  $g$ , if you are a mono- $g$ -ist) can be accomplished by instructing all children to employ the same mental rehearsal strategy. Another way to accomplish this is to prevent rehearsal altogether by having children say "the" repeatedly or to present the stimuli so quickly that rehearsal is not possible. With these considerations in mind, I believe that the purest commercially available measure of memory span is the CTOPP Memory for Digits subtest. It is like a traditional digit span test—except that two digits per second are presented (via audio recording) instead of one digit per second.<sup>27</sup> The CTOPP Non-Word Repetition subtest is also an interesting measure of memory span because it uses unfamiliar stimuli. The pseudo-words vary in syllable length and are spoken as if they were a single word, minimizing chunking. Unfortunately, it is unclear to what degree this subtest depends on auditory processing in addition to memory span. It is my impression that many children fail the difficult items not so much because of short-term memory problems, but because they did not encode the word properly in the first place because of difficult phoneme combinations. It would be interesting to compare the factor loadings of a test in which the pseudo-words were easily pronounceable (e.g., kanumisa) with a test in which they were difficult to encode and pronounce (e.g., statishraflirks).

It is not yet clear how relevant memory span is to predicting academic outcomes. The evidence is mixed. It is possible that the predictive validity of memory span tests comes from the sources of contamination discussed in the previous paragraph. It is possible that the predictive validity of these tests comes from the overlap with working memory. It seems reasonable that memory span is important for comprehending complex forms of speech in which distant parts of sentences (or even paragraphs) have to be held in mind and then linked in order for the meaning to be clear. However, most evidence suggests that working-memory measures are much more highly correlated with reading and speech comprehension (Just, & Carpenter, 1992).

## **Working Memory**

When reading the research and applied literature about working memory, it is helpful to remember

that the term *working memory* is invoked to mean two closely related but distinct things: either a complex theoretical construct or performance on complex span tasks.

When the term *working memory* is used, it is typically meant to refer to the theoretical construct proposed by Baddeley and Hitch (1974). Over the decades, it has undergone considerable elaboration but has retained most of its essential features (Baddeley, 2006). The theoretical construct of working memory is broad and is meant to explain a wide variety of memory-related phenomena. It encompasses all of what is called *short-term memory* and is integrated with Norman and Shallice's (1986) concept of the Supervisory Attentional System.

Much of the time, our actions are automatic and require little thought. If I am walking toward my house, I am not usually thinking about the subtle ways in which my balance is maintained, the care my neighbor puts in into maintaining her yard, the feel of the breeze on my face, or a thousand other things that I am capable of noticing but do not. I typically continue walking, guided by habit (schemas and scripts), until I reach my door. However, if something unusual happens, such as being confronted by a barking dog, my attention quickly focuses so that my actions can be guided by the demands of the moment instead of by habit. The Supervisory Attentional System is the hypothetical set of mental structures that monitor goal attainment (i.e., it is "aware" of which parts of a problem have been solved and which have not in order to reach a goal) and focus attention when something unusual happens or when some non-habitual response is required. Specifically, Norman and Shallice (1986) list five kinds of situations in which the Supervisory Attentional System is active:

1. When planning or decision making
2. When troubleshooting
3. When enacting novel (or not yet mastered) sequences of actions
4. When enacting dangerous or technically difficult sequences of actions
5. When overcoming a strong habitual response or resisting temptation

Baddeley (1986) inserted Norman and Shallice's Supervisory Attentional System into his model of working memory, grafting it onto his concept of the "central executive." It has all of the features described above but also allows a person to manipulate and transform information in short-term memory. It links current sensory information with

schemas stored in long-term memory and then uses the available information to take action.

How can one wonderful mechanism do so many wonderful things? Indeed, Baddeley's central executive has been criticized as a being a *homunculus*.<sup>28</sup> Baddeley's (2002, p. 246) response is instructive:

I have to confess however, that I am rather fond of homunculi, sharing Attneave's (1960) view that they can be very useful, if handled with care. They are, in particular, helpful in allowing one to put on one side important but currently intractable problems, while concentrating on more manageable issues. It is of course important to recognise that they do not offer a solution to a problem, merely serving a holding function.

Baddeley used the concept of the *central executive* as a holding container for all that he did not yet understand so that he could concentrate on describing other aspects of working memory. He and others are now working to "fractionate" the central executive, to divide it up into understandable pieces. However, this work has only just begun. Therefore, when you, as a clinician, say something like, "Johnny is impulsive because his central executive does not function properly," you should know that not even the central executive's inventor thinks that you are explaining anything. This statement essentially boils down to a tautology: "Johnny is impulsive because he is unable to control his impulses." "Central executive dysfunction" works perfectly well as a descriptive term but not as an explanatory one. Lamentably, this criticism is easily applied to many other terms in cognitive ability research and in psychological theory in general.

One influential preliminary step in fractionating the central executive identified three distinct but still related executive functions: *inhibit*, *shift*, and *update* (Miyake, Friedman, Emerson, Witzki, Howerter, & Wager, 2000). "The inhibit function" refers to the central executive's role in "deciding" when to inhibit one's habitual behavior (termed the *prepotent response*) and produce a novel behavior instead. A classic measure of this function is the Stroop test, in which an examinee is asked to look at color words ("red") that are printed in non-matching colors (e.g., the color blue) and name the color of the ink instead reading the color word. It requires controlled attention to inhibit the urge to read the word and name the color of the ink instead.

"The shift function" refers to deliberately shifting the focus of one's attention back and forth to different tasks. Not intuitively obvious is that, for

the shift to occur, a person must inhibit the urge to engage in the previous activity (failure to do so is called *perseveration*) and initiate a new activity (failure to do so is called *akinesia*, a common symptom of Parkinson's disease). It is not clear to what degree there is a difference between self-initiated shifts of attention (such as the shift of mental set required to perform well on the Wisconsin Card Sorting Test) and the task-driven back-and-forth shifting of mental set required by tasks such as the Trails B component of the Trail Making Test.

"The update function" refers to updating the contents of working memory. The central executive "decides" which information to hold onto and which can be let go. This is typically what is measured in complex span tasks.

In CHC theory, "working memory" refers simply to individual differences in performance on complex span tasks. What distinguishes memory span tasks from complex span tasks is that, instead of simply retaining information, the examinee must simultaneously store and process information in short-term memory. In the classic memory span paradigm, Digits Forward, no processing is required. The Digits Backward paradigm is a complex span task because the digits must be retained in memory while they are sorted in reverse order. Laboratory measures of working memory are usually modeled on the Daneman and Carpenter (1980) Reading Span measure in which the examinee reads a series of sentences aloud and must recall the final word of each sentence. Many variations on this paradigm have been used in research, including the Operation Span test (Conway et al., 2002), in which the examinee must remember a word or number after performing simple calculations. The only commercially available working memory test to use this paradigm is the SB5 Verbal Working Memory subtest in which the examinee must answer a series of questions correctly and then remember the final word in the questions. This is an ingenious improvement over the laboratory measures that required reading or math ability. It also requires the examinee to pay attention to the question instead of simply mentally rehearsing the words.

Working memory measures have a robust relationship with many aspects of academic achievement.<sup>29</sup> It is believed that working memory is important in reading comprehension for a variety of reasons, not all of them obvious (Cain, Oakhill, & Bryant, 2004). If a sentence is long, the full intent of the author may not be clear until the reader has reached the end of the sentence. Thus,

the first part of the sentence has to be held in working memory and then linked to the last part of the sentence. In the quote below, consider the necessity of working memory in understanding Cicero's use of the *zeugma*, a literary form in which a series of phrases are linked by a common noun or verb. Cicero is trying to shame a would-be dictator into backing down, sparing the citizenry of Rome the horrors of civil war.

Does not the nightly watch of the Palatine, does not the guard of the city, does not the fear of the people, does not the union of all good men, does not the holding of the Senate in this most defensible place, do not the looks and faces of these people move you?

—Marcus Tullius Cicero, *In Catilinam I–IV*

Often an author leaves it to the reader to make appropriate inferences. Children with poor working memory are presumed to have fewer attentional resources to make such inferences. It is believed that working memory facilitates vocabulary acquisition via informal inferences about the meanings of words (Gathercole & Baddeley, 1993). If reading were a simple act of decoding words, even children with low working memory could eventually become skilled enough at decoding that there would be sufficient attentional resources left over. However, reading comprehension does not consist of simply decoding words successively. Instead, it is a complex process that involves constant prediction of what is coming next. As children read, they anticipate what is about to happen, and they update their predictions based on whether their expectations have been confirmed or not. Here is an example of a pair of sentences in which the first sentence causes a predictive inference that is confirmed in the second sentence:

As Brad pulled out the blue math worksheet he had worked on so hard last night, he noticed that everyone else was turning in a yellow worksheet. He had done the wrong homework assignment by accident!

Calvo (2005) measured where readers' eyes moved as they read sentences like these. Three distinct cognitive abilities were associated with different patterns of eye movements. Readers with poor decoding skills, not surprisingly, had long-lasting eye gazes, meaning that they took a long time to figure out what the words were. Readers with poor working memories often finished the second sentence and had to go back and read the first sentence. It appears that readers with poor working memories

could not retain the entire representation of the sentence or phrase from which the prediction was generated, and thus they had to double-check to see if their confirmation was correct. Readers with poor vocabularies often had to go back and read the first sentence again even before moving on to the second sentence. It appears that they had trouble making succinct inferences in the first place. Thus, if Calvo is correct, both vocabulary and working memory are related to making predictive inferences while reading, but they are important at different stages of the inferential process. Vocabulary facilitates the ease and speed of making initial inferences, whereas working memory facilitates the "tying together" of new information with initial inferences. This predictive inference process is not just an idle pastime. It is a form of deep processing that facilitates recall. Children with poor working memory have difficulty decoding words and making predictive inferences at the same time. Their reading experiences tend to be effortful, inefficient, and choppy instead of automatic, flowing, and pleasant. Furthermore, being less able to make predictive inferences diminishes one of the great pleasures of reading: authors delight us by playing with our expectations using foreshadowing, humor, and irony.

Working memory also plays a role in comprehension-monitoring while reading (Cain, 2006; Pressley, 2002). We have all had the experience of "reading" (sounding out words in our heads) and then discovering that we have not been paying attention to what we have been reading for about a page or two. Part of comprehension-monitoring is to ask, "Am I still understanding this? Where was the last part where I stopped paying attention?" Readers with poor comprehension-monitoring fail to notice inconsistencies in the text (and therefore miss irony and humor). Reading while juggling all these concerns requires working memory. Without sufficient attentional resources, readers with poor working memory have a less engaging experience with rich narratives.

Although it is certain that there is a relationship between working memory and competence in mathematics, much less is known about the mechanisms underlying this relationship (Bull & Espy, 2006). In the various Wechsler IQ tests, mental arithmetic is used as a measure of working memory. In order to perform mental calculations, information must be held in memory and transformed. This fits the definition of a working memory test: simultaneous storage and processing.<sup>30</sup> However, the role of working memory in computation is more complex than this.

In a process analogous to that of comprehension monitoring in reading, working memory plays an important part in solving complex, multi-step math problems. Consider the example of using algebra to solve simultaneous linear equations such as:

$$\begin{aligned} 2x + y &= 12 \\ 4x - 2y &= 0 \end{aligned}$$

Arriving at the solutions ( $x = 3$ ,  $y = 6$ ) requires many intermediate steps. It is easy to lose one's place in the middle of the sequence and for things to go awry. Without adequate working memory, it is hard to monitor where one is in the process, what is already known, and what still needs to be accomplished.

One final note about the domain of short-term/working memory. Baddeley and Hitch (1974) conceived of working memory as consisting of the central executive, which processed stimuli from all sensory modalities, and modality-specific "slave systems" that acted as temporary storage structures. For verbal/phonological information, the phonological/articulatory loop replays information in a continuous loop of high-fidelity imagined sound. For visual-spatial information, the visuospatial sketchpad holds information for the "mind's eye" to look at. Most of the linkages between individual differences in working memory capacity and academic outcomes are based on auditory measures. The role of nonverbal working memory in academic achievement is not yet clear. Therefore, it is my recommendation to administer and interpret auditory working memory tests and to de-emphasize nonverbal working memory unless the child has hearing problems or there is a highly specific referral question that requires the administration of nonverbal working memory.

Examples of tests that measure narrow abilities in the Gsm domain can be found in Table 13.7.

### Long-Term Memory Storage and Retrieval (Glr)

As the name of this broad ability implies, there is an important distinction between measures of long-term storage and measures of long-term retrieval (fluency). However, they are grouped together because it is impossible to measure one process without measuring the other, at least to some degree.

### Meaningful Memory

Humans are particularly good at remembering large amounts of information if it is presented in

**Table 13.7 Measures in the Gsm Domain**

\*These tests measure memory span in the easy items and then shift to working memory.

a narrative form. After hearing a story just once, most people can retell the gist of it fairly accurately. Unfortunately, few commercially available measures are designed to measure long-term memory of the gist of a story (the KAIT Auditory Comprehension Delayed is an important exception). Instead, examiners tell a story to the child and ask the child to tell the story back, word for word. The stories are often filled with details that are not relevant to the gist of the story (e.g., "On Monday, October 14th, a man named Frank Forbes walked six blocks down Market Street and then turned on Washington Avenue. There he saw an old man in a blue blazer selling balloons, books, and games. Before buying a balloon

for his son Carl, Frank asked the cashier..."). Such details make these tests more like memory span tests and less like gist memory tests. It is perhaps for this reason (and the fact that the child retells the story immediately) that both Carroll and Horn and Cattell grouped meaningful memory with short-term memory. However, immediate recall and delayed recall of stories are so closely related (Tulsky, Ivnik, Price, & Wilkens, 2003) that it is hard to conceive of them as being on separate broad factors.

It is important to note that Meaningful Memory tests often have strong secondary (if not primary) loadings on  $G_c$  (listening ability). In a sense,  $G_c$  is the historical record of the child's use of meaningful memory. However, the influence is not unidirectional. Children who have more background knowledge can chunk more information together while listening to a story because they have a richer, more nuanced, more integrated, and broader framework on which to hang new information (Hirsch, 2006). Thus, knowing more leads to remembering more.

The relevance of meaningful memory for academic achievement is obvious. Remembering stories is vital for the accumulation of knowledge about most academic fields, even in disciplines such as chemistry or physics. It is much easier to remember important scientific theories when they are embedded in narratives of scientists working to explain puzzling or controversial phenomena.

### ***Associative Memory***

Some information is not embedded in a narrative. It must be memorized by brute force (e.g., math facts are typically learned in this manner). *Associative memory* is the ability to remember the links between facts or pieces of information that have been paired (e.g., Einstein–Relativity, "th" – /θ/, mammals–milk).

There are two primary methods of measuring this ability. In the paired-associates paradigm, pairs of unrelated words (e.g., Book–Door, Candle–Fence) are presented in the learning phase of the task. Then the examiner names one of the words of each pair, and the child must identify the other member of the pair. If there is just one opportunity to learn the pairs, this task is actually a short-term memory task. However, most commercially available variants of this task have multiple learning phases in which the word pairs are presented again and recall is tested each time to measure how quickly the child can remember all the word pairs correctly. After a delay of at least 20 minutes, recall is tested again in a delayed condition.

In the structured learning paradigm, the effects of individual differences in short-term memory are minimized because each new item is presented individually and then tested. The procedure begins with teaching a single association (between two words, between two symbols or pictures, or between a word or name and a symbol or picture). For example, in the WJ - III Memory for Names subtest, the child is shown a picture of a space alien and is told its name. The child then points to the picture and says the name. The child is shown a new alien and is taught the name. The examiner shows both aliens and asks the child to name them both. This process is repeated many times. Each time a new alien's name is taught, memory for the name of that alien is tested first, and then the child is asked to name each of the other aliens. Each time the child makes an error, the examiner gives the correct name. In this way, an early memory failure does not result in a total loss of points for all subsequent test phases. It is clear that the structured learning paradigm is a purer way of measuring long-term memory processes because it minimizes the role of short-term memory. However, the paired-associates paradigm allows for the observation of a child's learning strategy that would not be apparent in the structured learning paradigm.

Delayed conditions of associative memory tests do not typically reveal additional information that was not already apparent in the immediate-recall conditions (Tulsky, Ivnik, Price, & Wilkens, 2003). An important exception to this generalization is in the assessment of dementia (not a concern for most children, thankfully), in which the delayed scores are much lower than the immediate scores (Delis, Jacobson, Bondi, Hamilton, & Salmon, 2003). It is unclear if there are other special populations in which this pattern is common.

Associative memory is known to be an important predictor of both math and reading achievement, particularly in the first few years of school, when basic reading decoding skills and math facts and calculation skills are being acquired (Evans, Floyd, McGrew, & Leforgee, 2002; Floyd, Evans, & McGrew, 2003). That is, skilled readers shift from phonologically decoding each word to recognizing familiar words automatically. To be skilled in math, something similar must occur with math facts. To be good at algebra, you have to stop counting on your fingers and develop effortless recall of all the basic math facts (Fleischner, Garnett, & Shepherd, 1982). Effortless recall of math facts frees working memory resources for complex problem-solving.

## Free Recall Memory

This factor, like several other narrow abilities in CHC theory, has a name that describes the kind of tests that measure the factor rather than a name that describes a psychological process. The fact that a theorist as knowledgeable as Carroll could not think of a theoretical construct to link this factor to makes me suspicious that what emerged in the factor analysis was a method factor rather than a distinct psychological ability. With apologies to E. G. Boring, free recall memory is what free recall memory tests test.<sup>31</sup>

*Free recall memory* tests typically begin with a presentation of a list of words, pictures, or other stimuli. This list's length is designed to exceed the child's memory span (hence the term *supraspan* tests). The child immediately attempts to recall as many items as possible. The number recalled is an estimate of memory span. However, the list is presented again and the child has another chance to recall the entire list. This process is repeated several times (typically four times in all). After a long delay, the child is asked to recall the list one more time.

It is probably safe to say that performance on free recall memory tests predicts performance on exams in which lists need to be memorized (What are the five pillars of Islam? Name all 50 states.). However, I am aware of no such study that has demonstrated this effect nor of any other specific effect of Free Recall Memory on academic achievement.

## Retrieval Fluency

There are about nine or so different kinds of retrieval fluency in CHC theory. I will not describe them all because few of them are measured by major test batteries. Fluency measures have been used extensively by creativity researchers because the ability they measure is thought to be a precursor to the creative production of ideas.

*Ideational fluency* is the ability to produce many examples related to a specific topic. The classic ideational fluency test is to name as many animals (or foods, furniture, names, sports, and so forth) as possible in a specified time limit. Cattell originally placed this ability in the *Gc* broad factor. He was not wrong about this. He used very generous time limits on his tests so that the speed of retrieval was unimportant and instead the breadth of the examinee's knowledge was tested. In contrast, most variations of ideational fluency tests given in commercially available tests have very short time limits and thus measure the fluency of responding. Ideational fluency tests measure what Guilford (1967) would call

*divergent production ability* (as opposed to *convergent production ability*) because there is not a single correct answer, but a large pool of correct answers that can be offered. Ideational fluency tests are sensitive to brain injuries and have long been used by neuropsychologists to measure word-finding problems (dysnomia). I am unaware of any specific relationships ideational fluency has with academic achievement.

*Word fluency* is very similar to ideational fluency, except that the examinee is told to generate as many words as possible that have a common orthographic or phonological characteristic, such as words that begin with a "t" or end with "ion." Word fluency tests are also used to assess for dysnomia, a common effect of brain injuries.

*Naming facility* is also known as *rapid automatic naming*. It is the ability to recall the name of an object or symbol as quickly and fluently as possible. Tests of naming facility consist of an array of objects or symbols that are well known to the examinee. The object of the test is to name the elements in the array as quickly as possible. This ability is quite different from ideational fluency and typically has low correlations with it (Woodcock, McGrew, Schrank, & Mather, N., 2007). Naming facility tests are what Guilford (1967) would call *convergent production tests* because the examinee "converges" on a single answer, which is judged to be correct or not. Naming facility is known to be an important independent predictor of reading decoding, fluency, and comprehension. In a sense, reading is the act of naming words fluently. However, there is some controversy about whether the effect of rapid automatic naming on reading only occurs in rapid digit-naming and rapid letter-naming tasks, or if it is a more general effect of the ability to name any object fluently (Bowey, McGuigan, & Ruschena, 2005).

A comprehensive investigation of memory-related abilities requires specialized knowledge that is beyond the scope of this chapter. There is not a single ability called "memory" but rather a loose affiliation of memory abilities. It requires a bit of detective work to deduce the source of memory problems. The correlations of most narrow abilities within *Gfr* are so low that it is not reasonable to expect scores from different domains to converge to a single number in most examinees. If there are concerns about long-term memory processes, it is probably best to use a comprehensive memory battery such as the Children's Memory Scale, the Test of Memory and Learning,

Second Edition (TOMAL-2), or the Wide Range Assessment of Memory and Learning, Second Edition (WRAML-II) and then conduct follow-up testing with more specialized measures as needed. If there are no specific concerns about long-term memory, a story memory subtest (e.g., WJ III Story Recall), a structured learning subtest (e.g., KABC-II Rebus Learning) and a rapid naming subtest (e.g., DAS-II Rapid Naming) can act as a good screener for common memory problems.

I addressed long-term visual memory somewhat in the  $Gv$  section. This area is not well defined in CHC theory (nor really anywhere else). It is not clear what the utility of measures of visual memory is either. Tests that measure recognition of faces, however, measure a highly specialized and distinct cognitive function that may have special utility in understanding social cognition deficits common in autistic spectrum disorders (Klin, Sparrow, de Bildt, Cicchetti, Cohen, & Volkmar, 1999).

Examples of tests that measure narrow abilities in the  $Glr$  domain can be found in Table 13.8.

## Processing Speed ( $Gs$ )

It is important to note that *processing speed* is probably too broad a term for what this factor entails. It is not the speed at which all mental processing occurs. Indeed, CHC Theory has three broad factors related to different kinds of mental processing speed and several narrow factors in other domains that have to do with speed as well (Schneider & McGrew, 2012).  $Gs$  is narrower; it is the speed and fluency at which very simple repetitive tasks (typically involving visual perception) can be performed. In Mirsky's (1987) taxonomy of attention-related abilities, the *focus-execute* aspect of attention is primarily measured by tests that load on the  $Gs$  factor. Were I to rename the  $Gs$  factor, I might call it something like "Attentional Fluency," because tests that measure this factor require sustained concentration and fluent control of attentional focus as each stimulus is engaged and disengaged successively.

The *perceptual speed* narrow factor measures the speed at which a child can compare and distinguish between simple visual stimuli. The *rate of test taking* narrow factor is the speed at which a child can perform very simple tasks such as sorting objects. There may be other narrow abilities in this domain, such as *visual scanning*, *number facility*, *speed of reasoning*, and *pattern recognition* (McGrew, 2005). Although it is clear that  $Gs$  is an important domain of cognitive ability, there is no research of which I am aware that demonstrates that it is important to distinguish between the various subfactors of  $Gs$ .<sup>32</sup>

Processing speed is a good predictor of performance once the skill has become overlearned and automatized. It not only has considerable predictive utility in predicting academic outcomes but also performance in many job categories, particularly jobs that require repetitive work (e.g., sewing; Ackerman & Cianciolo, 2000). Unlike the effect of  $Ga$  on reading abilities, the effect of  $Gs$  seems to increase with age (Benson, 2008), presumably because reading decoding has become relatively automatic.  $Gs$  also showed substantial relationships with math calculation and math reasoning (Floyd, Evans, McGrew, 2003), probably for the same reasons as with reading comprehension.

Examples of tests that measure narrow abilities in the  $Gs$  domain can be found in Table 13.9.

## Abilities Not Well Accounted For by CHC Theory

Attention and executive functions are not addressed very thoroughly in CHC Theory, possibly

**Table 13.9 Measures in the G<sub>c</sub> Domain**

Narrow Abilities	Measures
Perceptual Speed	WISC-IV Cancellation WISC-IV Symbol Search WJ III Cross Out WJ III Pair Cancellation WJ III Visual Matching
Rate-of-Test Taking	DAS-II Speed of Information Processing WISC-IV Coding
Speed of Reasoning	WJ III Decision Speed

because our measures in these domains are relatively crude and no dominant theory has emerged from which we could construct a well-founded taxonomy of attention and executive functions. There are many attention and executive function tests available (e.g., Conners's Continuous Performance Test II, Delis-Kaplan Executive Function System, NEPSY-2, and many others). These tests and test batteries contain measures that are clear markers of working memory and naming facility. However, many aspects of these tests are simply not well understood and thus have not yet been incorporated into major theories of intelligence.

There are many alternative theories to CHC theory that contain intriguing ideas. In Planning-Attention-Simultaneous-Successive Theory (PASS; Naglieri & Das, 1988), there is a distinction between tests that require simultaneous processing and tests that require successive processing. The terms *simultaneous* and *successive processing* were not first used by Luria (e.g., Bitterman, Tyler, & Elam, 1955). However, Luria's (1966) conceptualization of these terms has directly influenced at least two major cognitive assessment batteries (CAS and KABC-II). When cognitive psychologists use these terms, they typically are trying to figure out which types of perception rely on serial processing (each process completed one at a time, successively) and which rely on parallel processing (coordinated processes that operate simultaneously). It is known that the time it takes to find certain primitive features in a visual field does not increase so much as the number of distracters increases (Treisman & Gelade, 1980). For example, people can find a red X on a computer screen in about the same time whether there are 10 distracters (blue X's) or 20. This means that people do not typically have to scan each part of the screen

in successive fashion; the red X is brought to one's attention immediately because of simultaneous processes. However, when people have to find a red Y in a field of red X's and blue Y's, the search time increases with the number of distracters. This means that successive search processes had to occur.

Tests such as the CAS are intended to measure individual differences in successive and simultaneous processing. Thus the focus is not on *whether* simultaneous or successive processes are engaged to solve the task but on *how well* or *how fast* to those processes operate. That said, Das, Naglieri, and Kirby (1994, pp. 64–65) are careful to point out that there are not two abilities called "simultaneous processing" and "successive processing." Rather, these terms refer to two different categories of processing. The simultaneous processing used to complete a certain verbal task may be quite distinct from the simultaneous processing used to complete a spatial reasoning task. Thus, the theory does not predict that simultaneous and successive processing will necessarily emerge in a factor analysis. This subtlety is probably hard to keep in mind given that the CAS, which operationalizes the four basic cognitive processes in PASS theory, provides a composite score called *Successive* and another composite score called *Simultaneous*. With a single number, it is easy to think of these concepts as unitary abilities, even though the theory says that they are not.

If clinicians wish to interpret CAS subtests in terms of CHC theory, there is ample justification for doing so. Indeed, the CAS appears to have a factor structure that fits in with CHC theory better than a direct mapping of CAS subtests to PASS constructs (Keith, Kranzler, & Flanagan, 2001; Kranzler, & Keith, 1999). However, this does not mean that the CAS measures CHC constructs and CHC constructs only. The CAS subtests may measure aspects of cognitive functions that are not included in CHC theory, given that the CAS appears to out-predict some of the traditional cognitive batteries (Naglieri, 1999; Naglieri, De Lauder, Goldstein, & Schwebech, 2006). That said, it is likely that CAS subtests, ingeniously crafted as they are, probably are mixed measures of CHC abilities and PASS constructs, and it is a live hypothesis as to whether the CAS measures these extra-CHC sources of variance with sufficient reliability to be useful to the clinician. Thus far, Das, Naglieri, and colleagues have amassed an impressive and diverse body of validity data for their model, and for the CAS in particular (Das, Naglieri & Kirby, 1994; Naglieri & Das, 2005). It is likely that future validation efforts will

result in a synthesis of the distinctive aspects of PASS and CHC theory. The dual PASS/CHC interpretive framework of the KABC-II (Kaufman & Kaufman, 2004) is a step in this direction, but the links are, for now, more assumed than proven.

Several theories present a very broad view of cognitive abilities, so broad that the traditional boundaries between cognitive abilities, personality, interests, and motivation are blurred. Ackerman's (1996) Intelligence as Process, Personality, Interests, Intelligence as Knowledge (PPIK) theory integrates intelligence as process (akin to Cattell's original  $g_f$  factor), Big 5 Personality factors, Holland's Interests, and intelligence as knowledge (akin to Cattell's original  $g_c$  factor with emphasis on specialized knowledge that is difficult to test). Sternberg's (2005) Triarchic Theory of Successful Intelligence is broader still. His theory is so complex that it is unlikely that there will ever be a comprehensive battery that operationalizes all of the components of the theory. However, one of the intriguing aspects of Sternberg's work is his emphasis on *implicit knowledge*, the informal skills and unstated rules for success in highly specific domains of achievement. It might be very helpful in increasing our ability to assess aptitude if measures of implicit knowledge were commercially available.

### **Custom Composite Scores**

Closely tied to CHC Theory, the Cross-Battery Assessment approach (Flanagan & McGrew, 1997; Flanagan, Ortiz, & Alfonso, 2007) uses the taxonomy from CHC theory to classify subtests from diverse cognitive test batteries under the same interpretive framework, allowing clinicians to integrate diverse sources of information in a consistent manner. Flanagan and colleagues offer a comprehensive set of guidelines for selecting subtest across batteries. I will focus on just a few of them.

If you are designing an initial battery of tests to give to a particular individual, it is generally best to select subtests that are maximally different in terms of test format while still measuring the same broad ability. For the most part, it is best to estimate abilities at the broad ability level rather than the narrow ability level. ( $G_{lr}$  is probably an exception to this rule. There is little point in getting an average long-term memory score when the narrow abilities are so loosely related.) It is helpful to be mindful of subtests' narrow ability classifications so that broad ability composites can be constructed with minimal overlap.

If a child's test results are unexpected (too high, too low, or too inconsistent), follow-up tests should be given to confirm that the results are real instead of random errors or fluctuations of ability. When a person's profile of scores is strange, the results are not typically replicated with follow-up testing. What is not stable in testing situations is unlikely to generalize to anything else in the child's life. It is therefore usually best not to interpret findings that are not replicated. However, if scores within a broad domain are consistently different from each other, it is acceptable to interpret the scores at the narrow ability level. Even so, given the state of our knowledge of the incremental validity of narrow abilities, it is important to be modest in interpreting narrow ability differences within Stratum II broad ability clusters.

### ***Good Composites Are Theoretically Plausible***

It is important to group subtests by theory, not by intuition. As brilliant as Kaufman's (1994) Intelligent Testing system was, there is little evidence that any of the hundreds of subtle influences on test performance he lists has ever been measured with any reliability. Fly low to the ground and stick with a well-validated interpretive framework such as CHC theory (or simply IQ if you are a mono- $g$ -ist).

### ***Good Composites Are Either Unidimensional or Well Balanced***

If you wish to measure a single narrow ability, you can create composite scores that are reasonably unidimensional. However, it is important not to select measures that use the same format (e.g., multiple versions of the digits forward paradigm) or the scores will be overly influenced by format-specific factors that have little predictive validity.

A measure of a multidimensional construct such as  $g$  or any of the broad abilities should be measured with a well balanced selection of subtests. That is, you should not measure  $G_c$  with three vocabulary tests and a General Information test. It would be better to have two of each type, or, better still, four measures of four different  $G_c$  narrow abilities.

### ***Good Composites Produce Reliable Scores***

With  $G_c$  subtests, a very reliable composite score usually can be created with just two or three subtests. With less reliable or less correlated scores (e.g., some measures of  $G_v$ ), four or five subtests are necessary to measure abilities accurately. The less reliable the composite score, the more modest the interpretation must be. There are a number of

guidelines about acceptable levels of reliability. It is sometimes said that one should base high-stakes decisions only on scores with reliability coefficients of 0.98 or better, base substantive interpretations on scores with reliability coefficients of 0.90 or better, and base decisions to give more tests or not on scores with reliability coefficients of 0.80 or more. This is not bad advice, but I believe that reliability coefficients are not intuitively informative. When I say that the reliability coefficient for a particular population is 0.77, I find it hard to grasp exactly how unstable the score is. Instead, I recommend paying close attention to confidence intervals around the test scores and you will save yourself (and the children you assess) from over-interpreting test results. The more reliable the score is, the narrower the confidence interval will be. The 95% confidence interval of a score with a 0.80 reliability coefficient is about 26 index score points wide! That is, the true score for a particular individual might be, for example, anywhere between 64 and 90! The 95% confidence interval with a score with a 0.98 reliability coefficient is still about 8 index score points wide.

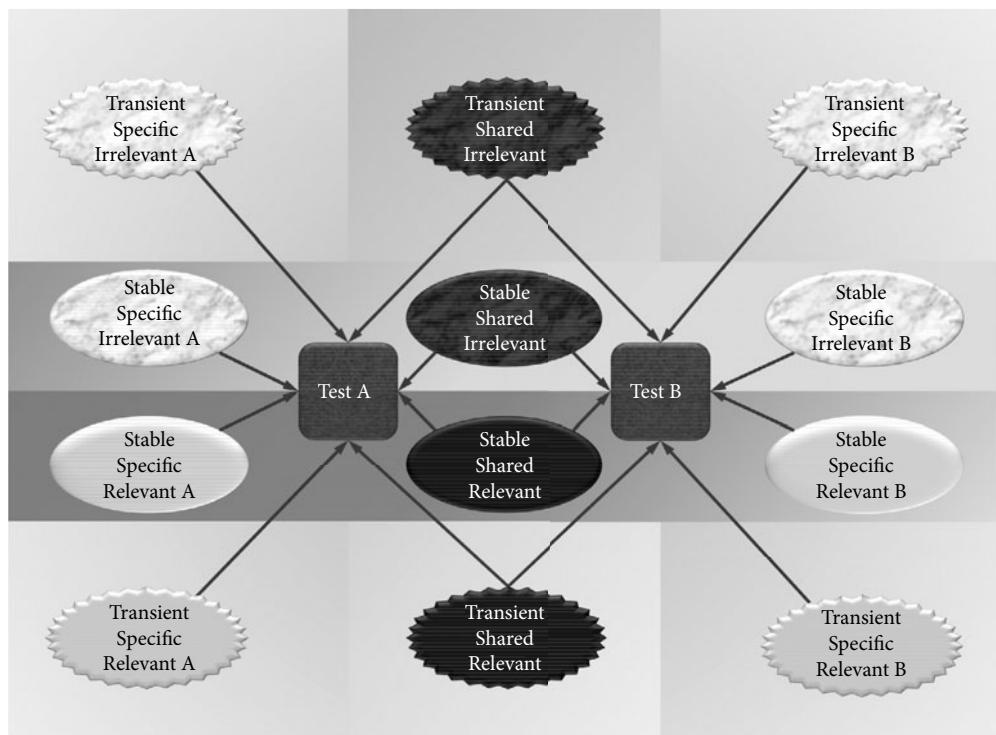

An additional point to remember is that reliability is not constant for all individuals. People

with unusual test-taking behavior or extreme scores may require more subtests to measure their abilities accurately. For most tests, only one confidence interval width is provided for each age range. However, in truth, confidence interval widths are typically (though not necessarily) larger for children who score very high or very low on the test. The WJ III is one of the few individually administered cognitive ability tests to calculate different confidence intervals for different levels of performance.

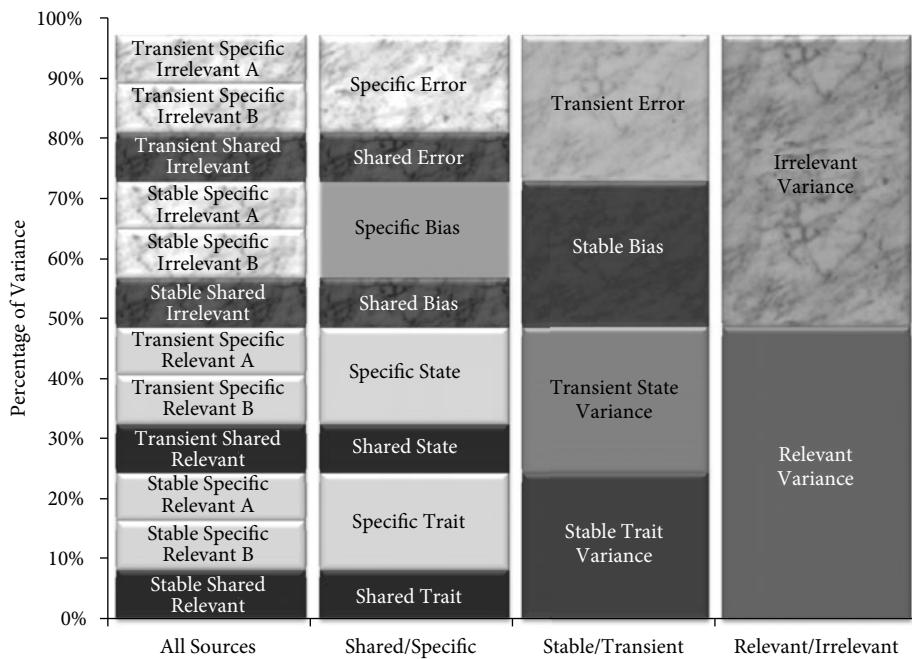

### Reliable Measurement Is Not Necessarily Construct-Relevant Measurement

It is possible for subtests with reasonably high internal consistency estimates (e.g., Cronbach's  $\alpha > 0.80$ ) to be added together to form a composite score with an even higher internal consistency coefficient. However, it is quite possible that much of the reliability of the composite comes from reliable but construct-irrelevant variance (i.e., variance not related to the ability we intend to measure).

Imagine that there are two subtests, A and B, that are influenced by the factors depicted in Figure 13.4. Both are intended to be measures of the same construct and their results are added to

**Figure 13.4** Types of Influence on Tests A and B: Relevant vs. Irrelevant, Shared vs. Specific, and Stable vs. Transient.

**Figure 13.5** Types of Influence on the Composite Score Formed from Tests A and B.

form a composite score. As shown in Figure 13.5, the sources of variance in the composite score can be shared or specific, be relevant to the construct or irrelevant, and be stable or transient. Many discussions of validity consider only the possibility of stable, shared, construct-relevant variance, but it is possible to have specific construct-relevant sources of variance if the construct is multidimensional and different tests are designed to differentially operationalize different aspects of the construct. For example, the construct of simple arithmetic could be measured by forming a composite score consisting of four tests, one for each arithmetic operation (addition, subtraction, multiplication, and division). Undoubtedly, the four tests would be correlated because of shared construct-relevant variance. However, each test would contain reliable specific variance that is no less relevant to the construct of arithmetic than the shared variance.

In cognitive measures, we typically only consider stable sources of construct-relevant variance, but it is possible for construct-relevant variance to be transient for some constructs. For example, when I am fatigued, my working memory capacity is lessened, and a good measure of working memory capacity will reflect this if I take a test in such a state. A good clinician would, of course, be alert to my fatigue and would readminister the measure on a different day. In Figure 13.4, the distinction between stable

and transient is dichotomous. In reality, everything is in a state of flux, but some things are more stable than others.

Not all shared variance is relevant to the construct the measures are intended to measure. Shared construct-irrelevant variance can result from any influence on both scores that has nothing to do with the construct of interest, such as method variance. Method variance arises from tests that are highly similar in their testing format and item content in ways that are unrelated to the construct. For example, in two speeded tests of General Information, the effect of the speed requirement on both tests is method variance. Method variance and other stable construct-irrelevant influences bias test scores in a particular direction, depending on how the test influence affects the particular evaluatee. Transient shared construct-irrelevant influences are usually called “shared measurement error.” When a child takes subtests A and B from the same examiner, any effects the examiner might have (e.g., sloppy administration or unusually poor rapport) are shared by both tests.

Some stable construct-irrelevant variance is specific to one test. For example, the WAIS-IV Working Memory Index consists of the Digit Span and Arithmetic subtests. Both subtests require familiarity with numbers (a potential shared construct-irrelevant influence) but only for Arithmetic does achievement in mathematics give a

substantial benefit. This specific and stable factor is not relevant to the construct of working memory.

It should be pointed out that construct-irrelevant variance (both specific and shared) can have predictive validity. For example, if children with higher  $Gf$  use better strategies on certain subtests intended to measure  $Gv$ , some of the composite's predictive validity will come from the  $Gf$  contamination. If the  $Gf$  component of the " $Gv$  composite" is unrecognized, the added predictive validity of the composite will be misattributed to  $Gv$ . The WAIS-IV Working Memory Index may be used to explain math performance, but some of its predictive validity may be due to the specific construct-irrelevant influence from the Arithmetic subtest.<sup>33</sup>

The ratio of stable (reliable) variance to total variance is measured by a reliability coefficient. There are many different measures of reliability, and unfortunately, none is perfect for all situations. It is important to remember that reliability coefficients are not measures of validity. It is frequently claimed that the validity of a test is no higher than its reliability. This is only true if all valid variance is stable. The idea that reliability is an upper limit to validity is further complicated by the fact that there are many different ways of measuring reliability and that they sometimes give substantially different estimates of reliability. Which reliability coefficient is the upper limit to validity? It is not always easy to tell.

The correlation between the same test given at different times is the test-retest reliability coefficient. The test-retest reliability coefficient can be misleading high or low if there are shared construct-irrelevant sources of variances such as practice effects, memory effects, and fatigue effects or if there are transient construct-relevant sources of variance (e.g., developmental effects). The correlation between alternate forms of the same test is called the *alternate-form reliability coefficient*. The correlation can also be misleadingly high or low, depending on how successfully the test developers made the tests to be truly parallel. Internal consistency measures of reliability measure how correlated the test items are and estimate the ratio of shared variance to total variance in the total score of all the items. These types of measures are popular (especially Cronbach's  $\alpha$ ) because they require no additional data collection. Internal consistency measures are lowered when there is specific construct-relevant variance and raised by shared construct irrelevant variance.

This discussion of test reliability is further complicated by the likely possibility that tests are not equally reliable for all populations. Typically, test publishers

present a variety of reliability estimates and present the case that the test scores are sufficiently reliable in most circumstances and populations.

The ratio of shared variance to total variance can be measured using a statistic called "McDonald's (1999)  $\omega$ ." What we would really like is a "validity coefficient," the ratio of construct-relevant variance to total variance. However, this is not easily obtained, so we must satisfy ourselves with a statistic like McDonald's  $\omega$ , which can be estimated using subtest loadings from factor analysis. McDonald's  $\omega$  can range between the internal consistency coefficient and the validity coefficient. Thus, it puts an upper limit to validity. That is, it gives an estimate of the construct-relevant variance to total variance ratio in the best-case scenario in which there is no construct-irrelevant shared variance.

### ***Even Good Composites Do Not Always Function as Intended***

The previously mentioned fact that a  $Gf$  test taken a second time is a suboptimal measure of  $Gf$  is a special case of a much broader principle: not every test measures what it is intended to measure for every individual. For example, I rock at the Tower of Hanoi. You could give me a stack of as many discs as you like, and I can move the whole stack from one peg to the other without any hesitation and without a single error. I don't mean to be immodest about it, but it's true. My performance is like 11.8 standard deviations above the mean, which by my calculations is so rare that if a million people were born every second ever since the Big Bang, there is still only a 2.7% chance that I would have been born by now. I feel very lucky (and honored) to be here. You would be forgiven for thinking that I had excellent planning ability but not if you voiced such an opinion out loud, within earshot of my wife, causing her to die of laughter—I would miss her very much. No, it is not by preternatural planning ability that I compete with only the gods in Tower of Hanoi tournaments-in-the-sky. In fact, the first time I tried it, my score was not particularly good. I am not going say what it was, but the manual said that I ranked somewhere between the average Darwin Award winner and the person who invented English spelling rules. After giving the test some thought, however, I realized that each movement of the discs is mechanically determined by a simple rule. I will not say what the rule is for fear of compromising the validity of the test for more people. The rule is not so simple that you would figure it out while taking the test for the first time, but it is

simple enough that once you learn it, you will be surprised how easy the test becomes.

All kidding aside, it is important for the clinician to be mindful of the process by which a child performs well or poorly on a test. For me, the Tower of Hanoi does not measure planning. For others, it might. Edith Kaplan (1988) was extremely creative in her methods of investigating how people performed on cognitive tests. Kaplan-inspired tools such as the WISC-IV Integrated provide more formal methods of assessing strategy use. However, careful observations and even simply asking children how they approached a task (after the tests have been administered according to standard procedures) is often enlightening and can save time during the follow-up testing phase. For example, I once read about an otherwise low-performing boy who scored very well on the WISC-IV Block Design subtest. When asked how he did so well on it, he said that he had the test at home and that he practiced it often. The clinician doubted this very much, but his story turned out to be true! His mother was an employee at a university and saw someone from the Psychology Department throwing outdated WISC-III test kits into the garbage. She was intrigued and took one home for her children to play with.

I once gave the WAIS-III to a woman who responded to the WAIS-III Vocabulary subtest as if it were a free-association test. I tried to use standard procedures to encourage her to give definitions to words, but the standard prompts ("Tell me more") just made it worse. Finally, I broke with protocol and said, "These are fabulous answers and I like your creativity. However, I think I did not explain myself very well. If you were to look up this word in the dictionary, what might it say about what the word means?" In the report I noted the break with protocol, but I believe that the score she earned was much more reflective of her lexical knowledge than would have been the case had I followed procedures more strictly. I do not wish to be misunderstood, however; I never deviate from standard procedures except when I must. Even then, I conduct additional follow-up testing to make sure that the scores are correct.

### ***Discrepant Subtest Scores Do Not (Necessarily) Invalidate the Composite***

A widely held view among clinicians is that if two or more subtests in a composite score differ widely, the composite score is not valid (Fiorello, Hale, McGrath, Ryan, & Quinn, 2002). This seems reasonable at first, but there are many problems with this belief. First, imperfectly correlated scores can differ because of error and specific variance, sometimes

by several standard deviations. Because these deviations just as likely to be positive as they are negative, the best estimate of the true score is actually the composite score. Second, the composite's predictive validity does not change whether its component subtest scores are consistent or discrepant (Watkins, Glutting, & Lei, 2007). Third, if you follow this recommendation to its logical conclusion, you should not interpret subtest scores if there is significant variability in the item scores. This recommendation ignores the whole reason that we aggregate scores in the first place: to distill true score variance from error variance. The point is that within-composite variability does not, by itself, invalidate the composite. Random error is to be expected. Of course, if you have reason to believe that one or more scores is incorrect, then by all means conduct more tests to estimate the ability with more precision. You may be surprised, however, how often the original composite score was not that far off the mark.

### ***Calculating Custom Composite Scores***

A quick-and-dirty way to calculate a custom composite score is simply to convert all the scores to index scores and then average them. This will be reasonably accurate for most purposes, including for on-the-spot profile interpretations. However, the procedure for combining IQ scores described earlier can be applied to any composite score to ensure maximum accuracy. The true composite score will always be more extreme than the average score. That is, if the average is below 100, the true composite score will be lower than the average of the subtest scores. If the average is above 100, the true composite will always be higher than the average of the subtest scores. The difference between the average and the true composite score is usually small, within a few index score points. However, the difference grows larger at the extremes and is larger for composite scores made from subtests with low inter-correlations. A more complete discussion of these issues can be found in a freely available position paper (Schneider & McGrew, 2011).

### ***Predicted Achievement Using Multiple Regression<sup>34</sup>***

If you believe that there are multiple cognitive abilities that influence academic achievement, you need some way of determining how unusual a child's achievement is, given the child's cognitive abilities. You can use *multiple regression* for this purpose if you know the correlations among all the predictors and the correlations between the achievement score

and each of the predictors. Multiple regression, as described here, assumes that all relationships among the predictors and the criterion are linear. Modeling non-linear relationships with multiple regression is possible, but it is unlikely that test manuals will give enough information to construct such models.

You might think that you need raw data from the standardization sample to make regression models. This is not so. Knowing the variables' means, standard deviations, and correlation matrix is all that is required. This information is typically included in test manuals.

Calculating regression coefficients is much simplified if all test scores are converted to index scores:

$$\text{Index Score} = 15 * (\text{Original Score} - \text{Original Mean}) / \text{Original SD} + 100$$

For example, a scaled score (Mean = 10, SD = 3) of 14 is converted to an index score of 120, like so:

$$120 = 15 * (14 - 10) / 3 + 100$$

The advantage of making all scores on the same metric is that the unstandardized regression coefficients equal the standardized coefficients, which are easier to calculate and to interpret. Standardized coefficients have this formula:

$$\beta = R_p^{-1} r_c$$

Where

$\beta$  is the column vector of standardized regression coefficients

$R_p$  is the correlation matrix of the predictors

$r_c$  is the column vector of the correlations between the criterion variable and each of the predictors

With a program such as Microsoft Excel, it is easy to calculate regression coefficients with just a correlation matrix. Suppose that we believe that performance on Applied Math ("word problems") is primarily determined by  $G_c$ ,  $G_f$ , and working memory (WM).<sup>35</sup> This is certainly too simple to be accurate, but it will do for the purposes of demonstration. If the hypothetical correlation matrix shown in Table 13.10 were in an Excel spreadsheet, the intercept and regression coefficients for  $G_c$ ,  $G_f$ , and WM predicting Applied Math can be calculated as follows.

1. Select a column of three cells outside of the correlation matrix (e.g., J2:J4).
2. Type “=MMULT(MINVERSE(B2:D4),A2:A4)” (without the quotes). The correlation matrix of the predictors “B2:D4” is inverted with the MINVERSE function, then the MMULT function post-multiplies it by the column of correlations of the criterion variable with each of the predictors “A2:A4.”
3. While simultaneously holding the Control and Shift keys, press Enter. The result will show the three standardized regression coefficients in the three cells selected in Step 1. The coefficient for  $G_c$  is 0.4886. The coefficient for  $G_f$  is 0.2386. The coefficient for WM is 0.1364.
4. Because all variables are index scores, the intercept is easy to calculate. Add up all of the coefficients and multiply the sum by 100. Now subtract this number from 100. In this example, the intercept is:

$$\text{Intercept} = 100 - 100 * (0.4886 + 0.2386 + 0.1364) = 13.64$$

**Table 13.10 Correlation Matrix of Hypothetical Measures of Cognitive and Academic Abilities**

Variable		AP	$G_c$	$G_f$	WM	BC	MFF
		A	B	C	D	E	F
Applied Math (AP)	1	1	0.7	0.6	0.5	0.6	0.5
Crystallized Intelligence ( $G_c$ )	2	0.7	1	0.6	0.5	0.5	0.4
Fluid Intelligence ( $G_f$ )	3	0.6	0.6	1	0.5	0.5	0.4
Working Memory (WM)	4	0.5	0.5	0.5	1	0.4	0.3
Basic Calculation (BC)	5	0.6	0.5	0.4	0.4	1	0.5
Math Fact Fluency (MFF)	6	0.5	0.4	0.3	0.3	0.5	1

*Note:* The non-standard formatting of this correlation matrix, with numbers and letters in the left and top margins, is intended to imitate how it might appear in a spreadsheet program.

5. Thus, the resulting regression equation is:

$$\text{Predicted Applied Math} = 13.64 + 0.4886 * Gc + 0.2386 * Gf + 0.1364 * WM$$

The difference between the predicted Applied Math score and the observed Applied Math score is the prediction error.

$$\text{Prediction Error} = \text{Observed Applied Math} - \text{Predicted Applied Math}$$

The multiple  $R^2$  is the percentage of variance in Applied Math that is explained by the three predictors. It is calculated by starting with 1 and then subtracting the determinant of the entire correlation matrix divided by the determinant of the predictor correlation matrix. That is,

$$\text{Multiple } R^2 = 1 - \frac{|R_{all}|}{|R_p|}$$

where  $R_{all}$  is the correlation matrix of all of the variables and  $R_p$  is the correlation matrix of just the predictor matrix.

For this example in Excel, the multiple  $R^2$  is

$$= 1 - \text{MDETERM(A1:D4)}/\text{MDETERM(B2:D4)} \\ = 0.5534$$

The standard error of the estimate is the standard deviation of the prediction errors. Thus, it is the typical size of a prediction error. Its formula is, when all scores are index scores,

Standard error of the estimate

$$= 15 \sqrt{1 - R^2} \\ = 15 \sqrt{1 - 0.5534} \approx 10.0242$$

To estimate the prevalence of a prediction error of a particular size and direction, the Excel formula is the same as it was with simple linear regression.

$$= \text{NORMSDIST}(-1 * \text{ABS}(\text{Observed-Predicted}) / (\text{Standard error of the estimate}))$$

This formula assumes that all variables are normal and that there are no non-linear relationships between any of the variables. These assumptions are likely to be approximately but not strictly true with most cognitive and academic variables.

Suppose that a girl is performing poorly in math, and her score on the Applied Math test was 78. Her cognitive scores are  $Gc = 96$ ,  $Gf = 91$ , and  $WM = 75$ . Without a method such as multiple regression,

we can simply observe that her math performance suffers, in part, because of her low working memory. This is a binary interpretation. Something either does or does not influence performance. With multiple regression, we can estimate how much her Applied Math performance depends on working memory (after controlling for the other predictors). In this case, her predicted Applied Math score is

$$\text{Predicted Applied Math} = 13.64 + 0.4886 * 96 + 0.2386 * 91 + 0.1364 * 75 \approx 92.49$$

Given the assumptions of normality and linear relationships only, about half all children with this girl's cognitive profile of  $Gc = 96$ ,  $Gf = 91$ , and  $WM = 75$  score above 92.49 on Applied Math. The prevalence of an Applied Math score of 78 is calculated in Excel like so:

$$= \text{NORMSDIST}(-1 * \text{ABS}(78 - 92.49) / (10.0242)) \\ \approx 0.074$$

It appears that the girl's poor math performance is still unexplained. Among children with her profile on  $Gc$ ,  $Gf$ , and  $WM$ , her Math performance is somewhat unusual. Some combination of other variables (including, perhaps, measurement error) is responsible for her low performance. Without the multiple regression results, we might have reasoned as follows.

1. Her math performance is low.
2. Working memory affects math performance.
3. Her working memory is low.

∴ Her low working memory accounts for her low math performance.

With the multiple regression results, we are now not so sure about this reasoning. Working memory certainly does matter. Had the girl's  $WM$  been 90 (1 SD higher so that it is consistent with her  $Gf$  and  $Gc$  scores), the predicted Applied Math score would improve by only 2 points, to about 95.5. However, the prevalence of Applied Math of 78 or lower among children with this new profile is 0.049, which is a 34% reduction of risk. Even so, we might need to look for additional explanations, perhaps outside of the cognitive domain.

One needlessly underutilized procedure is to think of other, more basic academic abilities as aptitudes (i.e., predictors) or precursors of more complex academic abilities. In this example, solving math word problems depends on basic calculation skills (BC) and math fact recall fluency (MFF). We can add these predictors to the three that are already there. Following

the procedures described previously, we select a 5 by 1 column somewhere outside the correlation matrix, type “=MMULT(MINVERSE(B2:F6),A2:A6)” and press “Enter” while holding the Control and Shift keys. The intercept is calculated by adding the six coefficients, multiplying by 100, and subtracting from 100. The regression equation now is:

$$= -2.9547 + 0.3605 * Gc + 0.2065 * Gf + 0.0786 * WM + 0.2275 * BC + 0.1566 * MFF$$

Supposing that her Basic Calculation score is 73 and her Math Fact Fluency score is 83, we can calculate a new predicted score, which is approximately 85.9. The prediction error has shrunk from -14.5 to -7.9. The prevalence of an error this size and direction is about 0.192, more than double what it was before the academic predictors were added. The multiple  $R^2$  has increased from 0.55 to 0.63, meaning that the two academic predictors explain an additional 8% of the variance in Applied Math beyond what the three cognitive predictors could explain. These changes mean that we have a more plausible explanation than we did previously. Even so, about 37% of the variance in Applied Math is not explained by the model. Realistically, a good portion of that 37% is due to measurement error (typically from 5% to 20%, depending on the test's reliability coefficient) but the rest comes from outside the model.

If we are saying that part of the reason that the girl performed poorly in Applied Math is that she has poor calculation skills and math fact fluency,

the next question we should consider is why her more basic math skills are low. Part of the reason, undoubtedly, is that working memory is low. The model in Figure 13.6 is an example of the use of path analysis. In most cases, path analysis is a set of interlocking regression equations. As long as there are no circular effects or bidirectional causation, the coefficients in a path analysis are simply the standardized regression coefficients from one or more regression equations. In Figure 13.6, there are three standardized regression equations.

1. Math Fact Fluency =  $0.36 * Gc + 0.06 * Gf + 0.12 * WM$
2. Basic Calculation =  $0.25 * Gc + 0.08 * Gf + 0.13 * WM + 0.34 * MFF$
3. Applied Problems =  $0.36 * Gc + 0.21 * Gf + 0.08 * WM + 0.16 * MFF + 0.23 * BC$

Path analysis is typically unable to tell us if a particular causal model is true, but it can inform us about the nature and size of various effects once we specify the causal model we believe is reasonable. For example, if the model in Figure 13.6 can be assumed, working memory's correlation of 0.5 with applied math is partly due to a direct causal effect (0.08) and three separate indirect effects. The indirect effect via basic calculation ( $0.13 * 0.23 \approx 0.03$ ) means that working memory has an effect on basic calculation which then has an effect on applied math. Working memory has an indirect effect on applied math via math fact fluency ( $0.12 * 0.16 \approx 0.02$ ). The third indirect effect on applied

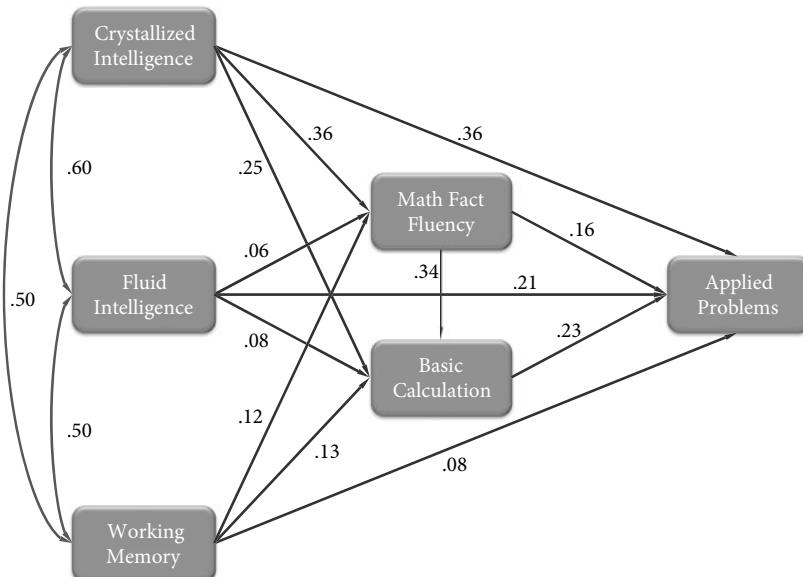

Figure 13.6 A Possible Causal Model of Math Achievement.

math comes about because working memory affects math fact fluency, which affects basic calculation, which then affects applied math ( $0.12 * 0.34 * 0.23 \approx 0.01$ ). The indirect effects total about 0.06. The indirect and direct effects together are about 0.14, which is the same value as the direct effect of working memory in the first model without the academic predictors. The sum of indirect and direct effects means that if working memory were one standard deviation higher but  $Gf$  and  $Gc$  stayed the same, Applied Problems is expected to be 0.14 standard deviations higher (about 2 index score points). About half of this small increase is due to the higher scores expected in Basic Calculation and Math Fact Fluency when working memory is higher.

When 0.14 is subtracted from the overall correlation of working memory with applied math ( $r = 0.50$ ), about 0.36 is not accounted for by the model. This occurs because working memory is correlated with  $Gf$  and  $Gc$  but no attempt was made to specify the causal nature of the relationships. Thus, 0.36 can be termed working memory's "unanalyzed" effect on applied math. If we were to specify a model that shows how the three cognitive variables cause one another (or are caused by one or more other variables outside of the model), the unanalyzed effect of working memory on applied math would be shown to be indirect effects via  $Gc$  and  $Gf$  or spurious effects (the parts of the correlation between working memory and applied math that are due to the fact they have one or more causes in common).

The fact that the multiple  $R^2$  increased when the two academic predictors were added to the model suggests that  $Gf$ ,  $Gc$ , and working memory are incapable of explaining all of the effects of basic calculation and math fact fluency on applied math. If we are to understand applied math in solely cognitive terms (which may not be possible), we need to look at cognitive variables beyond the three already included in the model. However, this is beyond the scope of this demonstration.

If the correlations between two particular tests are unknown, it is reasonable to estimate them from known correlations between similar tests. I hesitate to make this recommendation for fear of encouraging sloppiness, but I think it can be used responsibly. Whenever you use an estimate, your confidence in your conclusions should drop accordingly. Even so, I believe that using multiple regression in this fashion will reduce diagnostic error and overinterpretation. For users of the WJ III, these path analyses can be applied flexibly and automatically using the free software program *The Compositor* (Schneider,

2010). Using proper interpretive safeguards, this program can apply path analysis to estimate how much an academic outcome might improve if any of the precursor cognitive or academic abilities in the model were to be remediated.

## **Recommendations about the Assessment Process and Report Writing**

### ***Begin with the End in Mind***

You would think that being mindful of the purpose of an assessment is so obvious that it need not be stated explicitly. Unfortunately, it has too often been my experience that I am asked to give a child an assessment and no one involved with the child has a well-articulated understanding of why an assessment is needed. It is easy to accept the vague responsibility to give the child an IQ test and anything else deemed interesting and then figure it all out on the fly. This approach can lead to unnecessary testing. Worse, it can lead to a failure to answer questions that are relevant to the child's difficulties.

Teachers regularly complain that psychological reports too often tell them only what they already know: This child is struggling! It is well worth the extra time it takes to talk with parents, teachers, and to the child to formulate a set of answerable questions they have. Inspired by Finn (1996), I often ask, "After the interviews are finished, after all the testing is completed, after I write up the results in a report, and after we meet to talk about what the report has to say about Suzie, what would you like to know about her that you do not know already? To which questions would it be really helpful to know the answers?"

### ***How Allowing Yourself to Be Wrong Allows You to Be Right... Eventually***

*The greatest enemy of knowledge is not ignorance, it is the illusion of knowledge.*

—Stephen Hawking

*It is wise to remember that you are one of those who can be fooled some of the time.*

—Laurence J. Peter

We human beings are so good at pattern recognition that sometimes we find patterns that are not even there. I have never seen a cognitive profile, no matter how unusual and outlandish, that did not inspire a vivid interpretation that explained EVERYTHING about a child. In fact, the more outlandish, the better. On a few occasions, some of the anomalous scores that inspired the vivid interpretations turned out to be anomalies due to scoring

errors. In these humbling experiences, I have learned something important. I noticed that in those cases, my interpretations seemed just as plausible to me as any other. If anything, I was more engaged with them because they were so interesting. Of course, there is nothing wrong with making sense of data, and there is nothing wrong with doing so with a little creativity. Let your imagination soar! The danger is in taking yourself too seriously.

The scientific method is a system that saves us from our tendencies not to ask the hard questions after we have convinced ourselves of something. Put succinctly, the scientific method consists of not trusting any explanation until it survives your best efforts to kill it. There is much to be gained in reserving some time to imagine all the ways in which your interpretation might be wrong. The price of freedom is responsibility. The price of divergent thinking is prudence. It is better to be right in the end than to be right right now.

### ***Time Lavished on Hypothesis Fishing Trips Is Stolen from Children We No Longer Have the Time to Help***

*We do what we must, and call it by the best names  
we can.*

—Ralph Waldo Emerson

Cheetahs are the fastest animals on land but do not always catch their prey. For about 60 seconds or so, cheetahs give it their all. After that, they give up. Why? For a cheetah to persist, the expected rewards must justify the caloric expenditure, the risk of injury, and the considerable strain on their bodies that sprinting inevitably causes. In the wild, there is no glory in Pyrrhic victories. Sometimes it is better to cut your losses, even though you could “succeed” with more effort.

There is something analogous that happens in cognitive assessment. For a time, it is worthwhile to vigorously pursue a hypothesis, to clarify an anomalous finding, or to explain a curious behavior. However, when answers are not forthcoming, there is a point at which it is wise to give up, even before all alternatives have been exhausted. The time saved can be devoted to other questions about the child that may be important. It is perfectly acceptable to write in reports that, given the available data, it is not yet possible to distinguish between alternative hypotheses about a child. It is perfectly acceptable to speculate about those hypotheses, provided that those speculations are clearly labeled as such and that it is explicitly stated

that the true explanation might not be included in the list of speculations.

It is not possible to be precise about when one should persist in seeking explanations and when one should admit defeat. Some questions are so important to answer that it is hard to imagine a good time to give up. For example, imagine that the MRI was inconclusive and the neurosurgeon needs to know where in the brain to cut in order to spare as much of the child’s cognitive functioning as possible. Fortunately, psychologists are rarely faced with such awesome responsibility (not any more, at least).

Some questions are so clearly trivial that one should not bother with them at all. For example (and your mileage may vary), I never learn anything I care about from the WISC-IV Arithmetic subtest score. If the problem is poor working memory, it will show up on Letter-Number Sequencing and Digit Span. If the problem is low fluid reasoning, it will show up on Matrix Reasoning. If the problem is poor calculation skills or poor quantitative reasoning, it will show up on the achievement tests. I typically plan to assess these abilities anyway; therefore, the Arithmetic subtest provides little additional information. Furthermore, using a math test to explain math performance (“The reason you are bad at math is that you are bad at math”) is just silly. Even when it is available, I barely even look at the Arithmetic subtest score.

In your decisions about whether it is a good idea to administer further testing, it is advisable to imagine all of the possible outcomes that might occur after the additional testing has been done. Ask yourself how your course of action might change in these various scenarios (e.g., the test score might be high, low, or just as expected). If you cannot state explicitly how knowing the additional information could significantly alter how a child might be helped, it is best to discontinue testing. For example, suppose a child performed poorly on the WISC-IV Cancellation subtest but well on Coding and Symbol Search. Given the current state of our knowledge, what are the realistic odds that something useful will come of confirming that this pattern is real (i.e., not due solely to measurement error) with further testing? Once confirmed, what does such a pattern mean? I can speculate just as well as anyone else, but the sad fact is that no one yet has done the hard work of empirically specifying the practical utility of this information. To proceed with further testing when I am working on the clock is simply to indulge my intellectual curiosity on someone else’s dime.

## **Render Abstruse Jargon in the Vernacular**

*PRIMUS DOCTOR: Most learned bachelor whom I esteem and honor, I would like to ask you the cause and reason why opium makes one sleep.*

*BACHELIERUS: .... The reason is that in opium resides a dormitive virtue, of which it is the nature to stupefy the senses.*

—from Molière's *Le Malade Imaginaire* (1673)

*A man thinks that by mouthing hard words he understands hard things.*

—Herman Melville

The veil of ignorance can be woven of many threads, but the one spun with the jangly jargon of a privileged profession produces a diaphanous fabric of alluring luster and bewitching beauty. Such jargon not only impresses outsiders but comforts them with what Brian Eno called “the last illusion”: the belief that someone out there knows what is going on. Too often, it is a two-way illusion. Like Molière's medical student, we psychologists fail to grasp that our (invariably Latinate) technical terms typically do not actually explain anything. There is nothing wrong with technical terms *per se*; indeed, it would be hard for professionals to function without them. However, with them, it is easy to fall into logical traps and never notice. For example, saying that a child does not read well because she has dyslexia is not an explanation. It is almost a tautology, unless the time is taken to specify which precursors to reading are absent, and thus make dyslexia an informative label.

An additional and not insubstantial benefit of using ordinary language is that you are more likely to be understood. This is not to say that your communication should be dumbed down to the point that the point is lost. Rather, as allegedly advised by Albert Einstein, “Make everything as simple as possible, but not simpler.”

$$\sum_{i=1}^{\infty} (\text{Fact}_i) < \text{Useful Knowledge}$$

*I have made this [letter] longer, because I have not had the time to make it shorter.*

—Blaise Pascal, “Lettres provinciales,” letter 16, 1657

*The secret of being a bore is to tell everything.*

—Voltaire

*A little inaccuracy sometimes saves tons of explanation.*

—Saki, “The Square Egg,” 1924

The observation that in every fat book there is a much better thin one trying to get out also applies to reports. By stating everything we know about a

child, our reports become more accurate in a narrow sense, but such accuracy has diminishing returns and, at some point, has negative value. Student clinicians sometimes misunderstand their task. A report should not simply list the facts so that the readers can come to their own conclusions. Readers are rarely qualified to interpret raw data and cannot be expected to draw the conclusions you hint at indirectly.

Most of what is observed should not be included in a report. Many behaviors have no diagnostic value and may not even generalize to situations outside of the testing environment. A report should not describe the child in exquisite detail simply to paint a vivid picture. All descriptions should have a clear purpose. For example, it is fine to observe that the girl seemed confident on the easy math items but became a little anxious on the difficult items. But to observe without interpreting is to abandon your readers, leaving them vulnerable to wild speculations. Does the girl have performance anxiety? If she has performance anxiety, is it because she knows that she does not know how to do the hard problems and is ashamed, or is it because she knows how to do the hard problems but feels self-conscious in your presence and is thus unable to demonstrate her knowledge? Are the scores not valid estimates of her “true potential” (whatever that means)? Maybe all of the testing results are worthless! How common is it to be a little anxious? Did the anxiety *enhance* her performance, as described by the Yerkes-Dodson Law (Yerkes & Dodson, 1908)?

It is preferable to describe a child's behavior and interpret it so that the reader is better able to understand and help the child. Even if you are unsure which interpretation is correct, it is desirable to list plausible alternatives (clearly labeled as such) so that implausible and inappropriate alternatives are eliminated from consideration.

## ***Write about People, Not Tests***

At its best, the end product of a psychological assessment is that a child's life is made better because something useful and true is communicated to people who can use that information to make better decisions. How is this information best communicated? I believe that it is by the skillful retelling of the story of the child's struggle to cope with the difficulties that led to the testing referral.

Not only are humans storytelling creatures, we are also story-listening creatures. We are moved by drama, cleansed by tragedy, unified by cultural myths, and inspired by tales of heroic struggle. Most

importantly, through stories we remember enormous amounts of information. Tabulated test results are inert until the evaluator weaves them together into a coherent narrative explanation that helps children and their caregivers construct a richer, more nuanced, and more organized understanding of the problem. Compare the following assessment results.

### **EXPLANATION 1**

On a test in which Judy had to repeat words and segment them into individual phonemes, Judy earned a standard score of 78, which is in the Borderline Range. Only 7% of children performed at Judy's level or lower on this test. This test is a good predictor of the ability to read single words isolated from contextual cues. On a test that measures this ability, Judy scored an 83, which is in the 13th percentile, or in the Low Average Range. Reading single words is necessary to understand sentences and paragraphs. On a test that requires the evaluatee to read a paragraph and then answer questions that test the evaluatee's understanding of the text, Judy scored an 84, which is in the Low Average Range. This is in the 14th percentile. An 84 in Reading Comprehension is 24 points lower than her Full Scale IQ of 110 (75th percentile, High Average Range). This is significant at the .01 level, and only 3% of children in Judy's age range have a 24-point discrepancy or larger between Reading Comprehension and Full Scale IQ. Thus, Judy meets criteria for Reading Disorder. More specifically, Judy appears to have phonological dyslexia. *Phonological dyslexia* refers to difficulties in reading single words because of the inability to hear individual phonemes distinctly. This difficulty in decoding single words makes reading narrative text difficult because the reading process is slow and error-prone. Intensive remediation in phonics skills followed by reading fluency training is recommended.

### **EXPLANATION 2**

For most 12-year-olds as bright as Judy is, reading is a skill that is so well developed and automatic that it becomes a pleasure. For Judy, however, reading is chore. It takes sustained mental effort for her to read each word one by one. It then requires further concentration for her to go back and figure out what these individual words mean when they are strung together in complete sentences, paragraphs, and stories. It is a slow, laborious process that is often unpleasant for Judy.

Why did Judy, a bright and delightfully creative girl, fail to learn to read fluently? It is impossible to know with certainty. However, the problem that most likely first caused Judy to fall behind her peers

is that she does not hear speech sounds as clearly as most people do. It is as if she needs glasses for her ears: The sounds are blurry. For example, although she can hear the whole word "cat" perfectly well, she might not recognize as easily as most children do that the word consists of three distinct sounds: |k|, |a|, and |t|. For this reason, she has to work harder to remember that these three sounds correspond to three separate letters: |k| = C, |a| = A, and |t| = T. With simple words like "cat," Judy's natural ability is more than sufficient to help her remember what the letters mean. However, learning to recognize and remember larger words, uncommonly used words, or words with irregular spellings is much more difficult for Judy than it is for most children.

Many children with the same difficulty in hearing speech sounds distinctly eventually learn to work around the problem and come to read reasonably well. However, Judy is a perceptive and sensitive girl. These traits are typically helpful but, unfortunately, they allowed her to be acutely aware, from very early on, that she did not read as well as her classmates. She clearly remembers that her friends and classmates giggled when she made reading errors that were, to them, inexplicable. For example, for a while she earned the nickname "Tornado Girl" when she was reading aloud in class and misread "volcano" as "tornado." She came to dread reading aloud in class and felt growing levels of shame even when she read silently to herself. She began to avoid reading at all costs. She did not read for pleasure, even when the texts were easy enough for her to read, because she felt, in her words, "dumb, dumb, and dumb." Over the next several years, she fell further behind her peers. By avoiding reading, she never developed the smooth, automatic reading skills that are necessary to make reading a pleasurable and self-sustaining activity.

Although Judy's ability to hear speech sounds distinctly is still low compared to that of her 12-year-old peers, this weakness is not what is holding her back now. Indeed, her current ability to hear speech sounds distinctly is actually better than that of most 6- and 7-year-olds, most of whom learn to read without difficulty. With extra help, Judy can learn to decode words phonetically. However, in order for her to develop her reading fluency and reading comprehension skills to the level that she is capable of, she will need to engage in sustained practice reading texts that are both interesting for her and are at the correct level of difficulty. She is likely to be willing to read only if she is helped to manage the sense of shame she feels when she attempts to read a book. This may require the collaboration of

a reading specialist and a behavior specialist with expertise in the cognitive-behavioral treatment of anxiety-related problems.

## Comparing Explanations

I am reasonably confident that most readers would find the second explanation to be much more useful than the first. The second explanation is not better than the first simply because it is more detailed. Explanation 1 could have been supplemented with more details if I had taken the time to fill it with even more information about test results. The second explanation is not better simply because it avoids statistical jargon that is difficult for parents and teachers to understand. Even if the jargon were removed from the first explanation and inserted into the second, the second explanation would still be better.

The second explanation is better because it is more about Judy than about her performance on tests. The narrative explanation of how her reading problem developed and how it was maintained is better because it leads to better treatment recommendations. More importantly, it leads to recommendations that will be understood and remembered by Judy's parents and teachers. One of the problems with the first explanation is, ironically, that it is not difficult to understand if it is properly explained. Most parents and teachers will nod their heads as they hear it. However, they are likely to forget the explanation as soon as they leave the room. Most of us are not accustomed to thinking about people in terms of sets of continuous variables. Without a narrative structure to hold them together, assessment details slip through the cracks of our memories quickly. It is unfortunate that a forgotten explanation, no matter how accurate, no matter how brilliant, is as helpful as no explanation at all. I hope that in listing these principles of assessment that I have made them memorable enough for them to be of use.

*Those are my principles, and if you don't like them... well, I have others.*

—Groucho Marx

## Notes

1. Okay...not really...but I have seen some very sarcastic emails exchanged on professional listservs!

2. The term *positive manifold* at one time had a precise meaning drawn from mathematics, meaning that the correlation matrix of all tests was nearly a rank 1 matrix (i.e., a correlation matrix implied by Spearman's Two-Factor Theory). As it is

currently used, the term simply means that the correlation matrix consists entirely of positive correlations.

3. Not, at least, in more than one large representative sample. From time to time, someone gets an occasional negative correlation, but other researchers have trouble replicating the finding.

4. Hence, the intense controversy is not merely a result of "lies and damned lies."

5. So named because in perhaps the most important theory to deny the existence of *g* (Horn & Cattell, 1964), the most important abilities all have names that begin with a capital letter *G* (*Gf*, *Gc*, *Gv*, and so forth).

6. Full Scale IQ (WISC-IV, SB5, UNIT), Full Scale (Leiter-R, CAS), General Intellectual Ability (WJ III), General Conceptual Ability (DAS-II), Composite Intelligence Index (RIAS), Composite Intelligence Scale (KAIT), Fluid-Crystallized Index (KABC-II), and many others.

7. This table was created by calculating the standard deviation of the difference between two correlated normally distributed variables and then applying the cumulative probability density function of the normal curve.

8. "If I were to command a general to turn into a seagull, and if the general did not obey, that would not be the general's fault. It would be mine." —Antoine de Saint-Exupéry, *The Little Prince*

9. An Excel spreadsheet I wrote can calculate all of the statistics in this section and can be downloaded for free at <http://my.ilstu.edu/~wjschne/tests.html>.

10. This degree of profile variability is not at all unusual. In fact, it is quite typical. A statistic called the *Mahalanobis Distance* (Crawford & Allen, 1994) can be used to estimate how typical an individual profile of scores is compared to a particular population of score profiles. Using the given correlation matrix and assuming multivariate normality, this profile is at the 86<sup>th</sup> percentile in terms of profile unusualness...and almost of all of the reason that it is unusual is that its overall elevation is unusually low (*Mean* = 72). If we consider only the profiles that have an average score of 72, this profile's unusualness is at the 54<sup>th</sup> percentile (Schneider, 2012). That is, the amount of variability in this profile is typical compared to other profiles with an average score of 72.

11. And not every child with the same achievement scores will have the same IQ.

12. This section was inspired by the work of the nearly forgotten hero of the anti-*g*-ists, Godfrey Thomson. In what became known as "Bond Theory," Thomson (1939) proved mathematically that it is possible for statistical *g* to emerge without a single common entity influencing all scores. Thomson did not, however, discuss abilities in the same terms as they have been presented here.

13. Each of these abilities, of course, can be further subdivided into ever narrower categories until we begin to talk about specific neural assemblies of individual neurons. In the end, there is only one ability in the brain: the ability of a neuron to change the rate at which a few other neurons fire. Actually, that is not really the end of it. Inside each neuron there are all kinds of different organelles, each with different functions...and so this line of thinking goes until we reach the subatomic particles and on down to string theory. I am not sure it stops there, either. It might be cosmic turtles all the way down.

14. Horn (1985) tended to de-emphasize the biological/genetic interpretation of fluid intelligence.

15. Test developers have tried to create *Gf* measures with verbal content (e.g., WJ-R Verbal Analogies or SB5 Verbal Fluid

Reasoning) but find that verbal Gf tests do not always load on the same factor as traditional Gf tests (Canivez, 2008; Woodcock, 1990). It is possible that the KAIT Logical Steps subtest may be the only commercially available verbal Gf test that does not have substantial loadings on Gc (Flanagan & McGrew, 1998; Immekus & Miller, 2010), possibly because it does not use the verbal analogy format.

16. See Moody (2009) for a discussion of other methodological problems that may have compromised the validity of the Jaeggi et al. (2008) study.

17. I will use  $g_f$  and  $g_c$  when discussing Cattell's original theory and Gf and Gc, respectively, when discussing the later developments of the theory with Horn.

18. He did not mean to imply that such knowledge, once formed, was immutable; nor did he believe that talent was a kind of fluid that flows from one part of the mind into another part of the mind where it was transformed into crystal, diminishing the available supply of fluid. Cattell (1987) played a bit with the fluid/crystallized metaphor on occasion. For example, he noted that fluid ability was everywhere in the brain yet nowhere in particular; thus damage to any part of the cortex decreased Gf in proportion to the size of the lesion. In contrast, crystallized ability was in particular places in the brain, according to Cattell. The theory predicts that if there is a lesion in the region where a particular skill resided, the skill is lost. Otherwise the skill is spared completely.

19. IQ also has a direct effect on job performance if the job is one that requires novel problem-solving (Gottfredson, 1997).

20. Of course, dictionaries abound with antique words that were useful for a time but now languish in obscurity. For example, in our more egalitarian age, calling someone a "cur" (an inferior dog because it is of mixed breed) is not the insult that it once was. It is now used mostly for comedic effect when someone affects an aristocratic air. My favorite example of a possibly soon-to-be antique word is "decadent," which is nowadays almost exclusively associated with chocolate.

21. *Why would anyone be under a fire?* It means being shot at. *People are shooting at the White House?* No, it is just a vivid way of saying that the G.O.P. is criticizing the administration, which is symbolized by the White House, where the president lives. *Who is the G.O.P.?* It stands for "the Grand Old Party." *If they are old, why haven't I heard of them?* They are the Republicans. *Oh! Is the Democratic Party the new party?* No, they have been around longer than the Republicans. The nickname GOP was first used when the party was only a few decades old. *I don't understand.* I don't either, really. I just know that "old" is an affectionate way of describing something you have liked for a long time. *Could I say that I enjoy old ice cream?* No, that doesn't sound right. You should probably just avoid using "old" that way. *What does hunker mean?* I really have no idea. I just know that when you are under fire, you should hunker down. *If you don't know what it means, how do you know what to do?* True! I just looked it up. It means to squat, to sit on your haunches. I guess it all makes sense now. *So, when the Republicans criticize the president, he sits on his haunches?* That is an amusing image, but no. It means that you stick to your guns...er...I mean....

22. For this reason, this factor was renamed "Speeded Rotation" by McGrew and me (Schneider & McGrew, 2012), as suggested by Lohman (1996).

23. If test developers were to add such a test to a test battery, it would be a controversial decision. Speeded mental rotation tests are unusual in that there is a large gender difference

in performance (about  $0.75\sigma$  to  $1\sigma$ ; Voyer, Voyer, & Bryden, 1995). It is not yet clear if the difference represents a cognitive ability difference, a strategy difference, a confidence difference, a socialization difference, or some mix of the these explanations (Clements-Stephens, Rimrodt, & Cutting, 2009).

24. Carroll (1993, pp. 465) wrote, "It is with some hesitation that I classify [Closure Speed] as a speed factor because some people are seemingly unable to perform very difficult items at all, even given a very generous time-limit."

25. Visual memory tests are thus different from spatial working memory tests in which the visual stimuli are simple but must be recalled in a particular sequence.

26. This model assumes that all three variables are normally distributed index scores and that the relationships among them are linear.

27. The DAS-II Recall of Digits-Forward subtest also has this feature.

28. A *homunculus* is a little man. Trying to explain how we decide to do things by saying the central executive does it is no more informative than saying that there is a little man inside our brains and he makes all the decisions. Now we are begging the question, for we now have to explain how the brain of the homunculus makes decisions. Thus, calling a psychological construct a homunculus is meant as an insult: the theorist is trying to disguise what is not understood with a fancy name.

29. This review draws primarily from Cain (2006) and from Bull and Espy (2006).

30. Unfortunately, the load on working memory in such a test is much reduced with higher mathematical ability. For example, if asked to average 5, 10, and 15, it is possible to arrive at the solution by adding the numbers and then dividing by 3. However, a child of high quantitative ability might recognize that the numbers are evenly spaced and thus would infer that the average is the middle number. This solution to the problem puts much less of a load on working memory. For this reason, I tend to be wary of mental arithmetic tests as measures of working memory.

31. By the way, I am really tired of writers' smugly mocking E. G. Boring for being so stupid as to say that intelligence is "what the tests test" (Boring, 1923). It is fine to disagree with the philosophical position he was espousing (operationalism), but not if you do not know what it was.

32. An important exception to this statement is when we consider the various academic fluency measures such as reading fluency, calculation fluency, and writing fluency. It is obvious that these measures should be considered separately when attempting to explain academic performance.

33. Amazingly, Arithmetic, a math test, predicts performance on other math tests.

34. Just before this chapter was finished, Professor John Crawford's excellent multiple regression computer program became available at <http://www.abdn.ac.uk/~psy086/dept/psychom.htm>. His program can be used to do all of the calculations explained in this section and more. The program is described fully in Crawford, Garthwaite, Denham, and Chelune (2012). For users of the WJ III, my computer program *The Compositor* (Schneider, 2010; <http://www.woodcock-munoz-foundation.org/press/compositor.html>) is more convenient (i.e., less data entry). It offers many additional features, including path analysis. Both programs are free.

35. These are generic labels not tied to any commercial achievement test.

# Principles of Neuropsychological Assessment in Children and Adolescents

Cynthia A. Riccio and Cecil R. Reynolds

## Abstract

Neuropsychological assessment is often recommended for a variety of neurodevelopmental disorders. Neurological involvement may be presumed (e.g., learning disability) or identifiable (e.g., seizure disorder). In either case, possible consequences can include impaired cognitive, sensory, motor, educational, behavioral, and psychological functioning. Neuropsychological assessment provides additional information across a range of domains to aid in case conceptualization and formulation of treatment planning. There are multiple approaches that may be applied in neuropsychological assessment, as well as various measures that may be used. This chapter identifies key principles to guide neuropsychological assessment of children and adolescents consistent with ethical and professional standards. Included is a discussion of how neuropsychological assessment complements the response to intervention (RTI) movement. Some of the continuing issues with regard to measurement and additional research needed are also highlighted.

**Key Words:** neuropsychological assessment, benchmarking, Luria, fixed battery, idiographic approach; process orientation

## Introduction

Neuropsychological assessment is often recommended for a variety of disorders with an identified neurological basis (e.g., seizure disorder), as well as for disorders such as learning disabilities, where a neurological basis is presumed. In effect, historically, when an individual was referred for a neuropsychological assessment, oftentimes the primary purpose was to identify (or rule out) pathology. More recently, however, the emphasis has shifted to identification of strengths and weaknesses (Brickman, Cabo, & Manly, 2006; Hale et al., 2010; Riccio & Reynolds, 1998; Wong, 2006). This is in part due to the research that suggests that children with neurodevelopmental disorders are those who have, or who are at risk for, limitations in some or all life activities as a result of impairments in the central nervous system (Mudrick, 2002; Spreen, Risser, & Edgell, 1995). The possible

consequences and limitations range from mild to severe cognitive, sensory, motor, educational, and behavioral/psychological impairments (Mendola, Selevan, Gutter, & Rice, 2002).

The neuropsychological approach to case conceptualization incorporates information related to various behavioral domains believed to be reflect functional neurological systems (Luria, 1980; Riccio & Reynolds, 1998). A major premise of neuropsychological assessment is that different behaviors involve differing neurological structures or functional systems (Luria, 1980; Stuss & Levine, 2002); neuropsychological assessment is intended to be comprehensive enough to address all functional systems. As such, a neuropsychological evaluation provides for consideration of a wider array of functions than is addressed in a typical psychological or psychoeducational evaluation (Dean, 1986;

Reynolds & Mayfield, 1999) and includes assessment of perceptual, motor, and sensory areas; attention; executive function (planning, organization, problem-solving); and learning and memory (Dean & Gray, 1990; Reynolds & Mayfield, 1999; Riccio, 2008; Riccio & Reynolds, 1998). Although there is no agreed-upon model or approach (Wong, 2006), a number of models have been proposed to explain the interface between brain function and behaviors associated with childhood psychopathology, including Luria's model (Korkman, 1999; Luria, 1980).

It has been suggested that neuropsychological assessment of children provides a better understanding of the ways in which neurological conditions have an impact on behavior and the translation of this knowledge into educationally relevant information (Goldstein & Naglieri, 2008). Advances in the understanding of neuroanatomical correlates, as well as neuropsychological perspectives, have improved the understanding of autism (Carter et al., 2008; Iacoboni & Mazziotta, 2007; Kleinhans, Müller, Cohen, & Courchesne, 2008; Oberman, Ramachandran, & Pineda, 2008; Verte, Geurts, Roeyers, Oosterlaan, & Sergeant, 2005), attention deficit hyperactivity disorder (ADHD; Goldstein & Naglieri, 2008; Krain & Castellanos, 2006; Martel, Nikolas, & Nigg, 2007; Seidman, 2006), language impairment (Ballantyne, Spilkin, & Trauner, 2007; Chiarello, Kacnik, Manowitz, Otto, & Leonard, 2004; Cohen, Hall, & Riccio, 1997; Cohen, Riccio, & Hynd, 1999; Im-Bolter, Johnson, & Pascual-Leone, 2006), and other disorders. These advances facilitate the development of interventions and lead to better understanding. Improved understanding of the child's strengths and weaknesses potentially can be used to identify areas that may provide difficulty for the child in the future, as well as to suggest compensatory strategies or methods to circumvent these difficulties. Furthermore, many components of neuropsychological assessment can be helpful in providing documentation of changes in behavior and development over time with regard to genetic and neurodevelopmental disorders (Reynolds & Mayfield, 1999). Thus, neuropsychological assessment may be considered appropriate whenever a child is suspected of having a neurological disorder or when it is believed that the integrity of the central nervous system (CNS) has been compromised in some way. As previously stated, the intention of such an assessment is no longer the localization of damage or dysfunction; it also is not solely for diagnostic purposes, but for identification of individual strengths and weaknesses in order to

inform rehabilitation efforts. Neuropsychological assessment is "hypothesis-driven"; it involves integration of all the information obtained in the context of neurodevelopmental systems (Berkelhammer, 2008; Hale Fiorello, Bertin, & Sherman, 2003). The goal of this integration is the generation of recommendations for habilitation, accommodations, or modifications. The ultimate goal of the assessment should be to derive a case conceptualization that informs intervention or rehabilitation planning. This case conceptualization is based on the individual's performance across a variety of domains, with attention to developmental contexts, inferences about brain integrity, and application of the understanding of brain-behavior relations (Stuss & Levine, 2002). There is no single approach or combination of measures, but rather a set of principles and standards (some of which apply across all forms of assessment) that guides neuropsychological assessment. The purpose of this chapter is to present and discuss some of these principles in the context of neuropsychological assessment and theory. These principles are summarized in Table 14.1.

## **Ethical and Legal Considerations**

As with other types of assessment and service delivery in psychology, the most basic ethical considerations and standards are taken from the American Psychological Association ethical guidelines and code of conduct (American Psychological Association, 2002). In addition to APA ethics, the first set of guidelines formally reviewed and endorsed by the American Academy of Clinical Neuropsychology (AACN) was published in 2007 (AACN Board of Directors, 2007). The Board guidelines were developed as a next step in defining the training and practice of clinical neuropsychology; they incorporate the common features of previous endeavors to establish core training requirements (Hannay et al., 1998), as well as general approaches to valid and appropriate neuropsychological assessment (Lezak, Howieson, & Loring, 2004). Although specific to the provision of neuropsychological services, the guidelines were developed to be compatible with other existing ethical and practice guidelines, including those of the APA. As with all guidelines, those developed by the AACN Board are described as a means of facilitating development of the profession, and are aspirational. At the same time, they represent a "high level of professional practice" (AACN Board, 2007, p. 281). Some, but not all, of these ethical principles will be discussed specifically as they apply to neuropsychological assessment.

**Table 14.1 Principles in Neuropsychological Assessment**

Principle (Source)
General ethical principles:
Obtain informed consent; ensure understanding of the purpose and scope of the evaluation; determine competency to provide consent if age 18 or older (American Psychological Association, 2002; AACN Board, 2007; Bush, 2005; Heilbrun et al., 2003; Moberg & Kniele, 2006; Wong, 2006).
Discuss issues of confidentiality, billing, release of information (American Psychological Association, 2002; Bush, 2005; Bush & Martin, 2008).
Maintain records and ensure confidentiality consistent with ethical and legal requirements (American Psychological Association, 2002; Bush, 2005; Bush & Martin, 2008).
Clarify role and relationship, for example, as expert witness or clinician (American Psychological Association, 2002; AACN Board, 2007; Heilbrun et al., 2003).
Appropriately portray competency and limits of training (American Psychological Association, 2002; AACN Board, 2007; Bush, 2005; Hartlage & Long, 2009).
Planning and organizing the assessment:
Identify the most appropriate theoretical model to guide information gathering and interpretation (Heilbrun et al., 2003).
Obtain a comprehensive developmental, educational, and medical history from which to generate <i>a priori</i> hypotheses (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Use multiple methods and multiple sources for all aspects of the assessment (Heilbrun, et al., 2003; Reynolds & Mayfield, 1999).
Plan, conduct and integrate assessment so that it is informative to prevention/intervention planning (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
In choosing the specific measures and methods to be included:
Consider the neurodevelopmental context, as well as any medical or physical limitations of the child (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998; Simeonsson & Rosenthal, 2001).
Consider the family context and availability of family supports (Rosenthal et al., 2001).
Consideration of cultural context and primary language, both in the assessment and the design of interventions.
Consider school context through collaboration with school personnel in the assessment process (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Ensure coverage of all cognitive and higher-order processes that may impact on educational performance (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Ensure coverage of all four quadrants of the cortex (left, right, anterior, posterior; Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Consider psychometric properties of the measures to be included (reliability, validity, sensitivity, specificity; Reynolds & Mason, 2009).
Consider the extent to which the measures provide information about real world functioning (ecological validity; Rabin, Barr, & Burton, 2005; Sbordone, 2008).
Include measures to assess social, emotional, behavioral, and personality aspects (Teeter et al., 2009).

*(continued)*

**Table 14.1 (Continued)**

Principle (Source)
Inference and interpretation:
Make inferences that are based on all available evidence (Fennell & Bauer, 2009).
Identify any intact complex functional systems (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Identify the child's specific deficits (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Communication of results:
Provide a written report that is both comprehensive and understandable to the stakeholders who receive it (Heilbrun et al., 2003; Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Identify and communicate how these strengths and weaknesses relate to educational and social functioning (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998).
Make appropriate recommendations that follow from the conclusions and are consistent with the contexts in which the child functions (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998; Teeter, 2009).

### **Consent and Related Issues**

Taken together, both APA's ethical code and the AACN Board's guidelines include similar components with respect to the need for *consideration of informed consent*. With children and adolescents, there are special considerations involved with consent to psychological assessment and services, as their parent(s) or guardian(s) usually provide(s) the consent (Jacob & Hartshorne, 2007); these considerations are also in place with neuropsychological assessment. With older adolescents, and the transfer of rights from parents to the adult child at age 18, given that neuropsychological assessment is often considered in light of known or suspected brain damage, additional concerns may be present. As yet, there are no agreed-upon criteria for determining competency of the individual to give consent; most of the discussion related to competency is related to treatment issues or forensic situations (Moberg & Kniele, 2006).

Regardless of the consenting party, it is necessary for the neuropsychologist to *establish the aim and scope of assessment* in language that is readily understood and includes agreement on any financial aspects. As with any assessment, this should include the types of procedures to be used as part of the process; any change will necessitate renegotiation of the scope, and financial agreement as appropriate, with the consenting party (AACN Board, 2007; Jacob & Hartshorne, 2007). *Roles and responsibilities need to be defined and limits of confidentiality specified.* In forensic cases, it will be necessary for the neuropsychologist to carefully define whether they are conducting the assessment as an "expert witness" or as a "clinician," as this may affect

whether they advocate for the system or for the client (AACN Board, 2007; Heilbrun et al., 2003). With children, this includes defining one's role if the assessment is conducted as part of an independent educational evaluation (IEE) (Wills, 2008).

### **Clinician Competency**

Of the ethical considerations, probably one of the more controversial is the issue of clinician competency. Historically, there have been few formal training programs in neuropsychology, with the first documented guidelines for establishing competency in neuropsychology established by the International Neuropsychological Society (INS) in 1973 (Hartlage & Long, 2009). Since then, more formal training programs have emerged, with approximately 40 programs offering a degree in neuropsychology (Bieliauskas, 2008; Hartlage & Long, 2009), and various delineations of what should compose training for neuropsychology have been offered (Bieliauskas, 2008; Hannay et al., 1998). Definitions offered by both Division 40 of the American Psychological Association (Clinical Neuropsychology) and the National Academy of Neuropsychology (NAN) suggest at least two years of specialized training, including formal (university) training in neuropsychology and neuroscience (Division 40), or the study and practice of clinical neuropsychology and neuroscience (NAN). More detailed explanations are available from each of these organizations and in the Board document, as well as reviewed in Hartlage and Long (2009). Notably, consistent with the doctrine of the APA, the term *neuropsychologist* is presumed to

be reserved to those holding a doctoral degree in psychology, with the neuropsychology and neuroscience training additional to the base competencies for the practice of psychology (AACN Board, 2007). At the same time, the Board does not state that individuals must have this training to use specific measures that may be considered “neuropsychological”; rather, both the APA ethical code and the Board guidelines reflect the need for truthful representation of whether the training of the individual is consistent with the appropriate use of the title. *More advanced clinical training is prerequisite to the inferential and interpretation process* involved in neuropsychological assessment than for the actual test administration (Hartlage & Long, 2009).

### **Other Ethical Considerations**

All of the other issues related to confidentiality, record-keeping, billing, test security, and so on, apply similarly to typical psychological evaluations and neuropsychological assessment (APA, 2002). Application of the theoretical bases for understanding brain–behavior relations (e.g., the Lurian model) across cultures is also being considered, with more and more individuals being seen coming from a variety of cultures and linguistic backgrounds (Kotik-Friedgut, 2006); with the increasing Hispanic population, much of the discussion has focused on this population (Judd et al., 2009). Regardless of the person’s language or culture, however, it is increasingly being recognized that *it is important for cultural and first-language issues to be considered in the planning process* (Byrd, Arentoft, Scheiner, Westerveld, & Baron, 2008; Harris, Wagner, & Cullum, 2007; Judd et al., 2009; Llorente, 2008; Smith, Lane, & Llorente, 2008). Of particular concern is, not only the appropriateness of some of the tasks with culturally and linguistically diverse individuals, but also the use of interpreters (APA, 1993, 2002). Additional issues relate to the model of assessment being used, the approach to test selection, and psychometrics and test standards. These are discussed in the context of the assessment process.

### **Planning and Organizing the Assessment**

In planning and organizing the assessment, it is important that the clinician have some *theoretical model* in mind; oftentimes this is an application of Luria’s model (Korkman, 1999; Luria, 1980), but it may also reflect Cattell-Horn-Carroll or other models of cognitive ability (Naglieri, Conway, & Goldstein, 2009), which may or may not be in some way related to Luria’s model. Using Luria’s model, for example, neuropsychological assessment

generally consists of a number of functional domains that are, based on clinical evidence, associated with functional systems of the brain. Applying Lurian principles requires that the assessment itself be organized in such a manner that the majority of the areas of functioning, as well as the various contexts in which the child is expected to function, are considered. Measures and observations need to include the various contexts in which the child functions, and the associated expectations of the child, particularly within the educational context. For this reason, regardless of the theoretical model, the neuropsychological assessment should be organized to ensure *evaluation of the majority of cognitive and higher-order processes that relate to educational functioning*. Some key features from this perspective have been identified elsewhere and will be discussed further here (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998); methods and measures are discussed in other chapters. Regardless of the approach, however, *multiple sources of information should be used for each area or domain being assessed; multiple methods also should be utilized to maximize the information garnered from the assessment process* (Heilbrun et al., 2003; Reynolds & Mayfield, 1999).

Neuropsychological assessment of a child or adolescent needs to incorporate information from a variety of sources (e.g., parents, teachers, physicians, medical records, school records, and so on). In many cases, school records may include test results from a prior psychoeducational or psychological evaluation: *whenever possible, it is recommended that the neuropsychological assessment be coordinated with the child’s school district* (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998; Wills, 2008). If prior testing is not already available, it may be appropriate for school personnel (e.g., school psychologist, speech/language pathologist) to participate in the evaluation process, thus reducing the financial strain on the school system and family. Equally due consideration is the fact that schools are the second major environment in which children must function. In many ways, schools and school personnel have the greatest long-term impact on outcome, as the resources and support available from the school district will continue to follow the child through to graduation. This type of collaborative effort also can facilitate program planning for the child in the school setting in that school personnel will be intimately involved in any arrangements for school-based direct or indirect service delivery for the child (Riccio & Reynolds, 1998). Assessment of resources available in the schools, with in-service

training for educators and administrators as needed, may be appropriate (Goldstein & Naglieri, 2008).

### **Background Information**

The history and review of prior medical and educational records provide some standard information about a child and the basis for an initial hypothesis-formation. *Obtaining a comprehensive history is an important component of neuropsychological assessment*, as the complete history provides useful information to help differentiate chronic deficits or neurodevelopmental disorders from new, acute problems (Riccio & Reynolds, 1998). Information on the child's developmental and social history provides input related to the onset, duration, and intensity of the problems of concern; it provides the information needed to differentiate chronic deficits or neurodevelopmental disorders from new, acute problems (Reynolds & Mayfield, 1999). Family history and the identification of family stressors also provides information on the supports available within the family system; *as it is the primary setting in which a child functions, consideration of the family context is critical* (Rosenthal, Cohen, & Simeonsson, 2001). A number of developmental and social history forms exist for this purpose. Most of these forms can be either completed in interview format or completed independently by the parents. The Structured Developmental History form (SDH) of the Behavior Assessment System for Children—Second Edition (BASC-2; Reynolds & Kamphaus, 2004) is one example of a developmental history questionnaire. The SDH solicits information specific to the prenatal, perinatal, and postnatal early childhood development, medical problems and concerns, exposure to formal education, progress in school, and so on. It also asks for information specific to the family situation, housing, leisure activities of the child, preferred activities, and so on, that may be helpful in case conceptualization and intervention planning (Riccio & Reynolds, 1998). Family history for various disorders, disciplinary techniques used in the past, medications used in the past, and other prior treatment information can be solicited with this single form (Reynolds & Kamphaus, 2004).

Other considerations may be of importance in planning and organizing the assessment process, including *accounting for medical conditions or limitations in communication that may require special attention* (Simeonsson & Rosenthal, 2001). In particular, for individuals with chronic illness, the length of time required for neuropsychological

assessment demands that fatigue be considered and assessment be broken into smaller, manageable segments. Planning and organizing the assessment includes identification of the domains to be assessed to ensure comprehensive coverage. Specific areas that are included in the neuropsychological assessment that are not usually included in depth as part of a standard psychoeducational battery include the sensory, motor, auditory/linguistic, and visual perceptual areas; as well as learning and memory; attention; and the executive functions of planning, organization, and problem-solving (Dean & Gray, 1990; Riccio & Reynolds, 1998). These domains and the range of methods available for assessment have been identified elsewhere in this volume, as well as in other texts (see Hartlage & Long, 2009; Riccio, 2008, for examples). It is also important to ensure that measures are included that will directly address any *a priori* hypotheses (i.e., hypothesis-driven assessment). The assessment process is hypothesis-driven (Berkelhammer, 2008) to the extent that the methods and measures are selected based on hypotheses regarding the underlying pathology derived from the reason for the referral, the medical history, and any developmental information obtained in advance. With all these considerations, a theoretical model, and hypotheses, the next step is the actual selection of tests to be included, and a discussion of psychometric standards, sensitivity, and specificity.

### **Test Selection**

Cognitive and achievement measures are usually components of a psychoeducational evaluation; they are also components of a neuropsychological assessment. Many cognitive tasks (e.g., those requiring concept formation or reasoning) provide a general sense of CNS integrity. To make a determination of overall functioning, however, it is important to ensure that the results obtained allow for the *evaluation of the four major quadrants of the neocortex* (left, right, anterior, posterior; Reynolds & Mayfield, 1999). Therefore, it is important that the assessment sample the relative efficiency of the right and left hemispheres; this is important in that, to some extent, differing brain systems are involved in each hemisphere. Similarly, the anterior of the brain is generally viewed as subserving differing functions (e.g., regulatory) as opposed to the posterior region of the brain (receptivity). For this reason, anterior-posterior comparisons can provide important information for treatment planning. One reason to be sure to cover all four quadrants is that, regardless of

the nature or extent of the injury or disorder, there may be a greater impact on one area of the brain as opposed to others; most cognitive measures do not necessarily tap all four quadrants of the cortex (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998). Therefore, to accomplish this goal, additional measures are included in the assessment process.

### **FIXED BATTERY OR FLEXIBLE BATTERY APPROACH**

Many clinicians use a predetermined battery of tests for the neuropsychological assessment of children (Koziol & Budding, 2011; Riccio, 2008); this is often referred to as the “fixed battery” or nomothetic approach. Specific fixed batteries such as the Halstead-Reitan Neuropsychological Battery (HRNB; Reitan & Davison, 1974; Reitan & Wolfson, 1985), the Kaplan Baycrest Neurocognitive Assessment (Leach, Kaplan, Rewilak, Richards, & Proulx, 2000), or the Neuropsychological Investigation for the Children, Second Edition (NEPSY-2; Korkman, Kirk, & Kemp, 2007) may be used in neuropsychological assessment in conjunction with cognitive and achievement measures, as well as measures of behavior and personality. These neuropsychological batteries are designed to provide a sampling of sensory and motor functions so that information relating to left/right hemisphere differences and anterior/posterior differences are provided. Furthermore, they are intended to be compatible with the Luria model (Korkman, 1999; Luria, 1980). Of these, the HRNB continues to be one of the most widely used neuropsychological test batteries, but there are concerns with its normative data and the cultural loading of some tasks; if it is going to continue to be useful in clinical practice, it may need to be revised and updated normative data obtained across samples (Sinco, D’Amato, & Davis, 2008).

Alternatively, neuropsychologists may use a flexible battery approach (Koziol & Budding, 2010). With this approach, the neuropsychologist combines a number of tasks (some of which may come from one of the fixed batteries) based on their own training philosophy or a variation in a model; they may use a fixed battery for major components, but supplement it with additional measures. For example, other, but similar measures (e.g., a different trail-making task) may be used instead of the Trails A and B tasks of the HRNB; or specific tasks from the fixed batteries may be combined to provide additional coverage of domains of interest for a given population or related to a particular theoretical

model. The selection of tests is then intended to fit that model, but it should also ensure comprehensive coverage of brain function. The theoretical model should lead to accurate predictions about the individual’s ability to function in multiple contexts and inform intervention planning (Reynolds, Kamphaus, Rosenthal, & Hiemenz, 1997; Riccio & Reynolds, 1998). This is one of the core assumptions of the Comprehensive Hypothesis Testing model (Hale & Fiorello, 2004; Hale et al., 2003).

With one model, the deficit model, clinicians take a much more idiographic approach and tailor the selection of measures based on the presenting problems of the child, with other measures added based on the child’s performance on initial measures (Berkelhammer, 2008; Christensen, 1975; Luria, 1973). This type of approach is intended to isolate the mechanisms that are contributing to a specific, identified problem as part of hypothesis testing. Furthermore, the more idiographic approach may fail to assess domains that are important and will subsequently have an impact on rehabilitation efforts (Riccio & Reynolds, 1998). Alternatively, good organization and planning can identify in advance appropriate measures to accomplish the comprehensive coverage. Ultimately, a clinician could begin with a fixed battery, and then adopt a more idiographic approach to ensure more in-depth coverage of the specific areas of concern or the areas that might not be covered in an existing fixed battery. A concern with regard to the idiographic and flexible battery approaches is the potentially high number of differing normative samples used in generating the scores and the added error variance that can result (Wong, 2006). In some cases, test publishers are choosing to link normative samples of various measures to help address the potential problems in using a flexible or idiographic battery, or even when supplementing the fixed battery with cognitive and achievement testing. The profession, as represented by the various professional organizations, has yet to take a strong position on the issue of whether a fixed battery, flexible battery, or idiographic approach is better; as a result, this tends to vary as a function of clinician training and choice (Wong, 2006).

As noted earlier, even with a fixed battery, there is a need to supplement the battery in order to get a complete picture, including a summary of the child’s past history and family system, as well as any other factors that may explain the child’s current pattern of functioning. Furthermore, regardless of the type of battery or model one uses, the

assessment may or may not include naturalistic observation and informal assessment (Reynolds, 1997); the approach may be standardized or incorporate a process orientation (Kaplan, 1988, 1990; Milberg & Hebben, 2006); the orientation may be more quantitative or more qualitative. In fact, many clinicians prefer a combination of quantitative and qualitative measures to balance the strengths and weaknesses of both approaches; however, reliance on a qualitative approach is not easily replicated and inter-diagnostician agreement may be compromised (Poreh, 2006).

### PSYCHOMETRIC CONSIDERATIONS

Although there is much variation in neuropsychological assessment, *it is important to attend to the psychometric properties and limitations of available measures* (Reynolds & Mason, 2009). Neuropsychology, historically, has been criticized for its failure to incorporate psychometric advances in test use and construction (Cicchetti, 1994; Ris & Noll, 1994). One major concern relates to the extent and nature of normative data for many measures used in the neuropsychological assessment of children (Reynolds, 1986a). Sound normative data provide a necessary backdrop with which to validate clinical insight and hypotheses, yet it is often lacking (Reynolds, 1997). Because of the need for adequate normative data, some clinicians advocate the interpretation of traditional measures of cognitive ability (e.g., the Wechsler scales) from a neuropsychological perspective. Concerns and criticisms arise with the re-categorization of subtests from standardized measures that (a) were not developed based on neuropsychological theory, and (b) have not been validated for this purpose (Kamphaus, Petoskey, & Rowe, 2000; Lezak, 1995; Lezak et al., 2004). Others have developed cognitive measures in alignment with neuropsychological models (Das, 2001, 2002; Reynolds et al., 1997).

Not only are normative data oftentimes a concern, but neuropsychologists may overlook the psychometric concepts of reliability and validity, making interpretations based on the “clinical” nature of the tasks. The need for the *establishment of the reliability and validity of scores with differing populations and purposes*, as well as their interpretation related to neuropsychological test performance, has been an important issue in the literature (Reynolds, 1982; Reynolds & Mason, 2009; Riccio & Reynolds, 1998). Reliability is a key component not only in that it is directly related to inter- and intra-individual differences, but also because it is

the foundation for the validity of the test results and conclusions (Reynolds, 1986b). In this regard, the reliability of cross-cultural use of measures continues to be a concern (Smith et al., 2008).

A related concern is the *developmental appropriateness of measures with children*. Unfortunately, many of the measures used with adults are not appropriate to developmental issues, and, as a result, the usefulness of the same procedures used with adults for the neuropsychological assessment of children has multiple pitfalls (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998). Neuropsychological assessment of children and adolescents requires not only measures that have sufficient empirical support for the inferences being made, but, moreover, it is important to document that the measures are consistent with neurobehavioral and neurodevelopmental functioning in children (Cohen, Branch, Willis, Weyandt, & Hynd, 1992; Reynolds & Mayfield, 1999). Thus, in addition to selecting tests based on psychometric properties, it has been suggested that measures used in the neuropsychological assessment process need to vary along a continuum of difficulty, include both rote and novel tasks, and include variations with regard to processing and response requirements within modalities (Rourke, 1994, 2005).

The sensitivity of a measure is most often in the context of detecting a disorder; in this context, “sensitivity” refers to whether the measure is sensitive to brain damage or dysfunction in a global sense. For measures that purport to reflect more specific brain function, the question is whether the measure is in fact doing just that. Several studies have investigated the “science” behind the use of specific measures (Riccio & Hynd, 2000; Riccio, Reynolds, Lowe, & Moore, 2002). For example, there is evidence that continuous performance tests (CPTs) are *sensitive* to brain dysfunction, with various components of the CPT associated with the neural substrates of attention and inhibition (Riccio et al., 2002). A related aspect is that of specificity. It is not sufficient for measures to be sensitive to brain dysfunction and neurodevelopmental changes. They also need to have *specificity* in order to facilitate differential diagnosis and the identification of specific strengths and weaknesses. For example, the Luria Nebraska Neuropsychological Battery – Children’s Revision (LNNB-CR) has been found to be sensitive to deficits in language and rhythm as well as in reading and writing (Geary & Gilger, 1984), and in understanding learning problems (Tramontana, Hooper, Curley, & Nardolillo, 1990); however, the specificity of the LNNB-CR is questionable (Morgan &

Brown, 1988; Snow & Hynd, 1985). Similarly, continuous performance tests generally have a high level of sensitivity, but lack specificity (Riccio et al., 2002). Few studies have examined the sensitivity and specificity of measures cross-culturally. Thus, *it is important to consider the sensitivity and specificity of the measures and methods being used, particularly with regard to cultural and linguistic differences.*

### **PRACTICAL AND ECOLOGICAL CONSIDERATIONS**

As noted earlier, a key principle is the collaboration with and consideration of the school and home contexts. In order to effectively link assessment to intervention in a meaningful manner, it is important to consider all contexts and the child's level(s) of functioning in those contexts. In effect, even if the measures reflect integrity of brain function (or atypicality in brain function), the information obtained may not reflect the child's day-to-day functioning, or what has been referred to as "ecological validity" (Rabin, Burton, & Barr, 2007; Ready, Stierman, & Paulsen, 2001; Sbordone, 2008). It may seem logical to presume, for example, that measures of executive or frontal lobe functioning will *reflect the real world behaviors of the child* (or adult), but in fact, there is little evidence that this is the case. For this reason, it is important to include information from others (parents, teachers) as to daily functioning in the various domains. The Behavior Rating Inventory of Executive Function (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000) is one example of a rating scale that can be used to add to the information available from performance-based measures; it has been used effectively to examine day-to-day executive functions in several childhood disorders (Gioia, Isquith, Kenworthy, & Barton, 2002). The Behavior Assessment System for Children–Second Edition (BASC-2; Reynolds & Kamphaus, 2004) also covers these areas in detail, and if used, will negate the need for more specialized scales like the BRIEF.

### **SOCIAL-EMOTIONAL/PERSONALITY ASPECTS**

It is important to *consider social-emotional/personality aspects as a component of the neuropsychological assessment process*, both as part of the case conceptualization and in identifying targets for intervention or treatment. Research consistently demonstrates that adjustment and behavioral problems are associated with children who have neurodevelopmental deficits secondary to, if not as a direct result of, the neurological impairment (Beitchman, Brownlie, &

Wilson, 1996; Breslau & Chilcoat, 2000; Faraone, Biederman, Weber, & Russell, 1998; Miniscalco, Nygren, Hagberg, Kadesjö, & Gillberg, 2006; Teeter et al., 2009). Given this potential for adjustment difficulties a transactional/reciprocal framework is appropriate (Batchelor, 1996; Teeter, 2009). A transactional model takes into consideration the reciprocal interactions of the child; home and family members; teacher and peers; and other social environments in which the child functions.

The family system may be disrupted as a result of a child in the family having a disability; this is most evident with traumatic brain injury (TBI), but is also evident in the family systems of those with neurodevelopmental and congenital disorders. The family may react with denial or may avoid dealing with necessary issues associated with the child's disability; parents' hopes may be discrepant from realistic expectations (Ryan, LaMarche, Barth, & Boll, 1996). The importance of the family system in the long-term recovery and adjustment, as well as the effects of the injury on the family system, have been recognized in the literature (Gan, Campbell, Gemeinhardt, & McFadden, 2006; León-Carrión, Perino, & Zitnay, 2006); although not studied as extensively as with TBI, the family system is an important component to be considered for evaluating any child with a disability (Teeter, 2009). Therefore, some type of assessment (quantitative or qualitative) is needed to determine the impact of the child's functioning level on the family system in order to determine the extent to which family-based intervention should be included as part of the intervention program. At the same time, the supports and services available through the family system need to be identified.

The most common approach to emotional and behavioral assessment relies on published rating scales. A multifaceted (i.e., multi-method, multi-source) approach that includes parent and teacher rating scales, self-report measures, direct observation, and clinical interviews provides the most comprehensive and broad-based view of the child's emotional and behavioral status (Kamphaus & Frick, 2002; McConaughy & Ritter, 2002; Reynolds & Kamphaus, 2004). For example, the BASC-2 includes not only teacher and parent forms, but also a structured observation system (SOS) and, for children over age nine, a self-report measure that can be used to assess emotional and behavioral status effectively. A major advantage to the BASC-2 (rating scales and SOS) is the inclusion of positive adaptive behaviors (e.g., social skills, adaptability

to change in the environment) in addition to the more common maladaptive skills included on other rating scales. When adaptive behavior is an identified concern, completion of a more comprehensive adaptive behavior scale may be helpful for intervention planning. With the BASC's second edition, the additional content scales (e.g., Autism, Executive Function) are also helpful.

## Inferences and Interpretation

When neuropsychological theory is applied to children and adolescents, the premise that their behavior can be used to make inferences about their brain function and integrity has to be modified to include consideration of neurodevelopmental differences (Hooper & Tramontana, 1997; Koziol & Budding, 2010; Riccio & Reynolds, 1998). "Inference" refers to the process one uses to reach a conclusion on the basis of all available evidence (Fennell & Bauer, 2009). There are multiple levels of inference (Fennell & Bauer, 2009; Hartlage & Long, 2009). The initial or low level of inference involves the dichotomous choice of whether brain dysfunction either is the likely cause or is the contributing factor to the impaired functioning. In contrast, higher levels of inference implicate specific neurological abnormalities (e.g., a tumor, epilepsy) as the causal factor. Most often the inferences made fall somewhere in between, such that based on the data obtained, there is an inferred level of brain integrity or dysfunction with some stated relationship to the child's cognitive or behavioral presentation (Hartlage & Long, 2009).

The inferential process should adhere to some organized set of rules that includes the type of information needed to make an inference, and *the level of inference that can be made based on the data or evidence available, as well as the logical connections that can be made between the data and the conclusions reached* (Fennell & Bauer, 2009). Following from these presumably basic rules, in neuropsychological assessment, the "data available" include all of the available information gathered as part of the assessment process to make inferences about brain function and brain integrity. The extent to which one can reasonably infer that poor performance on a given task is indicative of dysfunction in a specific neurocognitive domain, or inferred to reflect brain function, is highly dependent on the neurological validity (i.e., the extent to which the measure has been shown to reflect specific neurological substrates; or criterion validity), as well as psychological validity (i.e., the extent to which the measure has been

shown to reflect some aspect of functioning in a meaningful way; or ecological validity). Across measures and methods, the extent to which inferences like these can be made differs at various points in development (Fennell & Bauer, 2009). Most importantly, the inferences or hypotheses are generated as a result of information obtained and data obtained. Inference involves an initial hypothesis or hypotheses, which are then tested to determine which one(s) are accurate (i.e., supported by the data). This is the basis of inductive inference, and it underscores the need to include multiple measures that examine the same domain from differing perspectives. This allows the neuropsychologist to examine performance on individual tasks as differing variables that function separately or in combination with other tasks, and the congruence or incongruence of a child's performance across these tasks allows for the inferences to be made about more specific aspects of brain function. At a very simple level, tasks of math calculation, math word problems, and math fluency all target some of the same math skills, but they also vary in some key ways. One may emphasize speed while another emphasizes reasoning; one might be limited to basic math facts with single digits to 10, and one involves more complex calculation problems. Employing a process approach, a fourth task might be added that includes a multiple-choice (recognition) format; alternatively, a fifth task might allow the use of a calculator in order to ascertain if the individual understands the concepts despite not knowing the math facts. Having a combination of tasks allows for some disassociation of the possible factors associated with the area of concern; it further informs the focus of intervention or remediation.

Thus, the cumulative performances of the child on neuropsychological measures are seen as behavioral indicators of brain function (Fennell & Bauer, 2009). The additional areas of functioning included in the neuropsychological assessment are needed to support inferences about the integrity of various functional systems of the brain. Results are interpreted based on functional neuroanatomy and brain development in order to approximate (i.e., hypothesize about) the extent and nature of brain damage or dysfunction while considering the context (Berkelhammer, 2008). As such, inference is the first step in the process of interpretation. The inferential process involves an initial development of hypotheses, as well as the validation of those hypotheses (Fennell & Bauer, 1997, 2009); hence, the hypothesis-driven conceptualization of the assessment process (Berkelhammer, 2008). This inferential

process needs to take into consideration not only the type of functional system(s) impaired and the number of systems impaired, but also the characteristics of the impairments (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998). Additional assumptions in neuropsychology dictate that the measures used as a basis for inference provide valid information (i.e., have demonstrated construct validity), and that the measures provide meaningful information on aspects of the individual's functioning (have ecological validity). Based on all of the data generated in the evaluation process and inferences, hypotheses are generated that are specific as to how and why the individual processes information; hypotheses are also offered as to what areas of functioning are likely to be affected in the future (Berkelhammer, 2008; D'Amato, Rothlisberg, & Rhodes, 1997; Dean, 1986). Information on strengths and weaknesses is then used to generate an appropriate rehabilitation or habilitation plan. The inferential interpretation process is heavily impacted by the neuropsychologist's clinical skills and acumen (Hartlage & Long, 2009).

One inference that may be made is a *general conclusion about integrity of brain function*. This conclusion may be based on the subject's overall performance level across tasks (Reitan, 1986, 1987). For example, one method is the use of criterion or cutoff scores, such that a score above (or below) a criterion is considered indicative of brain damage or impaired function. With increased emphasis on psychometric methods, use of normative data, and measures that provide valid and reliable results are emphasized in the contemporary literature, the use of a criterion score is not seen as strong evidence for the inference. This is particularly critical when working with individuals from diverse backgrounds and individuals who were not part of the sampling process (Llorente, 2008). With the actuarial or normative model, conclusions are reached based on a comparison of the child's overall level of performance to normative data. There are multiple problems with this model as well, including the variability among typically developing children, insensitivity for individuals with higher cognitive abilities, and a tendency to yield a high number of false positives due to the potential impact of fatigue and motivation on test performance (Nussbaum & Bigler, 1997; Reitan & Wolfson, 1985).

Another inferential model used in interpretation examines performance patterns across tasks (Reitan, 1986, 1987) as a means of differentiating functional from dysfunctional neural systems; this

may incorporate examination of intra-individual differences or *asymmetry* (i.e., lateralization of function; Reitan, 1986, 1987). Examination of intra-individual differences allows for identification of strengths as well as weaknesses; emphasis on a strength model for intervention planning is viewed as more efficacious than focusing only on deficits (Reynolds et al., 1997). Again, this is usually addressed in terms of *anterior-posterior differences* or *left-right differences*, rather than on consideration of single scores, but it also may be done by comparison of auditory/linguistic, visual/spatial, and domains of function that parallel the four quadrants.

Another model of interpretation involves looking for, or identifying, what are called "pathognomonic signs or clear signs of brain damage of some kind (Fennell & Bauer, 2009; Kaplan, 1988; Lezak et al., 2004; Reitan, 1986, 1987; Spreen et al., 1995). While this method has been used reliably with adult populations, the reliability of this approach with children has not been demonstrated (Batchelor, 1996). Similarly, the reliability of profile analysis has not been consistently demonstrated (Iverson, Brooks, & Holdnack, 2008; Reynolds, 2007; Watkins, Glutting, & Youngstrom, 2005). In practice, clinicians use any one or some combination of these features (Reitan, 1986, 1987; Riccio & Reynolds, 1998) in the interpretation process, including clinical judgement. The extent to which a clinician relies on the features with less scientific basis or reliability will in turn affect the accuracy of the resulting interpretation (Fennell & Bauer, 2009).

A major component to the interpretation process is the *identification of the child's specific deficits* as well as the *identification of any intact complex functional systems*. Along with the identification of deficits, depending on their number and severity, it may be necessary to prioritize these in terms of their importance in the settings in which the child is expected to function (home and school). Consideration of strengths may help inform which specific evidence-based practices may be most likely to be successful for a given child. The specific goals and objectives, as well as recommendations for intervention, also need to be responsive to the information obtained regarding the home and school contexts, the clients' expectations, and the resources available (Riccio & Reynolds, 1998).

### ***Communicating the Results and Recommendations***

Whichever model one uses, whether measures or methods, it is important that the information

obtained be understood not only by medical professionals, but by all stakeholders. A critical issue that continues to be a problem is the translation of knowledge from neuropsychology (the science component) to the contexts in which children function (the practice piece). There is a definite need to ensure that information garnered from neuropsychological assessment be useful to the consumers receiving the information—the parents, the schools, and the physician. One factor that may contribute to the impression that neuropsychological assessment does not transfer into rehabilitation programming may be that, all too often, neuropsychological reports are written expressly for medical personnel or acute-care facilities from a biomedical model (Fletcher-Janzen & Kade, 1997). Thus, *test results need to be presented in such a way that all stakeholders (including parents and educators) can understand both the abilities and the problems of their child.* Teachers, as well as parents, look to the report for information regarding the child's current status; they also may be concerned with the potential trajectory and prognosis. As noted by others (e.g., Reynolds & Mayfield, 1999), reports should be written in language that is easily understood, and concrete examples or explanations should be provided. The focus of the report should be on the child and the child's level of functioning, as opposed to the tests or psychometric studies. The report should clearly *link the strengths and weaknesses with the child's functioning in real-world situations.* This is consistent with the trend toward consideration of strengths and weaknesses in determination of specific learning disabilities (Hale et al., 2010).

Finally, based on the information gleaned, recommendations for appropriate interventions need to be provided. Recommendations need to include information specific to whether the child would seem most likely to benefit from remediation, compensatory training, or some combination of both; this may vary from one deficient skill area to another. Potential instructional materials or methods that may be best suited to the child should also be indicated. Neuropsychological results provide information relating to the appropriateness of using specific types of interventions, such as neurocognitive therapy, or for a specific group of interventions, such as cognitive behavioral therapy (Reynolds & Mayfield, 1999). Recommendations need to be viewed as flexible with a broad scope that is efficient, integrated, and promotes growth (Fletcher-Janzen & Kade, 1997). Based on assessment of the specific contexts for a given child,

environmental modifications that may facilitate the child's academic progress and that are reasonable need to be identified. These often take the form of extended time for test-taking, options for oral testing, preferential seating, and decreased extraneous information. These also may include the use of any of a number of educational support materials (e.g., computers, calculators, tape recorders, audiotapes). As noted earlier, involvement of school personnel and family members as part of the assessment process increases the likelihood of their involvement in the service delivery. Their early involvement increases the likelihood that they will be involved and work to ensure the child receives the necessary and broad-based services (Fletcher-Janzen & Kade, 1997). Recommendations provided in the neuropsychological report relating to intervention and instruction may not be exhaustive; however, enough information should be provided from the assessment to assist in developing the appropriate intervention to meet the needs of the individual child. With the current climate, it is important to identify the evidence-based practices that have support for children with neurodevelopmental disorders.

## Conclusions

Neuropsychological assessment, and the field of clinical child neuropsychology in general, have much to offer in the way of understanding the learning and behavior problems of children and youth. It is important, however, that those conducting the assessment adhere to the basic ethical principles, as well as to basic principles that apply only to neuropsychological assessment. At the same time, while there have been significant advances in the knowledge base and a proliferation of measures and methods in neuropsychology, there are continued problems with the application of neuropsychological practices and perspectives to child assessment. Historically, neuropsychological assessment of children has taken its lead from research and practice with adults, and predominantly adults with acquired brain damage (Riccio & Reynolds, 1998). Issues relating to developmental issues, manifestation of developmental disorders over time, and the varying contexts in which children function, make this approach untenable. Furthermore, the continued methodological and measurement problems impede progress in the field of child neuropsychology, affect the accuracy of diagnosis, and pose serious problems for clinical practice (Reynolds, 1986a; Riccio & Reynolds, 1998).

## Future Directions

Child neuropsychology has made significant contributions to our understanding of children; neuropsychological assessment has the potential to contribute in the context of special education decision-making and intervention-planning, as well as to the understanding of specific disorders (Augustyniak, Murphy, & Phillips, 2005; Feagans, Short, & Meltzer, 1991; Goldstein & Naglieri, 2008; Hale et al., 2010; Hendriksen et al., 2007; Peters, Fox, Weber, & Llorente, 2005; Riccio, Gonzales, & Hynd, 1994; Riccio & Hynd, 1995; Schwarte, 2008). Further research and study of the linkage between neuropsychological assessment of children and the provision of information that is educationally relevant rather than medically focused for intervention planning is needed. With recent trends toward a Response to Intervention (RTI) approach to identification of children with disabilities, there has been increased discussion of how neuropsychology and neuropsychological assessment will fit in this model (Fletcher-Janzen & Reynolds, 2008). At its core, the RTI model is not focusing on a specific disorder, syndrome, or disease, but whether the child makes expected gains as a result of an intervention. The RTI approach may be adequate for *describing* the child's performance, but it may fall short in terms of *explaining* the child's performance or deficits; in effect, it does not answer the question of why the child did not respond to the intervention.

Using a Lurian perspective, there are still many unanswered questions regarding the developmental progression of many functional systems. Furthermore, how the neurodevelopmental progression maps onto cognitive functioning is not fully understood. This is an area that is in need of additional research with attention to the sensitivity of various measures and methods to subtle impairments, as well as change over time. This will require longitudinal research that looks at the performance across domains not only of children with neurodevelopmental disorders, but also of those who appear to be developing normally. For prevention, as well as intervention, purposes, identification of critical developmental periods, with the establishment of basic screening (i.e., benchmarking) prior to or at these critical times may be warranted.

# Models for the Personality Assessment of Children and Adolescents

Donald H. Saklofske, Diana K. Joyce, Michael L. Sulkowski, and Emma A. Climie

## Abstract

Personality theories hold a central position in the study of individual differences, from models outlining the underlying factors of personality to understanding “how we are both like others and yet unique.” Notably, the effort invested by psychologists in the research of personality rivals that directed at intelligence. However, much of the focus has been on adult personality with the assumption that personality formation in childhood is more variable and thus less psychologically-relevant than other developmental domains. Conversely, research has demonstrated that personality, although somewhat dynamic in childhood and adolescence, is clearly present and measurable at these earlier ages, particularly traits such as extraversion and neuroticism. Furthermore, temperament has received considerable recent study and it is shown to be reliably defined even in very young infants. This chapter reviews the personality trait and temperament literature with particular attention to personality assessment.

**Key Words:** Personality assessment, children, adolescents, personality theory, temperament

## Introduction

Psychological assessment of children and adolescents is challenging for many reasons. Gaining an accurate understanding of a child’s psychological characteristics and traits requires that a trained clinician use appropriate methods including standardized tests, questionnaires, observation, and interviews. The significance of personality traits in a description of individual differences is as important as intelligence or conative measures such as motivation and self-efficacy. There is a pressing need to better understand the personality types of adolescents and the emerging personalities of preadolescent children, especially for those who may be experiencing psychological challenges. It is also important to understand that adolescents are not simply viewed as “mini-adults.” Thus, merely modifying existing adult personality measures through simplifying and reducing the number of

questions or adapting and creating new norm sets will not provide an accurate understanding of the complexities of adolescent development (McCann, 2008).

Although personality assessment measures for children are gaining more widespread use in schools, mental health facilities, hospitals, and forensic settings, a strong theoretical understanding of the development of children’s personality styles and what the research evidence indicates is important in any clinical assessment. The assessment of personality provides complex challenges as a variety of factors must be considered in the creation of personality measures. These measures must be grounded in a solid theoretical foundation that allows for individual differences in measurement and the research-based findings that personality and personality assessment differ across the lifespan. Theoretical models developed to explain

adult personality such as the “Big Five” theory have become the catalyst for similar assessment constructs of personality factors in children (Kamphaus & Frick, 2002). However, there is a notable difference between adults and children in this regard. In part, this difference can be understood from research showing that some personality traits do not stabilize until adulthood (for review, see Caspi & Roberts, 2001). Therefore, personality assessments used with children and adolescents often coincide with aspects of overt behavior and sometimes psychopathology in addition to traditionally defined personality factors (Martin, Hooper, & Snow, 1986; Weis & Smenner, 2007).

### ***Theoretical Underpinnings of Personality Assessment in Children***

Personality factors in children have received considerably less research attention than have similar factors in adults. In fact, personality is not a core or central theme in the assessment and psychological description of children as it is for adults, at least not until adolescence. Certainly particular traits and behavioral descriptors such as aggression, anxiety, shyness, social skills, and self-concept are frequently assessed when children present with anger management problems, interpersonal conflicts, learning and attentional problems (e.g., Learning Disorders, Attention-Deficit/Hyperactivity Disorder, Autism Spectrum Disorder), or other problem areas that might require a comprehensive psychological assessment. But again, it is not until later adolescence that personality traits are more commonly used to describe psychological characteristics. While non-cognitive factors including both personality and conative factors are found in developmental theories of children, such affective qualities are usually linked to temperament.

No specific theories of personality focus exclusively on children. Even Freud’s psychosexual stages (i.e., oral, anal, phallic, latency, genital) as they relate to the personality development of id, ego, and superego had more relevance to understanding the causes of adult “neurosis” than in focusing on the personality of the child (exceptions of course being Anna Freud and others). Certainly, the developmental theory of Maslow (1943, 1954) who proposed a hierarchy of needs in the process of leading to self-actualization has its beginnings in the early stages of infancy. Likewise, Erikson’s (1963, 1982) eight stages of psychosocial development can be used as a framework for examining the personality development of children with the resolution at each

stage (e.g., trust versus mistrust) laying the foundation for the next stage (e.g., autonomy versus shame and doubt) as one progresses through the life span.

The social-cognitive theories of personality presented, for example by Bandura (1986, 2006; see also Cervone, 2008) certainly have applications to the childhood and adolescent years. Trait theories such as Eysenck’s “Super 3” (Eysenck, 1991) or the “Big 5” (e.g., Costa & McCrae, 2008) have been extended downward to include child and adolescent versions of their better-known and often used adult scales but without particular reference to a comprehensive theory of child personality. However, theories of temperament, focusing more on traits associated with affect, arousal, and attention, are a major focus of discussion of childhood behavior and for later adult personality. Strelau and Zawadzki (2008) define temperament as “a set of relatively stable personality traits present since infancy” (p. 352). For them, it is temperament as biologically determined traits that comprise the core of personality. Strelau and Zawadzki (2008) have also described the following characteristics of temperament: can be measured with high accuracy from a very early age, may be diagnosed in humans, are universal, have a genetic/heritable background and are related to biological mechanisms, demonstrate high temporal stability, manifest themselves in overt behavior, determine behavior in every day settings, and moderate both normal and abnormal behavior.

Again, depending on the author or researcher, personality and temperament are discussed either interchangeably or as separate but related constructs. For example, Asendorpf (2008) provides a general definition of personality that subsumes temperament and is developmental in its scope: “...includes at any age, any social-emotional characteristic of an individual that shows some stability over shorter time periods...that varies between individuals of the same culture...includes temperament (traits related to affect, arousal and attention) but does not restrict early personality to temperament” (p. 101). Thus, this chapter will examine models that are both labeled personality and temperament.

Personality must also be viewed across the lifespan and both qualitative and quantitative differences must be understood within a developmental framework. Asendorpf’s (2008) argument that personality is not a collection of traits and qualities that only appear after childhood is reflected in several principles. Personality is plastic at all stages of life but especially in the early years. Roberts and DelVecchio (2000) reported that the Big Five

personality traits are most variable in childhood and then become increasingly stable through adolescence and early to mid-adult years; however, it is not until 50 years of age or later that they become especially stable. The underlying causes of personality stability reflect genetic factors, selection of environments to fit or match one's personality, commitment to a stable personal identity, and resiliency (i.e., the capacity to address external challenges).

## Trait Models

Trait theories tend to dominate the personality literature (Boyle, Matthews, & Saklofske, 2008a, b). Costa and McCrae (2008) have emphatically agreed with the view that "traits are alive and well, and tools for their assessment are flourishing." (p. 192). However, this viewpoint would appear to be truer of adult scales in contrast to personality trait measures for children and adolescents. Several well-established adult personality trait models have been extended downward to the childhood and adolescent years, including the descriptions of Cattell, Eysenck, and Costa and McCrae. In brief, all of these models have employed factor analytic procedures to determine the structure of personality although Eysenck's model also has a solid basis in Pavlovian respondent conditioning, behavior genetics, and brain-behavior relationships (e.g., extraversion; Saklofske, Eysenck, Eysenck, Stelmack, & Revelle, 2012)

### Raymond B. Cattell

The contributions of Raymond Cattell in both describing and measuring personality are documented in his many books and articles and are more recently summarized by Boyle and Barton (2008) and Cattell and Mead (2008). There are 92 primary factors proposed by Cattell that have been reduced using factor analysis to 29 broad factors (30 with the curiosity construct). Probably best known of these is the Sixteen Personality Factor Questionnaire (16PF) that describes the constellation of 16 normal personality source traits, five global or second stratum factors (referred to as the "original Big Five" by Cattell & Mead, 2008) and two third stratum factors. This model included a broader set of second-stratum dimensions that has served as the foundation for other extensions of Cattell's various personality measures. Cattell was also most supportive of using a multi-method approach to personality measurement including life record data (L-data), questionnaire data (Q-data), and objectively derived data (T-data). However, it is the very complexity of Cattell's psychometric model that has likely limited

the impact that his work and measures have had in the applied practice areas of psychology and especially psychological assessment.

While the majority of Cattell's research and the personality tests were developed for use with adults, several measures are intended for children and adolescents. Stemming from the basic 16 PF model, these downward extensions to younger age groups have a smaller number of factors as a function of the developmental differentiation in personality that occurs over the age range. The better-known personality measures for children and adolescents include the High School Personality Questionnaire (Cattell & Cattell, 1975) which has been updated and renamed the Adolescent Personality Questionnaire, the Children's Personality Questionnaire (Porter & Cattell, 1985), the Early School Personality Questionnaire (Coan & Cattell, 1959), and the Preschool Personality Questionnaire (Dreger, Lichtenstein, & Cattell, 1995).

Dynamic traits that are less stable than personality traits but more stable than transitory mood-state dimensions are assessed with the School Motivation Analysis Test (SMAT; Boyle, 1989) or the Children's Motivation Analysis Test (CMAT; Boyle & Start, 1988). The CMAT can be used with primary school age children and appears to be tapping four broad factors labeled superego, narcissism, play, and self-sentiment. However, the school orientation factor present on the SMAT was not found in the analyses conducted by Boyle and Start (1988). While gender differences have been noted on the CMAT, Boyle (2008a) concluded that "these instruments need extensive psychometric revision, not only to simplify their factor structure, but also to bring them up to date for contemporary use" (p. 263).

Boyle and Barton (2008) have also written a comprehensive overview of the various Cattellian personality measures. While the extensive and creative work by Cattell during his career has provided a most complex and detailed description of personality traits and their assessment, there seems to be less research on this work and the measures per se at present. However, a most compelling point made by Boyle and Barton is the need to continue Cattell's quest for "truly objective interactive personality tests."

### Hans J. Eysenck

Hans Eysenck was another prolific researcher of personality and individual differences, although his many contributions extend to other areas of psychology ranging from intelligence and aesthetics

to addictions and health (Furnham, Eysenck, & Saklofske, 2008). His first book, "Dimensions of Personality" (Eysenck, 1947), provided the foundation for applying factor analysis to determine the structure of personality along a set of quantifiable dimensions. O'Connor (2008) has described the three pillars that guided much of Eysenck's approach to analyzing and describing human behavior:

"First, adoption of a dimensional approach to quantifying individual characteristics; second, that a sufficient understanding requires a matching of correlational and experimental methods to be complete; and third, that accounting for person-situation variation is the key to building causal models of behaviour" (p. 215).

Eysenck's dimensional personality model has undergone several revisions, which are reflected in his questionnaires, beginning with the Maudsley Personality Inventory (Eysenck, 1959) to the most recent Eysenck Personality Questionnaire-Revised (EPQ-R; Eysenck & Eysenck, 1991). The children's version of the EPQ was developed under the guidance of Sybil Eysenck and has been extensively studied in many countries and cultures (Saklofske & Eysenck, 1998). The earlier MPI and Eysenck Personality Inventory (Eysenck & Eysenck, 1964) measured two of the three "super factors" proposed by Eysenck in his PEN (Psychoticism or tough-tender mindedness, Extraversion-Introversion, and Neuroticism or emotionality-stability) model but with the publication of the EPQ, all three factors were included.

Eysenck's dimensional personality model is one of the most parsimonious, focusing on the major factors of Psychoticism (P), Extraversion (E), and Neuroticism (N) although various primary factors are also noted in both his writings and measures (e.g., empathy, venturesomeness, impulsiveness). Extraversion and Neuroticism are the most studied and best known personality factors and are found on the Cattell measures as well as the Big Five. Based on cortical arousal theory, Extraversion has been extensively studied in relation to a wide range of human behaviors from academic performance to delinquency and crime. Neuroticism is tied to activation thresholds in the sympathetic nervous system and underlies very emotional expressions ranging from negative affect and anxiety to calmness. Described most fully by Eysenck and Eysenck (1976), Psychoticism has generated considerable controversy in contrast to the other two major personality factors. While the biological basis of P is linked for example to sex hormones, it has been

most often studied in the context of delinquency, psychopathy, and diagnosed psychosis. More recently, Rawlings and Dawe (2008) have revisited this debate and have further explored the relationship between P and impulsivity.

The most often used of the Eysenck personality scales are the EPQ and EPQ-R, including the short forms, all of which measure P, E, and N. The Junior EPQ has been shown to have adequate psychometric properties for children as young as 7–8 years, although the P scale does manifest lower reliabilities (e.g., Eysenck & Saklofske, 1983; Saklofske & Eysenck, 1998). These results are similar to the findings for the revised EPQ. Another important finding is the cross-cultural robustness of both the EPQ across 34 countries and the Junior EPQ based on studies in over 20 countries (Furnham, Eysenck, & Saklofske, 2008).

### ***Paul T. Costa and Robert R. McCrae***

In contrast to the more expansive personality model proposed by Cattell and the very parsimonious PEN model of Eysenck, the so-called Big Five is the most often cited trait description of personality in recent years. While much of the foundations for this model can be traced to Norman (1963) and later Goldberg (1983), it is the familiar measures for assessing the Big Five that are attributed to Paul Costa and Robert McCrae (e.g., see Costa & McCrae, 2008; McCrae & Costa, 2008) that are familiar to psychologists. This model reflects the view that personality descriptions have, over time, been incorporated into our language such that a search of the lexicon will provide a listing of the key traits or personality descriptors. Building from Norman's original five-factor model and drawing from the theoretical models, research, and measurement efforts of Cattell and Eysenck as discussed above, but also others such as Digman and Inouye (1986), the Big Five personality factors are Extraversion (E), Neuroticism (N), Openness (O), Agreeableness (A), and Conscientiousness (C).

The earliest three-factor model considered by Costa and McCrae included the already well-established N and E factors but added O (Costa & McCrae, 1980). Shortly after that the NEO-PI (Costa & McCrae, 1985) and then the NEO-PI-R (Costa & McCrae, 1992) were published and added A and C to complete the Big Five personality description. An impressive number of validity and reliability as well as cross-cultural studies of these five personality traits have given it a primary place in the personality assessment literature,

although not without its critics (Boyle, 2008b; Eysenck, 1991)

Although the NEO-PI has been further developed for use with children age 12 years and over, this scale and its counterparts such as the NEO-FFI are most often employed in the assessment of adults. However, research has shown that both children's personality as rated by self-report and teachers supports the Big Five description of personality (e.g., Mervielde, Buyst, & DeFruty, 1995). More recently, McGhee, Ehrler, and Buckhalt (2007) have published the Five Factor Personality Inventory-Children (FFPI-C), which is a 75-item scale normed with children 9 to 18 years of age. Reliabilities appear to be satisfactory across various age and groups of children and results reported in the manual suggest that the FFPI-C is a valid measure of the five major personality factors in children.

### Beyond Trait Theories

In contrast to the trait descriptions found in the 3-5-16 and other trait factor models of personality, many contemporary researchers have taken a more "eclectic and clinical perspective" to assessing personality characteristics of children and adolescents. The work of Theodore Millon has received considerable attention from practitioners and will be briefly outlined here (see also Millon [2008]).

### Theodore Millon

Theodore Millon is a contemporary leader in personality and psychopathology theory, and also in the development and interpretation of adolescent- and preadolescent-specific measures of personality. Millon's publications over the past several decades have garnered worldwide recognition and use as they inform personality assessment.

The history of the Millon scales began with the development of Millon's Biosocial Learning Theory (Millon, 1969), a theory of psychopathology that merged together existing knowledge of personality categories with acknowledged mental disorders. This theory is an integrative approach to personality and psychotherapy and emphasizes the relationship between biological and environmental factors (Choca, 1999; Dorr, 2006). Millon theorized that personality and psychopathology emerge as a result of interactions between the self and environment and that this interaction is continuous across the lifespan. Although two children may have the same biological predisposition, a combination of environmental and biological factors help to shape, facilitate, or limit the personality development of

each child resulting in two adolescents with differing personality patterns. According to the Biosocial Learning Theory, personality styles are learned strategies that are developed and implemented in order to enhance positive reinforcement and reduce punishment (Kamp & Tringone, 2008). For example, parents who value passiveness in their family may have children who develop submissive personalities.

In 1990, Millon reconceptualised his Biosocial Learning Theory to incorporate new knowledge from evolutionary biology and psychology (Choca, 1999). In general, he sought to explain the "structure and styles of personality with reference to deficient, imbalanced, or conflicted modes of survival, ecological adaptation and reproductive strategy" (Millon, 2008, pp. 666). Specifically, Millon emphasized that there are three important factors, each of which is necessary to support the evolutionary progress of organisms. The first of these factors is survival, in which organisms must make decisions that will enhance their chances of continued existence. Second, organisms must demonstrate environmental adaptation, whereby their behaviour must be modified as a result of environmental influences. Lastly, for continued existence, an organism must reproduce, allowing for new organisms to continue to grow and develop (Millon & Bloom, 2008).

Each of these factors is closely related to an individual's personality patterns and is expressed as "polarities," whereby unique personality styles result in individual personality patterns. For example, individuals seek to enhance favourable life circumstances (pleasure-producing) and reduce negative outcomes (pain-avoidance) to increase their chance of survival. To adapt to the surrounding environment, individuals must choose either to conform to the environmental circumstances (passive) or to actively influence the environment in an effort to maximize pleasure and minimize pain (active). Lastly, to support reproduction, individuals must critically decide whether they will look out for themselves, first in order to survive (self-oriented) or whether they will focus on nurturing and supporting those around them (other-oriented). Together, these personality polarities form the core of Millon's personality theory and are the guiding principles for the creation of his series of assessment measures. Table 15.1 provides a summary of each of the extremes of polarities and the corresponding *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (Text Revision)* (DSM-IV-TR; American Psychiatric Association, 2000) Axis II personality disorders.

**Table 15.1 Millon's Theory-Derived Personality Disorders, table adapted from [http://www.millon.net/content/evo\\_theory.htm](http://www.millon.net/content/evo_theory.htm)**

		Pleasure versus Pain		Self versus Other		
Imbalance, Deficiency, or Conflict		Pleasure (Low), Pain (Low or High)	Pleasure-Pain Reversal	Low Self, High Other	High Self, Low Other	Self-Other Reversal
DSM-IV-TR Axis II Personality Disorders	Passive versus Aggressive	Schizoid Melancholic	Masochistic	Dependent	Narcissistic	Compulsive
		Avoidant	Sadistic	Histrionic Hypomanic	Antisocial	Negativistic

An important distinction in the Millon scales from other personality measures (e.g., Cattell) involves the interpretative mechanism of these scales. Specifically, Millon utilizes base rates as a standard of comparison, which makes allowances for the frequency in which a behavioural personality pattern is present within society. Base rates take into consideration the fact that there are different prevalence rates of disorders within the population and that some disorders (e.g., depression) may occur more frequently than others (e.g., paranoid schizophrenia) (McCann, 2008; Strack, 2008).

**Assessment of Adolescent and Preadolescent Children.** Millon has been an instrumental leader in the development of personality measures for youth and adolescents. Though many psychologists who work with older adolescents and adults are familiar with the Millon Clinical Multiaxial Inventory-III (MCMI-III), use of the Millon scales for adolescent assessment began with the publication of the Millon Adolescent Inventory (MAI) in 1974. In 1982, the more well-known Millon Adolescent Personality Inventory (MAPI) was published, differing only slightly from the MAI. However, despite the fact that these measures were intended for use in school and mental health settings, clinical application and precision was restricted primarily due to the limited normative samples with which the measures were developed (Strack, 2008).

As a result, a new Millon scale was created and it is in widespread use today. The Millon Adolescent Clinical Inventory (MACI; Millon, 1993; Millon et al., 2006) was developed for a number of reasons. Of foremost importance, the MACI incorporated the revisions to Millon's personality theory, integrating the evolutionary perspective into the revised measure as well as provided a framework for the revised personality pattern scales. Additionally, although the MAI and MAPI had some clinical

utility, it was still necessary to align the MACI with developments in research, specifically through the current version of the DSM (DSM-IV, American Psychiatric Association [APA], 1994; DSM-IV-TR, APA, 2000) and through conversations with clinicians who required more clinically-oriented scales (Strack, 2008). Lastly, it was important to create a clinical adolescent personality measure with a norming sample that is more representative of a clinical population. Specifically, the norming process of the MACI included two separate groups of males and females (aged 13 to 15 and 16 to 19 years) from Canada and the United States. These individuals were referred from a number of clinical settings in which the primary clinical focus was on forming diagnostic impressions (Millon, Millon, Davis, & Grossman, 2006).

The MACI examines psychological disturbances and concerns such as depression, anxiety, eating disorders, or substance abuse, as well as problematic interpersonal behaviours and personality disturbances such as severe introversion, excessive dependency, egocentricity, and manipulativeness (McCann, 2008). It consists of 12 Personality Pattern scales (Introversive, Inhibited, Doleful, Submissive, Dramatizing, Egotistic, Unruly, Forceful, Conforming, Oppositional, Self-demeaning, and Borderline Tendency), eight Expressed Concerns scales (Identity Diffusion, Self-Devaluation, Body Disapproval, Sexual Discomfort, Peer Insecurity, Social Insensitivity, Family Discord, and Childhood Abuse), and seven Clinical Syndromes scales (Eating Dysfunctions, Substance Abuse Proneness, Delinquent Predisposition, Impulsive Propensity, Anxious Feelings, Depressive Affect, and Suicidal Tendency).

The MACI is unique in that, although it does not perfectly align with the DSM-IV-TR (APA, 2000), it incorporates ratings from both Axis I and Axis II

in its measurement and interpretation. Specifically, through the clinical syndromes scales, the MACI assesses syndromes associated with Axis I such as anxiety, depression, and eating disorders. Through the personality patterns scales, the MACI focuses on Axis II personality disorders including specific personality patterns such as avoidant personality or schizoid personality disorder (McCann, 2008; Millon et al., 2006). This will need to be revisited with the forthcoming publication of the DSM-V.

Millon also recognized the need for an assessment tool for preadolescents aged 9 to 12 years and created a measure to capture the *emerging* personality traits and patterns within this age group. The Millon Preadolescent Clinical Inventory (M-PACI; Millon, Tringone, Millon, & Grossman, 2005) was developed in order to expand the range of personality assessment to capture the personality patterns of younger children.

The M-PACI is based on the same theoretical foundations as the MACI. Within the M-PACI, there are seven Emerging Personality Patterns (Confident, Outgoing, Conforming, Submissive, Inhibited, Unruly, and Unstable) and seven Current Clinical Signs (Anxiety/Fears, Attention Deficits, Obsessions/Compulsions, Conduct Problems, Disruptive Behaviours, Depressive Mood, and Reality Distortions) that are based on Millon's three polarity model. The personality scales are referred to as *Emerging* Personality Patterns in recognition of the fact that, at this age, personality styles are emerging and are still malleable (Kamp & Tringone, 2008).

Together, the MACI and the M-PACI offer the opportunity for personality assessment with adolescents and preadolescents. The high correlations between assessed constructs on these measures and other psychological assessments (e.g., Behavior Assessment System for Children-2nd Edition, Children's Depression Inventory) along with their solid and theory-driven basis, collectively illustrate the clinical utility of these measures for assessing personality.

### ***Omnibus Rating Scales: The Achenbach and BASC-2 Scales***

The prior sections of this chapter discussed personality measures based upon theories that initially emerged to define broad adult personality variables (e.g., Super Three, Big Five, 16 Personality Factors) and were later adapted to measure some forms of adult pathology. As noted, many of these instruments also were adapted to measure the same constructs of personality and pathology in youth (e.g.,

CPI, FFPI-C, MACI). This section will continue the discussion of multivariate measures with a brief review of omnibus rating scales that were designed to assess a variety of psychopathological traits in children that have behavioural manifestations. Further, two widely accepted omnibus measures created specifically for children (e.g., the Achenbach Child Behavior Checklist [CBCL] and the Behavior Assessment System for Children [BASC]) are discussed in detail. The implications of single construct measures for assessment of specific personality variables also are reviewed. Finally, the last section of the chapter discusses temperament as a foundational substratum of personality assessment.

**Internalizing and Externalizing Dimensions of Psychopathology.** In 1961, Donald Peterson utilized data from teacher rating scales to describe two broad personality dimensions in children. These dimensions included *conduct problems* and *personality problems*. Peterson's problems dimensions related to specific types of psychopathology. Children with conduct problems had difficulties with following rules and they acted aggressively toward others. On the other hand, children with personality problems displayed shyness and a tendency to withdraw from social interactions. Peterson's original dimensions are still reflected in the design of many assessment instruments. In 1966, Thomas Achenbach analyzed data from case histories of outpatients and short-term inpatients to determine common factors that may explain patients' symptomatology (Kamphaus & Frick, 2002). From this analysis, two primary factors emerged. The first resembled Peterson's personality problems dimension but also included conduct problems. This factor was described as an *internalizing-externalizing* dimension because of its inclusion of mixed internalizing and externalizing psychopathology. Achenbach's second identified factor was labeled as a *severe and diffuse psychopathology* dimension due to its inclusion of severe forms of psychopathology such as psychosis.

Following subsequent analysis, Achenbach divided the internalizing-externalizing dimension and found that children with conduct problems tended to display more externalizing problems whereas children with phobias, anxiety concerns, and somatic complaints tended to display more internalizing problems. Additionally, other researchers were starting to replicate this finding in studies that used parent and teacher reports (e.g., Conners, 1969; Quay, Morse, & Cutler, 1966); however, the terms *internalizing* and *externalizing* did not become part of common vernacular until

1978 when Achenbach published a paper entitled: *The Classification of Child Psychopathology: A Review and Analysis of Empirical Efforts* in the Psychological Bulletin. Children with internalizing problems were described as “over controlling” their behaviors, being highly anxious, and being excessively shy. In contrast, children with externalizing problems were described as “under controlling” their behaviours, having conduct problems, and often engaging in acting-out behaviours.

Achenbach and Edelbrock’s (1978) dichotomization of psychopathology into internalizing and externalizing symptoms was incorporated into the Achenbach Child Behavior Checklist Parent and Teacher Rating Forms (Achenbach & Edelbrock, 1983). Research conducted with these rating scales has added additional support for the utility of separate internalizing and externalizing symptom dimensions (Cohen, Gotlib, Kershner, & Wehrspan, 1985; Compas, Phares, Banez, & Howell, 1991; Gjone & Stevenson, 1997; Greenbaum & Dedrick, 1998; Massey & Murphy, 1991; McConaughy, Achenbach, & Gent, 1988).

Research also has indicated that a number of educational outcomes are associated with internalizing and externalizing characteristics. In general, students who are high in internalizing psychopathology tend to have higher intelligence scores, better executive functioning abilities, read better, utilize more adaptive coping skills when dealing with stressful situations, and to be less disruptive in educational environments when compared to youth who are high in externalizing psychopathology (Austin, Groth-Marnat, Matthews, Saklofske, Schwean, & Zeidner, 2011; Cohen et al., 1985; Massey & Murphy, 1991; Matson & Fischer, 1991; McConaughy et al., 1988).

Research from biological-based fields such as behavioral genetics also supports the independence of internalizing and externalizing symptoms. As an example, Gjone and Stevenson (1997) found higher concordance rates in children with only internalizing or externalizing problems in comparison to those with combined problems. Further, a more recent study that aimed to determine the heritability of internalizing and externalizing symptoms found genetic factors to account for about 50% of the variability in children’s externalizing symptoms and 35% of the variance in internalizing symptoms in both males and females (van der Valk, van den Oord, Verhulst, & Boomsma, 2003). Therefore, similar to other relatively stable psychological traits (e.g., intelligence, extraversion), heritability also

plays a significant role in the development of internalizing and externalizing symptoms.

Following the work of Achenbach, many behaviour ratings scales including his own the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001), have adopted a dichotomous internalizing-externalizing format due to the preponderance of research supporting this framework (Kamphaus & Frick, 2002). Other measures include the Adolescent Psychopathology Scale (Reynolds, 1998) and the Adolescent Psychopathology Scale—Short Form (Reynolds, 2000), the BASC-2 (Reynolds & Kamphaus, 2004), the Reynolds Adolescent Adjustment Screening Inventory (Reynolds, 2001) and the Devereux Scales of Mental Disorders (Naglieri, LeBuffe, & Pfeiffer, 1994). Other child omnibus measures include the Personality Inventory for Children (Lachar & Gruber, 2001) and the Personality Inventory for Youth (Lachar & Gruber, 1995).

**The Use of Behavior Rating Scales.** The BASC-2 (Reynolds & Kamphaus, 2004) and the CBCL (Achenbach & Rescorla, 2001) are two of the most commonly used omnibus behaviour rating assessments with children. These assessments both include broad internalizing and externalizing composites under which various behaviour symptom scales are subsumed. Although slight variations exist across ages and rating formats (teacher, parent, or self-report), internalizing problems on the BASC-2 generally include somatization, anxiety, depression, and externalizing problems include aggression, conduct problems, and hyperactivity. On the CBCL, internalizing symptoms include anxiety, depression, somatic complaints, social withdrawal, and externalizing symptoms include attention problems, rule-breaking behaviour, and aggressive behaviour (Achenbach & Rescorla, 2001; Reynolds & Kamphaus, 2004). Thus, considerable overlap exists in the internalizing and externalizing symptoms assessed across measures even though slight differences can be meaningful and help guide assessment decisions (Ostrander, Weinfurt, Yarnold, & August, 1998).

Each type of personality measure or behaviour rating scale will likely provide slightly different information about a child based on the constructs assessed (Sattler & Hoge, 2006). In addition, raters such as parents and teachers observe children in different environments with differing demands. Therefore, multiple measures should be used to assess multiple constructs, at varying time periods, and across different raters to provide reliable data and minimize assessment bias. When considering

data from multiple measures, convergent evidence that particular attributes are more indicative of stable personality variables is suggested by consistency in data across settings and raters. However, when data differ significantly across settings and raters, this divergent evidence may prompt clinicians to consider other hypotheses such as various environmental variables that may better account for the child's behavior.

Recent advances in the development of brief universal behaviour screeners and behavior progress monitoring instruments may allow for even broader usage of behavior ratings scales, particularly for the early identification of problems. The BASC-2 Behavioral and Emotional Screening System (BASC-2 BESS; Kamphaus & Reynolds, 2007) is an example of a screening type of instrument. It allows for the quick assessment of behavior problems in children and can provide tables of cross-reference scores for whole classrooms of students. This type of screener is consistent with a multiple gating approach to identifying problems in children early so intervention services are available before symptoms become chronic or severe. The multiple gating assessment approach (Walker & Severson, 1992) involves the systematic screening of all children with brief rating scales followed by more extensive progress monitoring (PM) assessment of children who are receiving interventions. Progress monitoring with the BASC-2 PM system (Reynolds & Kamphaus, 2009) offers forms for assessing internalizing and externalizing problems. Psychosocial difficulties also may be assessed with more extensive rating scales (e.g., BASC-2), behaviour observations, and clinical interviews if an intervention is not effective and/or if exceptional student education eligibility is considered (Salvia, Ysseldyke, & Bolt, 2007).

**Assessment of Narrow Constructs.** Single-construct behaviour rating scales and checklists also assess a variety of adaptive and maladaptive behaviours and are usually completed by the child or those who are familiar with him or her. The transition from using an omnibus measure to a single-construct measure often is driven by the need to more clearly assess a child's strengths and weakness for diagnostic or intervention purposes. Omnibus measures may provide a broad overview of a child's psychosocial functioning but do not allow for in depth assessment of many relevant symptoms that a clinician may wish to address. For example, a study by Storch and colleagues (2006) indicated that the CBCL assessed many

broad symptoms of obsessive-compulsive disorder (OCD) that overlapped with other psychiatric disorders (e.g., anxiety, inattention), but the measure poorly discriminated between specific OCD symptoms and symptoms of other internalizing disorders. However, despite this noted problem, when the scores from the CBCL were compared with a clinically administered narrow measure of OCD symptoms (e.g., The Children's Yale-Brown Obsessive Compulsive Scale [Scabill et al., 1997]), reliable and consistent OCD diagnoses were achieved.

In contrast to omnibus measures, single construct measures also may allow for the assessment of behaviour change over time. Instruments that provide norms by small age increments (e.g., 6 months, 1 year) are important for evaluating children as they develop rapidly in multiple domains in early childhood. Progress monitoring single-construct measures are designed for repeated measurement and generally are sensitive to change; therefore, they have a unique utility because they can be used as outcome measures to assess the degree to which children respond to interventions. For example, changes in overall shyness or social skills T-scores on a progress monitoring single-contrast measure before and after implementation of a behaviour management plan can document school-based intervention efficacy. As a shift is made to a "response-to-intervention" (RtI) model (also called Multi-tiered System of Supports [MTSS]) for the provision of support services to children, highly sensitive, single-construct measures will be important for monitoring behaviour change in relation to implemented interventions (National Association of State Directors of Special Education [NASDSE], 2005). Additional examples of single-construct measures that assess narrow personality traits include the Social Skills Improvement System (Gresham & Elliott, 2008), the Piers Harris Children's Self-Concept Scale: Second Edition (Piers, Harris, & Herzberg, 2002), and the Tennessee Self-Concept Scale: Second Edition (Fitts & Warren, 1996).

On a final note, some behaviour rating scales combine features of omnibus and single-construct measures. For example, the Conners Third Edition (Conners-3; Conners, 2008) is designed to assess symptoms of Attention-Deficit/Hyperactivity Disorder (ADHD), but the measure also includes items that screen for internalizing disorders such as anxiety and depression. Therefore, in addition to differentiating between various ADHD symptoms and subtypes, the Conners-3 allows a clinician to

assess for comorbid conditions or other problems that may need further evaluation. The short form of the Conners-3 also can be used for as a progress-monitoring instrument since it provides wide coverage of ADHD symptoms and related aspects of adjustment (e.g., learning problems, executive functioning).

## **Temperament as a Foundational Substratum of Personality Assessment**

This final section of the chapter will discuss temperament as a foundational substratum of personality assessment. In beginning this discussion, it is important to note that temperament is not synonymous with personality; however, there is overlap in important constructs in both theoretical frameworks. Thus, temperament assessment can add additional insights in understanding personality.

In contrasting the definitions of personality and temperament, personality refers to a wide variety of personal qualities; demeanor characteristics such as social appeal and expressive energy; traits; cognitive attributions; emotional response patterns; behaviors; and temperament qualities that collectively form a unique constellation recognized by others as the individual's persona. Any of these qualities also can be identified as individual personality variables that are common to many persons. Thus, it is the unique combination and degree of expression of personality traits that is specific to the individual rather than the presence of particular traits in isolation (Joyce, 2010).

By contrast, temperament components are thought to have a biological basis that is evident earlier than the underlying basis is for personality traits. These predispositions are evident through physiological attributes and influence the reciprocal interactions between children and caregivers, eliciting particular types of responses and often are identifiable in infancy. For example, if a young child is outgoing or has a calm temperament, adults are likely to respond more positively than if the child is withdrawn or demonstrates an irritable temperament. Temperament characteristics also are subject to influence from environmental factors such as parenting styles, which may foster or stifle a child's emerging traits. Based on these premises, temperament is a foundational substrate on which later personality traits may evolve.

Temperament has been a topic of speculation for ages. Ancient Greek scholars such as Hippocrates, Plato, and Aristotle, whose writings date back to 400 B.C., have pondered human behaviour patterns

(Hippocrates, trans. 1939; 1988; 1994). They noted clusters of characteristics that commonly occurred in individuals as well as pathology such as malaise or foul tempers. Rudimentary theories included four humors or temperaments: choleric, phlegmatic, melancholic, and sanguine (Galen, trans. 1916; trans. 1992). Several iterations of these classical theories of temperament emerged throughout the following centuries. However, it was not until the early 1900s that a distinctly psychological theory of temperament was established. Over the past one hundred years, two temperament paradigms have yielded a number of assessment measures for children and adolescents: the psychological type paradigm and the constitutional-based paradigm.

## ***Psychological Temperament Assessment Paradigms***

Modern psychological temperament type theory emerged in the early 1920's with the work of Carl Jung (Jung, 1921/1971). Through his hospital-based psychiatry practice in Zurich, Jung observed reoccurring patterns of behavior among his patients. He noted that patients who were generally depressed or out of touch with reality (e.g., schizophrenic) exhibited pathology related to interactions with others or were preoccupied with internal musings. In contrast, patients with intact reality testing abilities more often exhibited outward forms of pathology, such as aggression or overtly negative interactions with others. Jung termed the broader set of internally focused temperament qualities as introversion and the outgoing qualities as extraversion. He noted that all individuals have the ability to act in an introverted or extroverted manner and each dimension could be expressed either positively or negatively. However, there is a propensity within each person for either introversion or extroversion to be preferred and thus more strongly developed. As noted earlier, Donald Peterson and Thomas Achenbach's contributions to rating scale measures of internalizing and externalizing behaviours in the 1960's is similar to Jung's early conceptualizations.

Jung delineated three dichotomous temperament dimensions: introversion-extraversion, sensing-intuition, and thinking-feeling. Persons who are introverted are described as introspective, cautious toward new circumstances, keenly interested in internal thoughts, and they prefer to renew their personal energy from solitude or small group interactions. For an individual who is strongly introverted, social skills, collaboration strategies, and support networks may be limited or restricted. Persons

who are extroverted are described as quick to make new friends, talkative, engaging, keenly interested in the external environment, and acquire energy from frequent interactions with others. Without developing the opposing introversion qualities, extroverts may lack self-reflection, share ideas before they are well thought-out, and intrude on others' need for privacy (Jung, 1921/1971; Wehr, 1971).

Sensing individuals are noted to learn best through tangible experiences. They prefer facts, seek specific details, enjoy fine points of information, and are pragmatic. Persons who prefer sensing styles may undervalue complexity, abstractions, and theory. In contrast, learning thorough intuition relies on quickly assimilating information that incorporates insights and hunches. Intuitive individuals prefer theories and broad patterns. They can easily overlook important details and practical implications when considering ideas (Jung, 1921/1971; Wehr, 1971).

The thinking-feeling dimension defines how individuals prefer to make decisions. A thinking style emphasizes logic, analysis of objective data, and a strong sense of justice based on unbiased and impartial values. In their eagerness for truth, individuals with a strong thinking orientation may seem blunt, calloused, critical, and insensitive although this generally is not their intention. With a feeling orientation for decision-making, subjective qualities such as empathy, mood, compassion, and prior experience are influential. As subjective qualities are variable and often in flux, feeling-based decisions may be perceived by others as unpredictable, acquiescent, and irrational. However, Jung perceived feeling as a rational quality because the decision was carefully pondered, albeit based on personal and different criteria from thinking decisions.

Katherine Briggs and Isabel Myers developed an assessment instrument based on Jung's theory and added a fourth dimension: judging-perceiving. This dichotomy reflected how individuals structure their daily lives (Myers & Myers, 1980; Quenk, 2000). Judging characteristics include the desire for a highly organized lifestyle with a need for structure, schedules, advanced planning, and routine in managing personal affairs. Persons with this propensity also seek closure and may be prone to prematurely eliminating options. On the opposite end of the spectrum, perceiving characteristics include spontaneity, last minute changes, as well as great tolerance and flexibility. This desire to keep all options open can interfere with predictability, meeting deadlines, and other's perceptions of dependability.

**Table 15.2 Myers-Briggs Type Indicator (MBTI)**

Myers-Briggs Type Indicator (MBTI) Psychological Types			
ISTJ	ISFJ	INFJ	INTJ
ISTP	ISFP	INFP	INTP
ESTP	ESFP	ENFP	ENTP
ESTJ	ESFJ	ENFJ	ENTJ

*Note.* I = introverted, E = extroverted, S = sensing, N = intuition, T = thinking, F = feeling, J = judging, P = perceiving

When utilizing the Briggs and Myers's assessment instrument, the *Myers-Briggs Type Indicator* (MBTI), T-scores are provided on each of the four dimensions, yielding a possible sixteen temperament profiles (see Table 15.2).

The MBTI can be utilized for temperament assessment with adolescents ages 14 through adulthood (Myers, McCaulley, Quenk, & Hammer, 1998). A parallel instrument, the Murphy-Meisgeier Type Indicator for Children (MMTIC; Murphy & Meisgeier, 2008) applies MBTI theory to the assessment of children ages 7 to 18 and grades 2 through 12. The Student Styles Questionnaire (SSQ; Oakland, Glutting, & Horton, 1996) is based on Jungian-Briggs theory and assesses youth ages 8 to 17 years. On this instrument, the judging-perceiving dimension is designated as organized-flexible to better reflect descriptors of the temperament qualities measured.

The MMTIC and the SSQ differ from adult measures of temperament in several ways. First, they consider school-related behaviour test items in assessing temperament and provide classroom learning applications. In addition, they support interpretations relevant to understanding and enhancing parent-child interactions. For example, some studies indicate a high prevalence of specific temperament preferences among children with particular diagnoses (e.g., oppositional defiant disorder, conduct disorders) and thus understanding these differences may help therapists remediate underdeveloped characteristics (Joyce & Oakland, 2005).

David Keirsey (1998) argued against the interpretation of the MBTI's sixteen types in favor of four clusters: sensing-perceiving, sensing-judging, intuition-thinking, and intuition-feeling. He developed the Temperament Sorter-II, which also has a student version. Unlike the parental rating scales method noted in the prior section of this chapter, psychological temperament scales for children are

self-report measures with the assumption that children best understand their own preferences.

## Constitutional-based Temperament

### Assessment Paradigms

Constitutional-based temperament assessments measure the earliest manifestations of personality traits from infancy through early childhood. Constitutional-based theories presume that characteristics have a strong biological basis. Costa and McCrae (2001) argue that behaviours exhibited by infants are the core tenets of personality as children have the least capacity for communication at that time, and thus are the least influenced by the perceptions of others. Instruments for measuring constitutional-based temperament qualities are primarily reliant on observational techniques and parent interviews. Through their New York Longitudinal Study (NYLS) research, Alexander Thomas and Stella Chess identified nine measurable behavioural characteristics: activity level, rhythmicity, approach-withdrawal, adaptability, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span/persistence (Thomas & Chess, 1977; Thomas & Chess, 1989).

Activity level referred to children's ratio of active and inactive times, whereas rhythmicity referred to the regularity of the child's daily activities (e.g., sleeping pattern). Approach or withdrawal was assessed by noting the infant's adaptive or maladaptive initial responses to new persons or objects. How quickly a child habituated to new stimuli was noted as adaptability and threshold of responsiveness measured the level of stimulus needed to evoke a response. The energy of the baby's response was called intensity of reaction and quality of mood evaluated the frequency of pleasant versus unpleasant responses. A child's ability to attend despite diversion was noted as distractibility and attention span/persistence qualities. Thomas and Chess also identified three behavioural response patterns: easy, slow-to-warm, and difficult. Over time, the difficult temperament category experienced the most negative long-term outcomes and the slow-to-warm children also reported significant psychological stressors whereas the children with an easy temperament had positive outcomes (Chess & Thomas, 1984; Thomas & Chess, 1977; Thomas, Chess, & Birch, 1968).

Another important contribution from their work is the concept of goodness-of-fit. From their observations, Thomas and Chess noted that some temperament qualities were less problematic when parents had similar characteristics or high tolerance

for differences. Therefore, educating parents about the innate differences between children's temperament and how these characteristics may align or misalign with those of the parent has the potential to improve parent-child interactions. Subsequent instruments based on their theory include the Parent Questionnaire and the Teacher Temperament Questionnaire.

In the following years, several researchers published measures based on the work of Thomas and Chess (e.g., Carey Revised Infant Temperament Questionnaire, the Toddler Temperament Scale, the Behavioral Style Questionnaire, and the Middle Childhood Temperament Questionnaire). Later adaptations found support for five rather than the original nine dimensions proposed (Lerner, Palermo, Spiro, & Nesselroade, 1982; Sanson, Prior, Garino, Oberklaid, & Sewell, 1987). Buss (1989) and Buss and Plomin (1975, 1984) identified only four qualities (i.e., activity, emotionality, sociability, and impulsivity) from their research and subsequently published the EASI Temperament Survey. Others argue for defining assessment of child temperament and personality through the concepts of reactivity and self-regulation, primary emotions, or overcontrollers and undercontrollers as integral components of temperament (Block & Block, 1980; Goldsmith & Campos, 1986; Kagan, 2009; Kagan & Snidman, 1991; Rothbart & Derryberry, 1981; Strelau, 1983). A variety of assessment instruments have been developed for each perspective.

## Validity Studies for Temperament Constructs

**Psychological-Based Temperament.** The validity of psychological temperament constructs is supported by heritability research, factor analyses of test instruments, and cross-cultural studies. Currently, the dimension of MBTI theory that overlaps the most with other major personality measures is introversion-extraversion (see Table 15.3). Some researchers refer to introversion-extraversion as a super trait (e.g., Saklofske, Eysenck, Eysenck, Stelmack, & Revelle, 2012) since this dimension has the strongest heritability support even when differing instruments are utilized to measure the trait (Buss & Plomin, 1984; Loehlin, 1982). Bouchard, McGue, Hur, and Horn (1998) found heritability to account for significant portions of phenotype variance for introversion-extraversion ( $h^2 = .60$ ) in a study of monozygotic and dizygotic twins that involved using the MBTI. To a lesser degree, heritability also explained considerable variance in sensing-intuition and judgment-perception traits

**Table 15.3 Overlapping Constructs in Personality and Temperament Measures**

Overlapping Constructs in Personality and Temperament Measures						
Big 5-16 PFI/Personality Theories	Cattell, 16PF Costa & McCrae, NEO-PI-R	Extraversion- Introversion	Anxiety	Tough-Minded- ness	Independence	Self-Control
Super 3	Eysenck, Eysenck EPQ	Extraversion	Neuroticism		Agreeableness	Conscientiousness
MBTI	Myers, Briggs, MBTI	Extraversion— Introversion		Intuition— Sensing	Feeling— Thinking	Judging—Perception

( $b^2$  approximately .40). Greater cortical arousal, limbic site activity, and heart disease among introverts as compared to extraverts have been noted in several studies (Kagan & Snidman, 1991, 2004; Shelton, 1996; Sternberg, 1990; Wilson & Languis, 1990). Higher cortical arousal among introverts may account for their propensity to need more solitude and to temporarily withdrawal from highly stimulating environments to renew their energy.

Within the brain lateralization literature, sequential processing of information, consistent with sensing temperament qualities, is considered a left hemisphere function. Holistic or simultaneous processing is thought to be primarily a right hemisphere function. Research does support greater left hemisphere brain activity for individuals with a sensing temperament. The opposite is true for persons self-reporting an intuitive temperament preference (Hartman, Hylton, & Sanders, 1997). Gender differences for the thinking-feeling scale are supported across multiple studies indicating more males prefer thinking and more females prefer feeling qualities (Myers et al., 1998; Oakland et al., 1996).

Cross-cultural research supports the reliability and construct validity for the MBTI scales in English-speaking and non-English speaking countries. Studies also support similar distributions of temperament preferences for the introversion-extroversion scale (Carlson & Levy, 1973; Kirby & Barger, 1996; Myers et al., 1998). However, these findings are based on a very limited number of cross-cultural studies. Research with students of African-American, Hispanic-American, and Euro-American ancestry within the United States that used the SSQ supports the four factor structure of temperament (Stafford & Oakland, 1996). In addition, studies of the SSQ across multiple countries (e.g., Australia, China, Costa Rica,

Pakistan, Philippines, Samoa, U.S., and Zimbabwe) also found a strong fit for the four dichotomous temperament dimensions (Benson, Oakland, & Shermis, 2008; Callueng et al., 2011; Oakland, Callueng, Rizwan, & Aftab, 2011).

**Constitutional-Based Temperament.** Heritability studies provide support for some constitutionally-based temperament constructs including activity level, emotionality, and sociability (Buss & Plomin, 1984; Floderus-Myrhed, Pedersen, & Rasmussen, 1980; Goldsmith & Gottesman, 1981). In research on the threshold of response factor, correlations are noted for increases in cortical arousal, larger evoked potentials, blood pressure, and heart rate when comparing high-versus low-reactive children (Kagan & Snidman, 2004). The Australian Temperament Project, a longitudinal study of infants through the age of 18, provided support for many of the early findings from Thomas and Chess (Prior, Sanson, Smart, & Oberklaid, 2000). Children with easy temperaments were noted to have more positive outcomes and children with difficult temperaments experienced more negative outcomes. Moreover, children with a more reticent temperament developed more anxiety-related symptoms.

### Practical Implications

There are a number of implications for considering temperament dimensions as a foundational substratum of personality and thus an important evaluation component. Many qualities such as extraversion, intuition, and self-regulation have positive attributes and describe personal qualities in nonpathological language traits (Oakland & Joyce, 2006). Additionally, early temperament assessment captures data from formative years of infancy and toddlers that other measures do not, which may help with identifying risk factors. Clinicians can utilize

early child temperament data to better assist parents in understanding their own child's traits as well as utilize the goodness-of-fit concept in addressing conflicting needs between the parent and child. The goodness-of-fit paradigm also has implications for assisting teachers in better understanding students' differences. Temperament qualities are considered somewhat malleable; and therefore, self-awareness of one's own strengths and lesser developed characteristics can foster personal development.

## Conclusion

This chapter reviewed the major paradigms on which are based the assessment of personality in children and adolescents. Although there is no consensus on a definition of personality, most theorists agree that personality traits have a biological basis, are moderately stable over time, and can be somewhat influenced by environmental factors. The early manifestation of personality variables as well as their stability facilitates measurement of these attributes in children. Several scientific methods including lexical hypothesis and multi-variant factor analyses have provided empirical support for multiple constructs of personality.

As noted in the chapter, many of the current measurements for children and youth have been derived from earlier adult measures. However, it is important to acknowledge that throughout the developmental stages of childhood and adolescence, expressions of personality are evolving. Especially for young children, these early personality qualities may be expressed differently and thus require different measurement methods. In fact, infant measures often rely on observations or parent interview reports of physiological manifestations (e.g., startle effects or crying) whereas child and adolescent measures may include self-report or parent and teacher ratings scales. Omnibus rating scales are designed to briefly sample a wide variety of factors. In contrast, single construct scales measure a narrow set of qualities with more depth. The scales or facets within personality measures are defined by the underlying theory and can range from positive qualities of demeanor and response patterns to pathology. Temperament is considered by some theorists to be a foundational substratum upon which adult personality is built. There are a number of instruments designed specifically for the measurement of early childhood and adolescent temperament as related to personality. Temperament theories and instruments can be conceptualized in two categories: psychological type and constitutionally-based. In many cases,

clinicians will utilize more than one personality measure as part of an assessment battery, thus, providing a broader multi-dimensional understanding of the individual's persona.

# Principles of Behavioral Assessment

Tanya L. Eckert and Benjamin J. Lovett

## Abstract

The chapter defines behavioral assessment and covers its historical developments over the last century. A review of the theoretical foundations of behavioral assessment is provided, including materialism, determinism, and contextualism. The chapter also discusses the methodological foundations of behavioral assessment, which are influenced by psychometric principles and a particular conceptualization of causation and functional relationships. Five general behavioral assessment methods are reviewed (behavioral observation, behavioral interviewing, behavior rating scales, psychophysiological measurements, performance tasks) and three specific applications of behavioral assessment methodologies (functional assessment, intervention evaluation, diagnostic classification) are discussed.

**Key Words:** assessment, behavioral assessment

The psychological assessment of children and adolescents is a field full of controversies, where a certain assessment tool or approach can be dominant at one point in time and viewed poorly only a short time later. Behavioral assessment is an approach that has become more popular in recent years, but has always been acknowledged as an important part of clinical assessment. In this chapter, we focus on the theoretical principles that undergird behavioral assessment techniques, leaving other chapters to cover the practical details of each technique. We define behavioral assessment, cover its history and conceptual tenets, explore relevant psychometric principles, and briefly discuss specific techniques and applications.

## What is Behavioral Assessment?

One challenge in defining behavioral assessment is that almost all assessment tools yield results that make reference, at least implicitly, to behavior. The administration of a standard IQ test typically leads

a child to engage in many behaviors, including responses to the task stimuli provided by the examiner. Similarly, an unstructured clinical interview will yield many verbal and nonverbal behaviors on the part of the interviewee. Although certain measures (e.g., behavioral observation systems) are more likely to be thought of as behavioral assessment tools than others (e.g., IQ tests), as we will see, behavioral assessment is more about an approach to interpreting information from assessment tools rather than the choice of the tools themselves.

This focus on a particular style of interpretation is important to keep in mind when examining common definitions of behavioral assessment, such as that given by Heiby and Haynes (2003):

Behavioral assessment is a scientific approach to psychological assessment that emphasizes the use of minimally inferential measures, the use of measures that have been validated in ways appropriate for the assessment context, the assessment of functional

relations, and the derivation of judgments based on measurement in multiple situations, from multiple methods and sources, and across multiple times. (p. 7)

This definition serves as a useful foundation and deserves a thorough examination, provided that we emphasize the role of interpretation of assessment data in determining whether assessment is behavioral.

Heiby and Haynes (2003) list four emphases of behavioral assessment, beginning with “the use of minimally inferential measures.” It would be more appropriate to say that behavioral assessment emphasizes minimal inferences from assessment data. For instance, if an adolescent girl referred for assessment tells an examiner that she has not been able to sleep through the night during the past month, inferring that the adolescent girl has been experiencing sleep problems recently requires only a minimal amount of inference. (Even this inference cannot be made with certainty, of course.) Inferring that the girl is anxious about something, based solely on her comment about sleep, incurs greater inferential risk. Inferring that she was severely traumatized one month ago would be an even riskier interpretation. A behavioral assessment approach would generally prefer those interpretations that require a minimal amount of inference. This preference does lead, albeit indirectly, to a preference for certain assessment tools—namely, those tools that require less inference to be useful. For instance, the data from a behavior rating scale completed by the mother of a seven-year-old boy referred for attention problems would generally require less inference than the data from a Rorschach inkblot test administered to the boy himself.

A second emphasis of behavioral assessment mentioned by Heiby and Haynes (2003) involves tools “validated in ways appropriate for the assessment context” (p. 7). For instance, if a school psychologist wishes to examine a child’s anxiety in the classroom setting, a teacher-report rating scale may be superior to a parent-report rating scale, whereas the opposite may be true with regard to assessing anxiety at home. This logic is closely related to the principle of minimal inference, as using a teacher-report rating scale to assess anxiety at home requires an additional, risky inference that the child exhibits the same anxiety-related behavior at home and at school. As Messick (e.g., 1989) noted, measures themselves are never valid or invalid; instead, *interpretations* have more or less validation evidence, so interpretations about behavior at home from

teacher reports have less validation evidence than do interpretations about behavior at school. As such, we could modify Heiby and Haynes’s characterization to say that behavioral assessment involves making interpretations that have validation evidence specific to the context that the measures cover.

Heiby and Haynes (2003) also mention that behavioral assessment emphasizes the assessment of functional relations—that is, the causal relationships between environmental events and behaviors. Behavioral assessment, then, goes beyond the description of behavior to encompass the explanation of behavior as well. Of course, other assessment paradigms make explanatory claims, but behavioral assessment uses principles of learning theory (discussed in detail below) to do so, and relies on direct evidence for these explanatory claims that require minimal inference from that evidence. For instance, a traditional clinical assessment of a preschool-aged boy referred for disruptive behavior may explain his behavior with reference to a neuropsychological condition such as attention-deficit/hyperactivity disorder (ADHD). Coming from a behavioral assessment perspective, the neuropsychological explanation might be viewed as incomplete (if not circular), and a behavioral approach to the assessment of this child would seek direct evidence of environmental variables (e.g., attention from peers) that are causing the disruptive behavior.

Finally, Heiby and Haynes (2003) note that behavioral assessment emphasizes measurements across different settings, sources, tools, and time periods. Although most best-practice recommendations for clinical assessment emphasize this as well, behavioral assessment again differs in its approach to interpretation. If two sources of assessment information (for instance, a referred child’s mother and father) provide different, contradictory information, the behavioral assessment approach would not conclude that one or both of the sources is incorrect, but instead that the child may behave differently in the presence of the mother than in the presence of the father. Similarly, if assessments of the child’s academic skills yield very different data one week from another week, the behavior assessment approach would be more likely to conclude that the child’s skill levels had changed, and less likely to attribute the discrepancy to unreliability in the measurement tools. These interpretations are consistent with the principle of minimal inference, because assessing a child in many different ways, through different sources, and at various times in various settings lessen the inferential burden for any individual piece

of assessment data. To summarize, then, behavioral assessment emphasizes direct measures of behavior and its environmental determinants, and minimal inferences from the data that these measures yield.

## Historical Foundations of Behavioral Assessment

The history of behavioral assessment is bound up with the history of behavioral models of psychological disorders, and the history of scientific psychology generally (Ollendick, Alvarez, & Greene, 2003). Pioneers of scientific psychology such as Wilhelm Wundt emphasized the importance of careful measurement, and although mental processes were often inferred from experimental participants' behavior, direct quantifications of behavior such as reaction time were studied as well (Goodwin, 2008). After studying animal psychology, Watson (1913) formally founded behaviorism by suggesting that psychology study humans in the same way that we study other animals: by only making reference to observable behavior and eschewing all but the most minimal inferences about unobservable mental processes.

Slowly, behaviorism began to penetrate the realm of clinical psychology. After Watson used classical conditioning to induce a phobia (Watson & Rayner, 1920), one of Watson's students used classical conditioning to treat a phobia (Jones, 1924). Similarly, B. F. Skinner's student Ogden Lindsley applied operant conditioning techniques to treat individuals with severe mental illnesses (Reed & Luiselli, 2009). In each of these cases, the behaviors associated with psychological disorders were carefully described and measured, so that the dependent variables were clear and any change in behaviors could be assessed with precision.

Behavioral assessment came into its own in the 1960s and 1970s as behavior therapy flourished, and behavior therapists developed assessment methods that were especially useful in their own clinical contexts. When the *Journal of Behavioral Assessment* began in 1979, the first full article (Hartmann, Roper, & Bradford, 1979) emphasized the large differences between behavioral and traditional assessment, including the central idea that in behavioral assessment, behavior exhibited during assessment is viewed as merely a *sample* of the client's behavior more generally, rather than a *sign* of underlying traits. Since the blossoming of behavioral assessment, an important feature of the field has been an insistence on rigor and validity, while at the same time thoughtfully questioning whether the typical metrics for

these qualities are appropriate for behavioral assessments (e.g., Hayes, Nelson, & Jarrett, 1986).

Today, behavioral assessment is an indispensable part of the clinical assessment of children and adolescents. It is a rare child assessment protocol that does not include standardized behavior rating scales, even if clinicians insist on interpreting the scales as revealing an underlying diagnostic status. School districts across the country are using behavioral measures of academic skills as part of a comprehensive evaluation to determine whether a student has a learning disability (L. Fuchs, D. Fuchs, & Zumeta, 2008). At times, U. S. federal law even requires the use of behavioral assessments to determine whether problem behavior is due to environmental reinforcement (Barnhill, 2005). Even if the growth of these procedures has at times outpaced proper training, and enthusiasm has occasionally outrun prudence, it seems safe to say that in the context of child assessment, behavioral assessment is here to stay.

## Theoretical Foundations of Behavioral Assessment

### Materialism

The first broad theoretical perspective that undergirds behavioral assessment is materialism, often defined as the claim that all that exists is (physical) matter. Materialism rules out the existence of nonmaterial entities, including nonmaterial entities that are often thought to control behavior (for instance, minds, spirits, or souls). Human behavior, then, can be viewed as matter (human bodies) in motion, and we can usefully search for the causes of that motion. Scientific study of the patterns of human behavior identifies two observable sources of behavior. First, the brain and nervous system are the proximal (immediate) causes of behavior. Various types of research (electrical stimulation experiments, single cell recording, neurological case studies) have shown the precise, specific relationships between different parts of the brain and nervous system and different kinds of behaviors (Andrewes, 2001). Any time that behavior is observed, it should be viewed as an immediate consequence of the activity of the nervous system.

The nervous system is not, however, the ultimate cause of behavior, since it is always responding to the environment. Typically, the nervous system causes behavior in response to a stimulus—some environmental event. Stimuli are extremely variable, of course, and this variability is consistently related to variability in behavioral responses. Different stimuli, for instance, reliably lead to behavioral responses

that we would interpret as anger, fear, or joy—that is, emotional responses. Behavioral assessment often involves the functional relations between stimuli and various behavioral responses, with the knowledge that these relations may be different for each person, although there is considerable similarity across people in these relations as well. For instance, behavioral assessment during family therapy may include observations of a fifteen-year-old boy interacting with his mother. If the boy's anger responses are consistently observed (seen 90% of the time) after the mother asks the boy a question, but they are not nearly as frequent (only seen 20% of the time) otherwise, hypotheses about the cause of the boy's anger can be generated.

Understanding that the environment is the ultimate cause of behavior relieves us of the burden of examining the nervous system directly. Although early behaviorists (e.g., Watson, 1930) spent considerable time describing the nervous system and its connections with muscles, in an effort to describe how individual “molecular” behaviors occur, later behaviorists (e.g., Skinner, 1974) placed the nervous system in the middle of a causal chain, between the environment and behavior, suggesting that neurological explanations of behavior beg the real question of what led the nervous system to respond in such a way. Therefore, behavioral assessment does not typically involve direct assessment of nervous system functioning, although as we review later in the chapter, certain physiological variables may be part of a behavioral assessment.

### **Determinism**

Behavioral assessment also assumes determinism, the doctrine that all events (including occurrences of human behavior) are determined fully by prior events. There are many versions of determinism in academic philosophy, but determinism is often thought to be incompatible with free will, and is often viewed as a necessary assumption to be made if human behavior is to be studied scientifically. Behavioral models of psychology are not just deterministic in a general sense; they make very specific and testable claims about the exact processes by which environmental variables determine behavior. Many of these processes can be usefully classified under two groups: respondent conditioning and operant conditioning.

In respondent conditioning (also called classical conditioning or Pavlovian conditioning), an automatic, reflexive response to one stimulus becomes transferred to a second stimulus, after the two

stimuli are paired repeatedly (Powell, Symbaluk, & Honey, 2009). In Pavlov's (1927) seminal experiments on classical conditioning, dogs began to salivate in response to such stimuli as the sound of a ticking metronome, after those stimuli had been paired with the presentation of food. Our understanding of the mechanisms underlying respondent conditioning continues to grow, and although early behavioral explanations of these mechanisms are no longer widely held (cf. Rescorla, 1988), we now can predict with great precision when the pairing of stimuli will lead to conditioning, and how strong a conditioned response will be.

Respondent conditioning has been implicated in many varieties of psychopathology (Plaud & Eifert, 1998), and behavioral assessment may involve detailing the nature of maladaptive behavior that follows respondent conditioning, describing the respondent conditioning situations that caused maladaptive behavior, or monitoring behavior change during the process of respondent conditioning-based therapy. Whenever behavioral assessment aims at explaining the origin of the behavior being analyzed, respondent conditioning is a likely explanation for behavior if an underlying reflex can be identified, and the unconditioned stimulus initiating the reflex has been paired with a second stimulus, to which the person now shows an unusual reaction (O'Donohue & Ferguson, 2003).

Operant conditioning is a second set of processes that determines behavior. Whereas respondent conditioning places emphasis on the stimuli that precede behavior, operant conditioning emphasizes the stimuli that function as behavioral consequences, namely reinforcement and punishment. Reinforcing stimuli increase the frequency of the behaviors that precede their presentation, whereas punishing stimuli decrease the frequency of behaviors that precede the punishment (Powell et al., 2009). Thorndike's (e.g., 1927) statement of the law of effect is often viewed as the first formal analysis of operant conditioning processes, but it was B. F. Skinner's work (e.g., Ferster & Skinner, 1957; Skinner, 1938, 1953, 1974) that first explored many of the details of operant conditioning, such as the presentation of reinforcing stimuli on various schedules, and the control that environmental cues acquire over reinforced behavior (“stimulus control”). Unlike respondent conditioning, which can only modify reflexive reactions that are already present, operant conditioning can lead to new behaviors through (for instance) the process of shaping, in which reinforcement is given for behaviors that come closer and closer to a target behavior (Miltenberger, 2008).

The role of operant conditioning in psychopathology is well established (Plaud & Eifert, 1998), and behavioral assessment techniques are often used to monitor changes in behavior in response to operant conditioning-based therapies. More recently, “functional behavioral assessments” have become common, in which behavioral assessment techniques are used to locate a hypothesized reinforcer that is responsible for maintaining maladaptive behavior. For instance, an eight-year-old boy referred for disruptive behavior may be disruptive every time that a math lesson begins in his classroom. A comprehensive assessment might find that the boy has very poor math skills, that he is sent to the school’s main office whenever he is disruptive in the classroom, and that in the main office he is not asked to perform any tasks. This suggests the possibility that the boy is disruptive in order to escape task demands, and being sent to the main office serves as negative reinforcement for disruptive behavior.

### **Operationalism**

A third theoretical perspective relevant to behavioral assessment, operationalism (also called *operationism*) is defined by Hung (1997) as the doctrine that “all terms should be operationally defined, and the meaning of a term is the set of the defining operations” (p. 226). Operational definitions define variables in terms of publicly observable operations performed to measure the variables, and so we might operationally define “hunger” as a person’s rating of their feeling of hunger on a scale from 1 to 10, or as a certain number of hours having passed without eating. Operationalism has had a large influence on psychology, with behaviorists in particular embracing operational definitions (Zuriff, 1985). Skinner (1953) exemplified operationalism when he noted that in terms of publicly observable behavior, “a single set of facts is described by the two statements ‘He eats’ and ‘He is hungry’” (p. 31).

Operationalism has particular relevance to assessment, since psychologists often assess traits that are in need of proper operational definitions. Whenever possible, behavioral assessment provides a statement of the publicly observable behavior itself rather than the trait name, since under operationalism, the two are functionally equivalent. Rather than describing a child as “highly intelligent” or “low in neuroticism,” behavioral assessment describes exactly what behaviors might lead to a judgment of intelligence or neuroticism by observers. If, after all, the reason why an evaluator believes a nine-year-old boy to have a phobia of dogs is that he runs away whenever he

sees a dog, the phobia label requires inferences that a simple description of behavior does not require. If a twelve-year-old girl is described as “hyperactive,” but the only evidence for this is that she constantly fidgets in her seat in the classroom, the frequency of fidgets should be quantified and noted, rather than applying a label that might suggest other behaviors that have not yet been observed to be present or absent.

Because of its commitment to operationalism, behavioral assessment has generally been considered to be against formal diagnostic labels (Spiegler & Guevremont, 2003). Although some diagnostic classifications (for instance, those found in recent editions of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders*) emphasize observable behavioral features and can be reliably assessed, diagnostic labels always carry the danger that they will be viewed as more than a summary of behavior. This tendency to “reify” labels and assume that they refer to latent, internal characteristics of people that *produce* the behaviors being assessed leads many practitioners of behavioral assessment to de-emphasize diagnostic labels, and only provide labels when necessary for official purposes. To operationalists, a psychiatric diagnosis is, at best, equivalent to the observable symptoms of the disorder being diagnosed, with no additional meaning attaching to the diagnostic label (Lovett & Hood, 2011).

### **Methodological Foundations of Behavioral Assessment**

Behavioral assessment is conceptualized as a psychological assessment methodology based on principles of scientific inquiry and inference (Heiby & Haynes, 2003). As a result, behavioral assessment methods are influenced by particular conceptions of causation and functional relationships as well as certain psychometric principles.

### **Causation and Functional Relationships**

One of the central features of behavioral assessment is an emphasis on situational determinants of behavior across time and environments (Kenny, Alvarez, Donohue, & Winick, 2007). As a result, behaviors and environmental events are repeatedly measured in an effort to derive precise and minimally inferential results. The methods of behavioral assessment have been conceptualized as falling on a continuum ranging from direct assessment methods to indirect assessment methods (Cone, 1977, 1978). Many of the indirect behavior assessment methods

rely on informant reports of behavior and events surrounding its occurrence to generate hypotheses regarding behavior-environmental relations (Gresham, Watson, & Skinner, 2001; McComas & Mace, 2000). Although these methods identify environmental events that influence behavior, this association reflects only a correlational relationship (Gresham et al., 2001; McComas & Mace, 2000). Interestingly, even the majority of direct behavior assessment methods (e.g., direct observation, performance tasks) reflect a correlational relationship when examined in relation to environmental events.

Determining causal factors in behavioral assessment is complex (Haynes, 1992; Kazdin & Kagan, 1994) and emphasizes temporally contiguous environmental events (i.e., antecedents and consequences), non-contemporaneous causes (e.g., family interactions) as well as the dimensions (e.g., magnitude, chronicity) of causal variables (Haynes, 2000). Haynes and colleagues (1993) identified five methods of inferring causal relationships from behavioral assessments: (a) empirical derivation from research findings; (b) causally focused self-report measures; (c) causal marker variables (e.g., physiological measures of arousal); (d) statistical analyses across time and behavior; and (e) manipulation of hypothesized causal variables. This last method, commonly referred to as experimental functional assessment, involves systematically manipulating antecedent and consequent events to verify functional relations between environmental events and behavior. Results from an experimental functional assessment identify one or more behavior-environment relations that maintain the problem behavior of children and youth (McComas & Mace, 2000). As noted by Carr (1993), the importance of identifying the functions of problem behavior cannot be overstated:

Thus, knowing that a young boy diagnosed as autistic exhibits self-injury is, by itself, not very interesting. What is interesting is why the self-injury occurs (i.e., of what variables is it a function) ... Topography (behavior) does not matter much; function (purpose) does. (p. 48)

### ***Psychometric Principles***

The psychometric models most appropriate to behavioral assessment approaches have created significant controversy, with some criticisms remaining unresolved (Dawes, 1994; Meehl & Rosen, 1955; Mischel, 1968; Peterson, 1968). Given the underlying assumptions of behavioral assessment, it has been argued by some that the application of classic

psychometric principles is inappropriate (Hartmann et al., 1979; Suen, 1988). Others, however, have argued that basic psychometric concepts (e.g., reliability, validity) as well as alternative concepts (e.g., generalizability theory) should be applied to behavioral assessment methods (Bellack & Hersen, 1988; Cone, 1988; O'Leary, 1979).

Given that many behavioral assessment measures are designed for idiographic rather than nomothetic purposes, intraindividual changes are of interest, systematic error is relevant, and variance across participants does not exist (Suen, 1988). In contrast, in nomothetic assessment, individual performance is compared to group performance and variance across participants is considered true and meaningful. In behavioral assessment, however, it is the variance across points of observations that is considered true variance (Suen, 1988). Furthermore, whereas systematic error, such as observer error, is irrelevant and can be partitioned out in traditional assessment, systematic error can be extremely problematic in behavioral assessment. For example, an observer who systematically overestimates the occurrence of a behavior in traditional, nomothetic assessment will do so across all participants, maintaining the rank order and amount of variability across participants. However, if an observer overestimates the occurrence of a behavior in idiographic, behavioral assessment, the error will affect the relationship between the observed score and the criterion.

Conventional psychometric constructs clearly apply when behavioral assessment approaches include standardized measures such as behavior rating scales and checklists. Consistent with professional standards in psychology (Standard 9.02; American Psychological Association, 2002), core dimensions of reliability (i.e., test-retest, interrater, alternate-form, internal consistency, internal structure) and validity evidence (i.e., content, discriminative, concurrent, predictive) should be examined and considered in the selection of standardized behavioral assessment instruments (Bagner, Harwood, & Eyberg, 2006). However, other behavioral assessment strategies, such as direct observation, are associated with different psychometric conceptualizations that focus on behavior and its variation within individuals (Johnston & Pennypacker, 1993; Nelson, Hay, & Hay, 1977). Although information regarding the psychometric qualities of standardized observational codes is reported in manuals, other psychometric qualities, such as interobserver agreement, can only be determined after direct observations are conducted.

Recently, Hintze (2005) argued that reliability of direct observation procedures should be evaluated regarding the sensitivity to individual differences and the likelihood that similar results would be obtained across a variety of students and practice situations. In his work, Hintze argues that direct observation methods developed by practitioners should examine: (a) internal consistency reliability; (b) test-retest reliability; (c) interobserver agreement; (d) content validity; (e) concurrent and convergent validity; (f) predictive validity; and (g) sensitivity to change. For those methods that are being used commercially or for research purposes, he argues that (a) interobserver agreement; (b) intraobserver reliability; (c) content validity; (d) concurrent and predictive validity; (e) convergent and discriminant validity; and (f) sensitivity to change should be formally evaluated. Moreover, one of the underlying assumptions of behavioral assessment is that decisions and the resulting consequences of these decisions (i.e., intervention development, diagnostic classifications) should be validated. This conceptualization includes producing socially significant outcomes, or social validation (Kazdin, 1977; Schwartz & Baer, 1991; Wolf, 1978) as well as valid treatment approaches (Messick, 1995). Thus, behavioral assessment strategies need to be considered within the context of a problem-solving and decision-making context (Barnett, Lentz, & Macmann, 2000), and the usefulness, or validity, of the behavioral assessment data obtained needs to be considered.

## **Behavioral Assessment Strategies**

Although dozens of behavioral assessment techniques have been developed, behavioral assessment strategies are generally organized into five general categories: (a) behavioral observation, (b) behavior interviewing, (c) behavior rating scales, (d) psychophysiological measurements, and (e) performance tasks. In this next section of our chapter, we provide a broad overview of each of these techniques.

### ***Behavioral Observation***

Among the various behavioral assessment strategies developed, behavioral observation is considered the hallmark for measuring and recording behavior (Gresham et al., 2001; Steege, Davin, & Hathaway, 2001). Behavioral observation can be used in a variety of situational contexts (e.g., school, home) to identify behavior deficits and excesses of children and youth as well as identify the determining or controlling variables of problem behaviors (Cone

& Hawkins, 1977). In addition, objective features of behavior, such as frequency, temporality, and intensity, can be assessed using observation-based recording methods. When data collected from behavioral observation strategies are quantified, behavioral trends and variability can be readily examined (Barlow & Hersen, 1984; House, House, & Campbell, 1981; Shapiro & Skinner, 1990).

*Systematic direct observation.* Systematic direct observations are often used to quantify the behavior of children and youth (Hintze, Volpe, & Shapiro, 2003; Wilson & Reschly, 1996). They can be used within the context of a multi-method behavioral assessment to measure students' adaptive and maladaptive behaviors (Hops, Davis, & Longoria, 1995), and are often utilized as part of a functional assessment, discussed later in this chapter, to identify events that may serve to reinforce a behavior under specific conditions. As highlighted by Volpe and McConaughy (2005), systematic direct observations measure specific behaviors that have been operationally defined and follow standardized coding procedures. Unlike unsystematic direct observations, systematic direct observations provide quantitative data that are synchronized across children and youth, settings, and raters. The systematic nature of these instruments reduces common threats to the validity of observational measures, which include interobserver reliability, observer reactivity, and observer bias (Merrell, 1999).

A number of well-validated systematic direct observation instruments have been developed. Many of these measures have been developed for use in elementary classrooms. For example, Volpe, DiPerna, Hintze, and Shapiro (2005) provided a comprehensive review of a number of instruments including the Academic Engaged Time Code of the Systematic Screening for Behavior Disorders (AET-SSBD; Walker & Severson, 1990), the ADHD School Observation Code (ADHD-SOC; Gadow, Sprafkin, & Nolan, 1996), the Behavioral Observation of Students in Schools (BOSS; Shapiro, 2004), the Classroom Observation Code (COC; Abikoff & Gittelman, 1985), the Direct Observation Form (DOF; Achenbach, 1986), and the Student Observation System of the Behavioral Assessment System for Children-2 (SOS; Reynolds & Kamphaus, 2004). In addition, Leff and Lakin (2005) reviewed playground-based observational systems and identified two well-established systems: the Interpersonal Process Code (IPC; Rusby, Estes, & Dishion, 1991) and the Peer Social Behavior of the Systematic Screening for Behavior Disorders

(PSB of the SSBD; Walker & Severson, 1990). Finally, McConaughy (2005a) reviewed three standardized observational instruments for use during test sessions and child clinical interviews, the Guide to Assessment for Test Session Behavior (GATSB; Glutting & Oakland, 1993), the Test Observation Form (TOF; McConaughy & Achenbach, 2004), and the Observation Form for the Semistructured Clinical Interview for Children and Adolescents (SCICA; McConaughy & Achenbach, 2001).

*Antecedent-Behavior-Consequence recording.* A second form of direct observation, anecdotal observation, involves the written narrative of behaviors and environmental conditions under which the behaviors were emitted (Cooper, 1981). Information obtained from this type of observation not only provides a record of behavior within an environmental context, but also identifies events that happen before or after the behavior of interest (Cooper, Heron, & Heward, 1987). Commonly referred to as Antecedent-Behavior-Consequence recording (A-B-C; Bijou, Peterson, & Ault, 1968), this approach involves collecting data on the observable events preceding the target behavior ([A] antecedents of behavior), the target behavior [B], and the observable events following the target behavior ([C] consequences of behavior) (O'Neill, Horner, Albin, Storey, & Sprague, 1990). Following the completion of the observation, the data are reviewed to examine the relationship between the antecedents, behaviors, and consequences observed. The analysis of A-B-C recordings involves either visually analyzing or quantifying patterns in responding to identify the types of environmental events that either precede or follow the problem behavior (Sterling-Turner, Robinson, & Wilczynski, 2001). Temporal relations among behavior and events surrounding its occurrence can also be quantified from A-B-C recordings based on conditional probabilities. Conditional probability analysis requires the computation of proportions that reflect the likelihood that an antecedent or consequence is related to the occurrence of a target behavior (Eckert, Martens, & DiGennaro, 2005; Sterling-Turner et al., 2001).

*Ecobehavioral classroom assessment.* A more specialized form of direct observation, ecobehavioral classroom assessment, assesses classroom variables affecting the behavior of children and youth in school settings. This type of assessment is designed to assess the association between various environmental and instructional factors in the classroom (e.g., physical arrangement of classroom, teacher prompts) and the ensuing behaviors of children and youth

(Greenwood, Carta, Kamps, & Arreaga-Mayer, 1990). Ecobehavioral classroom assessment is based on Carroll's (1963) model of classroom learning as well as empirical research demonstrating that active student engagement is highly associated with student achievement and learning (e.g., Brophy & Good, 1986; Greenwood, 1991; Sindelar, Smith, Harriman, Hale, & Wilson, 1986).

Unlike systematic direct observations and A-B-C recording, the focus of ecobehavioral classroom assessments is to simultaneously measure classroom context, teacher instructional variables, and student responding. This results in standardized coding procedures that can be complex in the types of behaviors observed (e.g., child, peers, teacher) and time sampling procedures (e.g., momentary time sampling, partial interval, whole interval) employed. As summarized by Stichter and Lewis (2006), ecobehavioral classroom assessments serve four major purposes: (a) they describe the instructional context of the classroom; (b) they compare instructional contexts across classrooms; (c) they identify contextual variables associated with positive academic and behavioral student outcomes; and (d) they monitor changes in the instructional context of the classroom.

Based on the literature base examining classroom variables affecting student behavior and achievement, Stichter and Lewis (2006) developed a hierarchy of classroom assessment metrics common to ecobehavioral assessments. At the first level of this hierarchy, physical and structural classroom arrangements are measured. Examples of metrics assessed at this level include classroom traffic patterns, accessibility of classroom materials, and posting of classroom rules and daily classroom schedule. Inherent at this level are specific physical aspects (e.g., Where is the pencil sharpener located?) as well as procedural aspects (e.g., Are there standardized procedures for hand raising?) of the physical and structural arrangement of the classroom. The second level of the hierarchy focuses on assessing instructionally-specific contexts of the classroom, including types of instructional delivery (e.g., independent seatwork, transition activities) and student grouping techniques (e.g., small group, peer collaboration). The third level of the hierarchy examines the specific instructional techniques used by the teacher in the classroom. Examples of specific techniques assessed include instructional talk, wait time, downtime, previewing, organizational prompting, modeling, and providing instructional feedback. The final level of Stichter and Lewis's hierarchy assesses students' academic

(e.g., work product accuracy) and behavioral (e.g., engagement) outcomes exhibited in the classroom.

A number of ecobehavioral assessment measures have been developed for use in classroom environments. Some of these measures, such as the Direct Instruction Observational System (DIOS; Englert & Sugai, 1981), focus primarily on teacher behaviors exhibited in the classroom. The majority of measures simultaneously measure teacher and student behaviors. These measures include the State-Event Classroom Observation System (SECOS; Saudargas & Creed, 1980), which assesses student and teacher behaviors; the Classroom Activity Recording Form (CARF; Sindelar et al., 1986), which assesses types of classroom instruction (i.e., direct instruction, independent work, non-instructional work) as well as student behaviors; the Teacher/Student Interaction Analysis (Sugai & Lewis, 1989), which assesses instructional behaviors and student responses; and the Setting Factors Assessment Tool (SFAT; Stichter, Lewis, Johnson, & Trussell, 2004), which assesses teacher and student behaviors across four levels (i.e., global classroom structural variables, nature of instructional content, specific teacher instructional cues, student behaviors). Furthermore, a number of computer-based ecobehavioral assessments have been developed including the Ecobehavioral Assessment Systems Software (E-BASS; Greenwood, Carta, Kamps, & Delquardi, 1993), the Mainstream Code for Instructional Structure and Student Academic Response (MS-CISSAR; Carta, Greenwood, Schulte, Arreaga-Mayer, & Terry, 1987), and the Ecobehavioral System for Complex Assessments of Preschool Environments (ESCAPE; Carta, Greenwood, & Atwater, 1985).

## Interviews

Interviews are routinely used measures of behavioral assessment (Hughes & Baker, 1990), and provide detailed information from the perspectives of children, youth, and caregivers (McConaughy, 2003, 2005b). Behavioral assessment interviews are conceptualized as structured and quantitative measures that emphasize overt behavior, behavior-environment interactions, and situational sources of behavioral variation (Haynes, 2000). Ramsay, Reynolds, and Kamphaus (2002) identified six steps inherent in behavioral interviewing: (a) identify the problem behavior and specify target behaviors; (b) identify and analyze relevant environmental factors; (c) develop an intervention plan; (d) implement the intervention plan; (e) evaluate

outcomes associated with the intervention plan; and (f) modify the intervention plan as needed and reevaluate outcomes.

Although the accuracy and reliability of information obtained through this process requires verification, interviews afford the collection of an extensive amount of information that may be challenging to obtain using other types of behavioral assessment strategies. For example, some behaviors, such as those associated with anxiety and depression, may be difficult to capture using systematic direct observation methods. Interviews provide children, youth, and caregivers with the opportunity to articulate their perceptions of behavior and its consequences. It is important to note that the congruence of these multi-source interviews may be limited (Finch & Rogers, 1984) due to a number of errors associated with subjective reports, such as biases and memory errors (Haynes, 2000). However, there is some evidence to suggest that the perceptions of children and youth may be as important for behavior change as obtaining reliable and valid indices of the behavior itself (Ollendick & Hersen, 1984).

Two general categories of interviews have been developed: semi-structured interviews and structured interviews. Semi-structured interviews broadly assess children's perspectives on their functioning using a flexible interview format (McConaughy, 2003) and permit alterations in the wording and ordering of questions (Orvashel, 2006). The *Semistructured Clinical Interview for Children and Adolescents* (SCICA; McConaughy & Achenbach, 2001) is one example of a semi-structured interview for school-aged children that can be combined with data obtained from parent ratings on the *Child Behavior Checklist for Ages 6 to 18* (CBCL/6-18; Achenbach & Rescorla, 2001), teacher ratings on the *Teacher's Report Form* (TRF; Achenbach & Rescorla, 2001), youth self-ratings on the *Youth Self-Report* (YSR; Achenbach & Rescorla, 2001), and direct observations on the *Direct Observation Form* (DOF; Achenbach, 1986). The *Semistructured Clinical Interview for Children and Adolescents* protocol form provides instructions for introducing the interview, outlines samples of open-ended questions, and outlines topics in nine broad areas (e.g., family relations; self perceptions and feelings; parent- or teacher-reported problems). Profiles on seven syndrome scales (i.e., Anxious, Attention Problems, Language/Motor Problems, Self-Control Problems, Withdrawn/Depressed, Anxious/Depressed, Aggressive/Rule-Breaking) can be derived based on the informant's responses.

Structured interviews systematically assess a broad range of symptoms and specific diagnostic categories. However, unlike semi-structured interviews, the question format, rating responses, and ordering items are systematic and unvarying (Orvashel, 2006). Examples of highly structured interviews include the *Diagnostic Interview for Children and Adolescents-IV* (DICA-IV; Reich, 2000; Reich, Welner, Herjanic, & MHS Staff, 1999) and the *National Institutes of Mental Health's Diagnostic Interview Schedule for Children-Version IV* (NIMH DISC-IV; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000). Both of these measures were developed to generate psychiatric diagnoses and cover the most common emotional and behavioral disorders of children and youth, including attention-deficit/hyperactivity disorder, conduct disorder, oppositional defiant disorder, major depression, dysthymia, and anxiety disorders. Admittedly, diagnoses such as these are not based solely on a child's observable behaviors. However, using structured interviews to make psychiatric diagnoses involves an equivalence between an informant's reports of symptoms and a psychiatric label, an equivalence that implies an operationalist conception of assessment (Lovett & Hood, 2011).

### **Behavior Rating Scales**

Behavior rating scales rely on a retrospective assessment of a child or youth's behavior by others (e.g., caregivers, teachers) in order to provide a comprehensive assessment of behavior, including the identification of strengths and weaknesses that characterize the child or youth's behavior (Greene & Ollendick, 2000). Informants respond to a set of standardized, structured written statements pertaining to attitudes, beliefs, feelings, opinions, and physical states (Reynolds, 1993). This information can be compared with normative data to quantify the degree to which a behavior strength or weakness is manifested relative to that seen in the general population (Eckert, Dunn, Guiney, & Codding, 2000).

Administering behavior rating scales to multiple informants assesses the systemic influences that may affect a child or youth's behavior as well as measures the interrelationship among various individuals and environments (e.g., school, home) in a child or youth's life (Beaver & Busse, 2000). However, the limited association between responses on behavior rating scale across individuals, environments, and time has been acknowledged. Merrell (2000) summarized the major research findings regarding cross-informant correlations with child and youth

behavior rating scales and concluded: (a) correlations of behavior ratings made by all informants are statistically significant, but modest; (b) agreement among pairs of informants in similar roles is higher than agreement among informants in dissimilar roles; and (c) cross-informant ratings of externalizing problems is higher than ratings of internalizing problems.

Often behavior rating scales are organized into two separate categories, broad-band and narrow-band rating scales (Eckert, DuPaul, & Carson 2003). Broad-band behavior rating scales assess an extensive range of behaviors. The *Achenbach System of Empirically Based Assessment* (ASEBA; Achenbach & Rescorla, 2001) is the foremost example of a broad-band behavior rating scale that can be used to assess behavioral competencies, adaptive functioning, and behavior problems among school-age children and young adults. In addition, the *Behavior Assessment System for Children-2* (BASC-2; Reynolds & Kamphaus, 2004) represents a broad-band behavior rating scale that can be used for school-aged children to assess adaptive and problem behaviors exhibited in school and home settings. Both of these measures incorporate broad-band taxonomy of behaviors.

Narrow-band behavior rating scales focus exclusively on a single, specific construct such as hyperactivity, anxiety, or depression. Similar to broad-based behavior rating scales, narrow-band behavior measures can be administered to examine systemic influences on the behavior of children and youth. However, only one behavioral construct is typically examined in order to conduct an in-depth assessment (DuPaul, 1992). A significant number of narrow-based behavior rating scales have been developed to assess social and interpersonal relations (e.g., *Social Skills Rating System*; SSRS; Gresham & Elliott, 1990), self-concept (e.g., *Multidimensional Self Concept Scale*; MSCS; Bracken, 1992), depression (e.g., *Children's Depression Inventory*; CDI, Kovacs, 1992), anxiety (e.g., *Social Anxiety Scale for Children-Revised*; SASC-R; La Greca & Stone, 1993), and attention-deficit/hyperactivity disorder (e.g., *ADHD Rating Scale-IV*; DuPaul, Power, Anastopoulos, & Reid, 1998).

### **Psychophysiological Measurements**

As the early behaviorists (e.g., Watson, 1930) pointed out long ago, behavior can be defined as the action of body parts, which are under the immediate control of the nervous and endocrine systems. Measures of muscle activity, as well as nervous

and endocrine activity, can therefore be viewed as forms of behavioral assessment. Psychophysiological assessment is the term for these types of measures (Stern, Ray, & Quigley, 2000), and although the equipment needed for psychophysiological assessment is not available in every clinical setting, clinicians who work with children should consider its potential contributions to their practice. Indeed, Wilhelm, Schneider, and Friedman (2006) argue that psychophysiological assessment often provides information that other forms of behavioral assessment cannot provide. Specifically, people—and children in particular—cannot always keep track of their behavior well enough to answer interview questions or complete a rating scale accurately. Behavioral observation overcomes this problem but relies on subjective judgments of observers. Psychophysiological assessment bypasses both of these problems by providing direct *and* objective measures of behavior.

Electromyography (EMG) is the physiological measurement of muscle activity, and can be accomplished by placing EMG electrodes almost anywhere on the skin, although the most common placements are on the head, neck, arms and legs (Stern et al., 2000). Greater amplitude (height) of the waves shown on the EMG recording corresponds to more muscle contraction, and EMG is sufficiently sensitive that even very slight contraction can be detected. This is especially helpful when measuring activity in muscles whose contraction is not visible (for instance, in the head or neck), and where increased tension is associated with stress, anxiety, or other psychologically relevant variables (Wilhelm et al., 2006).

Eye movements are another frequently measured behavior in psychophysiology (electrooculography, or EOG), although rather than measuring activity in the muscles that control eye movements, EOG actually measures the electrical potential of the eyes directly (each eye is like a magnet, with the front part exhibiting a positive charge and the back exhibiting a negative charge; Stern et al., 2000). EOG can be used to detect interest in visual stimuli, by examining how long the eyes are moved to focus on a stimulus that was placed in the periphery of a child's visual field. Examining eye blinks is a related psychophysiological procedure, and possibly one with more clinical relevance, since blink frequency has been related to the presence of anxiety disorders and ADHD (Wilhelm et al., 2006).

Muscle contractions and eye movements are both classified as voluntary actions, since they can often

be consciously controlled. These types of actions originate in the somatic nervous system (the system of nerves that innervate skeletal muscles), whereas involuntary actions (e.g., stomach contractions, the heartbeat, etc.) originate in the autonomic nervous system (Marieb & Hoehn, 2007). The autonomic nervous system has two divisions: the sympathetic branch prepares the body for quick action under conditions of stress, threat, or danger, by (for instance) dilating the pupils, increasing heart rate, and slowing digestive processes. The parasympathetic branch relaxes the body by reversing these and other processes. High levels of sympathetic activity are related to more intense experiences of stress and anxiety (Weems & Silverman, 2008), whereas low levels of sympathetic activity (e.g., pulse rate) have been found to relate to externalizing and antisocial behavior (Raine, 2002).

When determining whether to use psychophysiological procedures in clinical practice with children and adolescents, the core principles of behavioral assessment should be remembered: recall that behavioral assessment prefers data that require little inference to be meaningful. If there is reason to believe that tools such as behavior observation and interviews are yielding accurate information, psychophysiological assessment may be unnecessary. However, when observations and interviews are compromised in some way (e.g., through language barriers, unreliable informants, the covertness of the behaviors under examination), psychophysiological assessment techniques may be indicated, even if they are more cumbersome than other tools.

### ***Performance Tasks***

Performance tasks differ from many other forms of behavioral assessment in that they provide stimuli for the individual to respond to, rather than simply observing responses made in the presence of naturally occurring stimuli. The classification of performance tasks as *behavioral* assessment measures depends on whether those tasks satisfy our initial definition of behavioral assessment—that is, whether they are direct enough measures that they require little inference to be meaningful. Performance tasks used in this direct fashion have been developed for use with children and adolescents exhibiting academic and behavioral problems, and we discuss these tools separately.

*Performance tasks measuring academic skills.* A common criticism of many standardized tests of academic skills is that they are in some way “artificial,” a vague criticism but one with a grain of truth

in it. Certainly, many standardized tests of academic skills contain items different from those that students have seen during instruction, and many of the items are also unlike the real-world problems that students must one day solve using academic skills. The behavioral assessment of academic skills involves performance tasks that either directly map on to specific skills that are taught in the classroom, or that are used in everyday life outside classroom settings; either way, they link to stimuli that are not unique to the testing situation.

Measures that maximize the correspondence between test stimuli and stimuli presented during instruction are used in curriculum-based assessment (CBA; Hintze, 2009). There are several different models of CBA (e.g., curriculum-based measurement, curriculum-based evaluation), but they share many features, most importantly the construction of measures based on the academic curriculum that the student is exposed to. If a student's reading fluency is the skill under examination, the school's reading curriculum materials can be used to make a set of brief performance tasks, in which the student is asked to read passages aloud and the number of correctly read words per minute is recorded (for more details on construction, see Shapiro, 2004). The resulting score (the number of correctly read words per minute) is a portrait of behavioral assessment, since it has a much more direct interpretation than, for instance, a standard score obtained from a more typical reading achievement test.

Other performance tasks of academic skills maximize the correspondence between test stimuli and "real-world" tasks, and these measures are often referred to as "performance assessments" (Reynolds, Livingston, & Wilson, 2006). For instance, Gronlund and Waugh (2009) contrast several different ways of assessing a student's ability to apply math skills. One way would be to ask students how much change they would receive back if they paid one dollar for a toy that costs 69 cents. A more "authentic" performance assessment would involve asking students to serve as either customers or clerks in a mock "store." Many performance assessments do not have dichotomous, right-or-wrong answers, and require complex scoring rubrics to yield objective evaluations (Lane & Stone, 2006). For instance, a performance assessment of middle school students' science skills may involve the design of an experiment; the experiment will have many features, each of which could be assessed on many dimensions, and a rubric may be needed to direct examiners to focus on certain features and dimensions.

Importantly, both CBA and performance assessment have been plagued by psychometric concerns. For instance, Christ (2006) noted that many extraneous variables have been found to influence performance on CBA-type measures, and Christ and Hintze (2007) noted that even high reliability coefficients are not sufficient to show score replicability, since these coefficients assess whether the relative ranking of examinees change, and are insensitive to whether the examinees' mean scores change. Similarly, performance assessments have been criticized for showing low levels of agreement across different judges ever since Starch and Elliott's (e.g., 1912) classic studies of teachers' essay grading, and certain more recent evaluations of performance assessment programs (e.g., Koretz, McCaffrey, Klein, Bell, & Stecher, 1992) have reinforced these early conclusions. However, since these studies have generally been conducted using traditional psychometric theory, there is a need for newer evaluations incorporating a behavioral assessment perspective.

*Performance tasks assessing psychopathology.* Performance tasks can also be used in the clinical assessment of behavioral and emotional disorders. One such application is the continuous performance test (CPT), a measure of attention and impulsiveness used frequently in the assessment of ADHD (Gordon, Barkley, & Lovett, 2006). A typical CPT comprises several tasks; in one task, the child may be asked to press a key whenever he or she sees a particular stimulus ("X"), except when it follows another particular stimulus ("O"). Impulsivity is shown when the child responds to the X by pressing the key without first considering whether an O preceded the X. CPT scores differentiate children with and without psychopathology and are even sensitive to ADHD medication.

Another type of performance task is used in the assessment of anxiety disorders: the behavioral avoidance test (BAT; Southam-Gerow & Chorpita, 2007). In a BAT, the child is exposed to the feared stimulus and his or her reaction is carefully observed. Since children may have difficulty articulating the severity of their fear, or they may be unwilling to admit its true severity, a BAT can lead to a more accurate assessment, even if it is more unpleasant for most individuals than an interview or rating scale. Generally, BATs are conducted without a standardized procedure, but this is not necessarily a problem, as the BAT can be tailored to the client's desired outcome. For instance, a client who will merely need to be in the same room as a snake in a glass terrarium can be tested for his or her response to precisely that

stimulus, whereas a client who will need to actually handle a snake can be tested for his or her response to having a snake put in his or her lap.

## **Behavioral Assessment Goals and Applications**

In the beginning of our chapter, we reviewed many of the defining features of behavioral assessment that were discussed by Heiby and Haynes (2003). Based on these central features, the primary goals of behavioral assessment are to: (a) use direct measures of behavior and its environmental determinants across different settings, sources, tools and time periods; (b) emphasize the assessment of causal relationships between environmental events and behaviors; and (c) draw interpretations that have validation evidence specific to the measured contexts. Within the past two decades, advances have been made in the application of behavioral assessment methodologies that move the field closer towards achieving these primary goals. In the final section of our chapter, we will review three recent developments that address these goals: functional assessment, diagnostic classification, and intervention evaluation.

### ***Functional Assessment***

Functional assessment is a behavioral assessment methodology used to develop more effective and efficient interventions for children and youth (DuPaul & Ervin, 1996; Iwata, Dorsey, Slifer, Bauman, & Richman, 1982; Vollmer & Northup, 1996). Functional behavior assessment methods refer to a broad set of procedures that examine environmental and contextual events that maintain problem behaviors (Horner, 1994; Gresham et al., 2001; Witt, Daly, & Noell, 2000). These procedures can be used to identify antecedent and contextual factors as well as maintaining contingencies that directly influence behavior (Martens, Eckert, Bradley, & Ardoine, 1999). However, despite this widely accepted general definition, there is no consensus regarding the precise definition or the specific procedures that constitute a functional assessment (Ervin, Ehrhardt, & Poling, 2001; Ervin et al., 2001). Common procedures include many of the behavioral assessment methods previously reviewed in our chapter, including direct observation of problem behaviors and environmental events, as well as interviews with a variety of sources (e.g., student, parent, classroom teacher). More specialized procedures include systematically manipulating environmental events to examine the functional

relationship between the child's problem behaviors and environmental events.

DuPaul, Eckert, and McGoey (1997) provided a broad guide to conducting functional assessments in school settings, which contained three steps: (a) conducting formal interviews to obtain descriptive information regarding the problem behaviors (i.e., What are the problem behaviors?); (b) completing behavioral observations of the problem behaviors in relation to environmental events in order to develop hypotheses regarding the function(s) of the problem behavior (i.e., What environmental variables set the occasion for the problem behavior?); and (c) experimentally manipulating environmental events to validate hypotheses regarding the function(s) of the problem behavior (i.e., What is the relationship between the problem behaviors and manipulated environmental events?). The experimental validation of hypotheses assists with the selection of interventions directly related to the function(s) of the problem behavior. For example, if it is determined that the function of a third-grade student's off-task behavior (e.g., talking to peers, moving around the classroom) is to avoid or escape task demands, then a number of interventions can be implemented to either alter classroom tasks (e.g., reduce assignment length) or make escape from task demands contingent on alternative behaviors (e.g., attention breaks contingent on task completion) (DuPaul & Ervin, 1996).

These methods, in particular Functional Behavior Assessment (FBA), have received substantial attention since the Individuals with Disabilities Education Act (IDEA) Amendments of 1997 (P.L. 105-17; IDEA '97), which require that a FBA must be conducted when a school district intends to: (a) remove students for more than 10 school days in a school year; (b) change students educational placements by removing them from school; or (c) place students in an interim alternative educational setting for a weapon or drug offense (Drasgow & Yell, 2001). In addition, the Individuals with Disabilities Improvement Act of 2004 (P.L. 108-446; IDEA '04) stipulated that if a student's problem behavior is determined to manifest from a disability, then a FBA should be conducted.

### ***Diagnostic Classification***

The most common diagnostic classification system for emotional and behavioral disorders is a categorical approach, which is used by the Diagnostic and Statistical Manual of Mental Disorders (DSM; American Psychiatric Association, 2000) and

promoted by the Individuals with Disabilities Improvement Act of 2004 (P.L. 108-446; IDEA '04). One major limitation associated with categorical diagnostic classification systems is the limited treatment utility (Gresham & Gansle, 1992). Recently, an alternative system based on behavioral assessment techniques has been recommended. This approach integrates categorical classification and functional assessment models to address the needs of children and youth experiencing emotional and behavioral problems (Power & Ikeda, 1996; Zentall & Javorsky, 1995).

As outlined by Power and Eiraldi (2000), the integrated approach includes a multi-step diagnostic assessment model that is combined with a functional assessment model. In the diagnostic assessment model, the child or youth is first referred for an assessment. Next, the target behaviors are identified and record reviews are conducted. The third step of the diagnostic assessment model stipulates that a decision is made regarding the necessity of additional screening. If there is no need for additional screening, then a functional assessment is conducted, which includes developing an intervention plan, identifying outcome measures, and implementing the intervention. If it is determined that additional screening is warranted, the diagnostic assessment model continues. Once the screening has been completed, the fifth step of the diagnostic assessment model requires that a decision is made regarding whether the child or youth meets the screening criteria. If it is determined that the screening criteria are met, then a comprehensive evaluation is conducted, which includes conducting a functional assessment, to determine a diagnostic classification. However, if the screening criteria are not met, a functional assessment is still conducted, which includes developing and implementing an intervention. As part of the functional assessment model, the intervention is monitored closely and a maintenance plan is developed.

### ***Intervention Evaluation***

Both functional behavioral assessment and the integrated diagnostic classification model previously discussed (Power & Eiraldi, 2000) link assessment to intervention. Entrenched in this approach of linking behavioral assessment results to intervention selection is the evaluation of outcomes or data-based decision making. The use of data-based decision making evolved with the behavioral consultation approach developed by Bergan and Kratochwill (1990). A key component of this approach is to closely monitor

the effects of school-based interventions on the educational, behavioral, and mental health outcomes of children and youth while taking into considerations individual differences in responding to intervention components. This approach affords data-based judgments regarding intervention effectiveness and allows for intervention modifications when children and youth demonstrate inadequate progress.

An example of data-based decision making can be clearly illustrated using CBA (Shapiro, 2004; Shinn, 1998). For example, in order to evaluate the effects of an individualized reading intervention for a fourth-grade student experiencing oral reading fluency difficulties, CBA reading probes were administered twice a week over an eight-week period of time (i.e., progress monitoring data). Data are then graphed and compared to pre-determined goal and aim lines, which can be based on estimated performance, predicted performance, or mandated performance. Using this approach, progress monitoring data can be analyzed by comparing expected (i.e., goal line, aimline) and actual reading performance (i.e., CBM data points) (Shinn & Hubbard, 1992). An alternate method of analyzing progress monitoring data involves calculating a trend line for data collected over the course of an intervention. A trend line is computed to provide a statistical summary of student performance over time. Generally a line that represents the best fit to the data is drawn through the student's data. Based on the trend line, a slope value can be computed that allows for a mathematical analysis of student progress. In addition, weekly gain, or the number of words per minute the student has improved in one week, can be computed to provide a more meaningful index of student progress (Parker, Tindal, & Stein, 1992; Shinn, Good, & Stein, 1989).

### **Conclusion**

Historical developments in the field of psychology have influenced the theoretical and conceptual foundations of behavioral assessment. Major theoretical perspectives (i.e., materialism, determinism, operationalism) have shaped behavioral assessment methods, which have also been influenced by psychometric foundations and the concepts of causation and functional relationships. A number of direct and indirect behavioral assessment techniques serve as the foundation of behavioral assessment methodologies, and recent advances in specific applications, including functional assessment, intervention evaluation, diagnostic classification, have permitted the evolution of behavioral assessment so that clinicians

are better positioned to conduct comprehensive behavioral assessments of children and youth as well identify, select, and implement interventions.

# Therapeutic Assessment with Adolescents and Their Parents: A Comprehensive Model

Deborah J. Tharinger, Lauren B. Gentry, and Stephen E. Finn

## Abstract

The comprehensive model of Therapeutic Assessment (TA) as used with adolescents and their parents is introduced. TA is designed to answer specific questions parents and adolescents pose for the assessment, to form working alliances with parents and adolescents, to collaboratively engage adolescents and their parents in the assessment process, and to foster positive development in the adolescent and the family. TA uses a combination of assessment and intervention methods, is theoretically integrative and incorporates the unique tasks of adolescent development into the structure of the assessment itself. The goals and procedures for each step are provided and illustrated with a case study of an adolescent boy and his mother, along with effectiveness data. Finally, the application of TA across cultures, the use of selected steps of TA when the comprehensive model is not feasible, and the adaptation of TA to different settings and presenting problems are addressed.

**Key Words:** Therapeutic Assessment, adolescents, parents, collaborative

Psychological assessment and psychotherapy have traditionally been viewed as distinct endeavors. However, Therapeutic Assessment (TA) is a relatively new model of psychological assessment that has fused assessment and psychotherapy techniques. TA is a semi-structured form of collaborative assessment developed by Finn and colleagues (Finn, 1996, 2007; Finn & Tonsager, 1997). This model offers many of the benefits of a traditional assessment, while also serving as a short-term therapeutic intervention. Thus, with additional training and supervision, most psychologists could readily add TA to their repertoire by integrating their existing competencies in psychological assessment and clinical interventions.

Our primary goal in this chapter is to introduce TA to assessment psychologists, particularly as it applies to adolescents and their parents, and to encourage clinicians to consider how this model may be useful in their practices. A comprehensive

discussion of TA with pre-adolescent children and their parents is available in Tharinger, Krumholz, Austin, and Matson (2011), along with an illustration of its use in school-based assessment practice. TA with pre-adolescent children is also discussed and illustrated in Hamilton et al., 2009; Tharinger, Finn, Austin et al., 2008; Tharinger, Finn, Gentry, et al., 2009; Tharinger, Finn, Wilkinson, and Schaber, 2007; and Tharinger, Matson, and Christopher (2011).

To explicate the TA model with adolescents, we will first briefly discuss the developmental changes of adolescence, as these inform the particular methods used in TA with teenagers and their parents (as compared to those used with children and their parents). Existing models of adolescent assessment have largely overlooked these developmental distinctions. Second, we will comment on the assumptions and goals of traditional models of psychological assessment. We will then introduce TA, and review its

development and history, including its philosophical and theoretical underpinnings and core values. We will also summarize research findings on the efficacy of TA. In the latter sections of the chapter, we will turn to pragmatic issues. We discuss how to organize assessment findings so they are most likely to be therapeutic to clients. Next, we will delineate the comprehensive model of TA as used with adolescents, illustrating each step with the case of a 13-year-old boy and his mother. Finally, we will discuss the importance of evaluating the effectiveness of psychological assessment in both clinical practice and research endeavors.

## Developmental Changes in Adolescence

Adolescence is a developmental period that spans, roughly, the ages of 12 to 18, and may extend into the early twenties. This life phase is characterized by intense neurological, biological, cognitive, social, and emotional evolution. Many formulations of adolescent development have focused predominantly on cognitive advances, recognizing that adolescents' budding intellectual capacities exceed those of younger children. For example, Piaget (1972) proposed that individuals transition from concrete operational thought to formal operational thought in early adolescence, with formal operations being characterized by the capacity to manipulate ideas and abstract concepts. Thus, teenagers are able to think in more relative terms and envision possibilities, rather than consider only what is concrete and observable. Further, Elkind (1978) asserted that it is during this developmental period that individuals also become capable of *metacognition*—that is, of thinking about their own thoughts and feelings.

More holistically, in addition to adolescents' burgeoning cognitive capabilities, they simultaneously face the challenges of personal and civic identity development, establishing a self-concept, building self-esteem, seeking autonomy, and cultivating a future orientation (Gibbons, 2000). Adolescence is a time wherein youth begin to explore different adult roles and grapple with developing a sense of self that is separate from their parents' view of them (Dusek, 1977; Holmbeck & Updegrafe, 1995; Muus, 1988). More recently, some neuropsychological theories, fueled by an understanding of continued brain development, have framed change in adolescence as occurring within an interpersonal context. Within this context, a fundamental reorganization and individuation of the self occurs, and the neural mechanisms of self-regulation, memory consolidation, and motivation support the capacity

for critical thinking that underlies abstract thought (Keating, 2004; Tucker & Moller, 2007).

Adolescence is often portrayed as a developmental period defined by awkwardness, turmoil, discord, and angst. In fact, most teenagers emerge from their adolescence unscathed, and the vast majority actually thrive. Nonetheless, unique vulnerabilities emerge during this period that have significant implications for the well-being of both teenagers and their families. Families with adolescents have been found to experience emotional distancing (Seiffge-Krenke, 1999) and a decline in marital satisfaction that may be precipitated by such separation (Steinberg & Silverberg, 1987). Given the emphasis on independence and autonomy during adolescence for both boys and girls (Seiffge-Krenke), much of this emotional distancing may be developmentally appropriate. However, the reasons for such decreases in family cohesion may also be due to more worrisome emotional changes in adolescence. For example, depressive symptoms have been found to increase markedly during adolescence, with such symptomatology being twice as likely in adolescent girls as in boys (Lau & Eley, 2008). Incidences of anxiety are also higher in adolescence (Kelley, Schochet, & Landry, 2004). Perhaps due to such affective disturbance—but also related to the increase in risk-taking and novelty-seeking behavior—alcohol and drug use and abuse, sexual activity, and eating disorders also increase during adolescence. In sum, multiple vulnerabilities during the developmental stage of adolescence can greatly affect the immediate and long-term health and welfare of teenagers and their families.

Thus, when negative developmental experiences do permeate the lives of adolescents and their families, they probably would benefit from psychological interventions that both honor the adolescent's growing independence and integrate family members into treatment. Fishman (1988) asserted that "the most powerful social therapeutic intervention for working with adolescents is family therapy" because the family is the "pivotal point" in every adolescent's life (p. 4). He further stated that "the very presence of a troubled adolescent in the family creates pressures that require the therapist to pay attention to the other family members. It is only ethical that the therapist address the problems of the context as a whole" (p. 5). Additionally, Fishman highlighted that it is often the family that has the most resources with which to mobilize and sustain change.

A number of other important considerations must also be kept in mind when working with

adolescents. Teenagers are actively seeking to increase their autonomy as they work to successfully transition from childhood to adulthood. In an effort to maintain independence and self-consistency during this transition, they tend to resist people or situations that conflict with their developing self-concept (Meleddu & Guicciardi 1998; Muus, 1988). Thus, teenagers may be sensitive to situations where they feel their sovereignty is not being respected. This can create challenges within the family system as parents attempt to adapt to their child's new, and more autonomous, sense of self. Ideally, parents' relationships with their adolescents will begin to be characterized by cooperation and mutual respect rather than authority (Holmbeck & Updegrafe, 1995). In combination with appropriate and consistent limits, new responsibilities and freedoms need to be given to teenagers in order to foster the development of a mature self-concept (Dusek, 1997). The need for a balance between giving adolescents privacy and autonomy, while still providing needed support and limits, can present a similar challenge in the context of psychological assessment. Some adolescents may feel as if seeking help or admitting a problem conflicts with their strivings for autonomy (Oetzel & Scherer, 2003). Thus, teenagers may enter into psychological assessment unwillingly (Fitzpatrick, & Irannejad, 2008; Keating & Cosgrave, 2006). Compounding this, assessment psychologists may initially be viewed as authority figures who might not respect adolescents' newfound autonomy.

### **Psychological Assessment with Adolescents**

While a substantial literature exists on the psychological assessment of "children and adolescents" (e.g., Kamphaus & Frick, 2005; Kaufman & Kaufman, 2001; Knoff, 1986; Ollendick & Hersen, 1993; Smith & Handler, 2007), there is a dearth of information that directly addresses the subtleties of conducting psychological assessments specifically with adolescents. There are a few noteworthy exceptions, however. In his book entitled *Assessing Adolescents in Educational, Counseling, and Other Settings*, Hogue (1999) stated that adolescents "often [exhibit] characteristics and circumstances that set them apart from children and adults ... these unique features mean that, in many cases, assessments and interventions appropriate for younger and older age groups may not be indicated" (p. 1). Hogue's book begins with a thorough review of various aspects of adolescent development as they pertain to psychologists' work. He then similarly reviews the basic concepts underlying psychological assessment,

ethical issues, and various measures of aptitude and achievement, personality, and behavior. However, outside of highlighting that conducting interviews with adolescents "often presents special challenges for the mental health professional" (p. 157), and identifying specific forms or versions of measures that are tailored for use with teenagers, Hogue does not clearly integrate these two bodies of literature in order to address the unique *process* of psychological assessment with adolescents.

Similarly, in their book entitled *Assessing Adolescents*, Oster, Caro, Eagen, and Lillo (1988) review general developmental considerations for working with adolescents, and present guidelines on how to sensitively approach the initial interview, given that "adolescents rarely refer themselves for treatment" (p. 16). The authors then review a variety of content areas about which it is useful to get information from adolescents in the interview (e.g., bodily concerns, friendships, sexual involvement, school problems). Furthermore, the authors suggest that adolescents have the opportunity to ask any questions that may arise during the interview process, and that assessors seek the adolescent's input surrounding the development of a cogent plan for intervention (Oster et al., 1988). The authors also briefly review the importance, and the process, of the adolescent and his or her family receiving assessment feedback. However, throughout the text, the major emphasis is placed on a review of appropriate psychometric instruments and tests that have been widely used in the assessment of adolescents, whereas the unique processes of assessment with adolescents are addressed only briefly.

In spite of the limitations of their respective books, both Hogue (1999) and Oster et al. (1988) address a notable gap in the literature base on psychological assessment. As is evidenced in the predominant content of these two texts, the literature on adolescent assessment generally focuses on the development and use of adolescent forms of well-known tests or measures specifically designed for adolescents. The value of these contributions must not be underestimated. Measures specifically tailored to adolescents inherently recognize such factors as (1) adolescents' increasing ability to understand more advanced language, (2) their ability to evaluate more complex psychological processes and emotions, (3) the inclusion of more mature content that has increasing pertinence to adolescents (e.g., drug use and sexual experiences), and (4) unique norms that account for the developmental, physical, and emotional differences that permeate the

life stage of adolescence. However, as described earlier, there are additional considerations of great salience in conducting psychological assessments with adolescents. We will return to this topic after first reviewing traditional and collaborative models of assessment.

### Traditional Psychological Assessment

The psychological assessment literature, education and training models, and the practice of assessment have been dominated by a natural science perspective that advocates “the use of standard techniques and rigid protocols to collect ‘sterile’ data” (Finn & Martin, 1997, p. 131). Given that “the hallmark of science [is] objectivity” (Fischer, 1985, p. 7), within this traditional perspective, testing is viewed as a tool through which to obtain an “accurate” classification of a client for the purposes of diagnosis, easier communication between professionals, treatment planning, and treatment evaluation (Finn, 2007). Typically, traditional evaluations end, as Fischer (1985) notes, with the client being represented “in terms of scores, bell-shaped curves, traits, psychodynamic forces, or diagnostic labels” (p. v). The assessor is viewed as “a scientist whose task [is] to identify the patient’s traits, defenses, symptoms, and diseases through measurement” (Fischer, p. 7). Finn and Tonsager (1997) have called this the “information gathering” model of assessment. Handler and Meyer (1998) refer to this approach when applied to personality assessment as being executed by a “testing technician,” rather than an “assessment technician” (p. 4).

In order to achieve the neutrality and accuracy that is the goal in the information-gathering model of assessment, threats to the objectivity of the testing need to be minimized. In this model, it is presumed that the assessor obtains knowledge and information about the client that the client does not have access to otherwise. The traditional paradigm of psychological assessment, then, does not consider testing to be a collaborative venture. It is, instead, an undertaking in which the client is the object of the psychologist’s studied expertise (Riddle, Byers, & Grimesey, 2002).

### The Development of Collaborative Assessment Models

Over the past several decades, psychologists working within a human science tradition have advocated a more accessible approach to assessment where the client and assessor work together to form a productive understanding of the client’s situation

(Fischer, 1985/1994). Over time, this model of psychological assessment has come to be called *collaborative assessment* (Fischer, 2000). This move to shift the intent of psychological assessment is somewhat surprising given that many humanistically oriented clinicians initially voiced strong objections to assessment, viewing it as “dehumanizing, reductionistic, artificial, and judgmental … for clients” (Finn & Tonsager, 1997, p. 377). Thus, as a first step, key figures in the development of collaborative assessment, (e.g., Fischer, 1972, 1979, 2000; Handler, 1995, Purves, 2002) simply sought to make the assessment process more humane, respectful, and understandable to clients; they did not initially conceive of psychological assessment itself as a potentially therapeutic intervention. Fischer’s (1979) conceptualization of psychological assessment was grounded in phenomenological psychology, with all knowledge being inextricably dependent upon the method of study and the mode of understanding. Because truth is intersubjective, she maintained, “objective” test data are best interpreted consensually with the client, and are fundamentally grounded in “historicity, situatedness, and perspectivity” (Fischer, 1979, p. 118). Each individual person simultaneously shapes, and is shaped by, the world while moving through it, and the goal of an assessment is to take a “snapshot” of this complex process.

Therefore, Fischer (1979, 2000) proposed that life events, rather than test scores, are the primary data within which assessment information should be contextualized. Collaborative assessors are urged to attend to narrative or idiographic information throughout the course of the assessment (including when providing oral feedback and consumer-friendly written reports, Fischer, 1985/1994). A collaborative assessment also requires clinicians to consider the interpersonal context in which an assessment takes place, evaluating the interactions and transactions that occur between client and assessor as a valuable source of additional information (Finn & Tonsager, 1997; Handler & Meyer, 1998). Thus, the more humanistic and phenomenological approaches to assessment sought to shift the assessor’s focus from the integration of test scores back to understanding an individual’s life. Through such practice, the assessor can ensure that “the mirror they hold up” (Handler & Meyer, 1998, p. 6) to the client is accurate, and avoid the client’s feeling misunderstood, stigmatized or disrespected.

Collaborative assessment can be either loosely structured or semi-structured (Finn, 2007). Loosely structured techniques may use standardized testing

materials in an unstandardized way, primarily as facilitators or therapeutic tools wherein a “valid” score is not obtained. For example, Fischer (2000) advocates for interrupting standardized testing procedures at “natural breaks” (p. 5) when it seems fruitful to further explore any content or process that was evoked by the testing stimuli. Conversely, Finn (2007) and his colleagues developed TA as a form of collaborative assessment that is semi-structured. In this model, assessment measures are administered using traditional standardized procedures, with possible idiographic inquiry following the standardized administration. Subsequently, the client and assessor discuss and interpret the testing experience together, which, in and of itself, may act as a therapeutic intervention (Finn & Tonsager, 1997).

## **Therapeutic Assessment**

As in collaborative assessment, TA is based primarily on principles of phenomenological, intersubjective, and interpersonal psychological theories (Finn, 2002). This framework helps redefine aspects of psychological assessment, and delineate the different motivations that drive clients to seek assessments. Various theories of human change provide a lens for understanding three such underlying motivations: self-verification, self-enhancement, and self-efficacy/self-discovery (Finn & Tonsager, 1997). *Self-verification* concerns the well-known fact that people strive to maintain their self-views, and make every effort to discount conflicting information (Swann, 1996, 1997). This phenomenon was extensively discussed by Sullivan (1964), by Kohut (1977), and is recognized in intersubjectivity theory (Atwood & Stolorow, 1984). Accordingly, in psychological assessment, clients prefer to receive information that confirms their self-concept and aids them in maintaining a coherent view of themselves (Finn, 2007). Finn (2007) posits that clients often present, or are presented, for assessment when they are experiencing “disintegration anxiety,” which is the uncomfortable (and possibly disorienting) feeling associated with receiving information that conflicts with an existing self-concept.

The second motivation, *self-enhancement*, is discussed within object-relations psychology as the need to feel loved and accepted by others, and to think highly of oneself (Fairbairn, 1952; Winnicott, 1957, 1975). Thus, clients participating in psychological assessments hope to receive praise and acceptance from the assessor and to internalize this experience (Finn & Tonsager, 1997). The third and final motivation, *self-efficacy/discovery*, initially posited by

self-efficacy theory and ego psychology, describes the need for humans to increase their knowledge of, and control over, themselves and their world (Freud, 1936; Hartmann, 1958; Hartmann, Kris, & Lowenstein, 1946; & Bandura, 1994). Through psychological assessments, then, clients seek to grow creatively, acquire self-knowledge, and obtain more control over their world.

## **Core Values of Therapeutic Assessment**

TA is guided by a set of core values held by the assessor. These include collaboration, respect, humility, compassion, and openness/curiosity (Finn, 2009). We describe each in turn, as they are foundational to the practice of TA.

### **COLLABORATION**

Assessors practicing TA believe that assessments are most useful, and the results most accurate, when clients are engaged as full collaborators. Clients are central in establishing the goals for their assessments; assisting in identifying relevant background information; aiding in deriving meaning from the test results, including tying them to real life examples; and providing input into recommendations. Clients also review and comment on any written documents that result from their assessment. Finally, assessors also collaborate with referring professionals and, when appropriate, with other important people in clients’ lives, which may include family members, teachers, judges or employers.

### **RESPECT**

TA seeks to respect clients’ dignity; in so doing, assessors should treat clients as they would wish to be treated. Thus, clinicians practicing TA thoroughly explain assessment procedures so that clients may make an informed choice about whether or not to participate. Clients are also encouraged to provide input as the assessment unfolds, and to collaboratively construct recommendations at the end of the assessment. Clients are regarded as “experts on themselves” who work with assessors to better understand life impasses or dilemmas. TA is also suited to clients of different cultures in that assessment procedures are adapted to specific cultural contexts; clients are asked to help assessors understand how assessment findings relate to their unique cultural identities.

### **HUMILITY**

Assessors practicing TA are acutely aware that they bring their own perspectives and biases into

their work. They acknowledge that they can never fully understand another person's inner world. Assessors are also knowledgeable about the limitations of psychological tests, and do not view them as providing infallible "Truths" about clients. Test scores and interpretations are seen as starting points for discussions about clients' lives, and as tools for generating hypotheses that may assist clients in discovering new "self stories." Assessors trained in TA work to "find their own versions" of the struggles experienced by clients. They are humbled by how their clients' struggles mirror their own and are also acutely aware that all of us are growing, struggling human beings, generally doing the best we can given our respective backgrounds and resources.

### **COMPASSION**

In TA, assessors integrate empathy and psychological testing to "feel into" their clients' lives, seeking to understand puzzles, behaviors, and patterns that are incomprehensible to others. This often results in clients' feeling more compassion for themselves, and receiving more acceptance and support from others in their lives. Often, as compassion increases and shame decreases, clients find that they are able to make needed changes that formerly eluded them.

### **OPENNESS/CURIOSITY**

Assessors practicing TA aspire to conduct each assessment with openness to learning about themselves, the world, and the amazing resourcefulness of human beings to adapt and respond to challenging circumstances. They are genuinely curious about each person who presents for an assessment, and find that their curiosity often inspires clients to step back and view themselves and their life circumstances in new ways.

### ***Research Findings***

TA has been utilized with adults, couples, adolescents, and children and has shown great promise clinically. In controlled research with outpatient adults, TA has been shown to lead to decreases in symptomatology (Finn & Tonsager, 1992; Newman & Greenway, 1997), increases in self-esteem (Finn & Tonsager; Newman & Greenway; Allen, Montgomery, Tubman, & Escovar, 2003), and increases in hope (Finn & Tonsager). Compared to traditional information-gathering assessment, collaborative assessment has also been shown to lead to better compliance with treatment recommendations (Ackerman, Hilsenroth, Baity, & Blagys,

2000), and better alliance in subsequent psychotherapy (Hilsenroth, Peters, & Ackerman, 2004). With inpatient adults, a very brief (four-hour) TA resulted in better alliance, cooperation, and satisfaction with treatment; lower distress; and an increased sense of well being, as compared with a manualized, structured, supportive therapy or standard psychiatric treatment and milieu therapy (Little & Smith, 2008). A recent study with children under 13 and their families showed decreased symptomatology in children and mothers, decreased family conflict, and increased communication and cohesion following an eight-session TA. In addition, mothers had more positive and fewer negative feelings about their children after the assessment (Tharinger, Finn, Gentry, Hamilton, Fowler, & Matson, 2009).

Regarding adolescents, we are aware of two comparison studies. Newman (2004) compared distressed adolescents who received a brief (two-hour) TA ( $N = 18$ ) to those receiving five hours of psychotherapy ( $N = 18$ ). The group who received the TA showed significantly less symptomatology and depression, and increased self-esteem, compared to the group receiving therapy. Ougrin, Ng, and Low (2008) compared TA with traditional, non-collaborative assessment in a group of 38 adolescents referred because they engaged in self-harm. Those receiving TA were much more likely to attend the first community follow-up appointment (75% vs. 40%) and to become engaged with services (62% vs. 30%); both factors have been associated with better psychosocial outcomes in this population of adolescents. In addition to controlled research, a number of case studies have been published on TA with adults (Finn, 1996a, 1996b, 2003, 2007; Finn & Martin, 1997; Finn & Kamphuis, 2006; Fischer, 1978; Fischer & Finn, 2008; Gorske, 2008; Peters, Handler, White, & Winkel, 2008; Wygant & Fleming, 2008); with children (Guerrero, Lipkind, & Rosenburg, 2011; Handler, 2006; Hamilton, et al., 2009; Haydel, Mercer, & Rosenblatt, 2011; Smith & Handler, 2009; Tharinger, Finn, Wilkinson, & Schaber, 2007; Tharinger & Roberts, in press); with couples (Finn, 2007); and with adolescents (Michel, 2002).

### ***Principles for the Organization of Assessment Findings***

In TA, assessors share aspects of their insights and interpretations with clients throughout the assessment process rather than waiting to share all their impressions at a closing feedback meeting (Riddle et al., 2002). In fact, Finn (2007) has

re-conceptualized “feedback sessions,” in which the assessor reports “data” obtained about the client, as “summary/discussion sessions,” in which clients are invited to provide input as the assessment findings are interpreted. In these closing sessions of a TA, the assessor pays close attention to the order in which assessment findings are presented to ensure that clients are best able to internalize, and make use of, the assessment information (Finn & Tonsager, 2002).

Attending to the order of feedback is informed by the research on Swann and Read’s (1981) *self-verification theory*. Their research indicates that individuals tend to accept feedback more readily when it is consistent with their self-views than when it is discrepant; this tendency persists whether people view themselves positively or negatively (e.g., Collins & Stukas, 2006; Finn, 2007; Giesler, Josephs, & Swann, 1996). Thus, Finn (1996a) recommended that the assessment findings that are congruent with how clients view themselves be discussed first (Level 1 findings). When working with adolescents and their families, it must also be considered whether assessment results are consistent with how parents view their son or daughter, as well as how parents view themselves in relation to their child. Presenting the most self-verifying information first serves to put adolescents and parents at ease, and supports their expectation that the assessment findings will be valid and useful.

Level 2 findings are those that reframe or amplify clients’ typical ways of thinking about themselves or their families, and should be presented next. Although clients may be somewhat surprised by Level 2 feedback, and may not immediately accept it without question, it is expected that they will be able to integrate this new information into their self-views fairly easily. Ideally, the majority of the findings presented during the summary/discussion session should be Level 2 information (Tharinger, Finn, Hersh, et al., 2008); this is the information that is most likely to facilitate change in parents and adolescents.

Lastly, if the previous information is relatively well received, the assessor may go on to introduce Level 3 findings, which fundamentally conflict in some way with clients’ self-views or the understandings of their family (Finn, 2007). Adolescents and parents are likely to become anxious upon hearing Level 3 information, and may initially challenge or reject these findings. Although parents or teenagers may be threatened by this higher-level feedback, within the context of a collaborative and supportive environment, and with the passage of

time (e.g., weeks or months after the assessment is completed), they may come to understand and integrate these findings into the way they see themselves and their family. In addition, when their needs for self-verification and self-discovery are met through Level 1 and Level 2 feedback, many clients are quite open to receiving and integrating Level 3 feedback in the summary/discussion session.

The assessors’ goal in the summary/discussion session is to help adolescents and parents accept and assimilate as many of the assessment results as possible. However, presenting too much new information may be overwhelming. Furthermore, some Level 3 feedback may be so threatening that it would not benefit clients to hear it for the first time in the summary/discussion session. For example, hearing that their adolescent suffers from significant depression may overwhelm parents if they have not been previously prepared for such a “bombshell.” Furthermore, if the assessors know that clients are especially fearful of the word “depression,” it is prudent to use phrases such as “lots of sadness” or “feeling really down” instead. If parents have, in some way, been exposed to Level 3 findings earlier in the assessment, and if the sequencing of information has been well executed and language mindfully used, clients are more likely to absorb and incorporate this higher level feedback into their existing views of themselves or their family. This then allows them to address their problems in living more effectively.

It is important to note that all of the assessment sessions should be executed with the intent of transforming Level 3 information into Level 2. When adolescents and parents have had the consistent experience of viewing themselves or their adolescent in a new way, hearing corresponding information from the assessor in the summary/discussion session is likely to be much easier. The practice of organizing feedback around clients’ assessment questions also increases the likelihood that Level 3 findings will be accepted. If the information can be framed as an answer to a confounding question or an explanation for something that clients have long wondered about, they may be more motivated to process and consider the information rather than defensively reject it (Finn, 2007).

### ***General Steps of Therapeutic Assessment***

Finn (1996, 2007) has outlined a semi-structured, six-step, general model for TA. There is variation in the steps as applied to children, adolescents, adults, and couples. Each of the steps of TA, according to Finn, is important in its own right; additionally,

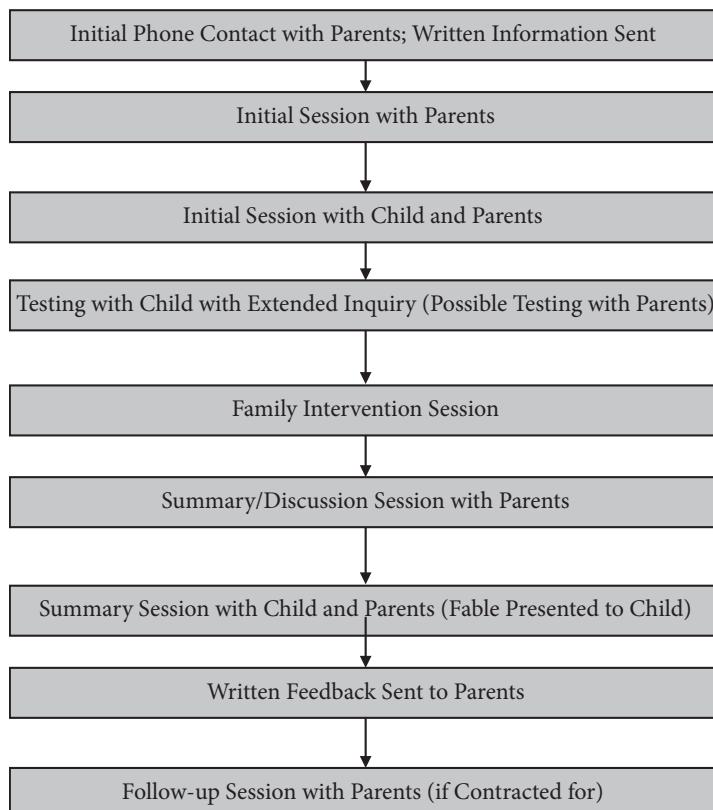

however, in our experience, the whole is greater than the sum of the parts. The steps in the general model include: (1) the assessment question-gathering phase, (2) the standardized testing phase, (3) the intervention phase, (4) the summary/discussion phase, (5) the written communication phase, and (6) a follow-up phase. Finn acknowledges the reality that specifics of the client, setting, assessor, and resources available may preclude assessors' adoption of all six steps, and encourages assessors to adapt the model to their particular needs and circumstances.

### The Model of Comprehensive TA with Adolescents

Figures 17.1 and 17.2 depict the comprehensive TA model as used with (1) children and their parents and (2) adolescents and their parents, respectively. The general steps of TA, as described above, are evident in both. As can be seen when comparing Figures 17.1 and 17.2, the major distinctions between TA with adolescents and TA with children is (1) the privacy and confidentiality afforded adolescents as compared to children, and (2) the direct work with adolescents in exploring and processing

their own testing findings, in contrast to the direct work with parents in exploring and processing the test findings of younger children. These distinctions are intended to reflect the differing developmental needs of children and adolescents discussed earlier. However, particularly in the age range of 11 to 13, a hybrid of the adolescent and child models may be used to fit the needs of individual children and families. As mentioned earlier, a comprehensive chapter on using TA with children and their parents also is available (Tharinger, Krumholz, Hall, & Matson, in press).

To grant adolescents some privacy and confidentiality, and with their parents' agreement, adolescents are allowed and encouraged to pose both shared and confidential assessment questions. In contrast, with pre-adolescent children, all their questions are disclosed to their parents. In addition, adolescents' testing sessions are not observed and processed by their parents, as they are in TA with children. Furthermore, adolescents often participate in an individual intervention session with the assessor, whereas children typically participate only in an intervention session in which their parents also

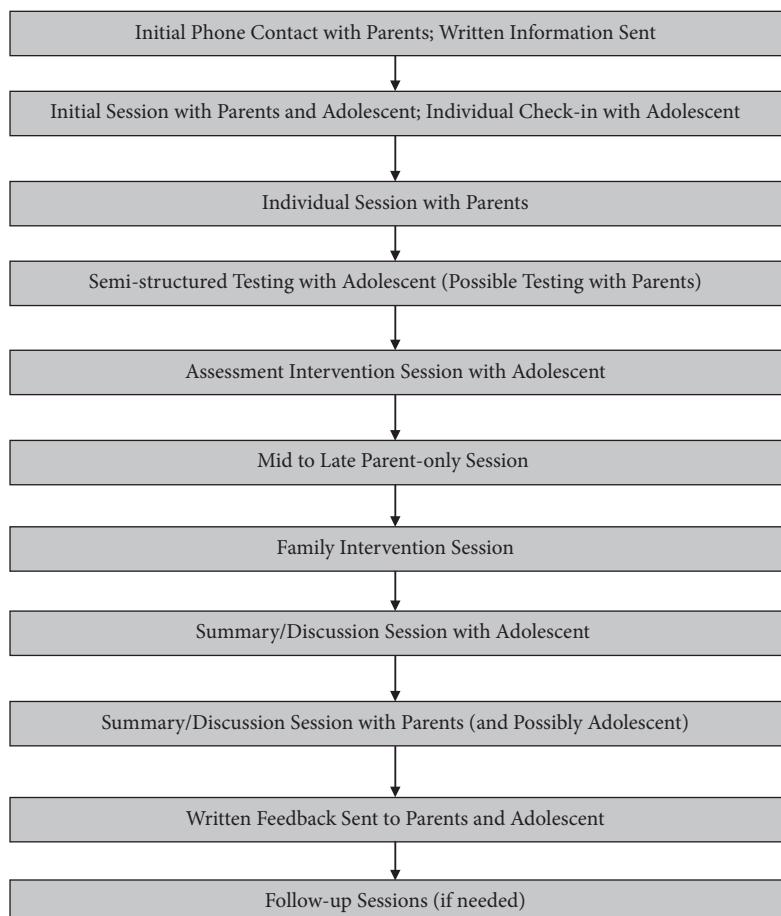

**Figure 17.1** TA with Children and Their Parents.

participate. Also, adolescents are provided with oral feedback addressing their private assessment questions prior to their parents' receiving oral feedback, which is not the case in the child model. Adolescents are also given a preview of the feedback their parents will receive, after which they may be given the option of attending their parents' feedback session, whereas children are not. In addition, adolescents receive a separate (and private) letter summarizing their specific feedback, while children's written feedback (usually in the form of a story or fable) is given to children and parents in a joint meeting. Thus, multiple steps in TA provide adolescents with privacy and confidentiality.

There is also a major distinction between adolescent and child TA with respect to the primary focus of clinician attention and intervention. In TA with children, the assessor works with the parents as they observe and process their child's test responses. The intent is to shift parents' "story" about the child, so

that it is more coherent, accurate, compassionate, and useful (Tharinger et al., 2007). This is the main focus of attention because children respond readily to shifts in their environment, and their self-stories are not as "fixed" as are those of older clients. In contrast, in TA with adolescents, assessors work with the youth directly to further their insight into themselves. The extensive social and cognitive shifts that occur in this developmental stage allow adolescents to comprehend information derived from their cognitive and personality tests; they are able to scrutinize previously unexamined beliefs, behaviors, and values, and to observe themselves as the objects of their own thought (Elkind, 1978; Piaget, 1972). Thus, by affording privacy, confidentiality, and active processing of findings in the moment, the assessor invites adolescent clients to actively participate in their assessments as equal partners, which, in turn, allows them to feel that they are respected as valuable contributors throughout the intervention.

**Figure 17.2** TA with Adolescents and Their Parents.

While this work with the adolescent is occurring, assessors also work with parents in a series of separate sessions, to facilitate and coordinate shifts in how they view their children, themselves, and their family.

We now describe and illustrate the goals and procedures for each step in the comprehensive TA model with adolescents and their parents. The majority of this material is abstracted from training materials designed by Finn and presented nationally and internationally over the past decade. We will illustrate each step with a recent case. The assessment presented herein was conducted as part of the Therapeutic Assessment Project (TAP) at the University of Texas. The assessment team consisted of the second author, Lauren Gentry, and Jamie Kuhlman, both doctoral students. The TA was supervised by Deborah Tharinger, licensed psychologist; and Pamela Schaber, licensed psychologist. Consultation was provided by Stephen Finn, licensed psychologist.

In TAP, we are studying the processes and outcomes of TA with children and adolescents. Variables of interest for potential change have included child symptomatology, family functioning, affective attitudes, and satisfaction with the assessment experience. Participants are recruited from the waiting list of a local outpatient community mental health clinic for children. If they meet entrance criteria, clients are offered a comprehensive TA, and, upon its completion, are placed at the beginning of the waiting list at the clinic, should they want additional services. The TAs are free of charge and take place at the university. Each assessment is conducted by an assessment team of two advanced graduate students in a doctoral-level professional psychology program, and supervised by licensed psychologists experienced in TA. In the TA model used in TAP, one assessment team member works primarily with the adolescent and the other with the parent(s). The assessment team comes together for all joint meetings with the family. The family members also work with independent research assistants to complete extensive pre- and post-assessment research measures and interviews, as well as brief interviews after each assessment session. Informed consent and assent is obtained from all family members prior to the start of the assessment. For the case illustrated in this chapter, both the mother and the adolescent boy gave their additional consent for us to write about them and their assessment experience in a published book.

TA with adolescents and their parents typically consists of 8 to 10 weekly sessions that take place over a two- to three-month period (although these sessions can be condensed into a shorter period if necessary). Meetings of an hour and a half are usually sufficient. We have found that weekly sessions allow time between sessions for adolescents and parents to process what they are learning, and to begin to construct a new story about themselves. This schedule similarly allows assessors time to absorb findings and thoroughly plan for the next session. This pacing, then, more closely resembles that of therapy or counseling than that of a traditional assessment.

### ***Initial Phone Contact with Parents to Discuss Referral and Provide Information on TA***

In the initial conversation with parents to explore the family's engaging in a TA, the assessor explicitly states that the assessment is intended to be a collaborative process, and stresses that parents' input is essential to the success of the TA. This assertion is then put into practice by asking parents to begin thinking about what questions they wish to address through the assessment, including those concerning their child, themselves, and their family. This invitation demonstrates from the beginning that parents will help to determine the course of the assessment. After the initial phone contact, more extensive information about the TA process is mailed to the parents, as is a separate information form designed specifically for adolescents. The intent of this separate information sheet is to support adolescents' individuation from the beginning, as well as to highlight the importance of their collaboration in the assessment process. The form for adolescents asks the following questions: "What is a Therapeutic Assessment?" "Why me, and what will this be like?" "What will I get out of this?" "What's the downside of this?" "Will you really tell me what you figure out?" "Who else will get the results of the assessment?" "Suppose I don't want to do the assessment?" and "What if I say yes, and then later I want to stop?"

For example, the information sheet answers "Why me and what will this be like?" as follows:

Your parents have agreed that a psychological assessment with you could be useful to help them understand you better and help you understand yourself. Your parents will be invited to pose questions for the assessment that we will attempt to answer. In

our experience, parents ask questions such as, “Why is our son so angry all the time?” “Why is our daughter suddenly failing in school?” or “Why do we all fight all the time?” We will let you know the questions that your parents ask. We hope that you will work with us to figure out the answers to your parents’ questions. We will also ask you, when we meet with you and your parents together, and when we meet with you privately, what questions you have about yourself and your life that you would like to ask. We will then work together to answer your questions as well. You can share your questions with your parents or you may keep them private. You might want to start thinking about questions you want the assessment to try to answer. Usually we can handle up to 4 or 5 different questions. Examples of questions teenagers have asked include, “Why don’t my parents trust me like they should?” “Why do I get overwhelmed so easily?” “Why can’t I get along with my parents any longer?” “Why is school so hard for me now?” and “How come I’m having such problems with my friends?” After we settle on your and your parents’ questions, we will be asking you to come for about 10 or so appointments. We will talk with you about your life, ask you to fill out some questionnaires, and ask you to do some psychological tests and talk with us about your experience. At the end of the assessment, we will meet with you privately to talk about the results of the assessment and answer your questions. Afterwards, we will meet with your parents to answer their questions. And at the end, we will write you a letter that tells you what we all figured out.”

## ***Initial Session with Parents and Adolescent***

This first session is guided by multiple goals and procedures. The assessment team typically begins by meeting with the adolescent and parents together. This conjoint meeting may constitute one-half to two-thirds of the session, and is followed by a check-in with the adolescent alone. The session then closes with the parents rejoining the adolescent. In this initial meeting, the assessment team works hard to make connections with the multiple individuals involved, who often have long-standing conflicts or “feel stuck,” which has led them to seek the assessment. For example, conflict between the parental subsystem and the adolescent is commonplace, as is disagreement within the parental subsystem. These conflicts are often exacerbated by the developmental tasks of adolescence discussed earlier. The competencies required of assessors in this first session are much like those used in therapy with adolescents and families: for example, listening, balancing, validating, summarizing, and exploring. We now discuss the goals and procedures of the first session, and illustrate by continuing our case example.

### **ESTABLISHING RELATIONSHIPS AND ALLIANCES**

The first goal of the initial session is for assessors to begin establishing relationships and alliances with the adolescent and the parents. This includes helping the family to feel welcome, safe, accepted, and that they are truly valued as collaborators in the

**Case material:** Matt is a 13-year-old Caucasian male nearing completion of the eighth grade. He was referred for mental health services by his mother, Lisa, who reports that Matt is bright and mature beyond his years, but that he has recently been experimenting with an assortment of illicit and prescription drugs. Although Matt has yet to run into trouble with legal or school authorities, his mother is extremely concerned about his experimentation at this young age, as well as the influence that several of his friends have on his behavior. Lisa is a single mother who became pregnant with Matt when she was 16 years old and ended the relationship with Matt’s father prior to his birth. Lisa describes her relationship with Matt as being close and open, but recently as more distant. Matt’s contact with his biological father is sporadic at best, which has been upsetting for Matt throughout his life. Matt has a close relationship with Lisa’s longtime boyfriend, Peter. Matt was diagnosed with Type 1 Diabetes at the age of seven and, although he is fairly responsible about managing his blood sugar, his health is an ongoing concern for Lisa. For example on one recent occasion, Matt had an overnight hospital stay after recreationally drinking a bottle of cough syrup. From the initial phone contact, we hypothesized that Lisa was probably struggling with letting her son individuate, as she described them as “best friends.” We also felt that she genuinely had no understanding of why Matt was choosing to experiment with drugs.

**Case material:** In establishing relationships and alliances with Lisa and Matt, it was important for the assessment team to validate the concerns and experiences of each as they began to discuss their recent challenges. For example, the assessors normalized for Matt that it is developmentally appropriate for adolescents to distance from their parents as they work on their own identity formation, while they simultaneously validated how difficult this separation must be for Lisa. In further building rapport with Matt, it was invaluable for the assessor to engage him in a conversation about the things he liked, including music, sports, and leisure-time activities, rather than focusing exclusively on his recent problem behaviors. Both Matt and Lisa were highly personable, appeared to have a positive relationship with one another, and were willing participants in the assessment; as such, relational foundations were established with ease in this initial session.

assessment process, thus establishing a foundation of trust that will be further developed throughout the assessment. We have found the following steps to be especially useful:

- (1) Warmly welcome everyone and explain the goals of the session;
- (2) Introduce the session from a collaborative perspective;
- (3) Ask if the adolescent or parents have any questions about the assessment at this point;
- (4) Listen attentively, with interest and concern;
- (5) Restate what you learned from talking to the parent over the phone and ask for clarification;
- (6) Ask for any reactions to the information sheets that were sent home;
- (7) Listen carefully and ask questions of each person present; give each family member the opportunity to state how he or she views the situation and, if there is disagreement, how each person feels about that.

It is also important to give the adolescent and parents permission to ask questions about you, the assessor, and any aspect of the assessment, as well as to discuss the limits of confidentiality. Additionally, in our experience, it is also very useful in this first session to ask about previous assessment experiences that the adolescent or the parents have had, and to listen for past hurts or disappointments, to accept and empathize with these, and to then offer an assessment contract that addresses the previous negative experience. Assessors should also encourage the family to alert them if they feel upset or poorly treated during any part of the TA. Finally, it is imperative that the assessor be attuned to interactions between family members during this session and throughout the assessment, gaining first hand experience of the family members' relationships and readiness for change.

#### NEGOTIATING SOME PRIVACY FOR THE ADOLESCENT

A second goal of the initial session is for the assessors to suggest and negotiate appropriate autonomy and privacy for the adolescent throughout the assessment. Typically, this involves securing the parents' permission for the adolescent to ask private assessment questions and to receive confidential feedback that addresses those questions. As most adolescents being assessed will be under the age of 18 and, thus, not *legally* entitled to confidentiality from their parents in relation to health and mental health care, this request is not made lightly and is understood not to be legally binding. The intention of seeking such privacy for adolescent clients is therapeutic. It acknowledges that most adolescents are beginning to individuate from their parents, and that, in our society, this is typically developmentally appropriate. Most adolescents appreciate this recognition, and thus are more likely to engage in the assessment. The request also encourages parents to accept this age-appropriate shift in their child, and to tolerate some expression of their son or daughter's autonomy. In many families, this request (and the subsequent negotiations) are, in and of themselves, an intervention, wherein boundaries are challenged and developmentally appropriate privacy needs explored. Such a request can also provide an opportunity to educate parents about the appropriate developmental needs of adolescents.

In our experience, most parents are very open to the request that their teenagers be able to pose private questions and receive individual feedback. Generally, parents appreciate their children's developmental changes and hope that their adolescents will confide in the assessor, obtaining needed help that they no longer seek from the parents. We have also found that some parents are not able to tolerate this request, or that one parent can but the other

**Case material.** Having normalized Matt's separation and individuation from his mother led relatively seamlessly into discussing Lisa's willingness for Matt to pose private questions for the assessment. Lisa readily agreed to honor such privacy for her son. However, the assessment team assured her (and informed Matt) that if Matt were to disclose any information in the course of the assessment that indicated a threat to his safety (particularly given that Matt's drug experimentation had previously resulted in a hospital stay), Lisa would be informed immediately. As is sometimes the case, in spite of Lisa's affording Matt the opportunity to pose confidential assessment questions, Matt chose to be continually open with his mother about his experience of the assessment.

cannot. When this is the case, more time is often needed to discuss the issue, and slowing the assessment process down until the matter can be satisfactorily resolved is generally good for everyone. We have also found that, by the end of the assessment, adolescents often choose to share their private questions and feedback with their parents, perhaps as a reflection of the paradox of trust.

#### OBTAINING ASSESSMENT QUESTIONS FROM PARENTS AND ADOLESCENT JOINTLY

The third goal of the initial session is to gather and co-construct assessment questions from the parents and the adolescent together, with the adolescent knowing that, if they are so negotiated, he or she will still have the opportunity to privately pose additional questions later. In our experience, most adolescents pose some questions with their parents present and some questions privately. In helping parents and adolescents frame questions to be explored through the assessment, it is important to use the clients' own words if possible, and to refine questions that are too broad or too narrow. It is also helpful to continually engage clients' curiosity, as this tends to suspend their emotional reactions, instead putting them in a role wherein they are more objectively exploring themselves. It can also be very useful for assessors to suggest implicit questions that they have heard with their "third ear" (i.e., queries that have been alluded to or implied, but not explicitly articulated), thus assisting the client in making the question explicit. If a client is struggling with posing questions, or insists that he or she has no questions, it may be useful to return to discussing the aims of collaborative assessment and the importance of its being guided by clients' curiosities about themselves or their families. In cases like these, it is possible that the relationship and trust are not adequately established and the process may need to be slowed down. In other cases, it may be that one of the participants, perhaps one of the parents, is not fully

on board with the assessment. In these cases, it is useful to comment on this and ask about the person's reservations so that the assessor may work to address these concerns.

In our experience, assessment questions are a crucial component of the collaborative assessment process. They serve to lower clients' anxiety by defining the contract for the assessment and, from the start, engage clients as active participants in the assessment process. Constructing questions also tends to engage clients' curiosity about themselves or their children, and very importantly, provide "open doors" to discuss difficult or awkward information. For the assessor, the constructed questions provide information about clients' current self-schemas/stories and indicate where those self-structures may be open to change. Finally, collecting assessment questions from clients sets the stage for them to "mentalize" (Allen, Fonagy, & Bateman, 2008) about their problems, which in itself can be therapeutic. Many clients report that they experience relief just from framing their persistent problems in the form of questions.

After the questions are formed, the assessor typically collects relevant background information to flesh out the history and context underlying each question. In collecting background information about each question, we have found queries such as the following to be very helpful: "What does the problem look like in daily life?" "If this problem were resolved today, what would be different about your life?" "If you had to answer the assessment question today, what would you say?" and "What would be the most difficult thing to hear at the end of the assessment?" In posing such follow-up questions, however, it is essential to respect the client's right to privacy at all times. Information-gathering questions should be connected to the client's agenda for the assessment in a face-valid way, which is exemplified by the client's assessment questions. If the assessor wishes to ask a follow-up question that does not appear to be related to the client's concerns, it

**Case material.** With minimal guidance, Lisa and Matt readily developed questions for the assessment. Lisa's questions were: (1) Why is Matt experimenting with drugs? (2) "Am I communicating with him in the right way?" and (3) "Why is Matt not motivated to reach his potential in school?" The question that Matt posed in his mother's presence was: "Why does my mind go blank in tests for algebra?" He subsequently alluded to the fact that he sometimes has difficulty putting his thoughts into words, but did not develop an additional question about this. While discussing Matt's recent history of drug experimentation (which had also included taking prescription stimulant medications and smoking marijuana), Lisa made a comment about how she was unable to relate to Matt's behavior because she had never experimented with drugs in her youth. Although it seemed somewhat uncomfortable for Matt to hear his mother talk with two relative strangers about his experimentation with drugs, he did not become defensive or withdrawn at any time. In fact, he only contradicted his mother on one occasion, saying that his experimentation with drugs had nothing to do with "peer pressure," and he remained engaged throughout the session.

is important that the assessor ask permission and explain why the question is relevant. In addition, it is important to allow clients to declare certain topics "off limits," even though the absence of the information may constrict the ability to fully address a particular assessment question.

In wrapping up the information gathering portion of the session, the assessor summarizes the assessment questions that have been agreed upon, invites both the parents and the adolescent to develop additional questions as the assessment unfolds, and reminds everyone that there will be ample opportunity to further discuss the questions as the TA progresses.

#### **OBTAINING PRIVATE ASSESSMENT QUESTIONS FROM THE ADOLESCENT**

The next goal of the initial session is to gauge how the adolescent is experiencing the process, and to invite him or her to meet individually to pose private questions. If so negotiated, the parents are asked to leave the room, and the assessor solicits reactions from the adolescent in response to the session so far. The assessor attempts to align with the adolescent, conveying genuine understanding of the difficulties that come with adolescence, including that relationships with parents can be challenging. The assessor continually encourages questions and reactions from the teen, seeks his or her explicit agreement to take part in the assessment, and highlights that the process will only be useful if the adolescent is on board and curious. If the teen is hesitant or unsure, the assessor may suggest that he or she take more time to think about it, and will support the adolescent in doing so. If, at any time, the adolescent decides not to participate, the assessor must respect this decision and agree to represent to the parents that this is not

the right time for a TA. If the teen agrees to participate collaboratively, the assessor then invites private assessment questions and again reviews the legal limits of confidentiality. The process of constructing questions and exploring their context is very similar to that described earlier for the joint session with the adolescent and the parents.

However, it should be mentioned that sometimes it is difficult to get adolescents to formulate individual questions to be answered through the assessment. This can happen for a number of reasons, including an underlying reluctance to participate in the assessment, distrust of the assessor, limited intellectual abilities, or, in some cases, an inability to "step back" and become curious about oneself. If an adolescent says he or she has no questions, but seems very willing to participate, it is best to proceed, keeping in mind that assessment questions may emerge in subsequent sessions. If the lack of questions seems to be a reflection of marginal motivation to participate (perhaps accompanied by a desire to mollify parents), the assessor should once again reassure the adolescent that it is not necessary to do the assessment, and that the assessor will back up the adolescent with his or her parents. Again, some adolescents will insist on proceeding and may generate questions once they develop more trust with the assessor.

#### **REUNITING AND COMPLETING THE ASSESSMENT CONTRACT**

The fourth goal involves reuniting the adolescent and parents to summarize what has happened in the first session, as well as discuss what is to come. We have found that meta-processing can be useful at this point. Questions such as: "What was it like to talk about these things today?" or "How are you feeling as you leave today?" may help

**Case material.** In his individual check-in, Matt was open to discussing his recent struggles, including his experimentation with drugs; he readily came up with private assessment questions. These included: (1) “Why do I feel distant from my friends sometimes even when I’m hanging out with them for hours on end?” (2) “Why did I take Adderall the second time without weighing the pros and the cons?” and (3) “Why do I smoke pot when I don’t remember anything the next day?” When the assessor asked Matt what his best guess was about the answer to his final question, he said that, when he smokes marijuana, “it’s an hour or two that I don’t have to contain myself. It feels like nothing can, kinda, tear me down at all.” The assessor then reiterated that smoking marijuana allows him to “let go,” and asked if he felt like he had to “contain himself” during other times in his life. He said: “At school, I feel like I can’t be myself. I can’t wear what I want to wear. I have to be careful about jokes I make because I might offend someone.” Matt also talked at length about all of the research he had done on the drugs he had used, including that he did not have the experience he was “supposed” to have when he drank the bottle of cough syrup. In fact, Matt was very forthright about his embarrassment at having ended up in the hospital following that incident. During this conversation, Matt also asserted that there are many drugs he would “never” try, including drugs like “meth, coke, PCP, and heroin.”

solidify the experience and unite the family in their commitment to the assessment. The desired outcome at the end of the first session is for the family to leave feeling less shame, and more calm, understood, curious, and hopeful. Before ending the session, any additional details of completing the contract for the assessment are discussed, such as the projected number of sessions, ending date, procedures, and if any formal written feedback will be needed (although some details may be handled privately with the parents, such as cost, insurance, etc.). Releases to contact collateral professionals are also obtained from parents, and even though it is not legally necessary, we generally also ask for adolescents’ permission to contact previous therapists, teachers, etc. Finally, the next session is scheduled, which typically involves a meeting with the parents to obtain family and developmental history. As addressed shortly, it is important for the assessor to explain to the adolescent the reasons for the upcoming meeting with the parents alone “e.g., we want to ask your parents questions about when you were little and we think it might be boring for you to sit there”, and to address any

questions or concerns he or she may have about such a plan.

#### **REFLECTING ON THE SESSION AND INITIAL IMPRESSIONS/HYPOTHESES**

The final goal of the initial session involves the assessor taking time to consolidate initial impressions and hypotheses, and to sort through any emotional reactions and anxieties that may be surfacing in relation to the clients. Such reflection underscores that the assessor and his or her reactions to, and relationships with, family members are a valuable source of information throughout the assessment process.

#### ***Session with Parents Only***

The primary goal of this session is to further explore the parents’ assessment questions by asking about relevant developmental and family history. This private session also allows the parents to share information that they might not have felt comfortable discussing in front of their child, or that would not have been appropriate for the teenager to hear (e.g., marital conflict, details about financial stress,

**Case material.** Upon coming back together, neither Lisa nor Matt expressed any lingering hesitations about participating in the assessment, and, in fact, both were very upbeat about their willingness to take part. Matt asked some brief questions about the kinds of assessment activities he would be doing in the ensuing weeks, but he had no concerns about the assessment team meeting with his mom individually the following week. Additionally, both Lisa and Matt appeared somewhat reenergized by the end of the first session.

**Case material.** Upon reflection, the assessment team noted that both Lisa and Matt were immediately likable. They were personable and seemed bright and open. They were both engaged and present throughout the session. In spite of the challenges their family was facing, they appeared to have a close and positive relationship with one another. The assessment team felt they had made a good connection and that the case would proceed well.

information about an absent parent, etc.). Parents may also have additional assessment questions that they were not comfortable posing in front of their adolescent. If this is so, the assessor works with the parents to formulate these additional assessment questions so they may be shared comfortably with the teen. For, while the adolescent may be allowed private assessment questions, all of the parents' questions for the assessment are shared with the adolescent—except in very rare instances. This session is also an opportunity for the assessor to strengthen the collaborative relationship with the parents, and to empathize with aspects of their lives, especially the difficulties of parenting and frustration with their adolescent. Additionally, it allows the assessor the opportunity to discern parents' readiness for change. In our experience, some parents need much of the session to complain about their adolescent in a scapegoating manner before they can begin to develop or resurrect empathy for their child. Other parents need time to express guilt for the challenges their child has had to endure, and to seek some "absolution" from the assessor before being able to move on. The assessor needs to be flexible and able to adjust to parents' specific needs, gathering information and offering support in ways that will facilitate the family's moving toward positive change.

It is also in the first parent-only session that the assessor typically introduces the idea of parents undergoing some psychological testing as well. This possibility is usually raised seamlessly if the parents have posed an assessment question that addresses their parenting style or how their personality fits with their adolescent. For example, a parent may have asked, "Are there ways that my reactions to Sam's behavior contribute to his withdrawal and secrecy?" or, "My guess is that my personality really clashes with Ellen's sometimes, resulting in a real firestorm between us. How can I get that under control?" If parents have provided such an opening, the assessor offers to do some testing with them with private feedback focused on the interface of their personality and parenting style and how these factors impact their adolescent. This parental

assessment feedback remains within the bounds of the goals established for the assessment. In the TAP project, if parents agree to be tested, we typically use the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) with them, but depending on the parents' questions about themselves, any of a number of tests may be appropriate. Sometimes, adolescents are aware that their parents are engaging in testing of their own, and this can help them feel less scapegoated. Regardless, typically they are not privy to their parents' test results, unless their parents offer this information.

### ***Testing Sessions with the Adolescent***

Typically the standardized testing begins in the third session of a TA with an adolescent. Although the number of testing sessions varies by case, four or five is average. As Finn (2007) has recommended, it is of utmost importance to begin with assessment measures that clearly reflect the clients' central concerns. Commencing with tests that are tied in their face validity to the adolescents' and parents' goals communicates to clients that: (1) they are being taken seriously; (2) their concerns are the first priority; and (3) their questions will be addressed collaboratively from the start. The tests administered vary based on clients' presenting problems and assessment questions. Nonetheless, assessments often consist of: (1) cognitive testing, (2) academic achievement testing, (3) basic neuropsychological measures, (4) socio-emotional testing, which may include behavior rating scales like the Behavior Assessment System for Children, Second Edition (BASC-2), the Child Behavior Checklist (CBCL), (5) a self-report inventory, such as the Minnesota Multiphasic Personality Inventory for Adolescents (MMPI-A), and (6) performance-based personality measures such as the Rorschach, sentence completions, projective drawings, apperception tests. Again, depending on the issues to be explored, there are a number of other psychological assessment tools that may be useful in informing the assessment questions. Beginning with the first assessment measure and continuing for all remaining testing

**Case material.** Lisa needed no time to vent or disclose guilt. Rather, she began by discussing Matt's development chronologically, including willingly disclosing many of the details surrounding her teenage pregnancy. In so doing, Lisa matter-of-factly detailed her remarkable efforts to keep her life on track after finding out about her pregnancy. While continuing to attend high school, she also took night classes in order to complete her graduation requirements prior to giving birth. Lisa then spent the summer at her parents' home. That fall, when Matt was about four months old, Lisa began college, finishing her degree four years later. In discussing Matt's early life, Lisa also talked about the trauma and overwhelming feelings associated with Matt's diabetes diagnosis. It appeared that she had sought out positive ways for Matt to manage his illness. She arranged for him to give presentations to his classmates, involve his peers in his treatment, and attend a summer camp for diabetic children and their siblings annually. Nonetheless, Lisa did report feeling that Matt's diabetes had impacted him emotionally. Lisa also described Matt's relationship with his biological father as being characterized by unmet promises and infrequent contact, and highlighted how hurt and disappointed Matt continued to be by his father's failure to maintain a relationship with him. She also relayed how painful and angering this was for her. In spite of his father's absence, Lisa noted that Matt had positive relationships with her many close male friends, and that Matt also was extremely connected to her longtime boyfriend, who had been actively engaged in Matt's life since he was six.

In discussing developmental history, Lisa stated that Matt had been an easy child, notwithstanding his recent drug use, and that he was respectful and obedient. While Lisa emphasized her closeness with Matt, she also highlighted the importance of acting as a mother and not as a friend with her son when he needed to adhere to structure and limits. She also indicated that, although he had many friends, Matt appeared less confident with his age mates than with adults, and often allowed himself be "taken advantage of" by his peers. She suggested that many of his problem behaviors (like drug use) were due to his succumbing to peer pressure. When asked what she would be most afraid to learn through the assessment, Lisa stated that the worst thing she could find out would be that Matt wanted to commit suicide, and that he could be that depressed without her being aware of it.

Finally, while Lisa was obviously very concerned about Matt's drug use, she also recognized, and was troubled by, a shift in their relationship towards less open communication. Given the systemic nature of her question about whether she was communicating with Matt in the "right way," it seemed very appropriate for the assessors to explore her willingness to engage in testing of her own. Lisa readily agreed, stating that she was willing to do anything necessary to help her son.

activities, the assessor explains to adolescents, in an accessible way, how each test will address their (or their parents') agenda for the assessment. Following standardized administration of each task, the assessor then asks teenagers to expand, reflect upon, and discuss noteworthy responses or experiences as they completed the activity.

This exploration of the testing experience and particular responses may take the form of *extended inquiry* or *testing the limits*. In extended inquiry, the assessor seeks to further engage clients as collaborators by inviting them onto "an observation deck" where they can think about their own test responses more objectively (Finn, 2007; Handler, 2006). From this viewpoint, clients are encouraged to connect their test responses to their lives outside of the assessment room, as well as to access any painful affect that is revealed through the assessment

experience. Through such conjoint observation, clients can begin to collaboratively "weave a new story" about themselves that often relates to their assessment questions.

So, after completing a particular standardized test, the assessor simply inquires about clients experiences of the task ("What was that like for you?" or "What did you think of that?"). The assessor then asks follow-up questions on any observations that clients' have made, and encourages them to make connections to their outside lives, as well as to their assessment questions. After seeking clients' input, the assessor is then free to share relevant observations or thoughts; however, the assessor must do this tentatively, inviting clients' feedback and honoring their reactions to the assessor's suggestions or ideas.

Extended inquiry can take different forms, depending on the assessment tool with which it

is being used, as well as the nature of the parents' or adolescent's questions for the assessment. For example, it may be useful for the assessor to inquire about a client's experience of the performance IQ tasks as compared to the verbal IQ activities, or to ask about their feelings about the timed versus untimed academic tasks. With the MMPI-A, it is often helpful to look at the critical items and follow-up with the adolescent on any items that were endorsed. Typically, there are at least a few surprising responses. It is important to remember that adolescents can have a multitude of reasons for endorsing a particular item, some of which may be more benign than they seem. These endorsements

could be affecting elevations in the profile and it is important to fully understand the reasons underlying such responses. With the Rorschach, it can be useful to pose such queries as: "Does this response remind you of anything we've been talking about?" "Could you tell me a story about ... ?" or "If this monster could talk, what would he say?" (Handler, 2006). The assessor can also ask clients to review their own responses and identify those that have personal significance. When engaging in extended inquiry, it is important for the assessor to assure clients that the only intent is to understand why they endorsed certain items, or gave particular responses.

**Case material.** When taken together, Matt's assessment data suggested that he was quite bright; he performed in the high average range of cognitive functioning, exhibiting a significantly stronger performance in tasks that were verbal as opposed to visual-spatial in nature. In his academic achievement testing, Matt's scores ranged from the low average range to the superior range. While he exhibited some difficulty with academic fluency, spelling, and reading novel words, his profile was not indicative of the presence of a learning disability in any area of academic functioning.

When Matt was completing the Woodcock-Johnson Tests of Cognitive Abilities, after he exhibited substantially more difficulty on the performance IQ tasks as compared to the verbal IQ activities, the assessor asked "Matt, if you had a choice between working on a puzzle or doing something that had to do with language or vocabulary, which would you choose?" Matt, not surprisingly, explained that he would prefer a language-based task. Similarly, when Matt completed the Woodcock-Johnson Tests of Achievement, the assessor inquired about his experience of the timed versus the untimed math tasks, and how these activities might have related to his tendency to "go blank" in algebra class. Matt's social-emotional-personality assessment results indicated that he was experiencing a great deal of negative emotionality, including depression and anxiety. Further, Matt appeared to engage in over-introspection and excessive rumination, and to be vulnerable to chronic feelings of insecurity, inadequacy, and sensitivity to criticism. Socially, Matt exhibited a tendency to withdraw and be passive in relationships, a propensity that led to his needs for interpersonal closeness not being met. Further, he indicated often feeling misunderstood by others, distant, lonely, and plagued with social anxiety.

Related to these feelings, we noted that Matt failed to give any full human responses during the standardized Rorschach administration. The assessor subsequently gained more information about Matt's ability to perceive humans and human connection through testing the limits with Matt in this activity. In so doing, the assessor chose the two Rorschach cards in which the human form is most readily recognizable (III and VII) and said, "A lot of people see humans in this card. Do you see where the people might be?" When Matt immediately said that he recognized the human figures, the assessor had him identify each part of the human form he saw in the inkblot in order to ensure that he was, in fact, seeing the popular response. In the event that Matt had been unable to accurately identify the human figures in these blots, the assessor would have used a scaffolding technique to help him recognize these more common percepts. For example, saying: "Most people see this as a face. Can you show me the different parts of that face?" Matt's success in seeing humans on the extended inquiry suggested that his initial failure to report such percepts was not due to some serious deficit in interpersonal perception. Instead, Matt seemed to "leave out" these percepts to focus on non-human content. To us, this suggested that Matt's feelings of social isolation were very real and may have been triggering a tendency to exercise poor judgement in decision-making; additionally, his risk-taking activities (like drug use) were possibly an attempt to cope with his loneliness.

In garnering more information about clients' assessment data, the assessor can also "test the limits," which is a process that seeks to establish if clients can give a better performance, or more common test response when provided with additional resources (time, encouragement, help, etc.). While widely utilized in traditional assessment, "testing the limits" in TA is practiced with the intent of collaborating with, "scaffolding," or emotionally supporting clients in such a way that they more capably perform the task at hand. So, for example, a client who has significant test anxiety in her math class may, following standardized administration, be given unlimited time on an alternate form of some math subtests to see if that testing context ameliorates her stress response. Such exercises can give the assessor a sense of which contextual variables are related to clients' problematic behaviors, and which variables could be changed to help them improve their performance. It is important to note that the additional information that is gleaned through extended inquiry and testing the limits in no way alters the standardized scoring of the assessment measures; however, this additional data can be used to more comprehensively interpret and derive meaning from the assessment results.

### **Adolescent Intervention Session**

In addition to what the adolescent may learn through the testing and exploration through extended inquiry methods, an important component of TA with adolescents is an individual intervention session that provides an opportunity for the adolescent and assessor to experientially work together to provoke a salient problem and enact a more adaptive solution. This *in vivo* experience can shed light upon the reasons for teenagers' problems in living and provide them with an alternate experience that is, in some way, corrective or healing. Although increases in self-knowledge and understanding are valuable, they are not synonymous with behavior change. Thus, facilitating such experiential learning increases the likelihood that the TA will have an enduring impact on clients' lives. Intervention sessions are highly complex, and, as such, are conducted with an eye to a multitude of smaller goals. The assessor is seeking to engage clients in:

- (1) exploring hypotheses derived from the testing,
- (2) understanding aspects of the assessment findings,
- (3) heightening awareness of findings that would otherwise probably be rejected,
- (4) experiencing a "living example" of an assessment finding,
- (5) independently discovering assessment findings,
- (6) testing out possible interventions for managing clients' problems in living and experiencing more adaptive solutions, and
- (7) preparing for the summary/discussion sessions.

See Finn (2007) for a more complete explanation of the goals and techniques of individual assessment intervention sessions.

Given these ambitious goals, extensive planning is needed. First, the assessor needs a clear understanding of the adolescent's problem behaviors and how he or she names, understands, and experiences them. The assessor must also be capable of aiding clients in drawing connections to experiences outside of the assessment room; that is, conjointly extrapolating how these problematic behaviors present themselves in clients' daily lives. Furthermore, the assessor needs a hypothesis regarding the factors that are necessary and sufficient to produce the problem behaviors, and must be prepared to engage clients in an exploration of the context of their problems in living. Such contextual understanding is imperative to enlisting clients in imagining (and experiencing) solutions to their challenges. The assessor must also have some idea as to how contexts might be altered in order to elicit more adaptive strategies from clients. It is these collaboratively generated possible solutions, then, that are tested *in vivo*. It is the hope that as this exploration unfolds, the client will have a more positive experience and will exhibit more adaptive behavior. If not, the assessor must continually revise the possible solutions until clients experience some success. Thus, adolescent intervention sessions can take a wide variety of forms, and are an opportunity for the assessor to be creative.

Once the adolescent has a new or more successful experience in the intervention session, the assessor then engages him or her in a discussion about how to implement and generalize the experienced solutions to life outside of the assessment room. In these discussions, it is also important for the assessor to consider and address the challenges that may be faced as adolescents attempt to broadly implement these new behaviors in their lives, as well as how these difficulties might be managed. The assessor then asks clients to report back at the following assessment session after they have reflected on the intervention experience, and have had the opportunity to try to apply it to contexts outside of the assessment.

**Case material.** The intervention session was introduced to Matt as an “experiment” during which he and the assessor would try to address some of his assessment questions in a more experiential way. As usual, the assessor assured Matt that his experience of the session would be discussed at the end, including how well the “experiment” had worked for him. As reviewed above, Matt had reported a tendency for his mind to “go blank” in various situations. Although this tendency may have been exacerbated in part by his diabetes, it was hypothesized on the basis of the standardized test findings that his “bottled up” emotions were “leaking out” at times, overwhelming his capacity to cope, and also contributing to this “blankness.”

Thus, Matt’s intervention session was planned as follows: he would begin the session by rating his “blankness” on a scale of 0 to 10, (with 0 being “totally blank/unable to express himself” and 10 being “completely clear/able to express himself perfectly”). Matt would then complete a memory-for-words task, followed by telling stories drawn from two to four thematic apperception test (TAT) cards. The first card was to be relatively benign in order to introduce him to the task, followed by progressively more emotionally evocative cards, with the intention of getting him emotionally aroused or “stirred up.” In the event that his stories failed to be emotionally evocative, the assessor was going to prompt him to: “... tell a story that is emotional, sad, or worrisome in some way....” Following this exercise, Matt would again be asked to rate his “blankness” and would then be administered an alternate memory-for-words list. It was hypothesized that his performance would worsen (due to his emotional arousal), at which point the assessor would provide him with various emotional regulation strategies, such as mindfulness techniques and/or muscle tensing and relaxing exercises in order to ameliorate his “blankness.” After working through these coping strategies, Matt would then be given a third form of memory-for-words, at which point, it was hoped, his performance would improve. Lastly, he would be asked one final time for a rating of his “blankness,” after which he and the assessor would discuss the experience.

In spite of the careful attention that went into the design of this session, as sometimes happens with assessment interventions, it did not unfold as planned. In fact, Matt did only negligibly worse on the second administration of the memory-for-words list, indicating that either: (1) the TAT stories did not sufficiently emotionally arouse him, or (2) it was not his emotional arousal that was precipitating his “blankness.” So, after some impromptu consultation with the other assessor and a supervisor, the primary assessor abandoned the plan for the session and instead transparently talked with Matt about what the hypothesis had been for the session, what his thoughts were about that hypothesis, and about his general experience of the session. The assessor also began to “trickle in” some feedback from the assessment data to see how accepting Matt would be of it.

Although Matt had previously informed the assessor that he tended to “bottle up” his negative emotions for fear that they would threaten his interpersonal relationships, he had a very strong reaction to the assessor’s suggestion that he was experiencing any negative affect at all. This fit with Lisa’s presentation, for whom, the assessment team slowly learned, it was important to tirelessly present herself as a positive and strong person. Matt similarly insisted that he was “basically a happy person” and worked very hard to keep his negative feelings to himself. The assessor validated Matt’s “content” self-presentation, and recognized his work to keep his negative emotions “in check.” However, the assessor also sought to normalize, accept, and help Matt acknowledge and “sit with” his painful affect. Subsequently, Matt relayed that he had just told his mother during the past week that he tended to not express any of his negative feelings, but, instead, bottled them up and held them inside. The assessor was then able to tie this disclosure back to what Matt had said in his first session about being able to “let go” when he smoked marijuana. He acknowledged that smoking “weed” was the only time his bottled-up feelings went away. By the end of the intervention session, Matt was able to “name” his negative feelings as “sadness, anger, and frustration.” The assessor was then able to validate Matt’s feelings and compliment him on his insightfulness, given that much of the assessment data indicated that he was experiencing just those kinds of feelings. Thus, this case illustrates that, even when adolescent intervention sessions do not go as planned, they may still serve to offer clients a corrective emotional experience and a more integrated view of themselves.

In Matt's next meeting with the assessor, before the start of the family intervention session, he shared that he was still struggling with some of the assessment findings that had been discussed the week before. He said that he had thought a great deal about it, and he continued to believe that he did not exhibit any negative emotionality. In fact, he had talked with some friends about whether or not he came across as sad or angry, and they had confirmed that he did not. In response, the assessor validated that, in casual interaction, Matt did not come across as sad or angry. In that moment, Matt shared a realization that the activities he had completed throughout the assessment were not intended to get at the image he wanted to project, but at how he was really feeling. Compellingly, Matt was then able to recognize that he had "let out a little bit" of how he was really feeling in these activities. The assessor emphasized how much she appreciated and valued Matt's having shared himself with her. Matt was then able to disclose that he had told some of his friends about his negative emotions. The assessor then asked Matt if he had been satisfied with how his friends had responded to his inquiry about if he came across as sad or angry. He said that, while it felt good to be reassured that he did not come across as feeling mad or depressed, he had also wanted some of his friends to recognize his negative emotions, and was disappointed when they failed to do so. The assessor then talked with Matt about what it would be like for him to tell his friends that he sometimes wanted them to recognize and talk with him about his negative feelings. Matt seemed curious and open to undertaking this next step with his friends.

### ***Mid to Late Parent-Only Session***

Following the completion of the adolescent testing and intervention sessions, another parent-only meeting typically is scheduled. The goals of this session are as follows:

- (1) Continuing to build and develop the relationship with the parents,
- (2) Collecting additional background information that may shed light on some of what is being gleaned from the adolescent,
- (3) Assessing how the parents and family have been functioning since the start of the assessment, and
- (4) Beginning to tentatively provide and discuss some of the initial assessment findings, including feedback from the parents' own assessment (e.g., the MMPI-2).

In preparing for this session, several considerations are useful in guiding decision making. First, the assessor needs to evaluate whether the adolescent can tolerate the assessor meeting individually with his or her parents at this late point in the assessment. As the adolescent and assessor have met privately for the past many sessions, it is understandable that he or she could have concerns about what might be shared with the parents at this point, as well as how the parents may respond to any information that is divulged. It is important to let the adolescent know the plan and goals for the parent meeting, as well as to review and discuss any concerns the

adolescent may have. It is likely that the strong alliance and collaborative relationship that the assessor has developed with the adolescent, wherein respect for the teen's autonomy has been repeatedly demonstrated, will serve to allay any apprehension. If not, persistent concerns may be very useful in informing the remainder of the assessment.

Another question that is important to consider is, "Can the parents contain information without 'spilling it' to the adolescent?" This session usually involves "sprinkling in" some of the findings and assessing the parents' reactions in an effort to begin preparing them for the summary/discussion session. Therefore, if the assessor's experiences with the parents to date suggest that the parents would be highly reactive to a particular assessment finding, and would subsequently rush home and interrogate their child about his or her experience of this finding, the assessor would probably want to broach the topic conservatively at first. For example, the assessor might say: "I'm still bringing together and making meaning out of all of the assessment information, but one thing I wanted to do today is just get a little bit more information from you about the way you see John at home. Does it ever seem to you that he might feel a little sad or worried?" as opposed to, "The assessment information is indicating that John is severely depressed and anxious." If, however, the assessor judges that there are clear parental boundaries, and that the parents are more prepared for a given assessment finding, the assessor may feel safe being

less tentative. For example, the assessor may say: “Many of the assessment results suggest that John is struggling with some pretty significant feelings of sadness and worry right now. Does this fit for you? How have you seen this come across at home?”

Similarly, it is useful to explicitly consider the question, “What findings might be most difficult for the parents to accept?” As reviewed previously, such information can be conceptualized as “Level 3 feedback”—assessment findings that are highly incongruent with how parents see themselves, their family, or their adolescent. Often, parents are unwilling or unable to readily accept such information, due to fear, shame, or a conflicting worldview. It may be the case that testing supports parents’ worst fears about their child or their family. Often, parents may recognize on some level that their worst fears are well within the realm of possibility. As such, they actually may be more ready to accept the information than the parents who do not articulate such a possibility. Regardless, considering this question allows the assessor to “test the waters” by beginning to share pieces of findings that are expected to be difficult for parents to integrate, in order to see how they are received.

Giving parents feedback at this time allows the assessor to see how readily the parents can absorb personal feedback, as well as if they express curiosity about how their personalities and parenting

styles are affecting their adolescent. Again, parents’ openness is likely to be an accurate gauge of how they will approach final feedback, and is indicative of their openness to recommendations that may be more systemic in nature (e.g., a referral for family therapy). The assessor should be alert to the possibility of resistance or negativity, as some parents may be recognizing the complementarity that exists between their parenting style and their adolescent’s challenges for the first time. Some parents may be relieved to have this insight, while others may be overwhelmed, initially dismissing the information, or responding with feelings of guilt and shame. In our experience, within the context of a strong collaborative relationship, the assessor can accept the parent’s reaction and work with it in ways that offer potential for change.

Lastly, it is important for the assessor to be thinking about what can be learned in this session that would help in planning the family intervention session, which is coming up next. For example, if it is expected that parents are going to be highly resistant to a major finding of the assessment, it may be extremely useful to design the upcoming family intervention session around that finding (and the related assessment question), given that parents are likely to be more open to receiving unsettling feedback if they have recently experienced it *in vivo* with the emotional support of the assessor.

**Case material.** The assessment team began the session by checking in with Lisa about her week and asking if she had noticed any changes in Matt since the beginning of the assessment. She said that he had been more motivated to complete his schoolwork and had not, to her knowledge, used any illegal substances. She also reported a recent fight that she had had with her son wherein Matt had yelled at her, which he had never done before. Interestingly, Matt had just shared with the assessor that he was fearful of exhibiting any negative affect due to his belief that such expression would estrange his friends and family. The assessment team then inquired about how much Matt had shared with Lisa so far about his testing experiences. She said that typically they discussed the assessment only minimally, but that, in the last week, he had brought up his intervention session twice. As he did with some friends, Matt also told Lisa that he had been surprised to hear that the testing indicated that he was experiencing some sadness and worry. Lisa reported that she, similarly to Matt’s friends, had assured Matt that she did not view him as being sad or worried. As Lisa relayed this story, it did not seem that she had entertained the possibility that Matt might have been checking in with her about this emotionally laden feedback to see if she could “handle” his being depressed or anxious. If only subtly, it appeared that Lisa had communicated that, in fact, she could not accept it.

The assessment team then reviewed Lisa’s MMPI-2 feedback with her, sharing that her profile suggested that she was resilient, strong, optimistic, and a “superwoman.” Lisa readily agreed with this feedback and related it to her life experiences. She said that, rather than viewing the trials and tribulations of life as hard, they were “just what life gave her.” She further said that she has no need to “wallow”; problems just need to be fixed. She frequently referred to the metaphor that “sometimes you bite

off more than you can chew, but you just have to chew faster." While she ultimately acknowledged that "everybody crawls into bed and cries for a half hour sometimes," she said that Peter, her long-term boyfriend, was the only person in her life who had seen her "break down." Lisa then said that, when she is upset, the best way for her to feel better was to help others, and that, in facing obstacles, thought and action are better than emotion. Lisa was able to discuss some of the negative aspects of her personality style as well. She acknowledged that she tried to avoid confrontation "at all costs." Similarly to Matt, Lisa said that she feared that, if she confronted others, they would get angry and leave her.

When the assessment team asked Lisa if she viewed Matt as having this same coping style, she readily recognized that he did not, at which point the assessment team validated this, but also emphasized that it often seemed that Matt tried to be this way. Lisa was then able to acknowledge that he may have learned this coping style from her. At this point, the assessment team began to "trickle in" the sadness and worry evidenced in Matt's testing responses. Lisa was able to appreciate that Matt's outside presentation might be different from his internal experiences. The assessment team then addressed Lisa's worst fear, assuring her that nowhere in Matt's testing was there any indication of suicidal ideation. Upon hearing this, Lisa was visibly relieved and said, "If he's sad, we can fix it." She then wanted to know what, specifically, was triggering Matt's negative emotional experiences. While the assessment team acknowledged that there was no way of knowing definitively, these feelings appeared to be long-standing and may have been related to issues like Matt's feelings of loss related to his relationship with his biological father, as well as to his chronic struggle with diabetes.

Lisa then began to talk about how Matt often said that he did not have friends, or had a hard time making friends. In response, Lisa reported that she told him that he did have friends and that he did make friends well. Similarly, Lisa brought up how Matt had only recently shared with her that he had been struggling with some long-standing sleep disturbance. In response, Lisa relayed that she promptly tried to "fix it" by bringing several sleep CDs home the following day. When the assessment team inquired about Matt's response to Lisa's problem-solving and "wondered aloud" if this was always what he needed, Lisa was able to recognize that Matt might not always want her to immediately try to fix things, but may just want her to empathize or to try to understand how he is feeling. The assessment team ended on a positive note, praising Lisa for her insights and telling her of Matt's many strengths, as well as what a pleasure it had been to work with him. Nonetheless, it became clear in this session that it would be important to integrate Lisa's tendency to gloss over Matt's emotionality by entering "problem-solving mode" into the family intervention session: Matt needed to have the corrective emotional experience of having his mother "sitting with him" in his sad and worried feelings in order to learn that such emotionality was acceptable and not shameful. Also, unless he could get this kind of support from his mother and others, he was destined to find other ways (e.g., drugs) to manage his negative emotions.

### ***Family Intervention Session***

Just as is the case in adolescent intervention sessions, the overarching goal of family intervention sessions is for the assessor to create an *in vivo* experience that allows the clients to grasp a systemic formulation of the youth's presenting problems (Tharinger et al., 2008). In family intervention sessions, the assessor has the opportunity to meet with the adolescent and family together, and, in so doing, can gain rich information about these interpersonal relationships. The family context is vastly influential to teenagers' development; as such, the assessor may gain some insight into the ways in which family dynamics contribute to

adolescents' struggles, as well as any distortions adolescent clients may have about other family members. Working within the family context, the assessor is able to form and test systemic hypotheses. Simultaneously, the assessor encourages parents to develop more systemic views of their child's challenges, and experiment with potential solutions. Just as in adolescent intervention sessions, in family intervention sessions, the assessor seeks to give the family a positive, healing, and successful experience of managing family challenges. The development of a systemic perspective on adolescents' problems helps both teenagers and parents feel less blamed and more hopeful about managing

problems conjointly, thus fostering more positive family relationships.

### COMMON TECHNIQUES USED IN FAMILY INTERVENTION SESSIONS

There is a wide array of possible activities to consider when designing family intervention sessions (see Tharinger et al., 2008). We have found the Consensus TAT or the Consensus Rorschach to be especially useful in family sessions with adolescents. Family members are asked to work together to develop a story or a response to each stimulus card about which they all agree. They are to talk through the development of these responses aloud. These techniques, then, involve using projective assessment materials in a non-standardized way to help the family observe their own processes and interactions when completing a novel task (rather than obtaining responses that can be scored).

### QUESTIONS TO CONSIDER IN PLANNING THE FAMILY INTERVENTION SESSION

Planning family intervention sessions can be quite complex. We have developed questions that are useful in the planning process. First, *Whom should I invite to attend?* Generally, it is desirable for all family members who reside in the adolescents' household to participate in this session. It may also be useful for family members who play a significant role in adolescents' lives, but do not live with the teenager, to participate as well. Sometimes, when parents are separated or divorced, it is necessary to have separate intervention sessions for each parent, including the adolescent in each. Also, if one wishes to target particular aspects of the family's functioning, one may restrict the session to only certain family members. Second, *What do I most want the parents to learn?* Ideally, in family intervention sessions, parents become aware of how they contribute to their child's problems through experiencing the way in which *their own behavior change* (in the area that is problematic for the teenager) ameliorates their child's challenges. Third, *What do I most want the adolescent to learn?* It is hoped that through participating in the family intervention session, teenagers will come to recognize that their parents are willing and able to help them with their difficulties, and that they do not have to "go it alone" in managing their problems in living. Also, teenagers may come to see how their own behavior elicits certain responses in their parents, and consider the possibility of acting differently. Fourth,

*What are the most important assessment questions?* Often the answer to this question readily comes to light throughout the course of the assessment. It may be that the most central assessment questions are those related to the issues that are creating the most distress in the adolescents' lives, those that are most systemically rooted, or those that are most amenable to change.

Another important question is, *How does the system work to create and maintain the adolescent/family problems?* Again, the answer to this question may become clear during the course of the assessment. If not, it is likely to become apparent as the family intervention session unfolds. It is often the case that a youth's problem behavior is symptomatic of a larger, systemic issue. For example, the adolescent's difficulties may be masking marital conflict, or the adolescent's depression might be distracting from a parent's own mental health challenges. Therefore, the moment the parents begin to fight, or a father's depressive symptoms begin to be unearthed, the adolescent's motivation to maintain his or her problematic behavior is powerfully renewed. The assessor must be very sensitive to these possibilities throughout the course of the assessment, as well as in planning for, and facilitating, the family intervention session. Another important question is, *What are more adaptive solutions?* It is hoped that through participating in the assessment and experiencing the family intervention session, adolescents learn that they are not responsible for shielding their parents from their own, "adult" problems in living; that, in fact, parents are capable of managing their own challenges and helping their children with theirs. Assessors further seek to ensure that families have a different, and more positive, experience in the family intervention session than they typically enact at home, allowing them to recognize that they can create this more adaptive solution conjointly.

It is also important to consider, *How much intensity can the family handle?* Family intervention sessions can be very intense (see Tharinger et al., 2008). Family patterns are often quite resistant to change; therefore, the experience of altering ingrained systemic patterns can be quite powerful. When adolescents' challenges are symptomatic of a larger, systemic issue, illuminating the "real" problem (such as the parents' marital conflict or a father's depression) can be highly threatening because the family is being stripped of the coping mechanism they were using to manage those difficulties, which are now exposed and vulnerable.

As such, assessors must carefully monitor the way family intervention sessions unfold, assessing each family member's response to it and tolerance for the experience. In the event that one or more family member appears "flooded," the assessor may pull back from the plan for the session and/or enlist an appropriate family member to support the distressed loved one. Seeing this interaction, then, can provide the assessor, and the family, with additional information from which to derive understanding and meaning. Most importantly, the assessor must provide the family with an alternate and more adaptive way in which to manage their problems.

It is always a good idea when planning this session to ask, *What could go wrong?* Just as in adolescent intervention sessions, family intervention sessions sometimes do not go as planned. For example, one or more family members may become overwhelmed; parents may demonstrate an unwillingness to alter their behavior in any way in

order to better support their child; and the adolescent could be resistant to accepting a parent's new behavior, thus discouraging the parent from pursuing the more adaptive solution. Alternatively, family members may create an experience that is different from the one the assessor was planning, but one that is beneficial nonetheless. Such challenges and detours often cannot be anticipated fully. So the assessor must be adaptable, spontaneous, creative, and attuned to the family's experience and needs as the session unfolds.

### **Summary/Discussion Session with Adolescent**

TAs with adolescents culminate in summary/discussion sessions; the assessor first has a session with the adolescent alone, and subsequently a session with the adolescent's parents, preferably that same day or a day or two after. Sometimes adolescents are invited to this latter meeting, and sometimes, even if invited, the adolescent declines to

**Case material.** In the family intervention session with Matt and Lisa, the assessment team presented this mother and son with two thematic apperception test cards and one adolescent apperception test card, in turn. The pair was instructed to conjointly develop a story to each card, which they subsequently shared with the assessors. The assessment team introduced this consensus story telling task as being directly related to Lisa's assessment question concerning whether or not she was communicating with her son in the "right way." In planning for the session, it was hypothesized that Matt would contribute sad content to the stories, and that Lisa would cheerily transform these themes into happy endings.

Prior to the start of the session, while checking in one-on-one with the parent assessment team member, Lisa indicated that she had thought a great deal about the feedback provided to her in the previous sessions, and shared her fear that her positive, optimistic coping style was making it difficult for her son to share any sad feelings he was experiencing with her. She relayed that, because Matt continually saw her engaging in active and positively framed problem solving, he might feel that he, too, had to be this way. She wondered if this personality difference was precipitating some of their communication problems. Matt similarly shared with the adolescent assessment team member while meeting one-on-one that, when he was feeling down, another's extreme happiness and positivity made him feel not understood, and ultimately worse, while having someone "sit with him" in his negative emotion led to his feeling more understood and, ultimately, better.

While executing the intervention task, Matt and his mother generally worked well together; they were receptive to one another's ideas, and Lisa asked for Matt's opinion frequently as they developed their conjoint stories. As was anticipated, however, Lisa did attempt to positively reframe any negativity Matt brought into their stories. When she was able to preserve themes of negative emotionality, she consistently attributed these bad feelings to a neutral source ("They're just mad because it's raining"), or gave the option of a neutral feeling rather than a negative emotion ("Do you think he's lonely, or just hungry?"). In response to the most emotionally evocative card in the intervention activity (which came third), Lisa took the lead in telling a very humorous story that kept her and Matt laughing. Interestingly, Lisa was aware of the fact that Matt had created a very sad story in response to this same card in his individual intervention session. Both she and Matt commented on the fact that her story

was much less emotional than his had been. The assessment team then asked what kind of story Matt and Lisa thought most people told in response to this particular card. Matt acknowledged that most people probably told a sad story. The assessment team then asked Matt and Lisa to tell a story that was more similar to what they thought most people would tell. Again, Lisa appeared to shy away from negative emotionality through making jokes or attributing any negativity to neutral sources like having to “work in the fields.” The assessment team then made the observation that it seemed much easier for Matt and Lisa to talk about the details of chores, for example, than a story character’s feelings of loneliness. The assessment team went on to ask Matt and Lisa if the dynamics of this interaction related to their lives at all (with respect to it being more difficult for them to discuss negative emotions).

Ultimately, Matt was able to state that he thought “normal” people are supposed to be happy all the time, and that this was the way his mom acted. In response, the assessment team validated that Matt felt like an outsider when he had feelings that were not happy, and that it was really hard work for him to keep all of his negative emotions “bottled up.” Lisa was then able to share with Matt that she did, in fact, get sad. She powerfully stated that, often, when she took a bubble bath in the evenings, it was because she had had a difficult day and she needed to cry. Matt said that he was surprised to hear this, but promptly shared with his mom that his equivalent is going to his room, turning off the lights, and listening to music. Lisa then explained that, while she wanted to protect Matt from her negative emotional experiences, she wanted him to feel free to share any negative feelings he had with her.

However, even after these powerful exchanges, there continued to be occasions throughout the remainder of the session wherein Lisa would try to put a positive spin on Matt’s emotions and/or where she would enter “problem-solving mode,” glossing over Matt’s negative feelings. These occasions presented opportunities for the assessment team to model acknowledging and validating Matt’s feelings, and to explain to Lisa that, while her inclination to comfort or problem solve for her son was very natural, it was not what he needed in order to feel heard and understood. In an effort to emphasize this point, the assessment team then asked Matt if he preferred it when his mom entered “problem-solving mode,” or when she just listened and tried to understand his feelings. He said that, while it was “okay” when his mom tried to help him solve his problems, it felt better when she just listened and tried to understand how he was feeling. The resolution of the session was for Matt and Lisa to work together to “catch” Lisa when she entered problem-solving mode, and for Matt to tell her when he just needed her to listen. This family intervention session was central to creating a breakthrough experience for this mother and son. While they were both beginning to recognize their personality differences and how these dissimilarities affected their relationship, openly discussing and experiencing these differences in a concrete way opened the door to positive change for this family system.

participate. It usually is fairly clear from the topics to be discussed with the parents whether it is appropriate for the adolescent to attend the parental feedback. The goals of the adolescent summary/discussion session are:

- (1) to answer adolescents’ assessment questions and increase their self-knowledge;
- (2) to present a more accurate/compassionate story through which to understand the adolescents’ problems in living—for example, that they are depressed rather than being “lazy and unmotivated”;
- (3) to provide adolescents with the experience of being understood in an emotionally supportive environment;

(4) to promote systemic and contextual thinking rather than focusing on the adolescents in isolation; and

(5) to promote abstract thinking, which is developmentally appropriate, given adolescents’ burgeoning cognitive capacities.

Lastly, it is important to note that adolescents are typically given individual feedback prior to their parents in an effort to promote individuation, which is also developmentally appropriate.

Ideally, by the time the assessor reaches this stage of a TA, all of the most poignant assessment findings have already been discussed with, or experienced by, the client. Nonetheless, this may not always be the case; it is also quite possible that even when

the assessor has “trickled” certain findings into clients’ sessions, they have been resisted in some way. Finally, even when each finding has been discussed in isolation, it is often a different experience for the client when the assessor “puts the pieces together” to form a whole picture, so summary/discussion sessions must be carefully planned.

First, the adolescent’s questions must be considered. Reviewing teenagers’ assessment questions often sheds light on what they are ready to hear. However, this consideration must also be attended to with all of the major assessment findings. Furthermore, it is important to note that what adolescents are open to hearing does not always map onto what their parents are prepared to hear. Therefore, the information that is shared with teenagers must, at times, be tailored according to what their parents are judged to be capable of taking in. In considering this, it is helpful to bear in mind how differentiated the adolescent seems to be from his or her parents. Regardless, it is important that assessors not put adolescents in the position of harboring “secret information” from their parents.

Similarly, the assessor must carefully consider what the adolescent’s worst fears are and how much information the teenager can handle without becoming overwhelmed, as well as how the adolescent tends to behave when he or she is overwhelmed. In preparing for this session, the assessor also needs to carefully consider what language is accessible to the adolescent and how the various assessment findings can be presented in a way that is meaningful for the teenager. Finally, it is imperative that the assessor be mindful of incorporating knowledge of the adolescent’s strengths into the feedback in addition to data related to their areas of difficulty. In so doing, however, the assessor must prepare for the fact that such strengths-based information must be

sensitively delivered if it conflicts with the teenager’s self-perception. For example, an adolescent who views herself as being “stupid” may be rejecting of feedback from the assessor that her cognitive abilities are higher than those of 87 percent of her peers; such information is likely to be Level 3 information and must be prepared accordingly.

### **CONDUCTING THE SUMMARY/DISCUSSION SESSION WITH THE ADOLESCENT**

In beginning summary/discussion sessions with adolescents, it is often useful to review the purpose of the session. The assessor may then want to check in with teenagers about anything they feel anxious or worried about in beginning the session, or if there is any particular information they would prefer to review first. The assessor can then choose to begin with a discussion of assessment results as they relate to teenagers’ assessment questions, or to summarize the assessment information first, followed by a review of “answers” to adolescents’ assessment questions. The former format is typically preferable when the assessment information maps well onto the assessment questions; the latter approach may be better when the teenagers’ questions differ significantly from the findings of the assessment. Regardless of the order in which the assessor presents the assessment results, it is crucial that teenagers’ are continually asked for confirmation, examples, and any disagreements they have as findings are reviewed. Additionally, throughout the session, the assessor needs to stay carefully attuned to the teen’s reactions to the assessment information. If the adolescent appears overwhelmed at any time, the assessor needs to “back off” and provide emotional support. Once all of the feedback is reviewed, it is nice for the assessor to end with something he or she appreciates about, or has learned from the adolescent.

**Case material.** Matt was highly receptive to all of the assessment information. Following his experience in his individual intervention session, as well as in the family intervention session with his mother, all of the assessment findings going into the summary/discussion session were conceptualized as being Level 1 or Level 2 information. Given that his questions were congruent with the assessment results in many ways, the assessor began Matt’s feedback session with a discussion of his assessment questions. In fact, while reviewing Matt’s assessment questions, the assessor was able to cover nearly all of the assessment findings, and was also able to integrate a discussion of what would be shared with Lisa given her assessment questions (which also fit very well with the findings and with Matt’s questions for the assessment). Matt was consistently able to expand on the assessor’s presentation of the assessment results by discussing how they related to his experience in the assessment, as well as to his broader life experiences.

Prior to ending the session, it is also quite useful to review with teenagers what will be said to their parents at their upcoming summary/discussion session, and address if the adolescent will be invited to attend. Once this has been decided, the assessor should specify if there will be future contacts, such as a follow-up session in several months.

### ***Summary/Discussion Session with Parents***

This is the final session of the TA process, with the exception of a follow-up that may be scheduled several months later. This meeting follows shortly after the summary/discussion session with the adolescent only. As mentioned earlier, often parents attend without the adolescent, but in some cases the decision is made to include the teenager. Although this is the culminating session of the TA (and in traditional assessment would be where parents are first informed about the findings), paradoxically, if all has gone well in earlier sessions, much of the information in the parents' summary/discussion sessions has already been shared. This meeting, then, can be viewed as "icing on the cake," tying together all of the pieces of the assessment experience, and looking forward to next steps. This is not to underestimate the potential impact of these sessions, however. For, even if all the pieces have been shared previously, it often is very powerful for parents to hear them put together into a coherent story.

The major goal of this session is to answer the questions the parents have posed for the assessment. Adhering to the collaborative underpinnings of the TA method, the assessor seeks parents' continued input throughout the session and strives to provide them with continued emotional support and an experience of being understood. This alliance, which has been developed throughout the course of the assessment, provides the framework that allows parents to continue to absorb the findings from the assessment, and to consider their role in resolving their adolescent's challenges. Just as is the case with adolescents, it is imperative that the assessor conceptualize and organize feedback to the parents according to the "Level" system described previously.

As the assessor addresses the parents' questions in this thoughtful manner, he or she is offering a more accurate and compassionate story about the teen that serves to reframe the parents' thinking and adjust their earlier misunderstandings or distortions without overwhelming or "flooding" them. In most cases, the new story is systemically framed, serving to help the parents view their adolescent within the context of the family, its history, and how that has

impacted their son's or daughter's development. An implicit aim is to encourage systemic rather than individual change (i.e., it is the family's obligation to work together to develop and enact solutions rather than it being the adolescent's job to change in isolation). Lastly, this session is geared towards promoting differentiation within the family, supporting the growing autonomy of the adolescent, and empowering him or her within the connectivity of the family unit; this is, in many ways, the heart of the adolescent TA model.

We have found that in-depth planning is essential for an effective summary/discussion session with parents. While reviewing the parents' questions in light of the assessment findings, the assessor is well served by considering what the parents seem ready to hear, what their worst fears are, and how much information they can handle at this time. These considerations about parents' readiness for various findings very much shape the plan for this session. The success of the mid to late parent-only session, where initial, tentative feedback was provided (in some cases from both from the adolescent's and the parents' test findings) is probably a useful gauge in anticipating the pace and depth of the summary/discussion session. It is also useful to review how the parents have responded in the past when they become psychologically overwhelmed, and to build this knowledge into planning for this session. Assessors also need to review what was told to the adolescent in his or her feedback session, how enmeshed or triangulated the parents are with their child, and whether it would be beneficial for the teenager to attend this session. As discussed below, adjustments are made to the session if the adolescent participates.

### ***CONDUCTING THE SUMMARY/DISCUSSION SESSION WITH THE PARENTS***

We recommend that the assessor begin the session by acknowledging that feedback meetings can be anxiety-producing, and checking in with the parents about their emotional state prior to starting the session. It is then a good idea to review the plan for the session, including explaining what will happen, and encouraging questions and collaboration. Before beginning the discussion of findings, we suggest that the assessor thank the parents for participating in the assessment, and in particular acknowledge any factors that may have been especially difficult for the parents. It can be very helpful at this point to show some empathy for the parents' struggles with or confusion

about their child, perhaps by acknowledging that the assessor also struggled in putting all the pieces together, as their child is complex, and a thorough assessment was needed for understanding to be reached. The assessor then moves into answering the parents' assessment questions. In some cases (as is the case with giving adolescents feedback), it may be useful to provide an overview of the findings before moving into addressing the parents' questions. Regardless, because the assessor cannot accurately predict all of the parents' reactions to the feedback, parents' responses must be carefully monitored as the session unfolds. If parents appear to be experiencing overwhelming emotions, the assessor must modify the plan for the session and stop to provide emotional support whenever necessary.

In the event that parents disagree with the assessor about any assessment findings, it is imperative that the he or she avoid arguing with parents, and instead encourage them to share their own perspective. If necessary, the assessor can "agree to disagree" with the parents. Although recommendations may have been offered throughout the session, all recommendations are summarized at the end of the session. The parents are encouraged to discuss how feasible the recommendations may be, and whether they have any questions or concerns about how to implement them. The assessor then thanks the parents again, and shares genuine sentiments about what he or she appreciated about being involved with the family. Finally, just as was done with the adolescent, the assessor clarifies if there will be future contacts, such as a follow-up session within a few months.

There are some variations to this summary/discussion session if the adolescent does or does not attend, and advantages to each. If the adolescent does *not* attend, one additional step early in the session is to summarize the feedback session with

the adolescent, being careful to respect the confidentiality afforded the adolescent. The assessor may ask the parents if their child shared anything with them from the earlier summary/discussion session, and what they took away from that discussion. In addition, if the adolescent does not attend, it is important that the assessor discuss with the parents what to say to their adolescent after their summary/discussion session. It is often beneficial for the parents to talk more fully and openly with their child about integrating and making meaning out of the assessment findings; if this is the case, the assessor should encourage and scaffold such a discussion. If it appears that the parents are uncomfortable with the idea of independently broaching this topic, the assessor can offer a family session to help with the integration of the assessment findings and recommendations.

If the adolescent *does* attend the session, it is often useful to empower the teenager to summarize his or her understanding of the test findings; if they so choose, they may also share information that relates to their private assessment questions at this time. Subsequently, as the assessor reviews the findings in relation to the parents' questions, probably in more depth, everyone in attendance has the opportunity to work collaboratively with their own understandings of the assessment findings, and to express their respective views of how to proceed. Thus, when the adolescent is in attendance at this final session, it becomes an amalgamation of feedback and family therapy, wherein healthy family interactions are facilitated. With some families, this model will prove to be very effective; in others, it is overly ambitious, asking the family to take too many steps at once. Thus it is important to carefully weigh the potential costs and benefits of including the adolescent. It is also useful to note that the adolescent himself or herself may have insight into

**Case material.** Matt was invited to, and did attend, Lisa's summary/discussion session. This decision seemed appropriate, given that much of Lisa's feedback overlapped significantly with Matt's, and that a goal was to enhance their communication with each other. We noted that Matt seemed quieter and less active in this session than he had been in his individual session. Lisa seemed very well prepared to hear and take in all of the findings, as they had been shared with her in her second parent-only session and reviewed both verbally and experientially in the family intervention session. Thus, the session went very smoothly. Lisa readily related the assessment findings to their lives, and demonstrated great openness to reflecting on how her personality and coping style had contributed to Matt's challenges; she exhibited notable readiness for change.

the appropriateness of attending (the teen may adamantly refuse to join the session, or, alternatively, may push to be present); the adolescent's wishes should carefully be considered.

### ***Written Feedback for Adolescents and Parents***

It is customary in TA with adolescents to compose a letter for the teenager that closely follows the presentation of their summary/discussion session, usually organized around his or her assessment questions. The letter is written in the first person with colloquial language and active voice, and incorporates comments, examples, or even disagreements that the adolescent offered during the summary/discussion session. The written feedback to

parents typically follows a similar framework; that is, a letter is written rather than a traditionally organized psychological report (Finn, 2007). However, a formal report may also be provided if it is needed for other purposes, such as documenting a diagnosis or a disability for school accommodations. As the format of the letters is typically very similar to the organization of oral feedback, the preparation time put into the oral feedback pays off greatly when it comes to producing the letter. The letters are typically mailed, and the adolescent receives a copy of both his or her letter and the parent letter, while the parents receive only their letter. As is often the case with teenagers' private feedback, in our experience, many adolescents also end up sharing their letter with their parents.

#### **Case material.** Here is an excerpt from our letter to Matt:

“Why did I take Adderall the second time without weighing the pros and the cons?” First of all, it’s normal in adolescence to experiment with lots of different kinds of new things, and sometimes drugs are a part of that experimentation. But, with you, it seems like the way you have used drugs has been a little bit different—the testing we did together showed that you’re feeling quite a bit of stress right now that’s overwhelming your coping resources (this makes a lot of sense given everything you’re dealing with—school feels harder this year, your diabetes, your dad, not being at the same school as your closest friends … each one of those things is a lot, Matt—let alone all of them together).

“I know we talked a lot about how your mind goes blank sometimes—this ‘blankness’ is sometimes called ‘dissociation’ and may be related to being overwhelmed by feelings. This seems to happen to you more than it does to other people your age. When people feel overwhelmed like this, they sometimes don’t have as much self-control, or are more impulsive in their decisions and behaviors (they don’t carefully weigh pros and cons). It seems like trying different kinds of drugs is kind of an escape for you—it’s a way to let go of all of the hard feelings you’re trying to keep bottled-up inside. This fits with an item you marked on [the MMPI-A] when you responded ‘false’ to ‘talking over problems and worries with someone is often more helpful than taking drugs or medicines.’ It seems like escaping your bad feelings might be more important than facing the consequences for experimenting with drugs. It might be that the more you are able to talk about and express the negative feelings you’re bottling up, the less overwhelmed you’ll feel and the less you’ll need to escape them with drugs like Adderall.”

And here is an excerpt from Lisa’s letter:

“Am I communicating to him in the right way?” We could really see how important open communication has been for you and that you have always felt close to Matt. A part of adolescence is trying to find some independence and autonomy. As a result, teenagers often distance themselves more from their parents and start to become closer to their peers. We think that some of this shift in communication is a natural part of growing up. However, there may also be some other reasons why your communication has slowed down.

“It is really evident how much you care about Matt, are concerned about him, and want him to be happy. One of the ways in which parents tend to show this to their kids is to try to reassure them that ‘everything will be ok.’ Just like we talked about, this is a completely natural reaction to when children seem worried or upset, and it is important to show them that they are safe. However, sometimes teenagers need to know that adults understand how they are feeling. We think that some of Matt’s behaviors, like the drug use, may be his way of trying to let people know what is going on with him.

It's really important for teenagers that other people see how they are feeling, acknowledge it, and let them know that it isn't wrong to feel that way.

"Like we discussed in the family session, sometimes adolescents need to feel 'mirrored' and understood in their emotions. This helps them know that people understand them and see when they are in distress. It also lets them know that they are not 'bad' for having certain feelings. When adults communicate to teenagers that they see how they are feeling, and accept it, teenagers feel safer, more hopeful, and more protected. Just like you described that everyone sometimes need to cry and express negative emotions, Matt sometimes needs your help in doing this. Sometimes he may just need for you to let him be upset and talk about these emotions instead of having you try to 'fix it' right away. You did a great job doing this during the family session. It was really nice to see you listen to Matt as he admitted that sometimes he feels sad, and to open up to him about the feelings of sadness you experience sometimes. I think it was really important for him to learn that it is normal not to be happy all of the time. As we saw, this really made Matt feel better. Sometimes, all it takes to work through hard feelings is to have someone you love really listen to you."

"We know that this is very different from how you tend to approach problems. Like we discussed, your testing results showed that you are a very resilient, strong, and optimistic person. While you do allow yourself to be emotional at times, you tend to approach problems as things to overcome. However, you noted that Matt doesn't seem to have this same approach. You were really perceptive to notice that there may be aspects of your way of communicating and your coping style that might be preventing Matt from being open with you. As he shared, you being more open and willing to 'sit' with his painful emotions makes him want to communicate more with you."

### ***Follow-up Session***

If possible, it is highly recommended that a follow-up session occur one to three months after the TA has been completed with the adolescent and his or her parents. The assessor typically meets with the parents and the adolescent to discuss any progress the teen and family have made, as well as any difficulties they have encountered. Thus, the assessor has the opportunity to explore with the family any

factors that may be promoting or hindering their progress, as well as to answer any questions that have arisen for the parents and/or the adolescent since the conclusion of the assessment. In the event that the family is experiencing some ongoing challenges, the assessor can assist the family in problem solving any difficulties that may be interfering with the implementation of recommendations. New events in the family's life, both positive and negative, may also be

**Case material.** Matt and his mom returned for a follow-up session approximately 10 weeks after the final summary/discussion session, which coincided with the end of Matt's summer vacation. Matt's summer had been divided into spending a few weeks with his grandparents, a few weeks at camp, and a few weeks at home with his mother. Matt indicated feeling that the assessment had facilitated some changes for him and his mom. He said that he was talking about his difficult feelings more with a friend. He also acknowledged that, although his mother still almost always acted happy, it continued to be comforting to him to know that, underneath, she, too, struggled with some hard feelings. Matt also relayed that he better understood his academic and cognitive strengths and weaknesses as a result of the assessment, which was helpful given that he was about to enter high school. He also revealed more about his drug use that occurred prior to the assessment, and proudly described how he had recently resisted the opportunity to use various drugs. Matt also said he was using new coping methods to manage his negative emotionality, including writing and planning a community volunteer project. Lisa shared that she felt as though Matt had seemed more confident and more mature over the summer, and that Matt had commented on feeling more mature as well. Lisa also shared that she had made an effort to approach their interactions differently, and provided an example that supported her assertion.

explored as to their impact on the adolescent and the family. In our experience, it is often most useful to divide the session into three parts: individual check-ins with the parents and adolescent, followed by a joint meeting with everyone.

### ***Evaluating the Effectiveness of TA in Clinical Practice and Research***

We recommend that assessors using TA in their practices systematically and efficiently collect information to help gauge the effectiveness of TA as an assessment process and as an intervention. The process can be as simple as asking the parents and adolescent to complete a short, open-ended satisfaction measure at the conclusion of the assessment, accompanied by some standard items that can be rated on a numerical scale. For example, clients can be asked to describe how the process was

for them and then rate how well their assessment questions were addressed. This information can aid the clinician in becoming more effective at TA, and can help the clients know that their input—their collaboration in the process—is honored through to the end.

In addition, TAP is in the process of developing measures that can be utilized to assess the process of and satisfaction with psychological assessment. At this point, the Parents' Experience of Assessment Survey (PEAS; Finn, Tharinger, & Austin, 2008) has been developed, and is undergoing further study to address its length and psychometric properties. The PEAS has six subscales: Collaboration, Learning, Feelings about the Assessment, Assessor-Child Relationship, Assessor-Parent Relationship, and Family Involvement, and is filled out by parents at the end of their children's psychological assessments.

**Case material.** We were very pleased to see the research findings on this case. At pre-testing on the BASC-2, Matt had rated various clinical scales in the clinical range (Anxiety, Depression, Sense of Inadequacy, Internalizing Problems, and Emotional Symptoms Index). None of these scales was in the clinical range at post-testing, and the decrease across the previously elevated scales averaged a full standard deviation (e.g., Depression, 75 to 59; Anxiety, 73 to 62; Sense of Inadequacy, 79 to 69). Matt also evidenced much improvement on the adaptive scales of the BASC-2. His score on the Self-Esteem scale improved over one standard deviation (21 to 37); similarly, his score on the Interpersonal Relations scale increased almost one standard deviation (43 to 51). His overall Personal Adjustment score went from 34 to 43. On another measure developed for TAP, Matt reported a large decrease in his negative affect related to his future. Matt also indicated that his assessment questions had been addressed well.

Lisa's data told a bit of a different story, yet they fit well with her process throughout the TA. At pre-testing on the BASC-2, all of her ratings of Matt on both the clinical and adaptive scales were in the "normal" range. At post-testing, she rated Matt in the "at risk" range on the Anxiety scale (from 57 to 65), and noted improvement on Functional Communication scale (from 43 to 50). All other scales were in the normal range at post-testing. On another measure developed for TAP, Lisa also noted a substantial decrease in her negative feelings about Matt's future, as well as an increase in her positive feelings. Lisa reported feeling that her assessment questions had been extremely well addressed. On the PEAS, Lisa averaged a 4.5 out of 5.0 across the six scales, indicating a very high sense of satisfaction with the process and outcome of the TA. More specifically, Lisa indicated a 4.8 on the Collaboration subscale, a 4.9 on the Relationship between Assessor and Parent subscale, a 4.8 on the Relationship between Assessor and Child subscale, a 4.4 on the Learned New Things subscale, a 5.0 on the Feelings subscale, and a 3.8 on the Family Involvement subscale. Finally, on a measure of family functioning, both Matt and Lisa reported an increase in family cohesion.

In summary, both Matt and Lisa indicated high satisfaction with the TA and an enhanced sense of hope for the future. Matt perceived his internalizing symptoms as having decreased significantly, and his self-esteem and relationships with others as having improved greatly over the course of the TA. Lisa demonstrated a change in her "story" about her child that is illustrative of one of the primary goals of TAs conducted with youth and their families. Instead of minimizing or denying her son's distress (as she did before the TA began), at the end she was able to acknowledge his anxiety. She also perceived an enhanced parent-child relationship, which fit our observations. We certainly felt that our goals had been met in helping this family.

Similar instruments for children and for adolescents are also in development.

In TAP, as mentioned earlier, we are researching the processes and outcomes of TA with children and adolescents. We have focused on pre- and post-change in child symptomatology, family functioning, and parental affective attitudes, as well as satisfaction with the assessment experience, using the PEAS. The measures are well described in Tharinger, Finn, Gentry et al. (2009). We also have conducted brief interviews after each session with both the parents and the children. We briefly describe the findings of the case we have been following.

## Conclusion

Our intention in this chapter has been to introduce TA and its use with adolescents and their parents to current and future assessment psychologists and, in turn, to encourage psychologists to consider how this model may be useful in their clinical work. We believe we have made three major contributions. The first is the explicit acknowledgement that adolescents (and families with adolescents) are unique clients with distinctive clinical needs. Current assessment models have only begun to address these needs, and primarily through the development of measures and norms specific to adolescents. The TA model we presented and illustrated herein demonstrates the importance of integrating the unique tasks of adolescent development into the structure of assessment itself.

The second contribution is the TA model itself. TA is a unique integration of theoretical frameworks, as well as a combination of assessment *and* intervention methods and techniques. The TA model can be used with a variety of clients across all ages and many concerns, and may be particularly suited to adolescents in that it attends to such fundamental issues such as teenagers' simultaneous need for autonomy and their continued reliance on their parents. As such, we described and illustrated the goals and procedures for each step in the comprehensive TA model as used with adolescents and their parents, and illustrated each step with a case study. It is hoped that this approach provided the reader with concurrently conceptual and clinical lenses through which to view the workings of TA with adolescents and their parents.

The third contribution of the present chapter is that it encourages practitioners to evaluate the process and outcomes of psychological assessment in both clinical practice and research endeavors. Assessment practice has been challenged in the past

decade to demonstrate its usefulness. By providing clinical and research data that support its efficacy and effectiveness (thus building an evidence base), the practice of psychological assessment is more likely to be valued, advanced, and sought out by consumers and sites where psychological services are offered.

## Future Directions

We close by raising issues about the ongoing development of therapeutic assessment with adolescents and their parents. These include TA's application across cultures, the use of selected steps of TA when the comprehensive model is not feasible, adapting TA in different settings and with different presenting problems, and education and training opportunities to establish competence in TA.

It is imperative to consider cultural differences in the practice and research on TA. In the case we followed in this chapter, Matt and Lisa were Caucasian. Lisa was a single mother who had given birth to Matt when she was a teenager. How did these cultural factors impact their respective experiences of the assessment? How would their experience of the TA been different if, for example, they were Hispanic and had presented as an "intact" family? If they were African American? Asian? Native American? Wealthy? Living in poverty? A single-father-headed household? Factors of cultural variability in TA are yet to be formally explored. Questions such as: "Are there differential effects or experiences of TA based on culture differences?" are essential given the ever-increasing multicultural nature of our clients.

Further, are there particular components of the assessment intervention described herein that are more or less effective in precipitating therapeutic changes in various clients? Thus, future research should include inquiries into: (1) the differential experiences of participants from various cultural groups, and (2) the acceptability and efficacy of individual components of the intervention across cultural groups, particularly cultures with differing norms and values about adolescent development (e.g., differential impact of seeking assessment questions from participants; collaborative approaches to test administration, interpretation, and application to real life experiences of the participant; and implementation of intervention sessions and summary/discussion sessions). TAs are complex and multifaceted and must be retrofitted to the individual client and his or her family and cultural system. Inquiry in this area would increase our understanding not only of how to adapt TA to different cultural groups, but

also of the effective components of TA and how those interface with different contexts.

As briefly mentioned earlier, certain practitioners will find that it is not feasible to apply the comprehensive model of TA because of constraints (typically time and money) in their particular settings. Thus, a challenge for future research is to determine the relative effectiveness of components of TA. Tharinger and Finn have written elsewhere (Tharinger, et al., 2007) about the bare bones of TA that are required to deem that TA is being practiced and researched. In addition to adopting the core values described earlier, essential ingredients include:

- (1) Embracing a collaborative orientation to assessment, which in itself will enhance the intervention potential of assessment;
- (2) Co-constructing and addressing assessment questions from parents and children/adolescents;
- (3) Organizing the findings around the assessment questions and tailoring feedback to parents, children/adolescents in ways that are meaningful to them;
- (4) Adopting multi-theoretical orientations for integration and interpretation of assessment findings.

Questions remain about the added value of other steps. That is, what is the added benefit of intervention sessions? Follow-up sessions? Adolescent summary/discussion sessions? Data informing these questions could guide the psychologist in deciding which steps are essential and which are add-ons, but do not necessarily result in better outcomes. Anecdotally, the authors have noticed in TAs with *children* and their parents that some of the families appeared to benefit most from observing and subsequently processing the testing of the child; others, from the impact of the family intervention session; and still others, from the summary/discussion session. Thus, although future research should attempt to determine the moderators that might impact the efficacy of each step of TA, practitioners will need to thoroughly plan and flexibly adjust to meet the needs of individual clients—utilizing both clinical experience and research findings.

It is also important that TA with adolescents and their parents be conducted and studied across a wide range of settings, including psychiatric hospitals, pediatric hospitals, residential treatment centers, community mental health clinics, independent practices, and schools. Our research has been conducted at a university-based clinic,

and our practice has been conducted primarily in independent practice settings. We also have implemented components of TA with adolescents in the schools and have several other such projects underway. Others are using TA with children and adolescents in a community-based clinic that primarily serves economically disadvantaged children and their families (Mercer, 2011; Guerrero, Lipkind, & Rosenburg, 2011; Haydel, Mercer, & Rosenblatt, 2011). This work has shown that TA can be applied and is effective in such settings, but assessors must be acutely aware of the cultural context.

It is also our experience that careful determination of when TA will have the most payoff (e.g., in terms of adolescent and parental motivation and follow-through) will be wise, as the comprehensive TA model can be time-consuming and demands extensive competence from the psychologist. We recommend using TA with complex cases in which the adolescent and parents are stuck, and in their “stuckness,” may be doing psychological harm to themselves or each other, or at least obstructing progress. Also TA may be particularly applicable to adolescents and families where previous treatment efforts have repeatedly failed. These points underscore one more constraint on the practice and research on TA at this time—the competence of the practicing psychologist or supervised students in training. As we mentioned in the introduction, it is our experience that psychologists with expertise in assessment and several schools of psychotherapy can add TA to their repertoires by obtaining additional education, training, and supervised experience. Such opportunities are available and growing (cf. [www.therapeuticassessment.com](http://www.therapeuticassessment.com) for a list of training workshops), and Finn and colleagues are currently exploring setting up a certification program in therapeutic assessment. In addition, it is important for faculty in professional psychology graduate programs to introduce and teach the basics of TA to their students to encourage their consideration of additional training. It is our experience that graduate students are extremely excited about learning and practicing TA, and some see it as the pinnacle integrative experience of their graduate training.

# History Taking, Clinical Interviewing, and the Mental Status Examination in Child Assessment

Mauricio A. Garcia-Barrera and William R. Moore

## Abstract

Best assessment practices incorporate a multi-step and multi-method approach, as well as sensitivity to the client's cultural background, including their race, language, beliefs, and practices. In this context and emphasizing pediatric assessment, this chapter presents a review of some of the earlier steps in a psychological assessment process, including referral review and intake, review of records, history taking, clinical interviews, and mental status examination. Emphasis is placed on the relevance of the clinical assessment interview to the establishment of rapport and to gather information about the current functioning of the child. Information is significantly richer and more reliable if several sources are included; thus, background questionnaires, review of medical and academic records, interviews with teachers and others involved in the child's life, are recommended. Common methods of clinical interviewing are discussed, including unstructured, semi-structured, and structured formats. Finally, this chapter includes a review of the components of the child Mental Status Examination.

**Key Words:** clinical interview, history taking, semi-structured interview, structured interview, background questionnaire, mental status examination, rapport

## Introduction

The clinical assessment of a child is staged in a multi-step process, in which each component serves as a pillar for the next, and in which both structure and flexibility play important roles. Although there is no fixed model for child assessment practice, knowledge of each one of these steps will certainly help the clinician to organize an assessment plan that would serve as an instrument to better understand the child. It is worth noting that in the context of this chapter, the word "child" is brief for "children and adolescents." When assessing a child, the clinician will most likely be dealing with several sources of information, including the referral source, parents, teachers, other clinicians, and of course, the child. Thus, a strategic, organized, and efficient assessment process facilitates communication between the clinician and the parties involved,

with the ultimate goal of making informed decisions about the child's needs.

Furthermore, a clinical assessment is not just an activity, it is a professional responsibility; subsequently, there are several stages of professional training that must take place before facing an evaluation. Most frequently, a clinician has completed supervised clinical practices or externships and an internship; in some cases, she or he has received post-doctoral training. Most likely, the professional conducting the evaluation has received a graduate degree in psychology and has obtained a professional license to practice. The clinician may be in advanced stages towards completion, in which case her or his assessments are conducted under the close supervision of a licensed psychologist. A professional license in psychology gives full privileges to clinicians to conduct independent evaluations in

their area of expertise. Moreover, a pediatric clinical assessment requires an integration of several layers of knowledge, including areas such as normal and abnormal child development (e.g., psychopathology, neurodevelopmental disorders, personality theories), clinical practice (e.g., establishing rapport, ethics, diversity issues) and psychometrics (e.g., test mastery, statistics). In North America, the American Psychological Association (APA) and the Canadian Psychological Association (CPA) regulate the academic curricula of institutions offering a clinical degree in psychology, to assure that the necessary content areas are included in each program of studies.

Finally, a clinical assessment is not a process in isolation; each evaluation includes a series of recommendations that should provide parents, teachers, and other professionals involved with some tools to initiate both short-term and long-term intervention programs for the child. The psychological report, which summarizes the assessment and includes the recommendations, is a very important piece of the process. In several cases, this report initiates a progression of events in the life of the child, such as individual interventions and counseling, special education accommodations, and follow-up assessments including specialized medical examinations and pharmacological interventions; some of them with life-long repercussions. Due to the sensitive implications of psychological assessment, state and provincial psychology boards in North America regulate this activity.

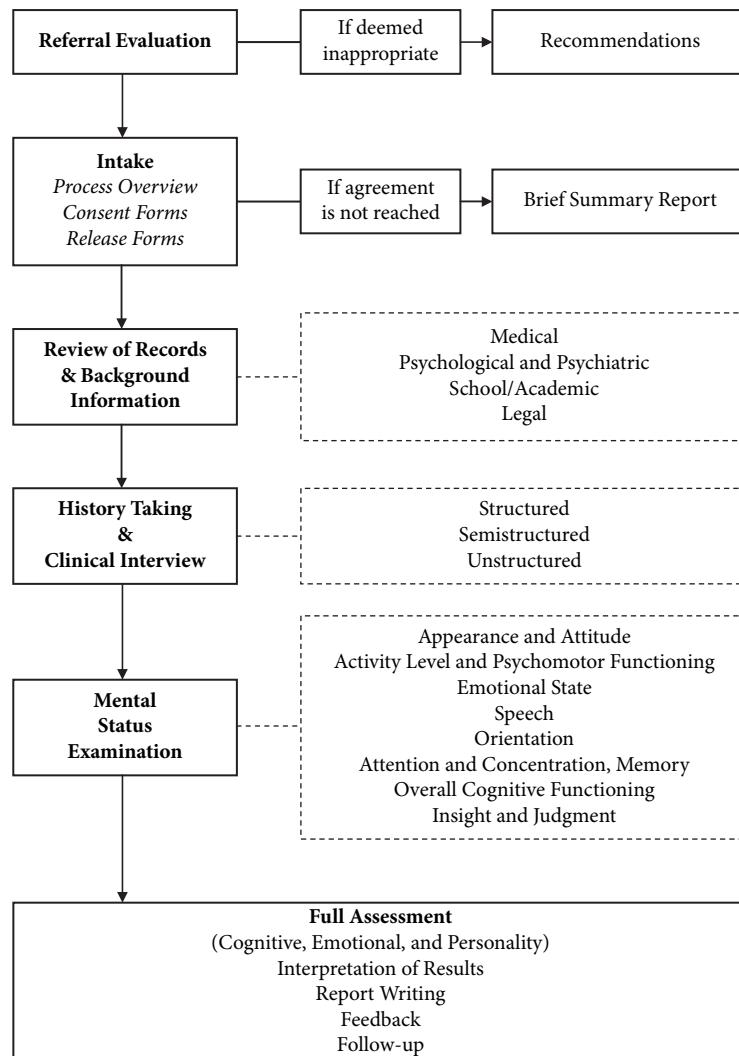

Best assessment practices incorporate a multi-step and multi-method approach (e.g., Baron, 2003; Garcia-Barrera & Kamphaus, 2006; Kamphaus & Reynolds, 2003; Lezak, Howieson, & Loring, 2004; McConaughy, 2005; Sattler, 2008). Emphasizing pediatric assessment within this context, this chapter presents a review of some of the earlier steps in a psychological assessment process, including intake, history taking, initial clinical interviews, and mental status examination. Information in this chapter does not attempt to substitute the broad spectrum of experiences that only practice can provide clinicians with, nor does it cover the vast extent of information that several clinical graduate courses would. This chapter aims to complement those two sources of knowledge, while providing you with specific best practice guidelines to develop your own child assessment protocols. Figure 18.1 presents a flow chart summarizing the assessment steps to be discussed in this chapter.

## Intake and Type of Assessment

### Identification

In most cases, a clinical evaluation process starts with an intake. This intake should be a formal step in the process and it is recommended that it follows the format of an interview. As is the case with any type of interview, the goal the clinician has in mind during the intake interview is to obtain as much information as possible about the referral in order to determine if it is appropriate for his/her area of expertise. In some cases, the appropriateness of the evaluation itself is also considered (Baron, 2003). Furthermore, the intake interview is an opportunity for those involved in the case (e.g., most likely, the guardian and the referral source) to better understand the characteristics of a pediatric psychological evaluation process, the nature of the questionnaires and tests that are usually administered, the potential goals and limits of the evaluation, and the type of assessment that best fits the needs of the child. Moreover, it could be the case that during this intake process the referral source will in turn be consulted with to clarify the referral question, to jointly formulate a strategy, and to obtain more information about the child, upon the guardian's consent. Communication about the case is facilitated by the creation of a common vocabulary with the referral source (Sattler, 2008). During the intake, the clinician clarifies his/her role in the process, along with the role that each player would perform; in other words, how much involvement may be required from parents, teachers, other informants, and the child.

The best case scenario for the intake interview is a personal one-to-one interaction, either in a visit to the clinician's office or in any other appropriate setting; however, in some cases a phone interview can be efficacious. Having the opportunity to meet personally with all parties involved in the process facilitates the early establishment of rapport. Regardless of how it is conducted, the intake interview should help all parties reach the final decision of whether the evaluation is appropriate, whether the evaluation goals and methods meet the clinician's qualifications, and whether the parties are compatible. It could be the case that the information provided during the intake is enough for the clinician to determine that a formal evaluation is not needed, and provided some interventions, the child's behavior may be consequently modified. However, if the evaluation is deemed appropriate, the next step in most cases is to obtain a written and signed consent from all parties involved. The written consent is a contract recording an agreement between the

**Figure 18.1** Flow chart of the initial steps in a multi-stage and multi-method psychological assessment of a child.

clinician and all parties, as well as documenting the authorization to initiate the process; certainly it is a document the clinician would like to keep. This agreement is crucial, as it establishes the extent of the expectations, goals for the evaluation, names and positions of the parties involved, permission to contact and discuss the case with them (e.g., teachers, other clinicians), and in some cases, future uses of the information collected (e.g., research purposes in academic settings, case presentations, court mandates).

Finally, the clinician may use the intake interview as an opportunity to create a list of records needed to better understand the case, have the guardian sign the appropriate release forms for these records,
