We extend our appreciation to Laura Elenbaas for her assistance with editorial work on the manuscript. We thank Courtney Ball, Shelby Cooley, Laura Elenbaas, Aline Hitti, Marc Jambon, Kelly Lynn Mulvey, Jeeyoung Noh, Michael Rizzo, and Wendy

Rote for their invaluable feedback on the manuscript, and Sharon Chan, Sue Cho, and Leon Li for proofreading the manuscript. We greatly appreciate the helpful editorial feedback from Michael E. Lamb.

INTRODUCTION

Morality is a central aspect of social life and has been at the core of psychological theories for more than a century. The scientific study of morality poses enduring questions about how individual psychological needs for autonomy and attachment to groups and society can be met while also ensuring the integrity, dignity, and equal and fair treatment of others. Drawing on philosophy, biology, anthropology, and sociology, developmental scientists have addressed these questions by studying the origins and acquisition of morality as well as the sources and nature of change.

Debates about the nature of morality have a long history dating back to the Greek philosophers. Plato, who wrote about idealized forms of morality in 380 B.C., was challenged by his student, Aristotle, who speculated about what it means to live a good life. Aristotle appealed to virtues as well as to core principles of justice. In the 1700s, debates about morality arose which have continued to this day. Hume (1739/1969) focused on the sentiments (emotions) that motivate morality, and Kant (1785/1959) theorized about rationality and the categorical imperative (e.g., “Act only in accordance with that maxim through which you can at the same time will that it become a universal law” (p. x). Evolutionary (Darwin, 1871/2004) and sociological theory (Durkheim, 1925/1973) also brought new claims to bear on the conceptualization of morality. Current philosophers have continued these debates, albeit in different forms. They have drawn on psychological theories and provided new interpretations of classic theories to develop more integrated treatments of morality, which are influential in how developmental scientists study morality today (Appiah, 2005; Gewirth, 1978; MacIntyre, 1981; Nussbaum, 1999; Rawls, 1971; Sen, 2009).

Despite varying interpretations, most developmental scientists agree that morality refers to individuals’ treatment of others, not (just) the self, and reflects individuals’ intentions and motivations for actions. Beyond this, there are many different emphases, issues, and methodological approaches, which we will review in this chapter. Because conceptual and methodological approaches vary, comparisons across different theoretical perspectives and research programs are often difficult. Nevertheless, as we detail here, developmental approaches derived from very different foundational theories have moved toward more integrative approaches. Progress toward integration does not mean that controversies no longer exist; they do and will be identified here. Yet, some of the heated arguments

of 50 years ago have changed, with disagreements taking on new dimensions.

Organization of the Chapter

Developmental scientists have made tremendous progress in understanding the origins and development of morality (for a review of different approaches, see Killen & Smetana, 2014). This is promising because developmental science and the study of morality continue to serve as reference points for scholarship and research across a wide range of fields, as well as foci for the popular media.

We begin with a description of the major developmental science definitions of morality. We provide a brief review of the theories that provided the foundation for research over the past half-century and then reflect on the controversies and misconceptions that still exist. Next, we review current literature on the developmental roots of morality, mental state knowledge and morality, and moral judgments and reasoning. Subsequent sections examine the various contexts, ranging from the family and peer groups to society, in which moral development occurs. We conclude with implications and directions for research. Throughout the chapter, we demonstrate how the study of morality has shed light on fundamental topics in developmental science, contributed novel methods, and discovered new knowledge about child development.

Overview of Definitions of Morality

In this section we review and highlight the different ways that developmental scientists have defined morality and its acquisition. We identify some of the central positions, recognizing that our brief overview does not fully capture the complexity or nuances of any given approach.

Deontological Moral Judgments

For researchers studying moral judgment, the definition of morality is derived primarily from moral philosophers taking a deontological perspective (Kant, 1785/1959). According to this approach, morality refers to a set of prescriptive norms about how individuals ought to treat one another, including concerns with fairness, others’ welfare, equality, and justice. To act in a way consistent with moral principles, one is required to be impartial and fair and to not be bound by the dictates of group norms or consensus when they are in conflict with fairness and justice. According to Gewirth (1978), morality is a set of categorically obligatory requirements for action for which compliance

is mandatory regardless of institutional norms, laws, or etiquette. Moral judgments, in their full and realized form, promote equality and reflect a focus on intentions, not outcomes. Further, Gewirth (1978) argues that moral judgments respect the integrity of persons and recognize the importance of promoting others' welfare. Notably, this definition identifies what is not included in the moral domain, such as personal desires and laws or customs. Researchers who study moral judgment development examine the emergence of these judgments in ontogeny and focus on the social experiences and relationships that contribute to the child's changing understanding of morality.

Morality as Empathy and Prosocial Obligations

Stemming from the moral philosophy of Hume (1739/1969), a robust line of research emphasizes the emotional basis of morality. Here the focus is on the human capacity for sympathy, compassion, and empathy, which are viewed as the motivations for prosocial and altruistic behavior. Morality is defined by these emotions, and research investigates how empathy and other emotions emerge and change over time. Empathy involves an emotional and cognitive reaction that often leads to acts that benefit others. Prosocial behavior includes sharing and donating resources, cooperating, comforting others, and volunteering to help another without benefit to the self.

Empathy is of concern not only in Hume's (1739/1969) theory but also in Kantian (1785/1959) philosophy, which has identified perfect and imperfect duties. Perfect duties involve acts with a high level of obligation, such as not harming others, acting in a fair and impartial manner, and treating others as an end rather than as a means to an end. Imperfect duties, including beneficence and caring for others, are acts that are good to do but not obligatory in the same way as perfect duties; while it is good to help others, there are contexts in which helping others is not viewed as a moral obligation. The focus of research on empathy and prosocial behavior has been on imperfect duties, such as being prosocial, kind, and compassionate toward others, and, centrally, caring for others. One goal of this research is to examine individuals' motivations to be moral. Moreover, both emotions and judgments (understanding) have been included in these investigations, albeit with different emphases and priorities.

Morality as an Evolutionary Mechanism

The developmental course of morality is an evolutionary one, and thus biological theories of evolution also have provided insights regarding the adaptive mechanisms

involved in moral development in humans. The evidence for this comes from cross-species comparisons as well as from neuroscience studies, with a focus on evolutionary principles of adaptation and change. Evolutionary theorists propose that morality functions to regulate social interactions cooperatively, not selfishly, and to promote the community's common good. The assertion is that the emergence of cooperation requires specific mechanisms that balance the organism's self-interest with concern and respect for others. Darwin (1871/2004) believed that morality was derived from a social instinct and developed toward rationality. Even though his goal was to introduce a biological (not philosophical) basis for morality, Darwin defined morality as the Golden Rule, which resembles the Kantian categorical imperative: "To do good unto others—to do unto others as ye would they should do unto you—is the foundation-stone of morality" (p. 166).

As discussed next, a wide range of researchers share the belief that investigating the building blocks of morality is essential for understanding moral development. Research on the evolutionary bases for morality has most often focused on the behavioral mechanisms that explain the adaptive functions of moral judgments and emotions that contribute to survival. Complementing evolutionary perspectives, technologies such as functional magnetic resonance imaging (fMRI) and electroencephalogram (EEG) have provided new lenses into moral judgments and emotions by documenting the neurological underpinnings of responses to a range of moral problem-solving tasks. Revealing the neuro-circuitry and brain activation associated with moral responses provides insights about what makes moral judgments and emotions unique.

Morality and Identity

Research on moral identity focuses on the extent to which morality is central to one's identity and motivates one to act in a moral manner. Moral identity is seen as the core of morality and is tied to judgments of personal responsibility and integrity, or the realization that consistency (between judgment and action) is at stake in moral action. The focus of this approach is often on individual differences in moral identity, moral motivation, and personality development. Current research on moral identity has focused on its role in promoting civic engagement, exemplary moral actions, and positive political action. Most of the research, however, has been conducted with adolescents and adults, although conceptual connections exist with early research on conscience, the emerging moral self, and shame in young children.

Morality as Conscience

Research on conscience stems from Freud's (1930/1961) theorizing and refers to the internalization of—and compliance with—parental (and societal) norms. Freud defined conscience as the development of the superego (a result of the internalization of parental values) and positive interindividual behavior toward others, which is maintained through a sense of guilt. Early views of conscience involved an internalized mechanism that enables children to do the right thing (as defined by one's society) and to feel bad when they misbehave. Current research on conscience measures internalization as a function of responses to parental disciplinary strategies, which produce individual differences in the strength of conscience. Conscience is most often measured in terms of children's behavioral and emotional responses, including resistance to temptation and self-regulation.

Morality as Cultural Norms

Researchers inspired by anthropological and sociological theories define morality in terms of cultural norms. Morality is seen as including justice and harm, but these approaches extend the moral domain to include interpersonal duties and familial obligations. Cultural perspectives often focus on cross-cultural variations in moral judgments, along with different perspectives on sources of influence and change. Historically, cultural-developmental approaches have defined morality in relativistic terms (e.g., as delineated and varying by cultures), but this area of research has also examined universal applications of morality (for instance, fairness and the avoidance of harm, as manifested by individuals in varying cultural contexts).

Cultural influences on children's acquisition of morality have been examined by studying how cultural agents communicate moral values. The categories of "individualism" and "collectivism" were introduced by cultural theorists to examine how morality is conveyed and developed in ways consistent with these broad ideological templates in Western ("individualistic") and non-Western ("collectivistic") cultures (Shweder et al., 2006). These categories have undergone extensive scrutiny, resulting in research examining their coexistence within as well as between cultures.

Classical Theories of Morality and Their Evolution

Definitions of morality reflect different theoretical approaches and traditions that guide the central constructs,

measures, descriptions of development, and conclusions to be drawn. Definitions, however, do not fully capture the complexity of theories, as we illustrate here. As one example, in recent years emotion researchers have come to appreciate the processes beyond emotions that are necessary for a full explanation of morality (Carlo, 2014). Conversely, researchers studying moral judgment have incorporated attributions of emotions as a fundamental aspect of morality (Arsenio, 2014; Turiel & Killen, 2010). For this reason and to highlight the source of many assumptions in current research, we review traditional developmental theories along with current extensions. Current researchers trace their theoretical roots to different foundational theories, which are reviewed here, along with extensions of these theories: evolutionary theory, prosocial developmental theory, and social domain theory.

Psychoanalytic Theory

Freud's (1930/1961) theory of morality was based on the centrality of parent-child relationships in early life. Freud (1930/1961) wrote about the necessity of understanding the reciprocity inherent in the "categorical imperative," which refers to the Kantian notion of the Golden Rule. Freud's developmental theory did not include an explanation of how individuals come to subscribe to the categorical imperative from the internalization of parental norms. Likewise, although Freud's theory of moral development was based on the social-emotional aspects of parent-child relationships, he did not provide a basis for the acquisition of a general set of moral principles, because the values that are incorporated into the superego were left unspecified (e.g., which parental values are incorporated?). Development was characterized in stages, but only through the first few years of life and culminating in the development of conscience, which was seen as formed by 5 years of age. Early social relationships with parents provide the basis for personality development as well as the formation of morality.

Current research on conscience examines how young children develop mechanisms for inhibiting negative behavior and promoting positive behavior as a result of internalizing parental norms. Conscience is conceptualized as an inner guidance or self-regulatory system involving an integration of moral emotion and conduct (with a limited focus on cognition). This emphasis is partly on the development of a mutually responsive orientation between the parent and child that sensitizes the child to learn proper conduct, codes of caring for others, and

committed compliance. This is exemplified by Kochanska's research on conscience (Kochanska & Aksan, 2006) as well as Thompson's research on early childhood morality (Thompson, 2014).

Behaviorism

Behaviorism, as described by Watson (1930), and later expanded by Skinner (1971), proposed that psychological theories should derive solely from observable behavior. Watson conducted animal experiments focusing on conditioning and also authored a book on the psychological care of infants and children using his behavioral theory of classical conditioning. This theory contributed to a line of research on how learning principles might explain the child's acquisition of morality. Skinner's (1950) theory of operant conditioning elaborated on these notions. Although not specifically applied to child development, Skinnerian behaviorism had a major impact on American psychology, including theories about morality. Skinner (1971) contended that moral values were subject to the same environmental contingencies as any other learned behavior, such as language acquisition and riding a bicycle. Rewards and punishments were deemed sufficient to account for the acquisition of new behavior. This theory created debates within developmental psychology because Skinner rejected the notion of age-related constraints on development, along with propositions about cognitive developmental changes.

Social Learning Theory

Following and extending Skinner's foundational research, Bandura and McDonald (1963) argued for a social learning theory approach to development. The proposition was that children learn through imitation and observation, not just through behavioral contingencies associated with reinforcement. The results from research using Bandura and McDonald's (1963) "forbidden toy" paradigms (in which children were asked to refrain from touching a toy when an adult was absent) suggested that childhood morality was acquired through adult mandates and from learning correct behavior from adult models. Extensive research conducted from this perspective has focused on the role of parental socialization, disciplinary strategies, and the environmental models that induce behavioral compliance to adult standards as measures of successful moral internalization. More recently, researchers from this perspective have argued for a consideration of parents' different goals for children's socialization (see Grusec, Goodnow, &

Kuczynski, 2000). Parents provide structure and strategies to learn domain-appropriate skills, respond to children's distress, and discipline appropriately.

Constructivism

Piaget's theory of constructivism (Piaget, 1932, 1970), with its larger goal of charting the origins of knowledge, provides a foundation for current research on moral judgment development. Piaget's (1932) classic book, *The Moral Judgment of the Child*, was an in-depth account of how moral judgment and behavior emerge in development. Piaget (1970) focused on how moral knowledge arises through the interaction of biological givens (adaptive mechanisms) and environmental influences (peer and adult-child interactions). His theory was based on the premise that knowledge stems from action and that the acquisition of moral knowledge is a continual process of experience, abstraction, reflection, and evaluation.

Reflecting on the unilateral constraint of authority relationships, Piaget proposed that children are initially heteronomous (defining morality as compliance with rules set by an authority) and then become autonomous by 8–10 years of age. This transition was thought to emerge not from parents but through peer interactions, which, due to children's equal status, are characterized by mutual respect. This assertion was a radical thesis at the time (and still is) because Piaget's proposal that parents inhibit morality due to their unilateral authority relationships with children contrasts with the commonly held assumption that parents teach children morality. Rather, Piaget viewed peer interactions as equal, mutual relationships that promote conceptions of equality and fairness. Piaget (1932) was concerned with social interaction (behavior) as well as judgments, as revealed in his analyses of children's actual conflicts and deliberations regarding social rules and norms in peer exchanges, as well as evaluations of hypothetical dilemmas drawn from the child's world. Research has clearly established that peer relations and particularly friendships play important roles in children's moral understanding. Moreover, unlike Piaget's characterizations, adult-child interactions reflect both unilateral and mutual forms of relationships. In addition, Piaget's description of early morality as heteronomous has not survived empirical scrutiny, as recent research has shown that even young children understand the intrinsic basis for rules and do not evaluate transgressions solely on the basis of authority. Piaget's early theories about morality launched research programs in the 1960s and 1970s focusing squarely on

morality (see Turiel, 2006, for a review), as well as current research on intentionality, mental states, cooperation, and theory of mind. These have illuminated the complexity of morality in early development and changes in moral judgments from childhood to adolescence.

Cognitive-Developmental Theory

In the context of American psychology in the 1960s, Kohlberg's (1969) extension of Piaget's (1932) theory of morality contrasted sharply with behaviorism. Kohlberg criticized socialization theory (and behaviorism) for ignoring the child's construction of moral knowledge. He argued that imitation and observation were not sufficient to enable children to understand concepts of justice, fairness, and others' welfare because adults are often erroneous, immoral and subject to flawed logic, leaving unanswered the question of how children who have immoral adult role models formulate mature moral judgments.

Cognitive developmental theory was applied to morality (Colby & Kohlberg, 1987) to identify the underlying logical thinking necessary for moral judgment development. Drawing from Rawls's (1971) theory of justice and his own interview studies, Kohlberg posited that morality develops through six stages organized within three levels (preconventional, conventional, and postconventional) of moral thinking.

Kohlberg's goal of empirically testing philosophical theories with psychological data sparked extensive debates between psychologists and philosophers. His conceptual model created a research agenda for studies of moral development for several decades. Kohlberg proposed that his moral stages were "structured wholes" and that his moral stage system reflected an invariant sequence, similar to Piaget's logical–scientific stages (see Lapsley, 2006, for an elaboration). Individuals were hypothesized to progress through one stage to the next and logically could not skip stages. Despite extensive research, this aspect of his theory was not empirically validated. Many criticisms have been applied to Kohlberg's system by researchers both within and outside his theoretical framework (see Lapsley, 2006; Turiel, 2014; Walker, 2006). Despite these limitations, this program of research was important for providing a developmental theory for the study of how individuals reason about moral issues.

Prosocial Development

Eisenberg and colleagues (Carlo, 2014; Eisenberg, Spinrad, & Knafo-Noam, Chapter 15, this *Handbook*, this volume) extended and revised Kohlberg's global stage theory by

focusing more specifically on prosocial development. They drew from Hume (1739/1969) as well as from Kant (1785/1963) to more closely examine the roles of empathy and sympathy in motivating prosocial behavior. Eisenberg and colleagues showed that children's prosocial moral reasoning, or their thinking about situations in which others have needs that require an opportunity to help, develops through a series of stages. Like Kohlberg, they viewed later stages as reflecting developmentally more advanced modes of thinking, but unlike Kohlberg, they proposed that individuals can use a variety of different levels in their reasoning and that reasoning may vary across different situations and circumstances.

Furthermore, as part of their account of prosocial development, these researchers distinguished between the moral emotion of *empathy*, an affective response that stems from the awareness of another's emotional state (and is similar to what the other person is feeling), and *sympathy*, or an emotional reaction in response to another's state without necessarily experiencing the same emotion as the other (Eisenberg, Spinrad, & Morris, 2014). Age-related changes in prosocial development have revealed that young children are sensitive to the needs of others, help others without external rewards, are not punishment-oriented, and are willing to engage in helping behaviors that do not benefit the self. This line of research has revealed the emotional and cognitive components of prosocial behavior and has offered a more specific and differentiated theory of morality than Kohlberg's global stage model.

Social Domain Theory

Over the past 40 years, social domain theory, formulated by Turiel (1983, 2006), Smetana (2006), and Nucci (2001), has asserted that morality is one of three domains of social knowledge and is constructed out of social interactions. Morality is revealed by the individual's evaluation and interpretation of social events (rather than from direct teaching or transmission). Rather than positing domain-general, global stages of moral development, social domain theory postulates that different domains of reasoning coexist in development. These include the *moral* (issues of fairness, equality, justice, rights, and other's welfare, e.g., physical and psychological harm), *societal* (concerns about conventions, group functioning, social institutions, group norms, traditions, and cultural rituals), and *psychological* (concerns with personal goals, autonomy, identity, and individual prerogatives; Nucci, 2001) domains. These domains of reasoning and social interactions emerge early in ontogeny and follow different

developmental trajectories. In contrast to traditional cognitive-developmental characterizations of early moral development, social domain theory research has shown that young children evaluate moral transgressions as wrong even when there is no punishment or authority mandate. In addition, social domain theory has shown that moral development does not emerge from a self-oriented, pre-moral level (Kohlberg's stages 1 and 2), moving through a group-conventional level (stages 3 and 4), and culminating in a justice level (stages 5 and 6). Instead, empirical research has demonstrated that moral, societal, and psychological orientations coexist within individuals and are brought to bear when evaluating both straightforward and complex events. Children focus on moral concerns in some situations but are also concerned with group functioning or conventions (the societal domain) or with autonomy and personal goals (the psychological domain) in other situations. As well, there are social issues that reflect aspects of all three domains; in these cases individuals may give priority to one consideration while weighing multiple factors.

Social domain research has examined the different criteria as well as the reasons children use to evaluate the legitimacy or wrongness of rule violations. This is important, because judgments of transgression severity, naughtiness, and deserved punishment do not necessarily reflect moral evaluations. For example, there are good (or more effective) ways to brush your teeth, as well as good, expected, or conventional ways of calculating algebra problems, and good (that is, more aesthetically pleasing) poems or artworks. Moral rules are considered to be generalizable across contexts. Theoretically, moral transgressions are wrong even if the agent does not get in trouble or an authority condones the act. Further, the evaluation of moral transgressions is not contingent on the presence of rules; moral violations are wrong even if there are no rules governing them. In contrast, conventional (societal) rules are those rules that individuals view as alterable and a matter of consensus; their wrongness is contingent on rules and authority mandates. Children have been found to apply these criteria to evaluate moral and conventional events at an early age, although perhaps unevenly at first. For example, very young children may recognize that conventional rules are contingent on authority (that authority can deem an act to be legitimate) but not yet understand that conventional rules are alterable and can be changed.

Current research on social domain theory has examined how complex issues such as social exclusion and prejudice (Killen & Rutland, 2011), parent-adolescent conflict

(Smetana, 2011), tolerance of cultural practices (Turiel, 2006; Wainryb & Recchia, 2014), and rights (Helwig, Ruck, & Peterson-Badali, 2014) reflect moral, societal, and psychological considerations. These studies challenge traditional views of global stages of development, which would expect that only one form of reasoning would dominate all of individuals' moral thinking at different development periods.

Evolutionary Theories

In his foundational and ground-breaking book, *The Descent of Man*, Darwin (1871/2004) claimed that human beings have a moral sense, or a prosocial disposition. This was seen as the outcome of a natural evolutionary process rather than divine intervention or religious teaching (Hinde, 1982). This has implications for debates about innate origins of morality as well as the role of adult transmission in moral development. Darwin believed that morality is an adaptation that provides a selective advantage, enabling civilizations to thrive and progress. As with Piaget (1932), morality was seen as stemming from experience and social interactions rather than from direct teaching, because the environment influences the behaviors that are selected.

Darwin identified two main steps by which a moral sense developed in humans. Morality was rooted in prosocial instincts, derived from caring for the young, which offset instincts to be aggressive toward outgroup members. The second step was in the intellectual faculties, revealed through memory, reflection, and the development of conscience (defined as reciprocity or "the Golden Rule"). Darwin theorized that humans were biologically inclined to be altruistic, sympathetic, and moral (de Waal, 2006, 2014) and not solely aggressive and competitive, as has often been mistakenly alleged.

Darwin contrasted nonhuman animals and early hominoids ("tribes") to modern humans. Much of this analysis is theoretical rather than empirical, drawing on his observations of human civilization and theory of natural selection. Evolutionary theorists often debate the evidence for what counts as morality in human and nonhuman primates. Moreover, because most of Darwin's writing focused on the phylogenetic emergence of morality (human evolution across cultures and species), he did not speculate about when during childhood the shift from an early social predisposition to a moral intellectual capacity occurs. Darwin's theory influenced developmental accounts of morality in humans as well as provided the groundwork for more recent research on the biological basis of morality and the existence of morality in nonhuman animals.

Current research on the biological basis of morality includes research on the evolutionary origins of morality as reflected in the behavior of nonhuman primates as well as other animals (de Waal, 2006), investigations of cooperation in young children and primates (Warneken, Chen, & Tomasello, 2006), genetic and biological markers for the recognition of distress in others (Hastings, Miller, Kahle, & Zahn-Waxler, 2014), and neurological evidence for moral thinking and emotion (Decety & Howard, 2014). These viewpoints share a common focus on the biological basis for morality, with some differences regarding the characteristics that are proposed to be uniquely human. The literature overwhelmingly supports a biological basis for morality, which is consistent with a developmental perspective.

Beyond False Dichotomies

A significant change over the past 50 years in the field of morality and moral development has been the move beyond false dichotomies. Below we discuss several such false dichotomies: nature versus nurture, judgment versus action, emotions versus judgment, justice versus care, and cultural relativism versus generalizability.

Nature Versus Nurture

The recent interest in the origins of morality, stemming from constructivist, nativist, biological, and comparative approaches, has led to renewed interest in what has been framed as debates between “nature versus nurture.” Yet, our understanding of the origins of morality (nature and nurture) has become more complex and nuanced. For example, our notions of nature are no longer restricted solely to genetic predispositions or inborn temperamental characteristics. Researchers who emphasize nature focus on the biological or evolutionary basis for morality, the innate capacities of the mind, neurological responses to morally relevant stimuli, and the genetic basis for individual differences in moral responses. Research on gene \times environment interactions has revealed that neither nature nor nurture is static. Genetic information is changed by environmental conditions before and after birth (epigenetic change) and, in addition, individuals respond differentially to environmental stimuli as a function of their genetic make-up (Fox et al., 2005). Thus, nature and nurture are intertwined and mutually influential.

In studying morality, nurture is no longer characterized simply as environmental contingencies or parental socialization. Whereas socialization initially referred to a

top-down process by which parents molded children, who were seen as passive “sponges” absorbing information, extensive research indicates that children are cognitive beings, actively interpreting, transforming, and evaluating social information as early as infancy. Thus, socialization occurs through varied social experiences involving bidirectional and interactive processes (e.g., Kuczynski & Parkin, 2007).

Judgment Versus Behavior

Another false dichotomy is that of judgment versus behavior. Traditionally, sharp distinctions have been drawn between approaches that focus on one or the other. Initial discussions about the relationships between judgment and behavior focused on whether individuals’ judgments about the right course of action are correlated with their actual behavior. A central limitation of framing the issue in this way, however, is that most situations are multifaceted. Actual situations are complex and involve multiple considerations (e.g., the relationship between a transgressor and a victim, their past history, the degree of harm inflicted, the intentions of the actor). To adequately compare hypothetical and actual situations there needs to be a control on the number of variables in each context (Turiel, 1983). It is important to know how individuals weigh these considerations in comparing judgments and actions; otherwise the analysis is incomplete. Reflections about the context bear on (and are related to) individuals’ determinations of the right course of action. Moreover, theorists often point out that behavior alone does not elucidate moral motivations because intentions can be positive or negative. Judgments that concern issues that individuals have confronted, whether abstractly or in actuality, provide the basis by which to draw connections between experiences, inferences, interpretations, and outcomes.

Further, neuroscience research has revealed the close interaction between cognitive functioning and behavior, making it difficult to fully differentiate the two. Cognition occurs while individuals are interacting in the world. Saxe (2009), a neuroscientist who studies morality, argued that observable behavior reveals only a small amount of information about “what matters,” because humans are much more interested in perceiving and inferring mental states. In fact, few researchers examine only judgment or behavior in actual situations; most studies include different measures of attitudes, judgments, and evaluations along with social experience, interactions, relationships, and behavior to study their interrelationships. This issue remains a prominent theme that warrants further investigation.

Emotions Versus Judgment

Emotions and judgments are both central to morality and yet, these constructs are too often portrayed as an overly simplified dichotomy. Hume did not define morality solely as emotions, nor did Kant define morality exclusively as judgment, although interpretations of their work and the psychological science research they have generated continues to discuss these constructs as mutually exclusive. Empathy and sympathy, for example, reflect feeling states but also cognitive components regarding the target of empathy, the attribution of harm or distress, and the motivation of the recipient of empathy (Hoffman, 2000; Nussbaum, 1999). Conversely, judgments about respect for life and the integrity of persons involve elements of caring for another individual (Carlo, 2014; Turiel, 2014). Artificially demarcating some responses as “emotions” or “judgments” runs the risk of ignoring the full meaning of morality. Yet, debates remain about whether morality is fundamentally about judgments regarding fairness and equality, or emotional processes and interpersonal care. Recent research on these different orientations reveals that both constructs are important and coexist within individuals.

A recent instantiation of the emotions versus judgments duality can be seen in writings emphasizing the role of moral intuitions over judgments (e.g., Haidt, 2001, 2007). Haidt’s social intuitionist view draws on both evolutionary theory and moral neuroscience to argue that responses to moral events are primarily affective, intuitive, and automatic, whereas moral judgments, when they occur, reflect post-hoc rationalizations (see Decety & Howard, 2014, for an alternate developmental neuroscience view). The argument is that an automatic, very fast, and emotional system evolved to respond to threat and does most of the moral “heavy lifting” (Haidt, 2001). Haidt argues that although moral deliberations may have a role in morality, the cognitive system is an evolutionarily newer and more limited adaptation that is restricted to overriding intuitive responses. These notions have gained much currency recently, particularly in social psychology, but the direct evidence for these propositions is limited and based on experimental tasks posing highly unusual and extreme situations (e.g., eating your dog; incest). Furthermore, developmental data supporting these notions are rarer still. Yet, as others have claimed (Turiel, 2006), processes that look automatic in adulthood may appear so because they have been deliberated and negotiated during childhood, thus becoming habitual over time. In addition, the intuitive viewpoint of morality does not help

to understand the sometimes difficult deliberations that children, adolescents, and adults engage in when making complex moral decisions.

Justice Versus Interpersonal Care

Interest in gender differences in morality has ebbed and flowed over the years. Gilligan (1982) pointed to statements that Freud, Piaget, and Kohlberg all made regarding gender differences in morality suggesting that morality in females is inferior to that in males. Gilligan (1982) argued instead that females and males have different moral orientations and that characterizations of females’ moral orientations were undervalued. More specifically, she proposed that Kohlberg’s moral reasoning stages, which focus on the developing understanding of justice, were characteristic of males, whereas females develop a morality of care entailing responsibility to others, the need to avoid harm, and the self as embedded in relationships. Gilligan believed that care reasoning was overlooked in theories of moral development because the prominent theorists were males and because Kohlberg’s theory was originally developed with a sample of boys.

Although Gilligan’s hypotheses generated a storm of interest, she conducted little systematic investigation of her hypotheses, relying primarily on exemplars of boys’ and girls’ reasoning. Extensive research in the 1980s and 1990s, as well as a meta-analysis of studies (reviewed by Walker, 2006) investigating her claims led to the conclusion that there are few systematic sex differences in children’s moral reasoning. In fact, much research revealed that both males and females value justice (e.g., equal rights) and care (e.g., family responsibilities). Indeed, the proposition that fairness is a male orientation ignores the significant efforts women have made to fight for their own just, fair, and equitable treatment. However, Gilligan’s work called attention to the need to include care, compassion, and others’ welfare in definitions and assessments of morality. These views have become integrated into current conceptions of morality and moral development.

Cultural Relativism Versus Cultural Generalizability

Finally, the issue of culture and context is fundamental to the study of morality, and there have been dramatic changes over the past several decades in how these issues have been conceptualized and studied. Culture is central on many levels. Cultural norms and ideologies often provide frameworks for considerations of who is worthy of or should receive fair treatment, as reflected in concepts of personhood, the status of nonhuman animals,

the relationship of humans to nature, and many other fundamental components of moral decision-making. Conceptually, the ways in which cultural ideologies frame, influence, and contribute to moral development continue to be extensively debated.

Defining morality in terms of cultural norms, however, runs the risk of relativism. Spiro (1987), an anthropologist, pointed out that some positions on relativism have a prescriptive basis, such as “one should not impose one’s values on other groups and cultures; each society has its own morality.” Spiro (1987) argues that this form of relativism is actually a call for tolerance, rather than an extreme form of “anything goes.” Moreover, acts of genocide, violations of human rights, and war crimes are viewed as wrong by most individuals around the world, because they involve suffering inflicted on others. At the same time, supporting universalism does not mean that cultural norms are unimportant or are not influential in morality. Cultural norms provide challenges and obstacles as well as protective factors in daily life and must be understood in relation to morality.

Use of expansive categories such as individualism versus collectivism (Shweder et al., 2006) to characterize cultures has declined over the past few decades. Instead, researchers have focused more on within-culture studies and have examined how different characteristics coexist within cultures (and within individuals; see Oyserman, Coon, & Klemelmeier, 2002; Wainryb & Recchia, 2014). Nonetheless, cultural psychology has been influential in pushing developmental scientists to broaden the samples used to study morality. For this reason, and because so many studies on morality include diverse cultural samples, we have incorporated issues of culture throughout the chapter rather than isolate culturally relevant studies in a separate section. In the next section we begin our review of the six central areas of morality and development covered in this chapter.

THE ROOTS AND EARLY EMERGENCE OF MORALITY

An understanding of moral development requires an examination of its origins. Documenting the roots of morality is important because it addresses fundamental questions about the role of nature and nurture and the evolutionary basis of behavior. We do not take a position here on what aspects of morality are uniquely human. Yet, the types of evidence supporting both continuity (what we share

with other species) and discontinuity (what makes humans unique) are relevant for morality, given that both developmental and comparative psychologists are interested in charting the origins of sociality.

In fact, current research demonstrates that infants are social beings from the very start, before there is much opportunity for imitation or the ability to learn from modeling. While research on the early roots of morality does not negate claims that these processes are important in moral internalization, it demonstrates that children have moral propensities at very early ages.

Early Origins: Awareness of Moral Categories in Infancy

The distinction between *sociality* and *morality* is crucial for interpreting research relevant to the origins of morality. All social behavior is not necessarily moral behavior; the bar for what counts as moral is more stringent and includes an obligation to treat others in a fair and just manner. Much of the research on the early roots of morality focuses on cooperation and prosocial behavior. Because these behaviors lack a prescriptive, obligatory basis, questions have been raised about whether these constitute moral behaviors—or positive socially oriented behaviors that contribute to the development of morality. Nevertheless, social awareness is a central prerequisite for morality. For this reason we review literature on early sociality that bears on moral development.

Recent research shows that infants spontaneously engage in social interactions without extrinsic rewards and orient toward helping and caring for others. Evidence for sociality in infancy is extensive and includes a wide range of behaviors, such as having intentional goals toward others (Woodward, 2009), engaging in reciprocal and positive interactions in family contexts (Dunn, 2014), helping others in the second year of life (Brownell, 2013), and responding to the distress of others (Hastings et al., 2014). Due to limitations in the types of responses obtainable from preverbal infants and toddlers, recent evidence has been experimental and laboratory-based, employing a constrained set of behavioral responses (for instance, looking time in infants; reaching behavior in toddlers). This is in contrast to early foundational studies of infant behavior, such as Piaget’s (1952) naturalistic observations of his own children’s reaching, grasping, and finding objects, and Bowlby’s (1969) studies of attachment, which documented children’s needs to maintain proximity to their caregivers in threatening situations.

Once children reach preschool age, the responses available to researchers widen to include verbal reasoning and judgments, spontaneous peer interactions, and responses to social dilemmas in the context of experimental situations. Next we focus on the roots of morality in infancy and early childhood, considering three areas: awareness of others' welfare (physical and psychological harm); awareness of equality, equity, and fairness (resource allocation and turn-taking); and children's cooperation, helping, and empathy.

Awareness of Others' Welfare

Research by Zahn-Waxler, Hastings, and their colleagues (Hastings et al., 2014) has demonstrated that toddlers respond to others' distress and make overtures to help, revealing an orientation toward concern for others. These studies have developed a standard experimental paradigm where an adult experimenter feigns accidental self-harm (cutting one's finger on a board or hurting one's knee and crying "ouch!"), and coders measure toddlers' responses to the experimenter's distress. Research employing this paradigm has found that, by 14 months of age but not before, infants show both nonverbal and verbal concern for the adult. This benchmark reflects toddlers' spontaneous response and orientation to help another without adult encouragement, extrinsic reward, or instructions.

Recently, Davidov, Zahn-Waxler, Roth-Hanania, and Knafo (2013) have called into question the assumption that concern for others does not emerge until the second year of life. Contrary to previous theories, they report that self-other differentiation is evident in 1-year-olds. For example, infants show more distress in response to another infant's cries than to their own (Dondi, Simion, & Caltran, 1999). Davidov and colleagues (2013) refer to these forms of self-other distinction as implicit rather than explicit (e.g., as evidenced by touching one's rouged nose in the mirror). Along with others, they view the self-other distinction as a prerequisite for responding to another's distress. Thus, they argue that their findings provide the basis for responding to the distress of another even earlier, in infancy, than presumed before.

While prosocial responses are a central aspect of morality, more research is needed to document when young children view acts as wrong because of the harm caused to another person and the experience of harm felt by a potential victim. A new line of research with infants provides more information on this issue. To measure whether infants under one year of age distinguish between positive and negative acts toward another agent,

Hamlin and her colleagues conducted experiments that measured whether 6- and 10-month-old infants preferred to look at a "helper" or a "hinderer," depicted in a short video where two blocks moved together up a steep incline (Hamlin, 2013; Hamlin, Wynn, & Bloom, 2007). A round-shaped block (animated with eyes) moved, while another square block nudged it from behind. On separate trials, infants watched the same round block move up the incline but with a triangular-shaped block pushing the round block back down the incline, thus hindering its actions.

The research examined whether infants would view the former actions as "good" and the latter actions as "bad" (for a review, see Wynn & Bloom, 2014). Findings showed that infants preferred to look at the helper longer and reached for the "helper" rather than the "hinderer" when given the option to choose. Other experiments have shown that infants will reach for puppets demonstrating prosocial rather than apparently antisocial intentions (Hamlin, 2013). These prosocial orientations, as measured by visual preference and behavioral reaching, are seen as providing evidence for an innate basis for morality. Although these findings have generated some controversy, the surprising aspect of the Hamlin et al. studies is the very early ages (6–10 months) at which human infants reveal an agent-oriented (social object) rather than object-oriented preference. This early agent-oriented set of behaviors may provide the basis for the development of evaluative rules about the prescriptive treatment of others, but further research is needed to demonstrate this by making direct connections between the types of responses observed in infants and in young children's moral judgments.

Research by Warneken and Tomasello (2009) with toddlers has shown that 14-month-olds will help an adult stranger open a box, get a pencil, and solve a problem when the adult looks mildly distressed or confused. Whether toddlers' behaviors reflect responses to the distress of an adult or prosocial actions designed to help another is not fully known, but the data have provided further evidence that responses to another's concern are evident very early in development (Warneken & Tomasello, 2009); importantly, these behaviors are not performed simply to obtain external rewards. Further research is needed to determine whether toddlers view it as necessary or obligatory to help and wrong if one does not. Research with toddlers has shown that they evaluate moral and nonmoral social interactions differently (Smetana, 1984), indicating that their sense of obligation emerges during this age.

Awareness of Fair and Equal Resource Allocation

Children's understanding of fairness is a central moral concept that also emerges in early childhood. Foundational research by Damon (1977) documented moral understanding regarding the fair distribution of resources by middle childhood. More recent research has investigated whether a preference for the fair allocation of resources, or an understanding of the wrongfulness of unfair allocation, emerges in infancy and early childhood. A range of approaches and methods drawing on behavioral economics (Fehr, Bernhard, & Rockenbach, 2008), comparative psychology (Brosnan & de Waal, 2012; Warneken, Lohse, Melis, & Tomasello, 2011), cognitive development (Geraci & Surian, 2011), and moral development (Cooley & Killen, *in press*; Smetana, 1985) have shown that children younger than the age of 6 years have a preliminary understanding of the importance of distributing resources equally or equitably.

Research on fairness in young children from various disciplinary perspectives has addressed somewhat different questions. Research from behavioral economics aims to demonstrate how individuals (mostly adults) maximize the best outcome given a range of possible strategies to achieve this goal. It also examines the strategies individuals use when playing the Dictator game, which involves choosing among multiple options for maximizing an advantageous outcome; the paradigm has been modified and simplified for children in several studies (Gummerum, Hanoch, Keller, Parsons, & Hummel, 2010). In contrast, evolutionary perspectives draw on cross-species and phylogenetic data, using behavioral tasks to address the central question of the origins of human cognition. In this view, resource allocation is viewed as an adaptive mechanism in development (Brosnan & de Waal, 2012). In contrast, the focus of infant cognition research is to determine how early in ontogenesis humans can discriminate between different stimuli that reflect constructs such as morality, albeit in a preliminary form. These studies rely on visual habituation and visual looking time to demonstrate preferential knowledge.

Geraci and Surian (2011) examined infants' (10- to 16-month-olds') preferential looking and behavioral choices to the outcomes of computer-animated events depicting equal and unequal distribution of resources. Older infants looked longer at the fair than at the unfair distributor. In addition, infants in the older group—but not the younger group—were more likely to pick up a toy that was identical to the computer-generated image of the fair rather than the unfair distributor. The researchers concluded

that a preference for fair distribution is evident in infancy. Furthermore, the authors noted that the results were consistent with other recent studies involving nonhuman primates; capuchin monkeys showed negative reactions to unequal reward distributions in exchanges with human experimenters (Brosnan & de Waal, 2003). In addition, monkeys refused to participate if they observed a conspecific obtain a more attractive reward for equal effort. These findings suggest that there is an evolutionary basis for a concern with fairness.

Warneken et al. (2011) showed that when 3-year-old children performed a task together that resulted in a reward, children were more likely to share equally than not, even when the rewards could be monopolized. In the first of several studies, children were more likely to share resources when the rewards were gummy bears rather than stickers, but the researchers did not find a difference between food and nonfood rewards in the follow-up study. These results indicate that there is an emerging sense of equality for distributing rewards, which leads to successful collaborations in early childhood. However, the researchers did not examine why 3-year-olds shared equitably and how this compares with other findings showing benefits to the self or ingroup preference regarding resource allocation; this issue requires further inquiry and explanation.

Moreover, decisions about resource allocation do not occur in a vacuum. A number of contextual features are activated in most allocation contexts, including social relationships, the history of interactions, and group dynamics. When such partner features are included in the research designs, young children weigh these social dimensions in their resource allocation decisions. For example, Olson and Spelke (2008) found that friendship status affected 3.5-year-olds' allocations; young children more often allocated equal resources to puppet friend than nonfriend dyads. Moore (2009) replicated this finding in the same age group when distributing resources to an actual friend. These findings suggest the importance of including relationship contexts and interaction features in this research. Moving forward, measuring social and moral reasoning may illuminate why children prefer one type of choice over another.

Several recent studies have examined young children's reasoning about resource allocation and revealed that young children (prior to the age of 6) understand equality and merit. Baumard, Mascaro, and Chevallier (2012) found that preschoolers focused on effort when they were given the option to distribute a large or small cookie to a hard-working child (who made the cookies) or a lazy

one (who did not). This study revealed a rudimentary understanding of merit in 4-year-olds. Although children were able to match the amount of the resource with greater effort, Baumard et al. (2012) found that children preferred to distribute cookies equally when this option was made available. In fact, only a small minority of children explicitly used merit as the reason for their decision. For example, children who gave the larger cookie to the harder worker often gave nonmoral reasons such as "She has a bigger mouth." These findings suggest that merit-based reasoning emerges slowly in early childhood, with some children acknowledging merit but most preferring equal allocation when given the opportunity to do so.

In another study, young children's preference for equality (equal allocation of resources) was pitted against their loyalty to group norms (Cooley & Killen, *in press*). When asked to divide resources between the ingroup and the outgroup (defined by classroom affiliation), 3.5- to 6-year-old children supported an ingroup member who wanted to divide resources equally, even when the rest of the group wanted to keep more for themselves. Children gave priority to equal allocation over group norms, and used reasons based on equality. With age, children increasingly expected that the group would be less favorable toward the equal allocating deviant than did younger children (even though they were favorable towards this "ingroup deviant"). These results differed from previous research because equal allocation in this study design meant going against their peer group's desire to keep most of the resources for their own group. Young children are willing to challenge an ingroup norm in order to maintain their preference for equality.

Cooperation, Helping, and Caring

Research has also shown that young children cooperate spontaneously. Brownell (2013) pointed to a dramatic shift in cooperation from the first to the second year of life when engaged in nonverbal tasks designed to enable two children to coordinate their actions to obtain a desired toy. Brownell, Ramani, and Zerwas (2006) found that 12- and 18-month-old peers did not take their partners' behavior into account in this task and were not able to cooperate to obtain their goals. However, 24- to 27-month-olds were able to do so successfully and by 30 months, they conveyed information to their peers about what to do. Thus, Brownell and colleagues have documented age-related shifts in the coordination of behavior to cooperate and achieve mutual goals. These findings contrast with those of Warneken and Tomasello (2007), who have shown that 14-month-olds

can cooperate with adults. The differences between these results may reflect differences in the partners (peer or adult) studied, because adults can fine-tune their behavior to accommodate children's intentions. Consistent with Piaget's (1932) claims, Brownell noted that social knowledge created in adult-child and peer exchanges are qualitatively different. Piaget believed that equal relationships between peers provided a basis for the construction of morality, but in the experimental studies demonstrating early cooperation in adult-child encounters, adult experimenters asked children for help in solving a problem and thus functioned more like peers.

Warneken and his colleagues (2006) have conducted other studies comparing children's cooperative behavior (with an adult partner) to that of chimpanzees. These studies examined whether shared intentionality (e.g., when both interacting partners have a joint goal and develop joint attention or plans for achieving their shared goal) is uniquely human. The tasks were nonverbal to facilitate cross-species comparisons. In one study, Warneken et al. (2006) gave 18- to 24-month-old children four tasks involving tools that required cooperation to solve successfully. For example, in one task, a tube with handles had a toy inside, and obtaining the toy required that two people simultaneously pull both ends. The results showed that cooperative behavior has roots very early in childhood. Children were able to cooperate with an adult partner, and the ability to coordinate significantly improved from 18 to 24 months of age. Studying even younger children (14-month-olds), Warneken and Tomasello (2007) demonstrated that infants helped an adult open a box for no external rewards. These studies point to the ontogenetic origins of cooperative behavior.

Vaish, Carpenter, and Tomasello (2010) studied prosocial behavior toward those who helped or harmed others. In many ways, this research is a natural extension of the Hamlin (2013) studies into early childhood. Vaish et al. (2010) recorded children's behavior while observing an adult who helped the recipient (by picking up the fallen objects) or harmed another child (by breaking necklaces, or tearing up pictures made by the other child). Children took into account another's harmful actions when deciding whether or not to help them. Children were less likely than would be expected by chance to help the adult who acted harmfully, but no differences were found for the adult who helped. The authors acknowledged that children may have been afraid of the harmful adult and thus acted out of self-protection rather than in response to moral concerns with fairness and rights.

To partially address this possibility, Vaish, Missana, and Tomasello (2011) investigated 3-year-old children's interventions in third-party moral transgressions using the same experimental paradigm but involving two puppets (not an adult). Children either observed a puppet destroy a picture made by another puppet or watched another puppet act in a similar manner without destroying the puppet's picture. Children protested the destruction of the picture and tattled on the actor; they behaved more prosocially toward the recipient who had an object destroyed than the one who did not. Thus, as young as 3 years of age, children protested another agent's moral transgressions.

Most of the studies reviewed here involve behavioral measures of cooperation, allocation decisions, or refraining from helping a harmful adult but do not reveal why children acted as they did. An interesting and important next step in this research would be to connect these behavioral responses with children's reasoning about their preferences and choices. This would add more information about children's motives and intentions regarding helping and cooperation, as well as their interpretation of these events. In the next section, we discuss research that includes young children's reasoning about issues of fairness, equality, and others' welfare; these issues will be expanded in the following section on moral reasoning and judgments.

Moral Judgments in Early Childhood

Researchers have conducted experimental and observational studies to determine whether children's decisions and methods of conflict resolution, evaluations of rule transgressions, and responses to peer and adult protests reflect an understanding of moral concerns about fairness, equality, and harm (Nucci & Nucci, 1982). In studies of conflict resolution, for example, young children left to play with toys on their own and in the absence of adults have been shown to use moral reasons about fairness when discussing object disputes, despite expectations from adults that they would resort to aggressive strategies (Hay, 2006; Ross & Conant, 1992). In fact, during adult-supervised activities, children are more likely to turn to teachers to resolve conflicts rather than to use collaborative modes of discourse to bargain, compromise, and trade toys, as documented in peer exchanges (Killen & Turiel, 1991).

Further, young children 2.5 to 6 years of age increasingly use verbal information to identify ownership when playing with toys. Blake, Ganea, and Harris (2012) found that by 4 years of age, children interpreted third-person statements, such as "That's Billy's ball," as more reliable

cues to ownership than first-person statements, such as "That's my ball." In a related study, Blake and Rand (2010) found that children's preferences regarding resources affected children's willingness to donate stickers; children donated their least favorite more often than their favorite stickers. These findings reveal that children use information regarding ownership and value preferences to determine how to allocate resources and that they considered these factors more with age.

A number of studies have employed structured interviews with preschool children to obtain their evaluations of straightforward, hypothetical, and prototypical moral violations (for instance, hitting, teasing, or taking another child's toys) as compared to conventional violations (such as standing during naptime, wearing pajamas to daycare, or not saying "please"). These studies provide robust evidence that by about 3 years of age and more consistently by the age of 4, young children distinguish moral from social conventional violations; both forms of transgressions are also understood as distinct from issues of personal jurisdiction and autonomy (see Smetana, 2013; Smetana, Jambon, & Ball, 2014, for reviews). For example, children treat moral transgressions as more generalizable wrong (e.g., wrong across several contexts) and more wrong in the absence of rules and authority sanctions than social-conventional transgressions. These distinctions have been validated in a wide range of cultures, including samples from North America, China, Central and South America, Europe, and the Middle- East (see review by Smetana, 2013). For instance, in interviews with 4- and 6-year-old Chinese children from lower socioeconomic status families in Hong Kong, Yau and Smetana (2003) found that all children viewed prototypical moral transgressions as more serious, more wrong across contexts, and more wrong independent of authority than conventional events, based on justifications regarding the harmful or unfair consequences of the events for others. They also distinguished personal domain events from both moral and conventional ones. Children in Cartagena, Colombia, as well, viewed moral transgressions about harm as distinct from conventions and issues about personal choice (Ardila-Rey & Killen, 2001). Thus, these studies reveal that these distinctions are broadly applicable across diverse cultures.

Young children also treat harm to others (such as a child pushing another child off a swing) as more wrong than harm to the self (such as when a child purposely jumps off a swing), even when violations have similar consequences (Tisak, 1993). Indeed, children treat moral transgressions as more wrong even when prudential violations have

more severe consequences than moral ones or when the consequences of moral violations are depicted as minor (Tisak, 1993). Thus, these judgments are not based on severity but rather on whether acts cause harm to others as opposed to the self.

Most of the research on moral judgments in early childhood has been cross-sectional, but recently, Smetana and her colleagues (Smetana, Rote, et al., 2012) examined longitudinal changes over 1 year in 2.5- to 4-year-olds' judgments regarding prototypical moral transgressions. At the first of the three assessments, children (divided into two age groups for this analysis) distinguished moral and conventional rules and transgressions on nearly all of the criteria studied (although younger children did not make this distinction in terms of deserved punishment). Furthermore, age-related changes in the acquisition of moral concepts based on these criteria as well as individual differences in the rate of growth were found. Thus, these findings suggest that robust domain distinctions are evident early in development and that different experiential factors influence how moral concepts are conceptualized and consolidated in early childhood.

Furthermore, experimental studies have demonstrated that children make moral judgments and distinguish moral from conventional rules on the basis of their features rather than their knowledge of the specific content of acts. When young children (3-year-olds) were asked to evaluate events that were unspecified and labeled using nonsense words, they made moral judgments when acts were depicted as wrong across contexts and having consequences for others' welfare. In contrast, they made conventional judgments when acts were described as contextually relative and prohibited by adults although they did not cause harm or violate rights (Smetana, 1985). These findings are consistent with studies described earlier showing that young children are concerned about harm and unfairness.

Preschool children's moral understanding also differs according to whether they were the victims or perpetrator of transgressions. Wainryb, Brehl, and Matwyn (2005) obtained preschoolers' (as well as 5-, 7-, 11-, and 16-year-olds') narrative descriptions of moral conflict situations where they either hurt or were hurt by a peer. Their extensive analyses demonstrated that children's descriptions became more complex with age, but they also varied as a function of whether children narrated experiences as victims or perpetrators. When reporting being victimized, children primarily focused on the harm inflicted on them and on their own emotions. In contrast, when narrating experiences as perpetrators, and increasingly with

age, children offered more complex narratives that focused on their own and the victim's experiences and included a broader range of concerns and emotions.

In keeping with these findings, preschool victims of actual moral transgressions (as observed in their preschool) rated those transgressions as more serious and more deserving of punishment than did the same children, when they were violators. However, when children were in the role of transgressor, they viewed their behavior to be more justified than they did when they were victims (Smetana, Toth, et al., 1999). The factors that contribute to different attributions of these situations warrant further examination.

In some studies, children apply moral criteria at younger ages when the moral events reference physical harm than when these events pertain to psychological harm or unfairness (see Smetana et al., 2014, for a review), but more research is needed to understand why children apply moral criteria at earlier ages to acts involving physical than psychological harm or unfairness and why some transgressions are more complex for children to understand.

Summary: Roots and Early Emergence of Morality

Over the past decade, there has been a substantial increase in interest in studying the early roots of morality in infancy and early childhood. This research has been motivated by a variety of different theoretical perspectives and concerns and has drawn on new methods developed for research with preverbal infants and young children. Studies of the fair allocation of resources, others' welfare and harm, and cooperation provide compelling evidence that children are attuned to moral concerns at very early ages. Thus far, however, little research has connected these very early predispositions to the development of moral concepts across different ages. This is a crucial next step for research and will be important for understanding trajectories of moral development across the lifespan.

At present, the early developmental story is intriguing but remains incomplete. More expansive criteria are needed for defining what "counts" as a moral behavior or response, especially in infancy, and particularly for the distinction between moral and prosocial responses. In addition, there has been little attention to issues of generalizability across different ethnic groups, cultures, and socioeconomic statuses. This may stem from the theoretical assumptions motivating these different lines of research, particularly the assumption that these reflect universal moral developmental achievements. These issues warrant further empirical attention.

Finally, the studies of early moral judgments reviewed in this section indicate that children make distinctively moral judgments regarding both hypothetical and actual prototypical transgressions when they are straightforward and involve simple connections between intentional acts and the negative outcomes produced. As we discuss in the following section, however, an understanding of others' mental states is needed to appreciate more complex situations, where the links among acts, intentions, and outcomes are less straightforward.

MORALITY AND KNOWLEDGE ABOUT MENTAL STATES

Over the past 10 years, there has been a great deal of new research examining the role of mental state knowledge in young children's moral development. This research has increased our understanding of both the limitations and emerging competencies in young children's morality and the developmental processes that may underlie them. In this section, we describe studies on theory of mind, psychological knowledge, and intentionality awareness as they bear on morality.

The notion that children's understanding of others' mental states may be implicated in children's developing morality is not new. Piaget (1932) was among the first to recognize the importance of children's psychological understanding in the development of moral judgments. As noted earlier, he believed that young children have a limited understanding of intentionality but that with age, they begin to consider actors' intentions in their moral judgments. These claims were extensively tested and expanded in the 1970s and 1980s, but as interest in Piagetian stage theories waned, research on the role of psychological knowledge in moral judgment development languished. Although research on theory of mind has flourished over the past 25 years, research and theorizing about the intersections between theory of mind and moral development has been quite recent (Chandler & Lalonde, 1996; Wainryb & Brehl, 2006; Wellman & Miller, 2008).

Despite ongoing theoretical debates about the nature of and processes involved in theory of mind, there is a fair amount of convergence in descriptions of the developmental trajectory of children's mental state understanding (see Hughes & Devine, Chapter 14, this *Handbook*, this volume). Infants evidence goal-directed behavior during the first year of life, reflecting an early precursor of intentionality and of children's psychological understanding more generally (Wellman, 1990; Woodward, 2009).

Most research on children's developing psychological knowledge has focused on achievements during the pre-school and early school years, especially the development of an understanding of false beliefs, although some researchers have shown that psychological understanding continues to develop well beyond these ages (Chandler & Lalonde, 1996). Mental state knowledge has been shown to develop in a fairly predictable sequence (Wellman & Liu, 2004), although some cultural differences have been found in the ordering of specific abilities (Fang, Wellman, Liu, Liu, & Kang, 2009). More generally, development is seen as reflecting a shift from a view of the mind as a copy of reality to a more active and constructivist view (Chandler & Lalonde, 1996; Wainryb & Brehl, 2006). Thus, children come to understand that their view of the world may differ from others' and that individuals actively interpret their experiences based on their beliefs and expectations.

There is less agreement about which theory of mind abilities are implicated in moral development and the nature of their interrelationships. Associations between mental state knowledge and children's moral understanding (and behavior) typically have been examined by studying children's responses to hypothetical, morally salient stories (sometimes but not always associated with theory of mind tasks). Some studies have also examined children's discourse or narratives for evidence of young children's use of mental state language. Increasingly, researchers have employed behavioral tasks or tasks that require minimal verbal ability (Vaish et al., 2010). Most of the research on intersections between theory of mind abilities and morality has focused on young children. This is changing, though, as we will demonstrate, with new measures allowing for investigations of mental state knowledge in middle childhood and adolescence.

In their research on references to mental states when discussing the roles of victims and perpetrators, Wainryb and her colleagues (2005) concluded that young children are unable to grasp the psychological aspects of their moral conflicts. References to mental states increased from the ages of 5 to 16 years (at which point half of their accounts include such references), and the large majority of older children's narratives focused on both their and others' beliefs, intentions, and emotions as they interpreted situations and tried to figure out what was happening.

False Beliefs, Diverse Beliefs, and Moral Judgments

Because the capacity to understand false beliefs is often seen as a hallmark in the acquisition of theory of mind in

childhood, a number of studies have focused specifically on how acquiring this understanding results in advances in moral judgments. For instance, Takagishi, Kameshima, Schug, Koizumi, and Yamagishi (2010) found that preschoolers who passed a standard false belief task proposed more equitable solutions than those who did not. Because more than a third of the children who failed the false belief task also proposed fair offers, the researchers concluded that mental state understanding may enhance fairness in this context but may not be a necessary condition for it. Yet, an explanation for why false belief knowledge might spur greater fairness remains to be delineated.

In a study of 4-year-olds, Dunn, Cutting, and Demetriou (2000) also found associations between false belief understanding and children's understanding of moral transgressions. These researchers found that more advanced false belief understanding as assessed on standard theory of mind tasks was associated with greater use of moral justifications focusing on the welfare and feelings of others when considering hypothetical victims of moral transgressions. Thus, Dunn et al. (2000) viewed children's understanding of other minds (as well as their emotion understanding) as central to the development of moral understanding.

Flavell and colleagues (Flavell, Mumme, Green, & Flavell, 1992) viewed the standard assessments of false belief understanding as reflecting only one type of false belief and examined commonalities between "factual" false beliefs and differences of opinion regarding conventional or moral values and property ownership beliefs. Children's understanding of these different beliefs was highly correlated, leading these researchers to conclude that the ability to appreciate diverse beliefs is applied in similar ways to different content domains. Furthermore, consistent with other research (Wellman & Liu, 2004), Flavell et al. (1992) found that 4- and 5-year-olds but not 3-year-olds were able to attribute different beliefs (including those about morality) to others.

Yet, Wainryb and Ford (1998) have asserted that moral judgments may change in ways that go beyond what would be expected based simply on cognitive advances in theory of mind. Children's developing psychological understanding may constrain but not necessarily predict children's moral judgments. These researchers examined the role of 3-, 5-, and 7-year-olds' moral beliefs and informational (factual) beliefs in making moral judgments. They found that 3-year-olds were unable to grasp that others held divergent beliefs of either type; in contrast, older children were able to correctly attribute different moral and informational beliefs to others. Further, with age, an understanding that

others may have different factual (but not moral) beliefs led to greater acceptance of unfair or harmful practices. Wainryb, Shaw, and Maianu (1998) found that tolerance increased with age, but acceptance of divergent moral and informational beliefs varied in complex ways depending on whether individuals were depicted as holding different beliefs, publicly expressing them, or acting on them.

Killen and colleagues (Killen, Mulvey, Richardson, Jampol, & Woodward, 2011) proposed that when false beliefs are embedded in morally relevant situations, different (and potentially more complex) considerations are implicated than when considering factual false beliefs. This notion was tested by directly comparing an understanding of false beliefs separate from moral judgments among children at 3.5, 5.5, and 7.5 years of age. A novel aspect of the study was the use of three separate measures: a prototypical moral judgment task, a factual false belief task, and a morally relevant false belief task. The findings revealed that morally relevant false beliefs were more challenging than standard false beliefs. Further, children who failed standard false belief tasks also incorrectly believed that the accidental transgressor's moral behavior was intentional, leading to judgments of greater harm and more deserved punishment.

Although all children evaluated the prototypic moral transgression as wrong, they did not fully understand accidental harm embedded in a false belief context until 7 years of age. Thus, successfully passing the morally salient false belief task accounted for some but not all of the age-related differences observed in children's moral understanding. Children's developing mental state understanding influenced their construal of the situation. In a follow-up study conducted with Chinese children, Fu, Xiao, Killen, and Lee (2014) replicated the U.S. findings and determined that second-order theory of mind was related to older children's moral judgments. These studies implicate the importance of intentionality in moral judgments, an issue we more fully explore in the following section.

Understanding of Intentionality and Moral Judgments

Piaget's initial insights regarding children's understanding of intentions (versus outcomes) in their moral judgments generated a great deal of research. Contrary to Piaget's findings, research has consistently shown that children as young as 3 years of age can take intentions into account and distinguish intentional from accidental transgressions, as long as information about intentions is made explicit

and intentions are not confounded with outcomes (Helwig, Zelazo, & Wilson, 2001; Zelazo, Helwig, & Lau, 1996).

Researchers such as Zelazo et al. (1996) have argued that the ability to coordinate intentions, acts, and outcomes is constrained by more general cognitive changes in children's information-processing abilities or executive function and their ability to coordinate different rules—abilities that are thought to increase between the ages of 3 and 7 years. In a clever study design, Zelazo et al. (1996) examined children's moral evaluations in situations entailing normal causality (e.g., hitting causes pain) or unusual or noncanonical causality (e.g., hitting causes pleasure). They found that 3-year-olds judged the acceptability of acts and the amount of punishment deserved based on the objective aspect of the situations (e.g., on the basis of the outcome or harm caused), even in noncanonical situations. However, children's ability to integrate different kinds of information and use higher order rules in making moral judgments increased with age during the preschool years. Other research has shown that, as children grow older, they increasingly distinguish intentions from other mental states such as desires, although they do not fully understand this distinction until around 7 years of age (Schult, 2002).

Until middle childhood, children lack the ability to fully integrate the information necessary to make accurate judgments in more complex situations, for instance, those that include considerations of negligence. This was demonstrated in a novel study by Nobes and colleagues (Nobes, Panagiotaki, & Pawson, 2009). They investigated 3- to 8-year-olds' coordination of information about intentions, consequences, and acts performed as a result of negligence. Nearly all children considered ill-intentioned acts to be wrong and deserving of punishment even when due to negligence, but with age, they were better able to distinguish between well- and ill-intentioned acts. In addition, 3- to 6-year-olds often misattributed negligence to transgressors, even when they were described as careful and not intending to cause harm.

Studies also have shown that preschool children's judgments of intentionality vary as a function of whether acts lead to negative moral outcomes (that is, whether the foreseen consequences of the act are harmful, or caused an actor to feel happy or sad). In a paradigm developed with adult samples, Leslie, Knobe, and Cohen (2006) demonstrated that 4- and 5-year-olds (but not 3-year-olds) judged that a foreseen side effect was intentional when that side effect was morally negative (for example, making someone sad), even when that actor was described as not intending to cause those consequences or not caring

about them, but not when the side effect was positive (for example, making someone happy). Thus these researchers asserted that this "side-effect effect" is evident by 4 or 5 years of age. Furthermore, the asymmetrical nature of children's intentionality judgments appears robust, regardless of different ways of manipulating the explicitness of the foreknowledge (Pellizoni, Siegal, & Surian, 2009).

As these studies suggest, the vast majority of research examining intersections between morality and theory of mind have focused on children between the ages of 3 and 7 years. Yet, an understanding of mental state knowledge continues to develop beyond age 7 years. Recently, Jambon and Smetana (2014) extended this to examine 5- to 11-year-olds' ability to coordinate the psychological perspective of others in their moral evaluations of situations of "necessary harm," or harm that is well intended and done to prevent additional serious harm. With age, children increasingly understood that causing harm to others may be morally justifiable in certain circumstances, based on justifications regarding the actor's positive motives and intentions. As children grew older, they demonstrated a greater tendency to coordinate competing concerns, particularly when considering psychological as compared to physical harm. Thus, along with others, Jambon and Smetana (2014) asserted that children's developing understanding of others' mental states allows for the emergence of novel, more complex patterns of moral thought but that this understanding does not in itself determine children's evaluations of particular moral situations.

The studies reviewed in this section converge to show that children's understanding of intentionality increases during middle childhood, especially when intentionality is embedded in complex moral situations involving multiple components.

Desires, Emotions, and Moral Judgments

Studies of how children coordinate intentions or desires with their emotions have yielded new findings about their understanding of intentionality. Extending research on children's concepts about others' desires in the moral domain, Yuill, Perner, Pearson, Peerbhoy, and Ende (1996) examined children's attributions of emotions in moral situations that vary the actor's desires and whether or not the actor achieved the desired outcome. These researchers sought to integrate children's understanding of others' "wicked desires" and associated emotions with research on "happy victimizers" (Arsenio, 2014). This research has revealed that young children (but not older ones) believe

that victimizers will feel happy when they obtain material resources through aggressive means.

Yuill et al. (1996) found that 3-year-olds judge that actors with bad motives feel sad, even though they have achieved their desired outcome. However, by 5 years of age, children matched desires and outcome in bad-motive stories and judged that moral transgressors would feel happy when negative outcomes were realized, as research on happy victimizers would suggest. But older children (7-year-olds) shifted back to believing that actors feel sad (remorseful). Thus, as found in studies of false beliefs, young children appear to evaluate the transgressor's emotions on the basis of the objective value of the outcome, but with age, they become able to fully understand the implications of moral transgressions for moral emotions. Likewise, when examining children's emotion and behavior predictions in situations involving psychological harm, Helwig et al. (2001) found that 3-year-olds evaluated psychological harm in terms of the objective aspects of the situations (for example, outcomes). With age, 5- and 7-year-old children focused on intentions or were able to coordinate intentions and outcomes.

Lagattuta (2005) has conducted a number of studies to examine how emotion attributions bear on children's social and moral cognition. For example, Lagattuta noted that the fulfillment of desires in transgression situations may lead to positive emotions, whereas focusing on rules may lead to negative emotions, because one has failed to follow the rules. She demonstrated that in early childhood, children develop the ability to coordinate an understanding of links between emotions and desires (for example, getting what one wants feels good) with an understanding of moral obligations in prohibitive rule situations (Lagattuta, 2005). When there were no rules, 4- to 7-year-olds reported very positive emotions associated with fulfilling their desires, but they reported feeling less positive when fulfilling desires by breaking rules. In situations involving emotions and desires with rules, 4- and 5-year-olds attributed positive emotions to rule-breakers (much as Yuill et al., 1996, found), with increasingly positive or mixed emotion attributions with age to hypothetical actors who were depicted as using willpower to abstain from rule breaking. The most dramatic shift in making connections among desires, rules, and emotions—as well as in employing mental state language—occurred between 5 and 7 years of age, when children, like adults, attributed positive emotions to actors who exhibited willpower and desisted from transgressing, while attributing negative emotions to transgressors. This approach to the development

of moral judgment includes social cognition as well as emotion attributions.

Direction of Effects Between Moral Judgments and Theory of Mind

Although the research reviewed thus far is almost entirely cross-sectional, it has been guided by the assumption that the development of children's mental state understanding leads to changes in children's moral understanding. However, there is also evidence for reverse causation; several researchers (Knobe, 2005; Leslie et al., 2006) have found that the presence or absence of negative moral outcomes influenced whether preschool children viewed acts as intentional. Smetana, Jambon, Conry-Murray, and Sturge-Apple (2012) explicitly examined connections between theory of mind as assessed using standard theory of mind tasks and moral judgments longitudinally over one year in a sample of 2.5- to 4-year-olds. Using cross-lagged path models, the researchers found that the direction of effects depended on the specific moral criterion judgment examined. Some of the moral criterion judgments led to greater theory of mind understanding, but, over time, children also came to view prototypical moral transgressions as less deserving of punishment and as less wrong (although still unacceptable) when they conflicted with school rules. This is consistent with past research suggesting that children come to make more forgiving moral judgments with age (Jambon & Smetana, 2014; Killen et al., 2011). Thus, young children's psychological understanding and moral judgments appear to be transactional, bidirectional processes. Moral experiences may provide children with opportunities that facilitate their understanding of others' minds, which in turn serves to inform and guide the development of moral thinking.

Neuroscience of Intentionality and Morality

With the expansion of neuroscience research more generally, there has been an outpouring of interest in the biological basis for thinking about intentionality and morality. Much of the innovation in this research has come from the development of methods, such as the use of functional magnetic resonance imaging (fMRI), which has only recently been used with children and adolescents rather than solely with adults. The findings of studies on mental state understanding and morality have been examined in recent research combining assessments of children's judgments of intentional versus accidental harm,

depicted as involving damage to people or objects, using neurophysiological measures (Decety & Howard, 2014; Decety, Michalska, & Kinsler, 2012; Young & Saxe, 2011). In an ambitious project that included participants from preschool-aged children to adults, Decety and colleagues (2012) yoked responses to morally laden scenarios with assessments of neurophysiological reactions, obtained using eye tracking and fMRI data. Decety et al.'s (2012) youngest participants were able to correctly identify whether an action was intentional or not and rated harm to persons as more wrong than harm to objects.

Ratings that intentional harm was more wrong than accidental harm to persons increased with age and also were associated in a curvilinear fashion with signal changes in the amygdala. Amygdala responses, which are associated with emotion processing, declined with age in childhood and then increased into adulthood. In contrast, among older participants, signals in the dorsolateral prefrontal cortex and medial prefrontal cortex increased. As these latter brain regions are associated with metacognitive representations, the findings reflect an increased integration between the prefrontal cortex and the amygdala (e.g., between emotion and cognition). Thus, evaluations of whether an act is morally salient or not depends on more than affective sensitivity; an understanding of others' mental states must be integrated with a representation of the consequences of actions.

Deception, Lying, and Theory of Mind

The topic of lying is also an important area of investigation. Research has examined changes with age in viewing lying as a moral transgression and their associations with mental state knowledge. As Lee (2013) explains, to lie successfully, "individuals must represent and differentiate the mental states of themselves and the listener, and make appropriate statements to conceal the truth while instilling false beliefs into the mind of the listener" (pp. 91–92). Age trends found in young children's lying in experimental resistance-to-temptation situations (e.g., being told by an experimenter not to peek or play with a toy when the experimenter leaves the room) are consistent with developmental trends in theory of mind understanding. While the majority of 2- to 3-year-olds who violate an experimenter's instructions confess their transgressions, older children often lie (stating that they did not peek or play with the toy). Their lies have been interpreted as efforts

to deceive the experimenter (Lee, 2013). Furthermore, older preschoolers (4- to 5-year-olds) are more likely than 3-year-olds to confess if there was an eyewitness to their transgression (Fu, Evans, Xu, & Lee, 2012), and young children who lie have been shown to have better false belief understanding than those who confess (Evans, Xu, & Lee, 2011).

In addition, and further revealing the role of intentionality in lying, there are developmental changes between 2 and 7 years of age in how children respond to follow-up questions about their lies. Although 2- to 3-year-olds are not good at covering up their lies and make blatantly inconsistent statements, as they grow older, children grow less clumsy and inconsistent in explaining how they acquired their knowledge of the identity of a hidden toy. As Dunn (2014) has noted, having an understanding of others' mental states can be put to good as well as nefarious ends. For example, lying to avoid being caught touching a forbidden toy has a different moral status from lying to avoid offending someone or to protect another person from danger. Further progress in this line of investigation may be made by studying the intention to deceive in conjunction with the type of act.

Summary: Morality and Mental State Knowledge

Research conducted over the past decade provides robust evidence that children's understandings of others' mental states, as examined in different ways and on various types of tasks, are associated with increasing sophistication in children's moral judgments. In particular, children's ability to consider mitigating circumstances and apply their understanding of others' emotions, intentions, and desires when making moral judgments increases with age, with major leaps in the coordination of different concerns occurring between the ages of 5 and 7 years. Additionally, new methods from social neuroscience have advanced our understanding of the biological bases of these interconnections.

In past research, studies were largely limited to the use of simple responses (e.g., ratings of naughtiness), as associated with early-developing theory of mind competence. Expanding the focus beyond early childhood to include more complex forms of moral and mental state understanding would be fruitful. More research determining whether the ability to coordinate concepts varies as a function of the type of moral acts depicted is also needed.

MORAL JUDGMENTS AND MORAL REASONING

The comprehensive literature on children's moral judgments and reasoning reveals that judgments about the wrongness of physical harm and unfair distribution of resources appear in infancy and toddlerhood. These two moral issues are predominant in early childhood due to their salience and frequency (e.g., hitting and not sharing toys) as sources of disputes, as well as their concrete nature. A large body of evidence now indicates that knowledge of other moral issues typically thought to be too complex for children to understand emerges early as well, although in a rudimentary form. This includes an understanding of psychological harm (such as teasing others), concepts of rights (such as freedom of expression, property ownership, and self-determination), knowledge about unfair treatment of others (such as prejudice, discrimination, and stereotyping), and awareness of social inequalities (such as unfair distribution of resources based on group membership). Thus, children's knowledge reflects various moral categories, which are coordinated (or not) with other concepts such as psychological and societal group issues in the context of moral judgment and decision-making.

Social-Cognitive Developmental Processes

In addition to the role of psychological knowledge (such as intentionality) in moral judgments, children and adolescents become increasingly aware of groups, group membership, and group processes, which bear on the development of morality in multiple ways. Group identity enables children to affiliate with a larger community beyond the family, which is essential for healthy development. At the same time, identification with groups creates ingroup preference that can lead to prejudice and outgroup dislike. In fact, morally relevant issues such as discrimination, exclusion, and prejudice require knowledge about groups, increasing the social-cognitive complexity of these moral judgments. Along with these multifaceted issues are judgments about rights, which require knowledge about the equal treatment of others and basic human needs (e.g., the right to express views freely or the right to self-determination). Further, other social cognitive skills such as processing capacities, attributions of emotions, and understanding of intentional states continue to develop and

bear on moral judgments. We discuss research on these topics in this section.

Straightforward and Complex Social Interactions

Even though judgments about the wrongness of intentionally inflicting physical harm on an undeserving person emerge very early in development, situations entailing harm can be straightforward or complex, regardless of age. Whereas most adults are likely to view prototypic acts of harm, such as the murder of an innocent child, to be wrong, other harmful acts involving provocation, retaliation, and retribution, as well as self-defense, deterrence, and security, may include different (e.g., psychological, societal, and nonsocial) considerations. Thus, the meaning and interpretation of harmful acts must be examined to understand how individuals evaluate and coordinate different types of concerns.

Similarly, for young children, judgments and decisions about how to distribute a few toys between two friends may be relatively straightforward, but concepts of the fair distribution of resources become complex very quickly. Considerations such as the nature of the resource (how necessary it is), the legitimacy of ownership claims, modes of distribution, and relationships among the recipients all bear on resource allocation decisions. In addition, judgments become more complex when different groups or communities have to consider competing claims, goals, and needs for how to distribute fundamental resources. Thus, although there appears to be a developmental trajectory in the types of considerations that individuals weigh when making moral decisions, the developmental picture is also complicated by the fact that there are variations in whether contexts are straightforward or multifaceted and contain different components.

As an empirical example of the distinctions between straightforward and complex events, Turiel (2008) conducted a study in which children's judgments about actual transgressions (on the playground, in the classroom) were compared with their judgments about hypothetical transgressions. The findings revealed that moral judgments were applied to both the actual and hypothetical contexts, but there were also differences between them. Moral transgressions in hypothetical contexts were judged as less permissible and more rule-contingent than in actual situations. Contextual information was brought to bear on judgments in actual situations requiring children to

weigh more diverse sources of information when making their judgments. For instance, knowledge of children's histories of interactions contributed to attributions of blame (e.g., transgressors were judged differently when participants reported that they had been taunted by the presumed victim for several weeks).

In the following sections, we review research on judgments about harm to others, the fair distribution of resources, the unfair and prejudicial treatment of others, and conceptions of rights.

Judgments About Harm to Others

As discussed earlier, research has shown that by early childhood, children judge straightforward acts of harm to be wrong due to the physical or psychological pain such acts inflict on other people. Beyond this, children are able to grasp such factors as the underlying intentions and the deservedness of the recipient. As we have seen earlier, they are also able to apply moral criteria (such as generalizability) to moral acts. In more complex contexts, other considerations are taken into account, such as whether the act was provoked and in retaliation for a previous act. For example, Smetana, Campione-Barr, and Yell (2003) found that U.S. middle-income 6- and 8.5-year-olds judged hypothetical, prototypical (e.g., unprovoked) moral transgressions to be more wrong and more deserving of punishment than provoked transgressions, and more wrong when retaliation involved hitting rather than teasing. However, children's moral condemnation of provocation increased with age. Thus, "in-kind" retaliation was more acceptable than retaliation that was greater in magnitude than the original offense.

Research in Colombia, South America, has examined moral judgments of harm among war-affected children, who had been exposed to high levels of violence, poverty, lawlessness, and displacement. Posada and Wainryb (2008) interviewed 7- to 15-year-old Colombian children living in a poor slum near Bogotá regarding prototypical instances of stealing and physical harm, as well as the same acts in the context of survival and revenge. All children judged it wrong to steal or hurt someone, even when it would help for survival, based on reasons pertaining to justice and others' welfare. However, a sizable proportion endorsed stealing and hurting in the condition of revenge and expected that others would do the same. Whereas younger children expected that the protagonist would feel guilt as well as shame, older children expected a mixture of guilt, shame, and happiness at revenge. Importantly, this study

demonstrates that concerns with others' welfare generalize to more extreme situations, but it also reveals some of the contextual factors that may change the application of moral concepts to different situations involving threats to the self.

To examine the role of socioeconomic status and exposure to violence on concepts of harm, Ardila-Rey, Killen, and Brenick (2009) conducted a study of both low- and middle-income children in Colombia. They found significant differences in 6- to 12-year-olds' moral judgments based on levels of exposure to violence and living conditions. All children viewed acts of harm (hitting) and unfair distribution of toys (not sharing) as wrong using moral reasons (e.g., concerns for others' welfare). However, displaced children from Bogotá shanty towns, who had suffered extreme exposure to violence and who lived in very poor conditions, judged it more legitimate to hit in reaction to provocation or retaliation than did nondisplaced children from Cartagena, who had experienced minimal exposure to violence. Surprisingly and somewhat hopefully, however, all children viewed postconflict reconciliation between the transgressor and recipient as feasible and worthwhile. Astor (1994) found somewhat similar results studying a sample of U.S. children in Chicago who experienced family and peer violence. Children justified their moral judgments using moral reasoning when evaluating straightforward issues, but they used less moral reasoning when considering provocation and retribution.

Posada and Wainryb's (2009) study, described previously, as well as a recent study by Gasser, Malti, and Gutzwiller-Helfenfinger (2012), also demonstrate that emotion attributions are important in the application of moral judgments regarding harm. Further, there are individual differences due to aggressive profiles. Gasser et al. (2012) studied 7- and 9-year-old Swiss children's moral understanding of retaliation as compared to unprovoked aggression and found that aggressive children judged retaliation as less serious and referred less often to the harmful and emotional consequences of retaliation than did nonaggressive children.

Another line of research has focused on "happy victimizers" and age-related changes in the reading of emotional cues in the context of aggression and inflicting harm on another. Nunner-Winkler and Sodian (1988) analyzed 4-, 6-, and 8-year-olds' victimizers and victims' emotional attributions after an incident in which the victimizer gained access to a material resource through aggressive means (e.g., pushing someone off the swing to get a turn). They found that the majority of 4-year-olds expected the victimizer to feel happy, in contrast to 8-year-olds, who

predicted that the victimizer would feel guilty or bad. Arsenio (2014) has argued that the shift from happy attributions to a mixture of emotions (happy and sad) reflects a conflict that is increasingly resolved with age during middle childhood.

As we described earlier in terms of Yuill et al.'s (1996) research on theory of mind, children must coordinate the victim's and victimizer's responses with their judgments about the wrongfulness of inflicting harm on others. In addition, this situation creates a conflict between children's judgments and their affective responses when gaining a desired resource (because it feels good to get what one wants). This is particularly so for children exposed to violence or who have been diagnosed with behavior disorders (Arsenio, 2014). However, there is a need for more research on how specific social experiences (such as experiencing violence) influence developmental changes in happy victimizer responses and moral judgments more generally.

Sampling low-income ethnic minority adolescents, Arsenio and his colleagues (Arsenio, Adams, & Gold, 2009) demonstrated that reactive aggression reflects social-cognitive deficits, such as failing to read social cues and over-attributing hostile intentions. This is in contrast to proactive aggression, which reflects intentions to victimize and harass others. This distinction is important because the researchers showed that lower moral concerns (but higher verbal abilities) were associated with proactive but not reactive aggression. Further, this line of research reveals connections between children's moral emotion attributions and aggressive behaviors and highlights the need for specificity (e.g., distinguishing among types of aggression) in making connections between moral judgments and behavior.

In addition to including emotion attributions, recent research has also examined whether concepts of harm are considered when children evaluate destruction of the environment. Severson and Kahn (2010) studied 7- and 10-year-old children of U.S. farm workers regarding their conceptions of harm to nature in the form of pesticide exposure. They found that children evaluated exposure to pesticides as wrong using moral criteria, providing an example of how concepts of harm can be applied to broader societal (environmental) issues at a young age.

Concepts of the Fair Distribution of Resources

One of the most robust developmental findings regarding conceptions of fair resource allocation has been the age-related shift from a focus on strict equality, which

involves relatively straightforward decision-making, to the consideration of merit, need, others' welfare, and other factors (Damon, 1977). As Rawls (1971) theorized, defining justice in terms of fairness implies that the method of allocation is only the means, not the end, to achieving fairness. Thus, researchers have sought to measure when in development children rely on equality to ensure fairness or take other considerations such as merit and need into account. Earlier we described studies that have shown that young children tend to distribute resources equally and that focusing on merit is only minimally understood. By middle childhood, however, children take merit as well as many more factors into account.

In one of the first comprehensive studies to examine children's judgments regarding various claims, Sigelman and Waitzman (1991) analyzed 5-, 9-, and 13-year-olds' evaluations of rules of equity, equality, and need in three contexts (work situations with rewards, voting situations with equality, and charity situations with principles of need). Younger children preferred equality in all three conditions, but with age, children considered both equity and need. Further, children reasoned about fairness to support their decisions. The authors cautioned that the findings did not imply that younger children could not consider merit but that their preference was to focus on equality. Documenting the generalizability of understanding merit, Liénard, Chevallier, Mascaro, Kiura, and Baumard (2013) found that 5-year-olds from a tribal society (the Turkana) in Kenya demonstrated a clear understanding of merit and took individuals' contributions into account when distributing a collectively produced resource. Another way to measure children's understanding of fairness is to document their protests in response to an inequitable allocation. Recent studies have found that 6- to 8-year-olds will discard additional resources provided in a distribution task (that would require inequitable allocation), even at a cost to their own benefit (Blake & McAuliffe, 2011; Shaw & Olson, 2012). Moreover, a recent study has revealed that 3.5- to 6-year-old children use fairness, equality, and others' welfare when evaluating necessary resources as compared to luxuries, suggesting that children take the type of resource to be distributed into account (Rizzo, Elenbaas, Cooley, & Killen, 2014).

Although there are normative developmental trends towards considering merit over strict equality, contextual factors also influence children's allocations. The recent findings also reveal that children display previously undocumented social cognitive sophistication regarding the fair distribution of resources.

Moreover, with age, children consider other social dimensions pertaining to resource allocation decisions, such as the history of the relationships, status, and reputation (Elenbaas, Rizzo, Cooley, & Killen, 2014; Paulus & Moore, 2014). For example, friendship status is related to equal allocation decisions (Olson & Spelke, 2008), along with self-presentational biases, such as whether one's resource decision is known to other members of a group or not (Shaw et al., 2013). Moore (2009) found that children made more equitable decisions with a friend than with a nonfriend peer (see also Paulus & Moore, 2013). They were even less likely to distribute equitably when the peer was a stranger, but they responded in a more prosocial manner with a stranger when the cost was not high. Studying 10- to 19-year-olds' allocation decisions, behavioral economists Almås, Cappelen, Sørensen, and Tungodden (2010) found that, with age, children became focused on merit rather than strict equality when merit was defined as individual achievement. Older children considered merit in some contexts and strict equality in others, indicating that older children used both forms of allocation depending on the specific situation.

Dividing resources is a frequent source of conflict in childhood and beyond, and understanding children's conceptualizations can be useful for effective conflict mediation. Research has shown that moral judgments about resource allocation involve not just the capacity to understand equal allocation or allocation based on merit but also other factors. Research has been conducted from many different theoretical perspectives, and integrating the age-related findings from these various views will provide a more comprehensive understanding of the foundations of distributive justice.

Judgments About the Unfair and Prejudicial Treatment of Others

Research on children's prejudicial attitudes and stereotyping has a long history in developmental science, and over the past two decades, a robust area of research has emerged on children's and adolescents' understanding of unfair and prejudicial treatment of others (Brown & Bigler, 2004). This research examines when children view it as morally wrong or unfair to treat someone differently because of their group membership (e.g., gender, race, ethnicity, culture, and nationality). These judgments are complex because they require the recognition that individuals belong to different groups and that they may be deliberately treated differently because of their group

membership. Research has drawn on theories regarding developmental intergroup attitudes and social identity theory to incorporate the role of group norms for investigating the emergence of prejudice and its association with moral reasoning. Here, we report on how children apply their moral judgments to contexts in which stereotypes and group identity play a role; later, we will discuss the role of peers and intergroup contact.

Moral Judgments in the Context of Stereotypic Expectations

Even though gender stereotypes regarding boys' and girls' activities are pervasive in early childhood (Ruble, Martin, & Berenbaum, 2006), young children sometimes view social exclusion based on stereotypic expectations (for example, about gender) as wrong and unfair. U.S. 3-, 4-, and 5-year-old children evaluated as unfair a girls' doll-playing group's exclusion of a boy from playing (or a boys' truck-playing group's exclusion of a girl) using moral reasons (Killen, Pisacane, Lee-Kim, & Ardila-Rey, 2001). When asked whom to include (a more complex decision), children were more likely to use conventional reasoning about group identity as well as stereotypic associations with activities. With age, children used both moral and nonmoral social forms of reasoning for a complex decision such as whom to include.

Generally, as children grow older, they take more considerations, such as talent, merit, and previous experience, into account, and these are sometimes given priority when making inclusion decisions involving gender or race (Killen & Stangor, 2001). Furthermore, social-conventional and autonomy reasons for why it is legitimate to exclude others increase from 6 to 12 years of age. In adolescence, moral reasoning both becomes more advanced (e.g., focusing on the wrongfulness of discrimination) and better coordinated with other concerns (Crystal, Killen, & Ruck, 2008). This approach to studying the development of children's evaluations of social exclusion has been applied to gender, race, ethnicity, nationality, and religion, as well as sexual identity (Horn, 2008).

An important new area of research focuses on adolescents' social reasoning about sexual minority youth (Horn, 2008; Poteat, 2007). Research has revealed that sexual prejudice (toward peers who identify as lesbian, gay, bisexual, or transgender [LGBT]) is multifaceted and involves moral, conventional, and personal reasoning, as well as stereotypic expectations. For example, adolescents use more conventional and less moral reasoning to exclude homosexual peers who are depicted as

gender-nonconforming than gender-conforming in appearance (e.g., cross-dressing) and activities (e.g., ballet for boys and football for girls; Horn, 2008). In addition, while half of the youth sampled by Horn (as reported in Horn, 2008) stated that they believed homosexuality was wrong, only 11% condoned exclusion as legitimate, using moral reasons such as unfair treatment. This indicated that their judgments about personal sexual identity differed from judgments of social exclusion based on identity. Further research could determine how adolescents' conceptions of sexual orientations as essential or innate rather than personally chosen bear on the decisions to accept or reject social exclusion and peer harassment of LGBT youth.

Moral Judgments in the Context of Group Identity and Group Norms

With age, group identity factors such as ingroup preference, outgroup bias, and status enter into judgments about exclusion based on group identity and group norms (Abrams, Palmer, Rutland, Cameron, & Van de Vyver, 2013). For example, with age, U.S. ethnic majority children (9 to 15 years old) were more likely than ethnic minority children to view interracial exclusion as legitimate (for conventional reasons) when non-race factors were mentioned (such as parental or peer pressure); in contrast, ethnic minority children were more likely to use moral reasons to reject such exclusion (Crystal et al., 2008; Killen, Henning, Kelly, Crystal, & Ruck, 2007).

Studies conducted in Switzerland, the United Kingdom, and Korea have shown similar findings according to high- and low-status nationality groups. Minority youth are more likely to use moral reasoning to reject intergroup exclusion, whereas majority youth rely on group identity and traditions to condone exclusion (for a review, see Hitti, Mulvey, & Killen, 2011). As an example, Serbian adolescents, who were evaluating a Swiss national peer's decision to exclude a Serbian peer from attending a sporting event (Malti, Killen, & Gasser, 2012), viewed exclusion in this context as more unfair than did Swiss nationals and were more likely to expect that the Swiss national peer would feel proud rather than sad about their decision. With age, children and adolescents take a number of contextual factors into account when evaluating group norms for their ingroup, especially when these norms reflect unequal or exclusionary behavior toward outgroup members (Hitti, Mulvey, Rutland, Abrams, & Killen, 2013; Rutland, Killen, & Abrams, 2010).

By middle childhood and adolescence, children define group identity by group norms rather than just by

group membership (gender, nationality, school affiliation). Thus, with age children recognize that the norms and values of the group are central to their identity (Rutland et al., 2010). Most of the research on group identity examines loyalty to the group without determining whether loyalty is based on norms related to fair treatment of others or to conventions and traditions, concepts that are differentiated at relatively young ages.

When investigating decisions to choose an outgroup member who supports equal allocation of resources over an ingroup member who does not, children 9 to 13 years of age gave priority to fairness over ingroup status (Killen, Rutland, Abrams, Mulvey, & Hitti, 2013). This finding challenges the view that ingroup bias is pervasive across contexts (including moral ones). Yet, prior research has rarely examined ingroup preference in the context of identification with a group that holds negative moral norms. As an example, 9-year-olds supported an ingroup member who voiced explicit concern about their own group's decision to keep more resources than to divide equally (Killen et al., 2013). While 9- to 13-year-olds were more willing to include an outgroup member based on gender who supported fairness norms, they were less willing to do so regarding group membership based on school affiliation, revealing variation by the form of group membership (Mulvey, Hitti, Rutland, Abrams, & Killen, 2014).

In these contexts, children and adolescents recognize that groups are more favorable to ingroup members who are loyal than disloyal, even in the context of fairness considerations. This recognition that groups are likely to exclude members who protest their norms contributes to age-related increases in being reluctant to choose an outgroup member over an ingroup member (Hitti et al., 2013). Thus, concerns about being excluded from a group for appearing disloyal provide a challenge to the application of morality in social contexts. The factors that foster ingroup and outgroup bias and the mechanisms that effectively enable individuals to recognize the unfairness of acting on biased expectations about others are not yet fully understood.

Research on national and cultural identity is a particularly central issue in Europe, with the recent influx of Muslim migrants, the disbanding of Yugoslavia, and long-standing regional conflicts based on religion. Moral judgments regarding exclusion in these cultural contexts have been examined. Verkuyten and his colleagues have conducted an extensive program of research on this topic. For example, Gieling, Thijs, and Verkuyten (2010) found that Dutch adolescents (ages 12 to 17 years old)

were more tolerant of acts committed by Muslim actors when the issue was viewed as personal (e.g., clothes) than when it was seen as moral and involving harm to others. With increasing age, adolescents became less tolerant of Muslim conventional practices, such as separate schools based on religion, which remains a controversial issue. On the one hand, this practice can be interpreted as reflecting an increased focus on the threat to Dutch norms with age; on the other hand, forms of segregation often contribute to inequality of access to resources.

Furthermore, adolescents who were high on multiculturalism, as assessed on a separate scale, were more tolerant of non-harm-related cultural practices than were those who scored low on this scale (Gieling et al., 2010). Issues of prejudice and bias in a moral context raise concerns about rights. In fact, with age, children and adolescents view the denial of individual rights as an issue of unfair treatment. Group migration has existed throughout human history, and yet, developmental scientists have only recently studied the tensions it raises and its moral implications. Further research on the types of cultural conflicts that emerge in societies absorbing large numbers of immigrants from different religious and ethnic traditions would enhance our understanding of conceptions of fairness and rights in contexts that create prejudice and discrimination.

Conceptions of Rights

Until recently, traditional theories of moral development viewed conceptions of rights and civil liberties as emerging primarily during adolescence. Over the past two decades, however, Helwig et al. (2014) have taken a moral developmental viewpoint to study children's and adolescents' conceptions of rights. They have examined how American and Canadian children's and adolescents' conceptions of freedom of speech and religion are viewed as moral or "natural" rights independent of authority and laws and generalized across contexts. While even children as young as 6 years of age support civil liberties by appealing to moral reasons, beginning around 8 years of age children understand the broader societal, cultural, and democratic implications of rights. As an example, children view freedom of speech as important because it can serve as a vehicle for correcting injustices. By adolescence, youth view freedom of religion as a more complex issue, involving multiple considerations such as religion as a matter of personal choice, as a way of being part of a group, and a freedom that should be protected from a moral viewpoint. The novel aspect of

Helwig's findings is that children and adolescents did not evaluate civil liberties as defined by authority or existing laws, but rather by morality, or what is often referred to as "natural law."

In an early study, Helwig (1995) examined Canadian 7th grade (12-year-olds) and 11th grade (16-year-olds) as well as college students' reasoning about the straightforward application of rights (e.g., giving a public speech critical of governmental economic policies), and complex situations involving civil liberties and other social issues (such as a speech that advocates violence). Children and adolescents viewed the straightforward civil liberties as moral (in that a denial would be unfair) and were mixed in their evaluations of the conflicts. For example, younger children were more likely than older adolescents to view it as unacceptable to exercise civil liberties when these were ruled as wrong based on a set of hypothetical laws, indicating that older adolescents used moral criteria to view the denial as wrong more than did younger children. Importantly (and as we discuss later, in the context of civic engagement), Helwig's findings have been replicated in other cultural contexts, particularly in those countries, like China, with economic and political attitudes toward rights and civil liberties that are different from North American countries.

Ruck and his colleagues (Ruck, Abramovitch, & Keating, 1998) have demonstrated that children distinguish two types of rights, nurturance (referring to children's rights to care and protection) and self-determination rights (referring to autonomy and control over their lives), and that these emerge in childhood. Children's justifications for nurturance rights focus on social and familial roles with little reference to rights, while reasoning about self-determination rights focuses on personal freedom and autonomy. By adolescence, 13- and 15-year-olds are more likely than their parents to endorse requests for self-determination rights (e.g., keeping a diary private) and less likely than their parents to favor request for nurturance rights in the home (e.g., talking to a parent when being emotionally upset). Ruck's research has been extended to show that British adolescents endorse same-age asylum-seeking children's nurturance rights over self-determination rights (Ruck, Tenenbaum, & Sines, 2007), demonstrating that the distinctions between these different forms of rights are generalizable to other cultural contexts. The factors that contribute to adolescents' support of nurturance over self-determination rights require further research. This could shed light on the biases that exist when a

majority group (e.g., British adolescents) denies rights to a minority group (e.g., asylum-seeking peers).

Neuroscience of Moral and Conventional Judgments

Only recently, and reflecting advances in methods, has it been feasible to extend neuroscience studies of moral judgments to childhood. As described earlier in the chapter, Decety and his colleagues (Decety & Howard, 2014) have investigated the neuroscience of intentional moral judgments in childhood through adulthood. To test distinctions between moral and conventional judgments in adolescents and young adults, Lahat, Helwig, and Zelazo (2013) recorded event-related potentials while participants read scenarios regarding moral violations, conventional violations, or neutral acts. When the acts were described as regulated by a rule, reaction times were faster across ages for moral than conventional violations, but when there was no rule, reaction time differences were found for moral but not conventional violations. Thus, this study identified some of the underlying neurocognitive mechanisms involved in processing and evaluating moral and conventional violations in adolescence.

In a series of experiments, Blair (described in Blair, 2010) has conducted neuroscience research using fMRI techniques to examine differences in brain activation in moral judgments in nonclinical and clinical samples (e.g., with neuropsychiatric patients). Blair (2010) reviewed extensive research, his own and others, with a nonpatient sample of adults, demonstrating that different neurocognitive systems are involved in moral reasoning. Both the amygdala (which is associated with processing emotional responses) and medial orbital frontal cortex (which is involved in reasoning) are activated when making moral decisions. Thus, consistent with Decety and his colleagues (Decety & Howard, 2014), Blair's research demonstrates that moral judgments entail an integrated neural response involving both emotion and cognition.

Furthermore, Blair and his colleagues (White, Leong, Smetana, Nucci, & Blair, 2013) have recently used fMRI techniques to demonstrate both similarities and differences in the brain regions activated when normal, healthy adults made judgments about moral (welfare and harm-based) and conventional transgressions. Blair et al. (2013) observed increased neural activation in the amygdala and ventro-medial prefrontal cortex when adults rated harm-based transgressions as compared to conventional transgressions,

but there was also activation in several regions in the frontal cortex when adults processed both types of transgressions. These findings provide interesting new evidence regarding distinctions between morality and social convention, specifically that judgments about morality involve both emotion and cognition. Thus far, however, only Lahat et al. (2013) have pursued this line of inquiry with adolescents, and the developmental trajectory of judgments from childhood to adulthood, as assessed using neuroscience methods, remains to be studied. Early moral neuroscience studies relied on overly simplistic definitions of morality, due to the limitations of neuroimaging assessment methods. Given the fast pace of changes in this field, collaborations between neuroscientists and moral developmental researchers using the most accurate assessments of moral development are essential. Further, connecting brain activation studies that have provided novel insights into the underpinnings of cognitive and affective processes with research on children's moral judgments and behavior is fruitful.

Summary: Moral Judgments and Moral Reasoning

During childhood and adolescence, moral judgments reflect a wide range of moral issues, including concern for other's welfare (harm), fair distribution of resources, equal treatment of others (exclusion, wrongness of prejudicial attitudes), social inequality, and concepts of rights. The literature demonstrates that as children develop, they begin to take more contextual factors into account. When making moral judgments and decisions, children consider a broader range of concerns, including judgments about the self (e.g., personal goals), social conventions, group identity, and group functioning. These decisions operate in actual situations, as shown in neuroscience studies as well as studies demonstrating associations between hypothetical and actual moral judgments. Furthermore, even when children understand and apply moral concepts, competing nonmoral considerations may be highly salient and important, making moral decisions potentially difficult. The contexts of development also influence whether moral principles are inhibited or facilitated.

Thus far we have reviewed research focused primarily on the cognitive, social, and emotional processes reflected in an understanding of morality in childhood and adolescence. However, moral development occurs in a context, and in the following section, we consider how morality is

facilitated in the family, and in subsequent sections, in the context of peer groups and societal groups, social institutions, and cultures.

MORAL DEVELOPMENT IN THE CONTEXT OF THE FAMILY

One of the more enduring topics in research on moral development has been the role of the family—and in particular, the influence of parents—on children's developing morality. Parents are seen as central influences because they generally have the primary responsibility for raising children and have the most time and opportunity to influence them. Parents are also fundamental because of the powerful affective bonds they have with their children, which may make children particularly receptive to parental influence. Much of the interest in the role of parents stems from psychoanalytic and behavioral (social learning) theory approaches, which have traditionally emphasized the importance of early experiences in the family on children's moral socialization. According to social learning theory accounts, the internalization of parental values and expectations occurs through interactions with caregivers during early childhood. Thus, research has focused on how parenting practices and particular discipline techniques influence these processes (see Grusec, Chaparro, Johnston, & Sherman, 2014, for a review).

Nativist and comparative approaches are less concerned with these issues, given that morality is seen as innate and emerging out of social cognition and social interaction. Yet, recent research has begun to provide more complex portrayals of the role of family relationships in moral development. Social learning theory approaches have acknowledged the importance of children's acceptance, reflection, and reactions to parents' discipline or attempts to instill morality (Grusec et al., 2000; Kuczynski & Parkin, 2007). Research on moral judgment development has moved to examine how different modes of parent-child interactions (both unilateral and mutual) bear on the construction of notions of justice, fairness, and rights (Dunn, 2014; Smetana, 1997; Walker, Hennig, & Krettenauer, 2000). Family systems theories have focused attention on how different family relationships, such as sibling relationships, interact with parent-child relationships to influence moral development.

Socialization approaches typically have been concerned with the parenting styles and disciplinary practices that most effectively facilitate the internalization of moral

behavior, and particularly, children's compliance with parental directives and responsiveness to parents (but see Grusec & Goodnow, 1994, for a critique). This has been assessed primarily using laboratory tasks that are seen as paradigmatic for measuring successful internalization, including following parental commands not to touch attractive toys (resistance to temptation tasks), heeding parental requests to help with cleanup, or cheating tasks focused on game rules. These tasks emphasize obedience to authority, compliance with parental directives, and the development of self-regulatory (inhibitory) abilities, with little attention to the type of norm to be internalized. As Kochanska and her colleagues (Kochanska, Koenig, Barry, Kim, & Yoon, 2010) recently acknowledged, however, most of the experimental tasks are social-conventional, not moral in nature. This has implications for how conscience is defined and the validity of these assessments as measures of the moral components of conscience. Thus, more research employing tasks that go beyond compliance to assess morally relevant dimensions (harm and welfare) is warranted.

There have been significant advances in considering bidirectional processes in children's development. In some of the current research, this has been considered primarily in terms of how parents adapt their disciplinary practices in response to children's temperamental characteristics. Successful socialization is still conceptualized in terms of children's accommodation to and compliance with parents' expectations and values. While heeding parents' directives is often very important, this focus on accommodating to parents' wishes is limited because parents have other socialization goals beyond compliance, and their diverse goals need to be recognized and studied (Grusec et al., 2000). Furthermore, children do not simply accommodate to parents; children take an active role in making meaning, interpreting and responding to parents and thus may influence parents. Finally, such approaches assume that parents, as agents of society, transmit positive values; they do not explicitly address situations where parents seek to instill immoral, prejudicial, or antisocial goals. Children do not accept parents' values as given; as discussed in this section, they negotiate, contest, and sometimes resist expectations that they deem unfair or illegitimate. In the following sections, we identify and consider different types of family influences (including both parents and siblings) on moral development, as conceptualized and measured from different perspectives. Although the majority of studies focus on mothers, we highlight studies that have also included fathers in their samples.

Attachment Relationships and a Mutually Responsive Orientation

The quality of children's attachment relationships to parents, formed during the first year of life, is widely considered to be important for moral development (Thompson, 2012), and this has been examined most directly by researchers studying the development of conscience in normative samples. In addition, insecure attachments to caregivers have been implicated, at least theoretically, in the development of conduct disorders and antisocial behavior. That is, insecure attachments are seen as resulting in fragile parent-child bonds and a lack of empathy toward others, predisposing children to trajectories of antisocial behavior (van IJzendoorn, 1997).

Attachment security has been empirically linked with young children's moral development. Denham (1994) found that toddlers who had secure attachment relationships with caregivers had prosocial and sympathetic responses to mothers' simulated displays of anger and sadness. In keeping with the attachment theory notion that attachment security leads to emotionally open and coherent discourse, Laible and Thompson (2000) found that mothers employed a greater frequency of moral evaluations (that behaviors were "good" or "naughty") when children were more securely attached. Furthermore, when children had secure attachment relationships or when dyads shared positive affect, mothers referred to feelings in their conversations about the child's past transgressions. The outcome was that children had the greatest moral internalization, measured in terms of behavioral compliance (Laible & Thompson, 2000).

The role of attachment security (measured retrospectively and across multiple interpersonal relationships) also has been studied in adults' construction of moral identity. Walker and Frimer (2007) found that adult moral exemplars (recipients of Canadian awards for exceptional bravery or caring) reported more secure childhood attachments than did a matched group of adults and that exemplars of caring reported more secure relationships than did exemplars of bravery.

Going beyond attachment, there is agreement across many different approaches that parental warmth and responsiveness facilitate moral development. In discussing moral internalization, Hoffman (1979) noted almost 25 years ago that parental "affection is important because it may make the child more receptive to discipline, more likely to emulate the parent, and emotionally secure enough to be open to the needs of others" (p. 958). Parpal and

Maccoby (1985), and more recently, Kochanska and her colleagues have articulated similar notions. For instance, Kochanska, Forman, Aksan, and Dunbar (2005) have highlighted the importance of a mutually responsive orientation for the internalization of morality. Mutually responsive orientations have their foundations in secure attachment relationships and involve parent-child dyadic relationships that are positive, trusting, cooperative, and reciprocal.

Researchers from the Kohlbergian tradition also have found that warm, supportive interactions facilitate moral judgment development. Whereas research has demonstrated that cognitively challenging and critiquing interactions between peers facilitate the development of more mature moral judgments (Berkowitz & Gibbs, 1983; Walker et al., 2000), similar types of interactions, when employed by mothers and fathers, do not. In fact, they have been found to hinder moral reasoning development, perhaps because adolescents perceive them to be hostile, interfering, or overly critical. Instead, Walker and Taylor (1991) found that mild cognitive challenge in the context of a warm affective climate that involved support and encouragement facilitated adolescents' moral maturity, particularly when discussing real-life dilemmas. Thus, research from diverse perspectives has converged in demonstrating the importance of secure attachments and warm, responsive interactions for facilitating moral development.

Parenting Styles and Discipline Strategies

Parenting styles and disciplinary practices have been examined as central precursors of moral internalization in studies of young children, perhaps most extensively in Kochanska and her colleagues' programmatic research (reviewed in Kochanska & Aksan, 2004). These researchers found that individual differences in children's biologically based temperament interacted with mothers' socialization in facilitating the development of conscience. The findings reveal that gentle maternal discipline that deemphasized power assertion and stressed inductive discipline as a way of facilitating anxious arousal facilitated conscience development, but only for relatively fearful children. The claim is that an optimal level of anxiety is necessary to help children process parental messages, thereby promoting successful internalization. For fearful children, this is accomplished by gentle parenting, whereas for fearless children, a mutually responsive orientation with their mothers provides the pathway to moral internalization. Although these findings have been very robust in studies with mothers, Kochanska, Aksan, and Joy (2007) did not

replicate the findings for child fearfulness in two different samples of fathers. Thus, more research on fathers' influence on conscience development is clearly needed, as well as the interactive effect of mothers' versus fathers' styles of parenting on moral development.

Furthermore, the interactions between parenting and temperament have not been consistently replicated in other research employing different methods and measures more directly focused on the harmful consequences of acts for others. Dunn, Brown, and Maguire (1995) examined various longitudinal influences on 5- and 6-year-olds' moral responses to moral stories. When children were 33 months old, the researchers examined mothers' observed use of control, mothers' other-oriented responses to managing sibling conflicts, and mother-reported positive sibling interactions. When children reached 40 months of age, the researchers examined children's emotion understanding. At 72 months of age (6 years), shy children demonstrated less internalized moral orientations (reflecting an empathic orientation reflecting feelings or concern for the victim) and fewer reparative story completion responses than other children; none of the variables influenced 5-year-olds' moral reasoning. Although the measures of moral internalization differed somewhat from Kochanska's program of research, these findings contrast with Kochanska's results on temperamental differences.

The definition of conscience has varied in different studies. In Kochanska's research, conscience in early childhood has been defined empirically in terms of two relatively stable factors consisting of moral emotions (children's distress following transgressions involving damage and harm to another) and conduct, or rule-following behavior in the absence of surveillance. However, reflecting the increasing importance of moral cognition in children's conscience development as children grow older, Laible, Eye, and Carlo (2008) found that conscience in middle adolescence consisted of two factors reflecting moral affect (including guilt, shame, sympathy, and empathic anger) and moral cognition (including moral values and prosocial moral reasoning). Furthermore, consistent with the results of Hoffman and Saltzstein's (1967) classic study of the role of parental discipline in moral development, Laible et al. (2008) found that power-assertive parenting was negatively associated with the affective dimension of conscience. Adolescents higher in this dimension engaged in more prosocial behavior, whereas adolescents higher in the cognitive aspect reported both more negative emotionality and parents' greater persistence in discipline. Both aspects of conscience were associated with more moral behavior,

including less encouragement of bullying and greater likelihood of helping a victim of bullying.

The roles of parenting styles and disciplinary strategies have also been examined in older children and adolescents. Patrick and Gibbs (2012) employed Hoffman and Saltzstein's (1967) classification of discipline techniques in their study of moral identity development. They found that parents' use of inductive discipline (but not love withdrawal and power assertion) was associated with a stronger moral identity, but only for middle adolescents and not for younger children. These findings are consistent with the notion that morally salient self-descriptions increase in frequency in mid- to late adolescence, as conceptions of self and moral identity become increasingly integrated (Hart & Fegley, 1995). However, little support for such age-related shifts have been found in recent research employing large samples of adolescents (Hardy, Walker, Olsen, Woodbury, & Hickman, 2013), highlighting the need for more research on the developmental dimensions of moral identity. In addition, Patrick and Gibbs (2012) found that adolescents who rated parents' use of induction as more fair and appropriate also reported stronger moral identities.

Researchers have emphasized the importance of authoritative parenting, where parents are both highly responsive but also relatively demanding in their expectation for mature behavior, and this efficacy has been confirmed in studies of moral development. In the United Kingdom, Leman (2005) found that early adolescents who rated their parents as authoritative rather than authoritarian were more likely to believe that hypothetical adults described in moral scenarios would justify expectations regarding moral misbehavior with references to reciprocity and equality. Pratt, Hunsberger, Pancer, and Alisat (2003) likewise found that more authoritative parenting was associated over a 2-year period with greater value congruence (for both moral and nonmoral values) between late adolescents and their parents.

Family Discourse, Conflicts, and Responses to Transgressions

Parents influence moral development in numerous ways that go beyond discipline encounters. In everyday conversations and discussions, caregivers articulate expectations for their children's behavior, reminisce about past (or future) moral behavior, or negotiate moral topics in the context of conflicts. Therefore, numerous studies have examined morality as it emerges in family discussions, discourse, and narratives, as well as in everyday conflicts.

Observations and Family Talk

Dunn (2014) conducted studies of naturally occurring conversations in the family to examine how children, siblings, and parents discuss moral and other types of issues in the home. Although these studies have focused only on maternal responses, Dunn viewed the parent-child relationship as a context that encourages reciprocity. She has emphasized how family members negotiate conflicts related to sharing and fairness. In addition, family members discuss the role of emotions and mental states in children's reactions to rule violations in the home. Within the context of family social interactions, children's emotional reactions, discourse, and ability to anticipate the intentions of others are viewed as central to the acquisition of morality.

These studies revealed that, from the second year of life onwards, children talk with their parents and their siblings about what is allowed and what is not and, specifically, about matters pertaining to fairness, property rights, and conventional rules. Mothers increasingly refer to social rules and use more sophisticated justifications as their children move through the second and third years of life. As Dunn (2014) noted, young children attempt to alleviate others' distress, show concern for others, and draw mothers' attention to siblings' misbehavior well before they are able to clearly verbalize these concerns in interviews. Dunn's observations also make clear that a much broader set of emotional reactions than guilt, fear, and anxiety, which are stressed by Hoffman (2000) and others as central to moral internalization, are at play in family moral interactions. Children also express positive emotions—pleasure, excitement, amusement, and glee—in violating rules, conspiring with siblings to subvert parental rules, and teasing and having conflicts with siblings.

According to Dunn (2014), all of these aspects of family interaction provide important motivations for acquiring moral understanding and highlight children's active agency in these processes. Mothers' concerns with harm, welfare, and rights in their interactions also help to emphasize the salience of moral concerns for their children. For instance, observations of mothers' and peers' responses to 2- and 3-year-olds' transgressions in the home (Smetana, 1989) show that moral transgressions occur primarily when target children interact with peers, with mothers mostly providing third-party interventions in peer disputes. Mothers made statements regarding rights, requested that children take the other's perspective, redirected children's attention to the harm or injustice that was done, and commanded children

to stop their misbehavior. Thus, these findings suggest that parents may scaffold the moral understanding children construct from their moral interactions with peers.

Parents' (and victims') emotional reactions to young children's moral transgressions also provide important information about the nature of the event. For instance, Dahl and Campos (2013) found that mothers of 11-, 13-, 15-, and 17-month-olds reported more anger in response to moral than to other transgressions. Reasoning and explanations for moral transgressions have been found among mothers of older children as well. That is, mothers of 6- to 10-year-olds have been shown to employ explanations for moral transgressions, in contrast to verbal force (yelling and threats) for conventional transgressions (Chilamkurti & Milner, 1993).

As Dunn's (2014) research has demonstrated, sibling relationships are an important context for moral development, and increasingly so with age. When mothers intervened in 33- to 37-month-olds' sibling conflicts, they consistently endorsed sharing and prohibiting property damage (Piotrowski, 1997). Ross and her colleagues (Ross, 1996; Ross, Tesla, Canyon, & Lollis, 1990), however, reported that when mothers intervened in peer and sibling property disputes, they were inconsistent in supporting owners over possessors when ownership claims were in conflict; mothers were more concerned with restoring harmony. Thus, Ross (1996) concluded that children do not simply internalize their parents' disciplinary messages, but rather construct notions of rights from sibling and peer interactions, drawing from the parts of parental messages that seem fair.

Children's other-oriented responses, such as statements focusing on others' rights and welfare, emerge between the third and fourth year of life and occur more frequently during arguments with peers than with mothers or siblings (Dunn et al., 1995; Smetana, 1989). Adult intervention in moral conflicts regarding object disputes decreases from the preschool years to middle childhood. Those interventions also differ according to setting, as children become more actively involved in negotiating and resolving moral disputes regarding more complex issues such as social exclusion and rights. Such evidence challenges the view of young children as passive recipients of adult moral values. This is also clearly evident in research on parental differential treatment of siblings.

Parents typically treat their children differently because they have different personal characteristics, needs, or interests. Children often view parental differential treatment as fair and appropriate in meeting a sibling's needs (Kowal

& Kramer, 1997; McHale, Updegraff, Jackson-Newsom, Tucker, & Crouter, 2000), but it becomes problematic for children's adjustment and family relationships when it is seen as unfair or not legitimate. This occurs more among second-born than first-borns, particularly in mother-son and father-daughter relationships. It also increases in adolescence, perhaps because, as adolescents grow older, they became more reactive to the unfairness of parental differential treatment (McHale et al., 2000) or, as we have shown earlier, become better able to weigh and consider different types of concerns. Parental differential treatment is particularly deleterious when it pertains to warmth as compared to perceived parental involvement or expectations regarding household chores (McHale et al., 2000).

With age, children view parental assignment of gender-associated household chores to girls or boys (e.g., asking only the daughter to sew curtains or the son to change the oil in the car) as legitimate (for a review, see Sinno, Schuette, & Killen, 2014). Younger children (5- to 8-year-olds) viewed this form of differential division of chores as unfair, but older children (9- to 10-year-olds) viewed it as conventional and therefore legitimate, and more so for male- than for female-stereotyped activities. Regarding the larger context of parental roles in the family (working outside the home or staying at home to take care of children), early adolescents view second-shift arrangements (when one parent is both working and caretaking) as more unfair for fathers than for mothers. Adolescents use stereotypic reasoning, such as references to prior experience (mothers are more used to doing both) or stereotypic expectations about effort and work (fathers work harder, to explain why fathers as compared to mothers should not be responsible for doing double duty) (Sinno et al., 2014). An interesting next step for this research would be to examine how growing up in different family arrangements influences children's judgments about the fair division of caretaking, work, and chores in the home.

Recent research also has focused on the specific challenges that minority parents face in socializing their children and, more specifically, the complex burden ethnic minority parents in the United States bear regarding moral development. For instance, most African American parents stress the importance of egalitarianism, yet they also must prepare their children for potential discrimination and unfair treatment (Hughes et al., 2006). How minority parents balance these competing, morally salient goals is an important area of inquiry that is not typically conceptualized in terms of children's moral development but could make a significant contribution to the literature if considered in this light (see Killen & Cooley, 2014).

African American parents in the United States often socialize their adolescents to cope with discrimination and unequal treatment (Hughes et al., 2006), teaching them about racial bias in the broader society and providing them with strategies to cope with prejudice. Indeed, research has shown that when ethnic minority parents in the United States talk to their children about potential discrimination and unfair treatment, this form of discourse promotes resilience in the context of exclusion and victimization (Neblett, Terizan, & Harriott, 2010) and leads to more proactive coping and better mental health outcomes (Hughes et al., 2006). Furthermore, a longitudinal study with African American families demonstrated that hearing parents' egalitarian messages led to better psychological adjustment among adolescents (Neblett et al., 2008). These forms of parental socialization reflect issues of unfair treatment that children must face every day.

Narratives and Discourse. Narrative methods also have illuminated the emergence and development of moral understanding in parent-child contexts. These studies have shown that when mothers use a more elaborative style in their reminiscences about their preschool children's previous moral behavior and misdeeds, their children display more behavioral internalization (as measured on a resistance to temptation task) and higher levels of emotional understanding (Laible, 2004). Mother-child conversations also differ when they focus on helping versus harming. Recchia, Wainryb, Bourne, and Pasupathi (2014) found that when European American mothers had conversations with their 7-, 11-, and 16-year-olds about instances where they helped (as compared to hurt) a friend, they focused more on others' needs and encouraging children to see themselves as prosocial moral agents. In comparison, conversations about hurting a friend were more elaborated and complex, involving more challenges and conflicting viewpoints, which may facilitate moral development. Children focused both on others' needs and their own internal states, thus integrating their understanding of others' needs with their motivations and feelings about harming others. Mothers highlighted children's wrongdoing but also helped their children to reconcile their negative behavior with a sense of themselves as moral agents. With age, children became more active in the conversations; children offered more psychological insights and were less reliant on their mothers to scaffold their moral reasoning.

In their recent monograph, Miller, Fung, Lin, Chen, and Boldt (2012) suggested that the types of maternal strategies described by Recchia et al. (2013), particularly those that bolster children's self-esteem, are culturally specific and reflective of Western cultural values. Miller et al. (2012)

employed ethnographic, longitudinal home observations and analyses of everyday conversations to study moral socialization in European American families of 2.5- to 4-year-olds in the United States and in Chinese families in Taiwan. They found that conversations in the two contexts occurred at similar rates and showed similar age-related increases in frequency and child participation, but they also observed culturally specific differences in moral socialization. In Taiwan, conversations were more didactic; caregivers focused on elaborating, narrating, and correcting children's misdeeds and privileged the roles of the bystander and narrator. In the United States, conversations were more affirming of the children, and downplayed children's rule violations to emphasize children's strengths and preferences.

These analyses highlight the dynamic, constructive nature of moral meaning-making. Although contextual differences were observed, this does not mean that children necessarily view all of their parents' discipline methods in a positive light. Children reflect on parents' behavior, and as they grow older, their evaluations of whether parental behavior is fair, right, or legitimate have a substantial effect on their moral development and adjustment. As Reccchia et al.'s (2013) analyses suggest children increasingly exert agency in their moral development. In a recent study, Helwig, To, Wang, Liu, and Yang (2014) compared 7- to 14-year-old rural and urban Chinese and Canadian children's evaluations of different disciplinary practices, particularly those involving psychological control and shaming in response to moral transgressions. They found that shaming and love withdrawal were more common in China than in Canada. But, regardless of setting, children preferred induction and, with age, became increasingly critical of shaming and love withdrawal. They viewed these disciplinary practices as having negative effects on self-worth and psychological well-being.

Research has also shown that cultural variations in whether children view parental discipline as fair and reasonable moderates its effects on children's adjustment. Lansford and her colleagues (Lansford et al., 2005) have studied mothers and children across a broad age range and in different cultures that vary widely in the normative status of physical discipline (spanking or slapping, grabbing or shaking, and beating) and in mothers' use of those practices. Regardless of the cultural context, frequent physical discipline had adverse effects on children's adjustment. Harsh forms of discipline have been shown to be associated with maladjustment in childhood. When children interpret physical punishment as administered out of love and concern, however, its negative effects are mitigated.

Although physical punishment is still deleterious, it is less so. Further research needs to determine how this form of discipline is justified by parents as well as how it is interpreted by children.

Summary

The family provides the first set of sustained social relationships that children encounter and is a rich context for the development of morality, whether conceptualized as identity, moral emotions, behavior, or moral judgments. Studies demonstrate that from early ages onward, secure attachment relationships, authoritative parenting, and inductive discipline facilitate children's moral development, as do parent-child conversations, reminiscences about children's past and expected behavior, and conflict negotiations. These offer children opportunities to reflect on and interpret their experiences, consider and integrate an awareness of others' internal states with their concepts of right and wrong, and challenge others' (including parents') interpretations of moral events. The current research described here details how parenting varies in different contexts and depends on the nature of the transgression. As children grow older, they increasingly reflect on parental treatment (of them and in comparison to their siblings) and evaluate whether it is fair, legitimate, and appropriate. With age, new sources of social influence, such as the peer group, become important, as we consider next.

MORAL DEVELOPMENT IN THE CONTEXT OF PEER AND INTERGROUP RELATIONSHIPS

Researchers have examined different types of peer interactions (from friendships to groups to crowds) and relationships of varying quality to determine how peer interactions bear on moral development (Rubin, Bukowski, & Parker, 2006). Peer interactions have the potential to facilitate moral development through opportunities to cooperate, negotiate, and compromise (Piaget, 1932). Positive peer interactions can lead to the conceptualization of others as equals and help children form concepts about the fair treatment of others.

Peer interactions are seen as differing from adult-child relationships, which Piaget (1932) originally characterized as unilateral, hierarchical, and authority oriented. Peer relationships may also be hierarchical, however, just as parent-child relationships can reflect mutuality and reciprocity. The hierarchical quality of peer groups has been studied in terms of bullying and victimization as well as

in terms of status, prejudice, and group identity, which are related to intergroup attitudes (identification with ingroups and outgroups). Group identity can play a positive role as a form of affiliation or a negative role as a factor in social exclusion and prejudice. We discuss each of these areas of research, highlighting key findings.

Peer Interactions Promoting Morality

From early ages on, peer interactions play a positive role in enabling children to consider other points of view and in understanding why it is wrong to hit someone or deny toys and resources. Children's interpersonal conflicts provide a context in which children learn about the connections between acts and consequences (e.g., that hitting causes pain). Children's recollection of these experiences, as well as their own observations of other children being hit and crying in response—can enable the inference that hitting is wrong, particularly when the child identifies with the victim. In early childhood, object disputes—sharing toys and taking turns—are the most frequent source of interpersonal conflict, but this changes with age, as conflicts and negotiations over social interactions and relationships become more frequent.

Dunn (2014) proposed that friendships provide a context for the development and growth of moral sensibilities. The results of studies further suggest that the interpersonal bonds of friendships may facilitate children's thinking about the mitigating circumstances in which transgressions may occur (an issue we discussed earlier when considering links between morality and theory of mind). For example, one study found that although moral transgressions were viewed as wrong, preschool children were more forgiving of hypothetical moral transgressions and treated them as more permissible when they involved a friend rather than a nonfriend (Slomkowski & Killen, 1992).

Research by Dunn et al. (2000) has shown that young children who were observed to have high quality friendships (marked by low levels of conflict and high levels of shared imaginative play) were more likely to respond to hypothetical moral transgressions with justifications that focused on others' welfare, feelings, and interpersonal relationships. Furthermore, few associations between the quality of play and children's judgments of the permissibility of moral transgressions were found, pointing to the importance of going beyond simple quantitative measures (of permissibility, severity, or goodness) to consider qualitative differences in children's reasoning about events. Age-related changes demonstrate that young children's

ability to negotiate fairness begins in dyadic interactions and moves to triadic and group contexts. Children often have conversations and discuss issues of others' welfare, fairness, and rights. Further, as discussed earlier, young children negotiate resource allocation using moral reasons, often in the absence of adults.

Friendships typically have been defined as mutually reciprocal relationships in which both individuals identify the other as a friend (Bukowski, Motzoi, & Meyer, 2009). Research has revealed that such reciprocal relationships involve responsibility, cooperation, and coordination. Much like high quality parenting, high quality friendships supply social support that provides the basis for the development of concepts such as fairness, empathy, and equality. For instance, McDonald and colleagues (McDonald, Malti, Killen, & Rubin, 2014) found that, when resolving conflicts about hypothetical social dilemmas, adolescent best-friend dyads with high-quality conflict resolution exchanges used more constructive discourse strategies and more moral reasoning than best friends who had poor conflict resolution exchanges. Research also has shown that adolescents' prosocial orientation toward peers is related to moral reasoning (Carlo, 2014). A noteworthy finding is that children who have friends are less at risk for peer victimization than those who do not, leading researchers to assert that friendship provides a buffer against the risk of bullying (Hodges, Boivin, Vitaro, & Bukowski, 1999). More systematic research focusing on the role of friendship and the processes involved in enhancing moral development is warranted.

As has been well documented, peer interactions during adolescence become more complex and more embedded in social groups and cliques, as we describe below. Through childhood and adolescence, peer interaction continues to play a unique role, expanding in multiple ways in terms of dyadic friendships, group affiliation, and group identity.

Hierarchies and Inequalities in Interpersonal Peer Relationships

Peer relationships have the potential to be mutual and foster equalitarian principles, but many peer relationships also reflect unequal, unilateral relationships that undermine or create obstacles for moral development. Exchanges involving bullying and victimization are moral violations in that they cause harm to others and involve treating others unfairly and disrespectfully. Further, children who experience high levels of victimization are at risk for a host of

negative outcomes, including poor school and academic achievement (Graham, Bellmore, Nishina, & Juvonen, 2009; Juvonen & Graham, 2001).

Extensive research has focused on peer rejection and its consequences. Researchers have identified children who are neglected, rejected, popular, or “average” on the basis of peer nominations of friendships (Rubin et al., 2006). Rejected children, who identify other peers as friends but who do not receive reciprocated nominations, are often victimized by peers, and, in turn, react aggressively using bullying tactics. Thus, these relationships reflect negative moral intentions on the part of the victimizers and negative outcomes for the victims. Intention to harm others is a moral issue, and research that has focused on the moral dimensions of bullying includes studies of relational aggression (Crick & Grotpeter, 1995), the intersection of developmental psychopathology and moral judgments (Arsenio et al., 2009; Malti, Gasser, & Buchmann, 2009), and moral disengagement (Hymel, Rocke Henderson, & Bonanno, 2005).

Crick and colleagues (Murray-Close, Crick, & Galotti, 2006) were instrumental in identifying social cognitive factors as well as moral reasoning associated with relational aggression. Relational aggression was defined as the negative intention to harm another through psychological means, such as damaging the victim’s relationships and status through social exclusion. Children engaging in relational aggression often lack self-control and self-regulatory abilities, are less skilled at reading social cues, and interpret others as having hostile intentions in ambiguous encounters (Crick & Dodge, 1994). These deficits include an inability to coordinate victims’ and perpetrators’ intentions, as reflected in their expectations that victimizers will feel happy. Lacking these skills, children are at risk for bullying behavior toward others or being victims themselves. Thus, this research helps identify children at risk for committing moral transgressions such as harming others. Arsenio (2014) and others have also examined how information-processing deficits are related to moral judgments. These deficits, which reflect individual differences, contribute to becoming chronic bullies or victims, and to the negative consequences of interpersonal rejection.

Children also experience exclusion based on their cultural group membership, and this has been shown to be detrimental from a moral developmental viewpoint. Huynh and Fuligni (2010) found that Asian American and Latin American adolescents reported more adult and peer discrimination than did their European American peers, and

Latin American youth reported more adult discrimination than their Asian peers. Discrimination reflects unfair treatment based on group membership, and these types of experiences are related to various negative outcomes. For example, the frequency of discrimination predicts lower academic performance and self-esteem and more depressive symptoms, distress, and even somatic complaints. School composition, teachers, and classroom climates are central to children’s and adolescents’ experiences of safety, freedom from victimization, and social exclusion. Rejection and exclusion due to group membership factors differ qualitatively from rejection due to personality deficits, however.

Studies that have directly compared how early adolescents (11- to 15-year-olds) evaluate peer rejection based on personality traits (aggressive and shy) in contrast to group membership (gender, ethnicity, nationality) reveal that early adolescents use personal choice reasoning to explain why interpersonal peer rejection is justified, and use moral reasoning to explain why intergroup social exclusion is unfair (Malti et al., 2012; Park & Killen, 2010). An important direction for further research would be to examine the intersection of these variables. For example, studies could test whether children use moral reasoning to explain peer rejection of an aggressive ingroup peer or personal choice reasoning to explain rejection of a nonaggressive outgroup peer. Analyses of social and moral reasoning help to elucidate the developmental processes contributing to patterns of inclusion and exclusion as well as prejudice, as we discuss next.

Interpersonal and Intergroup Aspects of Peer Relationships

In contrast to interpersonal rejection experiences, intergroup peer exclusion occurs when a member of a group excludes someone based solely on group membership, such as gender, race, ethnicity, culture, or sexuality (Killen, Mulvey, & Hitti, 2013). Intergroup approaches focus on the normative, societal expectations that foster group identity (and group affiliation) and often, at the same time, create ingroup bias and outgroup dislike. In turn, these attitudes have the potential to lead to prejudice, discrimination, and bias, both explicit and implicit (Abrams & Rutland, 2008; Killen et al., 2013; Nesdale, 2004).

Intergroup relationships are those in which ingroup and outgroup categories interact, and they contribute to both positive and negative aspects of moral development. On the one hand, forming a strong group identity provides

an affiliation that enhances self-esteem and bolsters confidence. On the other hand, ingroup identity often creates ingroup preference, which can result in outgroup dislike. Within the intergroup attitudes literature, there is debate about whether ingroup preference is necessarily linked to outgroup derogation (Nesdale, 2004). When outgroup derogation exists, however, the results are often in the form of negative and unfair treatment of others, including prejudice, discrimination, and exclusion.

Whereas the intervention goals in the case of interpersonal peer rejection are to train children who lack social skills to better read social cues, the aim of intergroup exclusion interventions are to train the majority group to be aware of both explicit and implicit biases in order to reduce prejudice and discrimination, which occur throughout development. Recent research applying this issue to moral reasoning has proposed that a central aim of intervention is to increase the understanding that prejudicial exclusion is a moral transgression because it reflects the unfair treatment of others. Children are both the perpetrators and recipients of negative intergroup attitudes, which create harm, injustice, and unequal treatment. Contrary to popular belief, children's prejudice is not a direct outcome of parental attitudes (Aboud & Amato, 2001). Instead, children form ingroup and outgroup categories early in life, which contribute to their evaluation of peer encounters including those that are morally relevant.

Intergroup Contact Facilitating Moral Judgments

Relying on Allport's (1954) intergroup contact hypothesis, which identifies the conditions under which intergroup contact can reduce prejudice, developmental researchers have examined when contact with members of outgroups increases moral reasoning, empathy, perspective-taking, and prosocial behavior toward others (Tropp & Prenovost, 2008). Studies examining which conditions for contact are most effective have yielded conflicting findings. A meta-analysis of developmental studies on the connections between intergroup contact and reduction in prejudicial attitudes (Tropp & Prenovost, 2008) revealed that the most significant factor for prejudice reduction was cross-group friendships. This is important because friendships and peer relationships play such a central role in moral development. Thus, having a friend from an "outgroup" was related to a reduction in negative attitudes toward the group as a whole. Aboud and Spears Brown (2013) report that discrimination emerges as early as 4 years of age,

and thus interventions focused on cross-group friendships are particularly important early in development.

Recent findings support the expectation that intergroup contact increases more positive moral judgment and moral reasoning regarding intergroup social exclusion (Brenick & Killen, 2014; Crystal et al., 2008; Feddes, Noack, & Rutland, 2009). As an example, a longitudinal study conducted by Feddes et al. (2009) cross-group friendships experienced by German children predicted positive attitudes about Turkish children, as well as positive attitudes about peers and peer relationships. Thus, cross-group friendships provide an important form of social experience that reduces negative moral treatment of others. Turner, Voci, and Hewstone (2007) investigated self-disclosure (sharing intimate details with another person) in children's cross-ethnic friendships and found that it led to more positive attitudes toward outgroups, with increased levels of empathy and intergroup trust, two forms of moral responses by peers. When U.S. ethnic majority children and adolescents attend ethnically heterogeneous schools and report cross-group friendships, they use fewer stereotypes and more moral reasoning when discussing interracial relationships and social exclusion than majority youth attending ethnically homogeneous schools (Killen, Kelly, Richardson, Crystal, & Ruck, 2010).

In another study, Aboud, Mendelson, and Purdy (2003) studied 6- to 12-year-old White Canadian and Black Caribbean children's friendships and found that children with less biased attitudes had more cross-race companions and more positive perceptions of their friends. These studies identify aspects of peer interactions and social experience that enable children to recognize why prejudice is wrong and unfair.

Peer Groups, Prejudice, and Classroom Expectations

The roles of teachers and classroom interactions in prejudice and bias have been investigated from many different viewpoints. Here we consider classroom variables that contribute to hierarchies and discrimination, as well as students' perceptions of unfair classroom or teacher practices that contribute to negative peer relationships. For instance, in investigating patterns of ethnic segregation among 8- to 11-year-old African American and European American children, Wilson and Rodkin (2011) found that when African American students were in the numeric minority, they were more likely to be friends only with same-ethnicity peers and disliked by ethnic majority peers.

However, this was not true when European American students were in the numeric minority in a classroom, revealing a status hierarchy that may contribute to prejudicial behavior.

In a series of studies by Verkuyten and colleagues, social exclusion among 10- to 12-year-old Dutch, Turkish-Dutch, Moroccan-Dutch and Surinamese-Dutch preadolescents was associated with school segregation (or desegregation) and multicultural education (Verkuyten & Thijs, 2002). Children experienced less exclusion if they believed they could tell teachers about unfair behavior toward them and that the teachers would take action. This demonstrates that children who could report on the unfairness of exclusion were less likely to be victimized. Dutch children also reported more awareness of ethnic exclusion when they came from classes that spent more time discussing multicultural issues, such as the need to be fair to others from different countries and recognize different cultures within the class and society.

Verkuyten's findings also indicate that youth are aware of the role of power imbalances between victims and perpetrators and that this awareness influences judgments regarding the wrongfulness of exclusion. When the perpetrator was from the majority-status group, exclusion reflected societal-level patterns and an asymmetrical power balance, in contrast to when the perpetrator was from the minority-status group (Verkuyten, Weesie & Eijberts, 2011). This supports the view that school climate is related to perceptions of safety and experiences of prejudicial attitudes. These studies reveal the challenges and obstacles for applying principles of impartiality and fairness to contexts in which stereotypic expectations are pervasive.

Møller and Tenenbaum (2011) examined 8- to 12-year-old majority (Danish) children's reasoning about peer and teacher exclusion stemming from increasingly overt discrimination against Muslims in Denmark. Danish majority children found it less acceptable for teachers to exclude children than for peers to exclude other peers. Children were sensitive to the roles of authority as well as of group status in such moral transgressions. They judged it less acceptable to exclude a less powerful group member, but they did not extend this judgment to peer encounters. The legitimacy of peer exclusion based on cultural membership raises concerns about the existence of underlying biases. Thus, teachers and school climates have significant impacts on children's moral development regarding issues of fair treatment of others based on group identity. Identifying measures of classroom climate that could

be used across studies would help promote comparison studies and enable a more systematic way of testing the effectiveness of different ways to promote fair treatment of others in classroom contexts.

Summary

Research on the roles of peers and social groups has expanded greatly over the past decade. Research demonstrates that friendships and peer interactions can be important—indeed central—contexts for moral development, as they afford opportunities for cooperation, reflection, and reciprocity among equals. New studies examining the specific characteristics of friends and friendships at different ages and their direct contributions to moral development will provide a more complete picture of the role of peer relationships in moral development.

Peer relationships that are unequal can cause moral harm through bullying, coercion, and harassment. Further, intergroup relationships, which are reflected in peer groups defined by group identity, may have both positive and negative influences on moral development. Cross-group (e.g., cross-race) friendships can reduce prejudice and increase moral reasoning about the wrongfulness of group-based exclusion. Yet, group identity can also contribute to prejudice and discrimination when children and adolescents prefer the ingroup and dislike the outgroup. Developmental science research has not fully analyzed the role of teachers and the larger school environment on the factors and specific mechanisms that provide obstacles or catalysts to promoting fairness and justice. Curricula that foster cross-group friendships may also help to reduce inequalities and facilitate moral development. These issues need to be examined systematically.

MORALITY IN THE CONTEXT OF CIVIC ENGAGEMENT, SOCIETY, AND POLITICAL INSTITUTIONS

Beyond family and peer groups, youth also engage in and are influenced by the larger societal and political context. Interest in how youth become engaged citizens of their societies has long been the province of political scientists, who have focused on associations between demographic variables and political behaviors such as voting (see Helwig et al., 2014). Increasingly, however, developmental scientists have addressed these issues by

studying the moral dimensions of civic life. Thus, we consider recent research on civic engagement, moral attitudes, moral identity, political reasoning, and social inequality.

Civic Engagement

A great deal of research has examined adolescents' civic behavior, including volunteer activities and political activities like voting or protesting for a cause, with an eye towards determining the factors that predict involvement (and with a concern about how to instill these values in childhood and adolescence so as to enhance civic engagement in adulthood). One of the central areas of research in this field concerns the connections between civic engagement, moral attitudes, and moral identity. These studies have focused primarily on community service and have been guided by the assumption that greater involvement facilitates moral identity. As Hart, Atkins, and Donnelly (2006) noted, youth who engage in voluntary community service often are motivated by altruistic intent; indeed, a survey of a large representative sample of U.S. teens demonstrated that stronger endorsement of moral attitudes (e.g., that it is important to help others in the community) is associated with more involvement in community service 2 years later. Similar findings have been obtained in a large survey of youth in seven countries (Flanagan, Bowes, Jonsson, Csapo, & Shlebanova, 1998). Further, in her studies conducted in 28 countries, Torney-Purta (2002) documented the school's role in promoting civic engagement, demonstrating the generality of this issue across the globe. Even when schools mandated teens' involvement in community service, engagement in these activities led to further interest in community service and civic participation (Hart et al., 2006).

Research on civic engagement has employed behavioral measures of these constructs (for instance, community service, voting in an election, protesting for a cause, joining a civic organization), but very little research has examined adolescents' conceptions of these different activities and their moral relevance. Metzger and Smetana (2009) showed that middle-income U.S. ethnic majority 17-year-old students judged community service involvement and volunteering (like helping to feed the homeless) as morally obligatory and praiseworthy activities. Moreover, adolescents who were more involved in these activities were more likely to reason morally and have a moral orientation to these activities. In contrast, political activities like voting in an election were seen as obligatory, but in a conventional sense (because they facilitate the

effective functioning of society). Further, engaging in community activities (like joining a neighborhood social club) was judged to be a personal issue. With age, adolescents viewed community service less as an obligation and more as a worthwhile activity (Metzger & Ferris, 2013). These studies demonstrate that adolescents have complex and differentiated conceptions of different types of civic engagement and suggest that the type of activity researchers operationalize as measuring civic engagement may influence the findings they obtain.

Hart and Fegley (1995) examined concepts of self and identity among poor, urban, primarily African American youth who were heavily involved in community service (and thus were designated as "moral exemplars"). They found greater congruence between morally exemplary youths' actual and ideal selves, their past and future selves, and their images of their parents than among a comparison group of youth, who were matched demographically but were not heavily involved in community service. These researchers suggested that personal ideals, parental models, and youths' sense of personal identity facilitated their commitment to community service, although, as they also noted, the cross-sectional design of the study makes the causal direction of the findings unclear.

Evaluations of Democratic and Other Forms of Governments

Numerous studies have examined children's and adolescents' moral evaluations of different political systems. For instance, Helwig (1998) compared Canadian children and adolescents' conceptions of the fairness of different governmental systems, including different forms of democracy (consensual, direct, and representative), oligarchy (rule based on wealth), and meritocracy (where decisions are made by the most intelligent and knowledgeable individuals). All participants evaluated democratic systems as more fair than nondemocratic systems, but by early adolescence, direct democracy was evaluated as fairer than other democratic systems, based on appeals to majority rule and representation. These responses did not mimic what adolescents learned in school, nor did they reflect their own political system (representative democracy).

To extend the research to children living in non-democratic political systems of government, Helwig and colleagues (Helwig, Arnold, Tan, & Boyd, 2007) replicated this study, comparing Mainland Chinese and Canadian adolescents. The participants included urban, middle class teens in Canada and Nanjing, China. All youth

asserted that democratic systems were better and fairer than the nondemocratic systems; they reasoned that people should have a voice and that they should allow for various segments of society to be represented in governance. Moreover, Chinese youth viewed representative democracy as better than democracy by consensus, based on concerns with practicality and utility. Thus, these findings suggest that adolescents in different cultures consider the features of political organizations independent of official cultural ideologies and connect them to judgments of political fairness.

Social Trust Beliefs

In a series of studies, Flanagan and her colleagues have examined social trust, or the belief that people are trustworthy and treat others fairly rather than maximize their own gain. These positive beliefs about humanity accord well with philosophical perspectives on morality (Nussbaum, 1999). Flanagan (2003) argues that individuals develop these beliefs from interacting with people who are different from them and in families that value equality, empathy, and tolerance. To test these hypotheses, Wray-Lake and Flanagan (2012) examined the development of social trust in a large sample of U.S. 11- to 18-year-olds that were followed longitudinally over 2 years. They found that adolescents' social trust beliefs were higher in early than in middle and late adolescence and that they declined over time. However, mothers' beliefs did not differ according to adolescents' age, nor did they change over time.

Wray-Lake and Flanagan (2012) found that democratic parenting, which involves respect for adolescents' autonomy, led to increased social trust for early and middle adolescents, whereas parental messages regarding compassion increased social trust for middle and late adolescents. Flanagan and Stout (2010) further found that beliefs about social trust became increasingly differentiated from interpersonal trust during adolescence. In addition, classroom climate (being in more open classrooms where student opinions were valued and students were respected) led to greater social trust over time, but these effects were mediated by feelings of school solidarity. Thus, these studies provide important insights into how the fair and respectful treatment of adolescents in different social contexts (families and schools) can facilitate positive moral views of others. Research discussed next examines adolescents' beliefs about other morally relevant aspects of society and political life.

Reasoning About the Sources of Social Inequalities in Society

Researchers also have examined children's and adolescents' conceptions of the sources of various social problems and economic inequalities (Olson, Shutts, Kinzler, & Weisman, 2012). For instance, Flanagan and Tucker (1999) examined adolescents' explanations for unemployment, poverty, and homelessness. Distinctions were drawn between explanations that situated causes in the individual and their dispositions versus those that focused on situational, societal, and structural reasons. Youth from lower as compared to higher socioeconomic status families were more likely to believe that individuals were personally responsible for their misfortunes, to endorse the belief that the United States provided equal opportunities for all, and to report that their family valued self-reliance more than compassion and social responsibility. In contrast, adolescents from higher socioeconomic status families were more likely to focus on structural and situational reasons for these social problems. Flanagan and her colleagues have asserted that differential access to societal opportunities (as reflected in social class) led to differences in their understanding of the social contract and the extent to which it offered opportunities for changing economic circumstances.

In a related study, Flanagan, Cumsille, Gill, and Gallay (2007) examined U.S. majority and minority (European, African, Latino, and Arab American) adolescents' beliefs that the United States is a just society, as measured using beliefs about equal opportunity. They found that regardless of ethnic origin, gender, or age, adolescents had stronger beliefs in the United States as a just society when they had a stronger sense of connectedness to their community, and particularly if they believed that their teachers employed democratic practices in their classrooms. The importance of social connectedness has been implicated in other studies of civic commitment as well. However, adolescents' beliefs in the United States as an equal opportunity society were also negatively associated with their experiences of ethnic and racial discrimination (Flanagan, Syvertsen, Gill, Gallay, & Cumsille, 2009). That is, the more discrimination African, Latino-, and Arab-American teenagers reported, the less they believed that society offers individuals a fair chance and equal opportunity to succeed. African American teenagers were least likely to believe that the U.S. government is responsive to individuals "like them" and that the police mete out justice fairly. These findings call for more research on connections between experiences of unfair treatment by authorities and judgments about trust

and confidence in governmental institutions. Such studies need to be conducted in different groups to determine the factors that contribute to adolescents' negative perceptions.

These findings are important, because they show the intersections between adolescents' interpersonal experiences with peers and their beliefs about the fairness and opportunities available in the broader society. The latter, in turn, has implications for ethnic minority youths' willingness to be involved in civic life and the broader society, which is important not just for citizenship but for developing a fair and just society.

CONCLUSIONS, IMPLICATIONS, AND FUTURE DIRECTIONS

As the research reviewed in this chapter indicates, morality is a central topic of inquiry in the developmental sciences, and in the past decade, research on the emergence and development of morality has flourished. Morality is being investigated across multiple disciplines, including economics, anthropology, social psychology, comparative psychology, biology, and the neurosciences. Questions and perspectives from these disciplines have enriched the developmental study of morality, which reciprocally, has raised challenges and questions for scholars in other disciplines. New areas of inquiry have emerged, theoretical approaches have become more integrated, and innovative methods have been applied to broaden and deepen our understanding of moral development.

Thus, for instance, and as we have shown in this chapter, research has demonstrated that the foundations of moral awareness are present in infancy and toddlerhood, as well as in nonhuman primates. Theory of mind competence has been demonstrated to be related to moral judgment. Neuroscience research has explored the biological bases of morality. Children's concepts of harm, resource allocation, fair and nonprejudicial treatment of others, social inequalities, and rights develop from a very focused and narrow form in early childhood to their application in different situational and cultural contexts. Thus, with age, moral judgments require the ability to weigh contextual variables. As well, moral judgments become more comprehensive and generalizable with age.

As this review of research findings suggests, morality cannot be characterized as developing along a linear path. Morality is embedded in cultural contexts and in social relationships; it is neither biologically predetermined nor entirely socialized. As with biological and

cognitive development, moral development is multiply determined; many processes help to ensure that children become morally competent adults. Moral cognition, emotion and behavior all interact and are woven together as children develop.

We have also seen that healthy family and peer relationships facilitate individuals' abilities to live together within societies and treat one another with justice, fairness, equality, and compassion. Secure attachment relationships with caregivers provide a strong basis for the development of trusting, compassionate, and just relationships with others (Cassidy, 2008), but this is only the beginning. Parenting that is responsive, respects the child as an autonomous individual, helps the child to understand his or her own and others' emotions, and scaffolds an understanding of justice, fairness, and others' welfare through reasoning all contribute to healthy moral development. Children reflect on and evaluate parental messages, which may facilitate moral growth, but also, when messages that are not understood or are seen as unfair or illegitimate, may be resisted or rejected.

Children's conflicts and negotiations with siblings and in the context of high quality friendships are central to moral development as well. Social interactions with equals and near equals provide children with opportunities to learn about cooperation, loyalty, respect, and fair treatment. Mirroring the types of interactions with caregivers that facilitate moral understanding and empathy, having teachers and classrooms that employ democratic practices also facilitate a sense of connectedness to their community. We have also seen that these developmental contexts can pose many challenges. Parenting that is harsh and punitive undermines moral development, as do peer relationships that are coercive or involve rejection, harassment, or are prejudicial. Furthermore, schools and societal practices that perpetuate inequalities and unfair hierarchies lead to challenges in children's moral development.

Where to go from here? Despite the considerable progress of research, much remains to be done; there are many new avenues for moral development research to pursue. The family, peer, and community contexts for development reviewed in this chapter rarely have been central to philosophical treatises of morality or its origins (Nussbaum, 1999; Okin, 1989). For example, Okin (1989), a political scientist and philosopher, observed that, despite the centrality of the family in foundational philosophical theories of morality (e.g., such as the view that morality originates in the family context), family arrangements have historically been one of inequality and inequity with

respect to women's roles, as well as to children's status as rational beings deserving of fair and just treatment. This is still the case today, and future research needs to more directly link the quality of parent-child relationships with moral concepts of equality and equity. This would also illuminate how family relationships and conventional norms about status, power, and hierarchies contribute to moral development.

More research also is needed to better conceptualize the role of children's and adolescents' interactions with family members, peers, and friends and their implications for moral emotions, cognitions and decision making. As we have seen, recent research has gone beyond a focus on parent-child relationships to more broadly consider how different relationships within the family contribute to moral growth. Much research has shown the importance of sibling relationships for morality, but research needs to consider broader definitions of families. For instance, in some groups and cultures, extended families, including grandparents and other relatives, are the norm, and stepparent, reconstituted, and single-parent families are increasingly common. Fathers play a crucial role, and too many developmental science studies continue to ignore the role of the father despite extensive evidence that children thrive when both mothers and fathers are involved in children's development (Lamb, 2010); this role applies to moral development as well. Further, we are in the midst of historic legal changes regarding same-sex marriage, and there will surely be a rise in families with children raised by lesbian, gay, bisexual, and transgendered couples. Studying the role of different family arrangements and roles is essential for our science and for public policy and could help illuminate moral developmental processes.

Although positive peer interactions and relationships contribute to moral development, we have seen that negative peer relationships—being the recipient of negative bias and expectations from one's peers based solely on skin color, ethnicity, gender, and sexual orientation—can have wide ranging detrimental effects for children's moral development. Some children, both from ethnic minority or majority backgrounds, are clearly aware of the unfairness of differential treatment and social inequalities, but others are not, and we need to better understand why this is. Furthermore, research needs to include children who are potential targets of unfair treatment and those who are potential perpetrators (from all backgrounds). Moreover, we have shown the importance of considering children's awareness of unfair treatment of others based on group membership and intergroup attitudes;

this research should be extended to other areas of moral development. Finally, while social inequality at a societal level is pervasive, we know little about whether and how this is perceived and evaluated by children and adolescents.

The current global landscape is filled with moral issues that bear on children's healthy development. Violence continues in many parts of the globe; children continue to experience crippling poverty, life in refugee camps, recruitment as child soldiers, and even slavery. Research on moral development can help us understand these many and overwhelming challenges that too many of today's children experience. Research on resilience has shown that children can survive and even thrive in the face of overwhelming odds, but we know very little about moral development in such catastrophic situations, which offer opportunities to understand healthy moral development, development gone awry, and the factors that tip the balance in either direction. Just as importantly, studying such situations can make an important contribution by helping to cast light on the inequalities and perpetuation of injustice around the world.

Moreover, many social issues worthy of study do not pertain only to children's status and well-being but also to the context of the family, schools, and social institutions. For example, recent protests regarding women's rights in India have implications for children's lives in the family context, and U.S. discussions on racial profiling of minority males as reflecting unfair and prejudicial treatment affect minority children's aspirations and motivations. Negative school climates create unsafe environments for children that bear on children's welfare as well as their rights to an education, and to become productive members of the workforce.

As children around the world are living in new communities and growing up in cultures that are more heterogeneous than in the past, parents, teachers, and educators are struggling to determine how best to teach children about fairness and inclusiveness, especially in contexts in which negative messages about individuals based on group membership are pervasive. The data reviewed in this chapter, however, reveal that children are neither passive recipients of information, nor are they ruled by selfish and aggressive instincts. Concepts of morality emerge very early, and for the most part, young children have an awareness of equality, fairness, and rights, which becomes much more fully formed by adolescence. In this chapter, we have demonstrated that what develops is not the ability to appreciate morality but rather the social

cognitive competence, knowledge, and experience required to apply morality to increasingly complex social situations. We do not yet fully understand why children feel, think, and apply moral understanding in some circumstances but not in others, and this remains an important issue for further research, as identified throughout this chapter. Parents and educators have to help children disentangle the complex considerations present in situations that call for moral judgments; they also have to foster positive social relationships that motivate children to choose the moral course of action.

Children everywhere experience discrimination and unfair treatment as a result of their age, gender, sexual orientation, race, ethnicity, religion, nationality, indigenous background and other categories. At the same time, and as research reviewed here indicates, children are also the perpetrators of exclusion and discrimination. Adults also play both roles, teaching children to respect others but communicating negative messages about outgroups, which contributes to unfair treatment of others. Legal frameworks are essential for providing the foundations for equity and justice in childhood and throughout development. However, this is only the first step toward securing a course of healthy moral development. Social and psychological attitudes and the types of relationships that form in development also need to change. Thus, understanding the psychological developmental underpinnings of the origins and development of morality is essential for creating effective intervention programs.

Moral development research has expanded exponentially across the globe in recent years. While much of the research reported in this chapter has been conducted by North American and Western European researchers, studies have included ethnic, religious, and racial minority subgroups, in addition to majority groups. This has been an important contribution to our knowledge. Nonetheless, more research in different contexts and across wide age ranges are required to more fully understand moral development.

There are ongoing debates more generally about the virtues of studying “within-culture” versus cross-cultural studies. Both types of studies are needed to build a comprehensive picture of moral development. However, studying moral development in another culture should not mandate a “comparison” sample from the United States. Conceptualizing the role of culture requires going beyond broad templates and overgeneralizations and towards acknowledgment of the diversity of perspectives present within all cultures. In an age of ever-increasing global

connectedness, immigration, and international political and economic collaboration, detailed investigations of how individuals in diverse cultures develop, evaluate, and apply morality in their everyday lives and interactions will help researchers to answer fundamental questions about the culturally specific and universal aspects of morality.

As we noted earlier, morality is being widely studied in other disciplines, and statements are being made about the nature of morality without adequate connection to developmental processes. Therefore, we encourage researchers to engage with scholars in other fields so that the types of innovative findings reviewed here can be better integrated across disciplines. The research described in this chapter reflects high-quality scholarship and science, providing examples of innovative theory and methodology that are driving new avenues of research. The developmental science of morality provides theories, evidence, and data for making a difference in children’s lives, and for promoting justice, fairness, and equality.

Vulnerability and Depression	781
Methodological Considerations	784
FUTURE IMPLICATIONS FOR CONCEPTUALIZING SELF	785
CONCLUSION	785
REFERENCES	786

Perhaps more than any of the domains of human development, self-processes have garnered long-term multidisciplinary interest and attention. Philosophical, theoretical and empirical views concerning self-processes have often served as conceptual tools, either for guiding responsive national policy or as explanatory devices for evaluating outcomes. Approaches to the nature of the self matter, as do interpretations of self-processes: Both are implicit in much education and youth-related policy. With broad, global media accessibility (see Swanson, Edwards, & Spencer, 2010), there are a much wider variety of influences on self-processes in contemporary society than in the past. Researchers are paying more careful attention to historical and contemporary everyday cultural practices that affect how diverse groups of humans live and adapt (e.g., see Lee, Spencer, & Harpalani, 2003; McGee, Hall, & Spencer, *in press*). Moreover, filtered through socially structured opportunities and challenges, media images and cultural practices provide the “interpretational framing” of our own lives, and those of others—all within the various social contexts of human development. Thus, our conscious and unconscious views about the nature of the self as implied for ourselves and inferred for “others” make a difference. They unavoidably contribute to the structuring

of everyday contexts constructed for others and those taken for granted by ourselves (e.g., structured inequality and conditions of privilege). As complex phenomena linked with evolving cultural contexts, life course psychosocial processes matter profoundly.

Consequently, this chapter posits that—given the social, economic, and cultural realities and complexities evident in 21st-century North America—conceptual cautions are needed. An emphasis on self-processes must provide, at minimum, equal attention to the widely disparate social and economic conditions. These social inequalities contribute heavily to differences in self-processes in the first two decades of life in all societies. Traditional psychological perspectives on the self did not emphasize differential access to resources and varying levels of exposure to developmental challenges, particularly for minority youth. Researchers have begun to emphasize these social inequalities when studying minority youth development (see Spencer, Harpalani, et al., 2006, for an overview), but there is much that can still be learned by conceptualizing self-processes specifically in terms of these inequalities. Given America’s growing racial and ethnic diversity—a phenomenon that is also occurring in many European and other nations across the world—there

is a need for developmental psychologists to place racial and economic inequality at the forefront, even when studying individual psychological phenomena such as self-processes.

While they share physical and psychological space and a national identity as Americans (see Spencer, 2011), the nation's diverse youth frequently face unique challenges related to racial and economic inequality. Given increasing racial and ethnic diversity, context-linked adaptive processes matter for youth character development and self-appraisal (see Spencer, 2008a, 2008b; Spencer, Harpalani, et al., 2006; Spencer & Tinsley, 2008). To name but a few environment-mediated factors, psychosocially significant values concerning attractiveness—even for males—(e.g., see Korobov & Bamberg, 2004), age-relevant criteria (e.g., Proulx & Chandler, 2009), gender (e.g., Davis & Stevenson, 2006; Dupree, Gasman, James, & Spencer, 2009), as well as race and ethnicity (e.g., see Harpalani & Spencer, 2009; Swanson, Cunningham, Youngblood, & Spencer, 2009; Swanson, Spencer, Dell'Angelo, Harpalani, & Spencer, 2002) are all salient messages that influence self-processes. The process begins early and continues across the life course as messages requiring adaptations or reframing become part of the culture (e.g., Davis & Stevenson, 2006; Harpalani & Spencer, 2009; Slaughter-Defoe & Wang, 2009; Spencer, 2008a; Swanson et al., 2002). From both long-term and recent theoretical formulations and contemporary reports representing links between self and a broad array of person characteristics, the topic's influence has not abated. It has enjoyed historical speculation, is consequential both for individual level and group members' adaptive processes, and is understood to have salience for the ultimate character of life course experience and outcomes.

William James (1892/1961) is generally credited as the individual who made foundational advances to our understanding self-processes. The "I-self" or sense of one's basic existence as a unique individual suggests consciousness and stability; that is, an awareness that one's unique experiences, thoughts, actions, feelings and perceptions continue across place and time. However, very young children's developmentally appropriate egocentrism prevents a full appreciation of the fact. Associated with a consciousness of self, as viewed by William James, is a gradual awareness of a sense of agency or inference which communicates that who you are is linked to and consequential for the experience of the environment or social context; in many ways, the implicit agency assumption is consistent with mid-20th-century theorists such as Robert White's (1959,

1960) representation of the construct as one of competence and effectance motivation and DeCharms's (1968) notion of personal causation. The second major aspect of William James's conceptualization is the "me-self," the distinctive description that generally refers to our knowledge about ourselves and to the ways of defining the self (e.g., age, gender, ethnicity). Individuals' objective categories about themselves may include roles (e.g., daughter/son), personality characteristics, cognitive distinctiveness, and physical individuality (e.g., height, skin tone) (see Harter, 1999). The latter categories suggesting "me-self" discernments are usually assessed as self-concepts (i.e., conceptions about the self). The noted constructions are associated with context.

As suggested in James's formulation, agency plays a critical role in self-processes. Although under-acknowledged in writing prior to the last quarter of the 20th century, societies contain diverse individuals. From a life span developmental perspective, it is critical to recognize human diversity and acknowledge the contributions of thought processes and environmental influences. This orientation also emphasizes the dynamism and *multidimensionality* (i.e., simultaneous consideration of biology, cognitive and psychosocial domains) for self-processes, especially given the varied experiences of diverse individuals. Acknowledging the breadth of developmental influences on self-processes makes the cross-domain manifestations exceedingly important (e.g., as illustrated by the disparity literatures across the fields of health, education, and juvenile justice). The fact of patterned disparities and assumptions about self-concept is particularly relevant when considering and comparing these processes in the diverse groups who share the same physical space. When considering diverse individuals beyond the "standard" (i.e., White, middle income, and, often, male), particularly in an era of global media intrusiveness, self-processes linked to body attributes and awareness become especially significant and complex. General body awareness themes are important; however, at the same time, issues of color awareness, social status (e.g., immigrant status), nativity, faith group, gender bias, and evaluative judgments about these issues matter in very special ways and have varying degrees of impact on the self as a function of the individual's developmental status and thus awareness.

In light of these themes, this chapter examines historical perspectives regarding self-development and presents contemporary conceptualizations of self-processes with specific attention to race and gender as visible characteristics associated with societal expectations that shape

conditions for privilege or marginalization. It then discusses factors that require negotiation of these processes by diverse youth. Family and school contexts are presented as contextual areas of vulnerability that affect identity development and coping outcomes necessitated by conditions of risk and challenge. The chapter concludes with an examination of methodological considerations in examining self-development and future implications for research on diverse groups of youth—research that will have to consider race, gender, and economic inequalities as they affect self-processes.

DEVELOPMENT: A LIFE-SPAN ORIENTATION

Human life course changes are vast (particularly between birth and late adolescence) and, as suggested, the underlying influences themselves are significantly intertwined. Accordingly, understanding age-related patterns of growth and change that take place both within and between developmental stages (i.e., infancy and late adolescence), and acknowledging the numerous contextual and cultural processes that mediate different life stage outcomes are critical. Considering and integrating the meanings for the self and particularly insights about the inherent processes significantly enhance the probability that effective policies and pedagogy will support all children and youth. Further, when considering developmental issues associated with the transitions that children make from stage to stage, it is critical to acknowledge that the combinations of maturational and environmental influences on development are unique for each child; accordingly, individual variation from the norm is more typical rather than the exception. Thus, the existence of individual difference increases the challenge to committed researchers, adding another test to policy makers (i.e., guaranteeing that supports actually function supportively for those they are intended to benefit).

The Self: Challenges and Opportunities

An inescapable challenge given individual variations of experience in myriad settings is that everyone is vulnerable. All humans represent some level of vulnerability: a high level, a balanced level (i.e., risks and supports are at an even keel), or a low level (more supports than challenges are evident or an inferred low level of risk is suggested). The balanced (or imbalanced) relationship between the level of support (i.e., protective factors) and perceived risk (and anticipated challenge) on a moment-to-moment

basis communicates the degree of protection afforded as a function of privilege and the accessibility to resources and support, as opposed to high-risk exposure with inadequate supports (see McGee et al., in press; Spencer, 1995, 2008a, 2008b; Spencer, Harpalani, et al., 2006). However, irrespective of vulnerability level, human resiliency is possible (see Dupree, Spencer, & Spencer, in press; Luthar & Cicchetti, 2000; Masten, 2001; Tinsley & Spencer, 2010; Werner, 1993). That is, for individuals high in vulnerability level, successful outcomes (i.e., resiliency) are nonetheless possible. At the same time, individuals low in human vulnerability can still show maladaptive outcomes and significant failure because the untoward aspect or downside of a privileged life status suggests less experience with adaptive coping (e.g., Luthar, Cicchetti & Becker, 2000; Luthar & Lattendresse, 2002). Privilege and excessive opportunity, which function as significant levels of protective factors, obfuscate the experience of challenge; more specifically, maladaptive coping in the event of significant challenge is due to an individual's lack of adaptive coping practice. Unacknowledged privileging conditions undermine opportunities for adaptive coping; accordingly, the situation leads to potentially less productive adaptive responses to everyday or normative stressors (see Spencer, 2008b; Spencer, Swanson, & Edwards, 2010). Accordingly, self-processes, combined with cross-domain relationships (i.e., physical, psychosocial, and cognitive) and linked to environmental interactions, become complex representations of human vulnerability. Such vulnerability is inextricably associated with nuanced self-processes that can serve as protective factors and positive options, or can become sources of challenge and risk. This chapter examines and delineates the complex interactions between self and social context, and it provides a conceptual framework and theoretical underpinning to analyze their impact on diverse groups of youth.

Domains of Self: Contributions of Risk and Opportunity

Developmental variation for individuals includes interactive changes within the biological, cognitive, and social/emotional domains as associated with environmental quality. Each period of human development, given the character of the context, presents opportunities for variations in the construction of the self and the associated adaptive processes engaged in by the individual (i.e., multiple levels of experienced individual–environment interactions). Acknowledging the latter is critical since growth and development do not occur in a vacuum but happen in contexts ranging from the parent, family, and peer

group to the complex and multitiered societal level (i.e., the frequently overlooked interactions with multiple layered environments). Developmental transitions may represent heightened periods of human vulnerability in formulating and expressing self-processes, to name just a couple, given (1) the upcoming period's specific expectations and requirements (e.g., the attachment-based developmental tasks of infancy, and later periods' sophisticated [cognitive, social, cognitive and physical] tasks for mastery); and (2) the significant variety of person–process–context interactions that mediate the net balance between the components of vulnerability: risk level versus protective factor presence salience across the several human domains (i.e., cognitive/intellectual, affective/emotional, social, and physical/biological).

To illustrate this set of interacting forces, Jean Piaget's theory of cognitive development is helpful; it describes how children construct an understanding of self and the world by interacting with their physical and social environments. Children adapt to their environments by developing mental organization or schemes to interpret and frame their understanding about the nature of the self and of the world. The biological need for balance between mental schemes and actual experiences drives adaptation, spurring the development of more differentiated and complex mental structures including social constructions of "me" and "not me" formulations. However, when young children are deprived of opportunities to interact optimally within their environmental and social worlds, their transition into the next stage of development and nature of the constructed self may be compromised. Hence, they are unable to take full advantage of the opportunities presented to them during the next stage of development because the foundational support necessary for optimal growth is lacking. Particularly with more multifaceted self-construction changes heralding the start of adolescence, self-relevant processes become more nuanced.

Erikson (1959) describes complex self-construction themes as eight stages of ego identity crises associated with developmental challenges and corresponding consequences as experienced across the life course. During infancy, the challenge is for infants to develop a sense of trust in the world based on responsive care-giving (i.e., to develop a secure attachment relationship). When infants' attachment and trust needs go unaddressed, they develop a sense that the world is not a safe place and, in worst-case scenarios, experience severe developmental delays. This sense of mistrust affects children as they get older and face the developmental challenge of becoming more independent (i.e., development of autonomy). Other

developmental challenges identified by Erikson include autonomy versus shame and doubt (toddlerhood), initiative versus guilt (early childhood), industry versus inferiority (middle childhood), group identity versus alienation (early adolescence), and identity versus role confusion (late adolescence). The ways in which children and youth cope with the developmental challenges of each stage help shape their developing sense of self and identity and their ability to cope adaptively with future challenges.

Although human developmental stages are characterized by *normative developmental tasks and disputes*, the transitions between stages are periods of enhanced vulnerability and accordingly pose their own unique challenges. For example, the transition into adolescence precipitates an increased focus on the self—both the inner self and the outer self. It is difficult for young people to escape a preoccupation with their physical appearance given the dramatic bodily changes ushered in by puberty. Further, with the onset of formal operational thought, adolescents become more introspective and more likely to engage in thinking about what others are thinking about them. For the first time, they begin to really see and appraise themselves through the perceived eyes of others, increasing feelings of self-consciousness and self-judgments. During early adolescence, self-evaluations are based predominantly on normative standards, social comparisons, and behaviors, evolving into personal beliefs and standards during late adolescence. Given that early adolescence is a period when the social environments of youth are rapidly expanding and their bodies are quickly changing, the task of meeting new people and trying to make a good first impression becomes a more frequent occurrence, and for some, a common source of anxiety. Support structures need to be in place to help adolescents through this transitional time of development, and to help children and youth during other transitional periods, as well.

Despite the opportunities and challenges associated with normative transitions of development and growth, the ability of children, youth, and adults to successfully give meaning to and cope with ongoing challenges presented by and experienced within their unique environmental contexts persists throughout life. The development of positive coping strategies (i.e., that lead to more positive self-constructions) is critical, especially when children are growing up in contexts where environmental challenges serve as distractions from normative developmental growth and learning experiences. More than ever before, given the central role of media (as well as its potentially intrusive character), children and youth experience an increased

prevalence of adverse influences including models of violence (i.e., domestic, community), exaggerated portrayals of beauty standards, and separation from family members (through death, incarceration, economic stress, etc.). Typically, children are not provided with opportunities and supports that enable them to effectively talk about and cope with their experiences unless they are diagnosed or labeled as having a particular disorder or disability, thus aggravating feelings of marginalization. In some cases, their seemingly maladaptive responses to these experiences are appropriate considering both the nature of the constructed experience and their developmental status. Nevertheless, it is rare that a child can receive the necessary intervention and support without having endured the process of being labeled or diagnosed, because funding for such interventions is often earmarked for certain populations or services. How policy makers deal with these issues remains to be seen. However, the prevalence of policies that discount normative developmental challenges and reward the practice of labeling children's reactive coping strategies as pathological may well seriously undermine the design of authentic supports; the latter suggests behavioral interventions designed, in fact, with the expressed intent to promote healthy development for all children and youth. However, the latter goal may not represent the actual intent.

As described by Spencer, Harpalani, et al. (2006), a normative human development perspective is essential for a maximal understanding of *resilience* and *vulnerability* given the pursuit of stage-specific life course competencies. The risks that youth face, along with the successful and unsuccessful strategies they employ in coping with these risks, must be understood in relation to *both* their maturational status and identity formation processes as linked to the larger social, cultural, and historical contexts of development. Research in developmental psychopathology and applied human development has increasingly focused on risk and resilience. Scholars have begun exploring important conceptual issues that require greater clarity, such as the various definitions of resilience as a construct, and the utility of these in various contexts (see, for example, Dupree et al., in press; Luthar, 2003; Luthar & Cicchetti, 2000; Luthar, Cicchetti, & Becker, 2000; Spencer, 2001; Tinsley & Spencer, 2010). Importantly, a key point to add to this discussion is that risk and resilience cannot be separated from normative developmental processes that occur in multiple contexts. Healthy and normal human development involves negotiating some level of risk and demonstrating a degree of resilience in the face of challenge. From our perspective, *risk* is properly

conceptualized as the exacerbation of normative challenges encountered in the pursuit of myriad stage-specific competencies and is linked to broad sociopolitical processes (i.e., racism, sexism) and/or lack of resources (e.g., Gallay & Flanagan, 2000; McGee et al., in press). These exacerbated normative challenges can be negotiated in conjunction with protective factors, including social (e.g., cultural capital) and material (e.g., the intergenerational transmission of wealth) resources that help individuals to cope with challenges and maximize available supports. We define *vulnerability* as the net experience of both risk and protective factors that an individual encounters (see Anthony, 1974). Productive coping outcomes as well as *unproductive* coping products are possible. Accordingly, as an outcome, *resilience* involves successful negotiation of *exacerbated challenges*; however, resilience is not possible without significant challenges and as linked to heightened risk conditions. The risk and protective factors of youth are key processes given the unavoidable self-awareness, which then leads to self-appraisals.

Self-Appraisal Processes

Self-appraisal processes provide the key link between personal identity development and the individual's relationship to the social world. These processes integrate various aspects of an individual's life and thus promote cognitive, affective, and social development. Self-appraisal is also central to self-esteem and feelings of competence in childhood and adolescence (Swanson, 2010). The long-term persistency of the literature's linking of self-appraisal with color, race, power, and gender deserves to be framed historically, as in the following section.

The Color Bias System and Its Salience to Self-Appraisal: A Historical Review. The color bias system has a complex and global history. Montalvo and Codina (2001) identified the historical roots of the caste classification in Latin America, specifically focusing on Mexico, and noted how differences based on skin color became associated with relative social positioning. They described the colonial involvement in Latin America and indicated how the Spanish and Portuguese colonial powers promoted an absorption ideology. African slaves and indigenous populations were encouraged to blend with White lineage, known as "Whitening," yet despite this color-blind policy, a subtle racial hierarchy developed. Montalvo and Codina described the caste system in Mexico, noting that it was established by the Spaniards in power based on phenotype so that the minority of European heritage was socially

and economically more powerful. The system established White and Black as the extremes, yet a fluid intermixture occupied the middle ranks and, as Whiteness was encouraged, families could improve their social and economic standing by marrying Whiter individuals. Considerations of power mattered.

Conflict between the lesser ranks of castes allowed the Spaniards to maintain power as a system of racial hierarchy and racial stereotypes endured. This caste system was not based on religion or a legal structure. “The incentives for whitening were powerful and not the least of these was the colonial belief that ‘the least drop of Spanish blood was sufficient to raise Mexicans from the rank of slaves’” (Montalvo & Codina, 2001, p. 324). Although the Mexican caste system was abandoned after the war of independence from 1810–1821, the caste system was eliminated and “replaced with informal arrangements that still managed to carry over social privilege based on phenotype” (p. 325).

Globally, other groups have histories similar to that of Mexico in which biases were perpetuated based on skin color. These include Brazil (Lovell & Wood, 1998), the Caribbean (Simonsen, 2003), and Australia (Trigger, 1989), each of which note patterns of behaviors explicitly linked to skin color and social practices created to enhance social control. With a somewhat different historical approach to biased practices, Dikötter (1994) reported that China incorporated a notion of race into its self-definition even as other scholars have claimed racism does not exist in China, stating that “In an era of economic globalization and political depolarization, racial identities and racial discrimination have in fact increased in East Asia” (p. 404). Dikötter discussed several examples of racist ideology dating to the 19th century in which the superiority of the yellow race in its alignment with the White race was claimed in contrast with the inferiority of the Black race and its cultural impurity. Color and status remained salient.

Montalvo and Codina (2001) suggested that, for particular areas of the lower U.S. South during the same period of the Spanish colonial period, a three-tiered system of race privilege developed in which mixed race individuals received more privileges in society and were used to manage Black populations of slaves. However, with the American Civil War, a two-tiered system developed due to the need to defend slavery. Following the war, the American South—where the majority of Black Americans resided—implemented a legal system of racial segregation (commonly known as “Jim Crow”), designed to keep the social lives of White Americans separate from those of Black Americans, and to keep the latter group in a

politically subordinated position. Interracial unions were legally forbidden and racial classifications were reduced to a dichotomy in which a White person was defined as having not a single drop of Black blood. However, within the Black community, lighter skin was more privileged and these perceived advantages remain today. Many Latinos/Latinas have managed to minimize race as a strategy to protect themselves from the American racial binary. However, those with darker skin born in America have suffered more discrimination. Montalvo and Codina noted that, as minorities will continue to grow in number in the United States, “Nevertheless without a basic cultural change in American institutions and attitudes, the reality will not improve the asymmetry in race relations as some believe, but will likely transform it into a hierarchical caste-like system as history proposed” (p. 337). Their perspective suggests that skin color preferences shape the experience of Latinos in America and that the silence that excludes this discussion makes this experience invisible.

The one-drop rule in the American context during slavery and afterwards was driven by a fear of contamination of the “White” gene pool. Any individual with any Black blood was considered Black. However, in the Deep South a three-tiered system developed in which mulattos had more privileges than Blacks. The Deep South had more isolated communities and fewer women and the mulattos acted as middle-men in dealings between Whites and slaves. Furthermore, mulatto slaves occupied indoor positions while physically grueling work was done by Black slaves. As pressure increased from the North to abandon slavery and Whites sought to preserve social hierarchies, the three-tier system eroded to a two-class society racially divided by the “one-drop” rule. The mixing of White, Black, and Native American individuals left a variety of skin colors in the Black population (see Sharfstein, 2007). This mixing across race and class became the basis of color classism among American Blacks. Accordingly, skin color, preferential treatment, and status suggested a foundation with interpersonal implications for both within- and between-group-relations.

The creation of “color classism” in the United States is similar to racialization in many other nations: For example, Bonilla-Silva (2001) notes the development of similar racial hierarchies in Latin America and South America. This suggests that group identity formation is central to understanding social and economic inequality—although not always based on race. Alam (2003) defines auto-centrism as “the tendency of social groups to claim superior attributes—racial or cultural—and, conversely,

to denigrate other groups" (p. 205). The author explored autocentrism throughout history and space. Alam's analysis suggested that while autocentrism existed among the ancient Greeks, Islamic and Chinese civilizations, distinctions were asserted based on cultural superiority, not specific to race. The one exception argued by the author is that, in the 19th century, the Chinese employed their superiority based on race (the author argued that this is an adaptation of a western characterization). Nevertheless, in modern societies—and especially in American society—race has become the central domain of autocentrism.

West's (2002) approach analyzed what gave rise to White supremacy in modern discourse in the west. The author suggested that White supremacy cannot be explained only in terms of economics, the political interests of slave holders, and the psychological needs of the dominant White group; rather, it was sustained by a particular scientific way of understanding the world and humans through description and rank ordering. The scientific revolution highlighted observation and evidence. Furthermore, West argued that the reemergence of classic aesthetic values was important in establishing a "normative gaze" for ordering and comparing.

During the enlightenment, White privilege was so entrenched that the connection between Black skin color and inferior human characteristics and a less civilized manner was assumed to be natural so no justification for racist ideology was needed. Hume, Jefferson, and Kant all expressed racist views without offering justification for them. West (2002) contended that science played important roles in "highlighting the physical appearances of people in relation to what it is to be human, beautiful, cultured, and intelligent" (p. 108). Furthermore, "race did matter in classical antiquity.... The crucial difference seems to be that racial differences were justified on cultural grounds in classical antiquity, whereas at the inception of modern discourse, racial differences are often grounded in nature, that is, ontology and later biology" (p. 108).

Considering these scholars collectively, it is fair to conclude that the idea of White supremacy as a cultural and aesthetic ideal operates along with the capitalist system of production. Thus, it is not surprising that the issue of self-appraisal, given its links with agency, continues to be a powerful contributor to assumptions about life course self-processes both for those without resources as well as for those enjoying significant privilege.

However, as described by Spencer (1985) and colleagues (see Harpalani & Spencer, 2009; Spencer, Harpalani, et al., 2006), the cognitive egocentrism of young children prevents them from internalizing the affect;

thus, they are able to maintain a positive sense of self even though they show awareness of color bias by age three. While young children are certainly affected by racial and economic inequalities, they have not yet developed sufficient self-consciousness for these inequalities to negatively influence their self-esteem. This changes with the onset of late middle childhood and adolescence, when self-consciousness is at its highest. For this reason, adolescence is a particularly important development stage in elucidating how self-processes are affected by racial, social, and economic inequalities.

Societal Expectations, Assumptions, and Influence on Self-Appraisal

Developing a sense of efficacy is crucial during adolescence due to the heightened self-consciousness and greater cognitive awareness of youth, and it is one of the key developmental tasks articulated by Erikson (1968). Successful performance on a particular task increases a sense of personal empowerment (i.e., competence) and the likelihood of future successes in subsequent tasks: Erikson's (1968) "Industry versus Inferiority" stage precedes the future developmental tasks of identity development and intimacy.

Individual development, however, is also determined by the opportunities and expectations of the larger society, and from the local environments where the individual resides and engages developmental tasks. Moreover, given the general developmental tasks associated with early adolescence, issues of competence are compounded by one's culture as well as one's status in the larger society. Therefore, competence is not only rooted in culture and prior successes, but is crucial for successful adaptation to subsequent adult roles. As described by Spencer and Dupree (1996) and suggested by Bandura's (1978) theorizing, self/other appraisal processes are key to social learning and identity development. During middle childhood in particular, these recursive self/other evaluative processes are unavoidably linked to experiences of stress. The stress response requires coping that leads to stable psychosocial responses that may be maladaptive or adaptive. Stable psychosocial coping strategies are linked to a coping outcome or product that may be either productive in quality (e.g., competency, self-efficacy, resiliency) or unproductive (e.g., school avoidance, "acting out" behavior, school-leaving/dropout). These coping outcomes set the stage for the recursive and subsequent experience of context, given individual self/other appraisal processes, as the individual progresses developmentally across the life

course. Recent conceptual framing provides a template for understanding the processes noted.

Phenomenological variant of ecological systems theory (PVEST; Spencer, 1995) elucidates all of the different facets that go into self-appraisal by integrating a phenomenological perspective with Bronfenbrenner's ecological systems theory (1989). A systems theory, PVEST consists of five components linked by bidirectional processes (Figure 18.1); it is a cyclic, recursive model that evolved during the subsequent decade and that describes identity development throughout the life course (Spencer, 2008b; Spencer, Harpalani, et al., 2006).

The first component, *net vulnerability*, consists of factors, such as psychosocial stressors, that can predispose individuals to adverse outcomes. The risks, of course, may be offset by protective factors (e.g., cultural capital). For urban minority youth, risks include socioeconomic conditions such as poverty, sociocultural expectations such as race and sex stereotypes—all of which can pose threats to healthy development. These conditions are also related to self-appraisal: how minority youth view themselves depends on their perceptions of these conditions and societal expectations.

Net stress engagement, the second component of PVEST, refers to the net experience of situations that challenge one's psychosocial identity and psychological well-being. These are essentially risk contributors that are actually encountered and manifested in everyday life and may be offset or balanced by available supports (e.g., interactions with supportive adults). Experiences of discrimination and negative feedback are salient stressors for minority youth, and these influence self-appraisal. In conjunction with normative developmental processes, such as the expression of adolescent male bravado, these stressors can have adverse consequences if appropriate supports and interventions are not in place.

In response to stress, *reactive coping methods* are employed to resolve dissonance-producing situations. Normative cognitive maturation makes awareness of these situations acute and unavoidable. Reactive coping responses include strategies to mitigate or solve problems that can lead to either adaptive or maladaptive solutions. As coping strategies are employed, self-appraisal continues, and strategies yielding desirable results for the ego in the short-term are preserved—even if they may have long-term maladaptive consequences. The reason for this is that

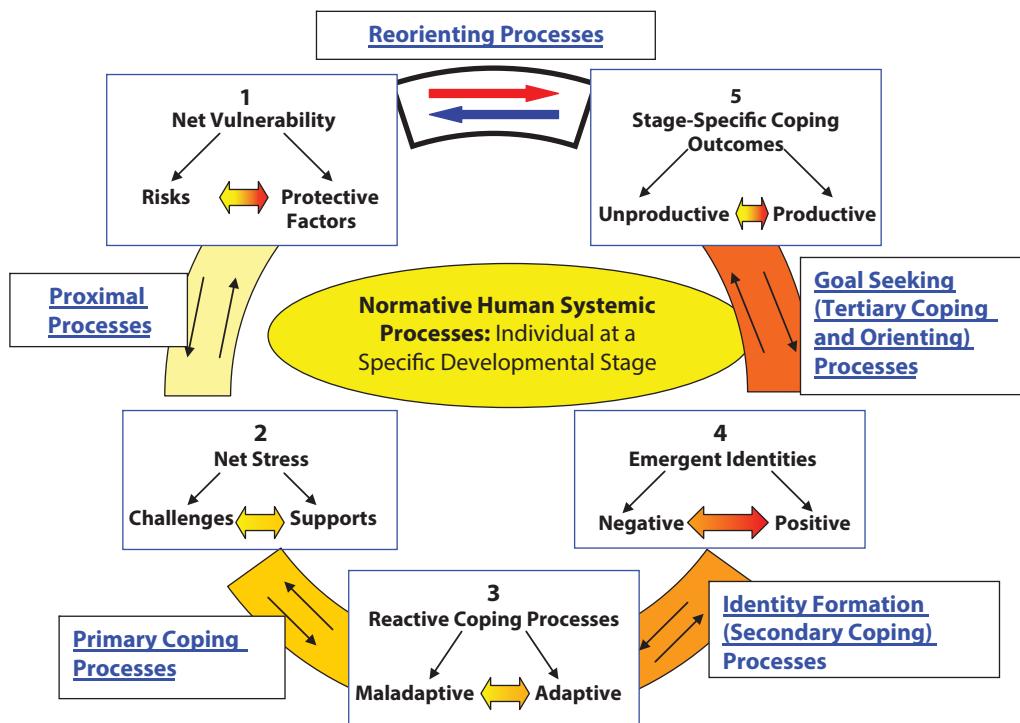

Figure 18.1 Phenomenological variant of ecological systems theory (PVEST: Cyclic version).

Source: Adapted from "Lessons Learned and Opportunities Ignored Since *Brown v. Board of Education*: Youth Development and the Myth of a Color-Blind Society," by M. B. Spencer, 2008, *Educational Researcher*, 37(5), pp. 253–266; and "Phenomenology and Ecological Systems Theory: Development of Diverse Groups" (pp. 696–735) by M. B. Spencer, in *Child and Adolescent Development: An Advanced Course*, W. Damon and R. M. Lerner, Eds., 2008, Hoboken, NJ: Wiley.

children and adolescents live “in the moment”; given their heightened and growing self-consciousness, immediate self-appraisal, rather than long-term projection, is key.

Over time, these strategies become stable coping responses which, coupled together, yield *emergent identities*, the fourth component of PVEST. Emergent identities define how individuals view themselves within and between their various experiences in different contexts (e.g., home, school, neighborhood). The combination of cultural/ethnic identity, sex role understanding, and self and peer appraisal all define one’s identity. Identity lays the foundation for future perceptions and behavior contributing to adverse or productive *life stage-specific coping outcomes*, the final component of PVEST. Productive outcomes include good health, positive relationships, and high self-esteem, while adverse outcomes include poor health, incarceration, and self-destructive behaviors. Accordingly, given context-linked life experiences, multiple possibilities can be explained.

The PVEST processes cycle and recycle through the lifespan as individuals balance new risks against protective factors, engage new stress levels determined by the ratio of challenges to potential supports, try different coping strategies and engage in self-appraisal, and redefine how they and others view themselves.

Within the PVEST framework, self-appraisal is key to coping and resultant identity formation. Relevant aspects of cognitive and social development include self-perceptions, self-efficacy, self-esteem, intelligence, temperament, and problem-solving and interpersonal skills (see Compas, Connor-Smith, Saltzman, Thomsen, & Wadsworth, 2001). Individual attributes develop as a function of behaviors or beliefs that reflect an active, selective, structuring orientation toward the environment. The ability to modify, select, and reconstruct the environment, however, depends on being enabled or empowered to engage in behavior that influences the environment, and appraisal of one’s own ability to influence that environment. The social structures and conditions, from the micro- to macro-level systems provide relevant experiences that interact with psychological processes to produce unique behaviors. In sum, the individual is engaged in a life course process of coping with environmental challenges (e.g., risk and stress), sociocultural contexts (e.g., expectations, attitudes, cultural beliefs and assumptions), and normative developmental tasks (see Havighurst, 1953), and self-appraisal provides the link between coping, identity, and outcomes.

As noted by Erik Erikson (1959), Anna Freud (1958), and more recently by James Marcia (1991), it is the pure

rapidity of physical and psychological changes, social fluidity, and the spatial mobility of youth that contribute to the enhanced high risk character of childhood and adolescence. Unfortunately, regardless of the life stage being considered, few have attempted to integrate the attendant *processes* of identity pursuits with coping responses and character development (Damon, 1997), as linked to the multiple levels of the ecosystem described by Bronfenbrenner (1979, 1989). These attendant processes include the perceptions and resultant meaning making accrued and experienced by the individual, and serve as a *feedback loop* of influence for subsequent decision making and coping outcomes. Self-appraisal is central to understanding all of these processes.

In addition, there are other important oversights—racial/ethnic identity and *identifiability*, contextual experiences, and available supports—to address when analyzing adolescents’ evolving self-appraisal. Characteristics such as race/ethnicity and skin color, gender and body type, and sexual orientation serve as *opportunities for identifiability* and are thus linked to the experience of stigma and related stress. As such, in conjunction with coping and identity, it is necessary to consider self-appraisal processes in relation to these individual characteristics. Although generally an uncomfortable factor to consider and integrate into conceptual analyses, race, ethnicity and human identifiability make a difference for life course experiences.

Race and Ethnicity

Several flaws have characterized scholarship on minority youth (Spencer & Harpalani, 2001). Generally absent from consideration is a systems analysis that considers risk level and the presence of protective factors. From our own work (Spencer & Dornbusch, 1990; Spencer & Markstrom-Adams, 1990; Swanson, Spencer, & Petersen, 1999) as well as that of others (e.g., Youniss et al., 2002), it is clear that identity formation during adolescence requires that youth understand themselves as members of a society within particular ethnic, cultural, religious, or political traditions—each of which is associated with potential and unique protective factors. Further, Youniss et al. (2002) have posited that an “orientation to habitual right action” is fundamental to identity insofar as the process of defining oneself entails becoming part of a normative cultural unit.

Youniss and colleagues’ notion is important when considering the experiences of culturally diverse young people who are often subjected to being “missed, dissesed, and pissed” as described by H. S. Stevenson (1997). The salient point made by Stevenson is that the person’s

phenomenology *matters*. Inferences made about an individual's experiences may be linked to: (1) the perceptions of challenges and available resources, (2) exposure to modeled strategies for reactive coping, and (3) the character of self-processes inferred and enacted, thus becoming a stable identity. Following this line of thought, individuals' life stage-specific coping products (i.e., as a consequence of a stable identity, these processes provide consistency in coping responses over time and space) have societal implications as outcomes for either noble versus ignoble deeds (Damon, 2002). How these outcomes are framed too frequently include inferences concerning group membership.

Race and Self-Appraisal

With regard to race, there is a need to focus on how race is lived on a daily basis and how individuals, including developing youth, make meaning of these experiences. Experiences of race are filtered through larger societal influences such as manifestations of structural racism (see Bonilla-Silva, 1997), as illustrated by residential and economic segregation, and by encounters of negative stereotypes in the media and in everyday life. Race and ethnicity are also separate but intertwined constructs: While "race" generally refers to perceptions of observable phenotypes, the latter refers to cultural background. At times, it is useful as researchers to focus on ethnicity; for example, the culturally specific family experiences of African Americans and African immigrants may differ, and these two groups may have different referents for self-appraisal. However, youth from the two groups may experience similar racial stereotyping and treatment based on the common denominator of race. Depending on the particular circumstances, it may be more useful to focus on one or the other. It is also important to note that many youth and adults perceive their racial and ethnic backgrounds as interchangeable if not identical. It may be useful to consider race and ethnicity together, and to emphasize how the two interact in shaping everyday experiences of self-appraisal processes (for an overview, see Fisher, Jackson, & Villarruel, 1998, pp. 1157–1166).

Additionally, consideration of race and ethnicity must include White youth; otherwise, this would only contribute to the normalization of Whiteness. White youth, like all others, must be studied as one of many diverse groups. While youth of color are disproportionately represented among the low economic resource population, many White youth are also in this group. White youth and youth of color face the same basic developmental challenges; the primary difference between the two is that White youth are

considered to be the "norm" and reap all of the privileges of this status, ranging from greater cultural consonance across school, family, and neighborhood settings to "racial invisibility" in everyday encounters.

Self-appraisal links coping with identity and theories of racial and ethnic identity apply Eriksonian and Marcian concepts of identity formation to racial/ethnic awareness. Racial identity development refers to the "process of defining for oneself the personal significance and social meaning of belonging to a particular racial group" (Tatum, 1997, p. 16). William E. Cross's original Nigrescence model (Cross, 1971; Cross, Parham, & Helms, 1991) delineated four stages of racial identity formation for African Americans. During the *pre-encounter* status, Black individuals view the world from a White, Eurocentric frame of reference, consciously or unconsciously holding pro-White and anti-Black attitudes. The second status, the *encounter* phase, involves an event or series of events that cause individuals to recognize that they cannot fully assimilate into White society. These may be tangible experiences of racism—crises in an Eriksonian sense—which facilitate exploration of racial identity. The third phase, *immersion-emersion* is a reaction to the encounter phase. Here, through coping and self-appraisal processes, individuals become more interested in their Black identity and show increased awareness of racism and sensitivity to it. This phase may be characterized by anti-White attitudes. Individuals will also show a superficial immersion in realms associated with Black cultural attributes (e.g., music, speech styles, etc.). *Internalization* occurs as individuals become secure with their Black racial identities and move toward a more pluralistic perspective. African Americans then represent the primary reference group, but individuals' attitudes are not anti-White. In contrast to the superficial displays of the immersion-emersion stage, individuals in the internalization stage have more stable, deeply rooted connections to attributes of their Black heritage, and they may also have the ability to connect comfortably with aspects of White society; for example, they may have diverse groups of close friends.

W. E. Cross Jr. (1991) modified the Nigrescence framework into a more dynamic and flexible model of racial identity development. He argued that individuals may recycle through the different stages at various developmental periods, and, depending on parental racial socialization, they may not start in the pre-encounter stage. Thus, the stages should not always be viewed as a literal progression. Cross (1991) also added a fifth stage to the original four; this stage, known as "internalization-commitment,"

represents a more consistent internalization phase. This last phase can vary among individuals and include bicultural identities.

White racial identity is also important to consider; most notable in this area is the work of Janet Helms (1990). Helms's model of White racial identity development consists of six statuses, organized in two developmental phases. The first phase, *Abandonment of Racism*, consists of three stages. *Contact*, the first stage, involves acceptance of the dominant status of White people, although not explicit awareness of this dominance or the subordinate status of people of color. *Disintegration* occurs through self-appraisal, as White individuals become aware of their dominant status in society and go through a period of dissonance. In *Reintegration*, the person acknowledges his or her Whiteness and holds the view that he or she deserves the privileges accorded by this status. The second phase of Helms's (1990) model was called *Defining a Nonracist White Identity*. This begins with the *Pseudo-Independent* stage; individuals begin to question the dominant status of White Americans and may become overly involved with trying to help or change people of color. In the *Immersion/Emersion* stage, individuals begin to focus on changing White people rather than African Americans. With the final stage, *Autonomy*, individuals achieve a positive racial identity and also appreciate and seek opportunities to learn from other groups.

Other theorists have built upon this work and have also examined ethnic identity. For example, Phinney (1992) drew upon W. E. Cross Jr.'s (1971, 1991) racial identity theory and J. E. Marcia's (1966) work on identity statuses to devise the Multigroup Ethnic Identity Measure (MEIM), a psychological assessment instrument that can be used across diverse groups. Nevertheless, in conjunction with the earlier points about race/ethnicity intertwinement, it is important to be clear about the particular conception of race/ethnicity (or combination of the two) at issue, and this depends on the context and issues under examination. For example, Chinese Americans, Vietnamese Americans, and South Asian Americans may all be classified as "Asian American" even though there is significant within- and between-group variation for these groups. At the same time, it is important to note that different groups such as Chinese, Vietnamese, and South Asian Americans may have similar racialized experiences; they may be identified by others as one racial group and thus stereotyped and stigmatized in a similar manner (i.e., the "model minority" myth; see Takaki, 1998). Thus, there may also be a dimension of similarity in their experiences, and depending on

the issue and context of investigation, it may be more useful to emphasize the similarities or differences among various experiences.

In that vein, racial stereotyping, in all of its manifestations, is a significant contributor to high vulnerability and risk for children of color. Awareness of racial stereotypes and group membership status plays a key role in self-appraisal and identity formation. In addition to the negative stereotyping noted earlier with regard to aggression and violence, racial stereotypes present a barrier to academic achievement and resilience for African American youth. Steele's (1997; Steele & Aronson, 1995) work on "stereotype threat" highlighted these issues. *Stereotype threat* is essentially the fear of confirming a negative stereotype under circumstances where that stereotype is primed and salient; Steele's program of research (1997; Steele & Aronson, 1995) has experimentally demonstrated how stereotype threat can negatively affect the academic performance of Black college students. Moreover, the phenomenon of stereotype threat is most salient for high-achieving Black youth who have a great desire and expectation to succeed. However, it is not the value of effectance motivation and desire to succeed which is emphasized in the literature but rather the problem of stereotyping.

Academic stereotypes can also be a source of significant increase in risk and high vulnerability for Asian American youth, who are often monolithically viewed as high-achieving "model minorities." This can create tremendous pressure to succeed and meet expectations. Even seemingly positive racial stereotypes have a negative side; Asian American youth are often taunted as "geeks" and "nerds," and they are viewed as passive and socially inept. Additionally, positive and negative stereotypes can be coupled together, as is the case with African American athletes (Harpalani, 2005; Stone, Perry, & Darley, 1997). Here, the idea of African Americans as outstanding athletes, a seemingly positive attribute, is linked to the notion that African Americans are less intelligent and inherently lower achievers, due to genetic (J. P. Rushton, 1995) or cultural (Hoberman, 1997) factors. With regard to academic racial stereotyping, another subtle facet of opinion offered that contributes to the level of vulnerability is lenient feedback and low expectations from teachers; again, this becomes a risk factor as normative human development progresses. Cognitive maturation renders adolescents more sensitive and aware of feedback from elders and peers, and they themselves are more perceptive of false or deceptive tactics than younger children—and these also feed into self-appraisal.

Additionally, White privilege is a critical, although often ignored, element of any discussion of race and racism. Whiteness, specifically the history of White Americans as a racial group in America, has been the normed reference group. The group must be understood and considered to explain the current privileges and challenges of White youth. In her widely cited article, "White Privilege: Unpacking the Invisible Knapsack," McIntosh (1988) defined White privilege as a "package of unearned assets which [Whites] can count on cashing in every day... an invisible weightless knapsack of special provisions" (p. 10). In this vein, White privilege basically encompasses the advantages that White people secure on the basis of skin color. In many instances, White Americans themselves may not be aware of guaranteed advantages; more specifically, many are incidents that *do not* take place, such as *not* being stopped unjustly by the police, *not* being followed in a store or suspected of being a thief, and/or *not* being questioned about one's national loyalty. Because these are incidents that they *do not* experience, many White Americans do not understand the everyday burdens that people of color encounter, or they tend to minimize the salience of these burdens. White Americans often take their own advantages for granted and attribute them solely to hard work and "merit." Moreover, the social and cultural practices of schools and workplaces are defined by White American norms, and cultural expressions by people of color, ranging from hair and clothing styles to language, are either discouraged or embraced superficially under the rubric of "diversity," without any deeper exploration of their meaning and significance. All of these factors contribute to the continuation of White privilege as a salient issue. Nevertheless, there is also a "downside of privilege." In the context of Whiteness, "privilege" is typically viewed as a racially dependent advantage, usually unfair in some broad sense. On the surface, privilege appears to serve as a protective factor, offsetting potential risks that more marginalized individuals may face. However, one who is privileged is not subject to particular experiences of stress engagement—for example, negotiating cultural dissonance or racial stereotyping. Youth who must negotiate these challenges acquire valuable coping skills, whereas privileged youth do not. This lack of requisite coping skills, due to non- or minimal engagement with stress, may lead to adverse outcomes. Privilege precludes the opportunity to hone coping repertoires, through self-appraisal and demonstration of resilience, which are necessary to cope adaptively with later life challenges. The consequent lack of coping skills is the *downside of privilege* (see Spencer, 2008a). Not just the fact

of monoracial identification and coping opportunities (e.g., Whiteness and privilege status) but, additionally, a multiracial identity may introduce psychosocial complexity.

The increasing number of Americans identifying as biracial or multiracial also complicates the notion of racial identity and self-identification. Beginning in 2000, the U.S. Census allowed individuals to identify more than one race, and America's growing attention to diversity has promoted such multifaceted identification. Historically, like most minority groups, researchers tended to pathologize biracial and multiracial individuals, assuming that they suffered from inferiority complexes, hypersensitivity, and other psychological problems (Stonequist, 1937). By the 1970s, however, biracial/multiracial identity research had turned toward a *comparative or equivalent approach*: Researchers presumed that monoracial, biracial, and multiracial individuals developed racial identity in a similar manner (Thornton & Wason, 1995). Drawing from her clinical work, Root (1990, 1992, 1996) was among the first to argue that biracial individuals can make different healthy identity choices. Root's work identified four distinct positive identities for biracial and multiracial individuals: (1) acceptance of the identity ascribed by the larger society; (2) identification with a single racial group (typically the minority group); (3) identification with more than one racial groups; and (4) identification as a new and different racial group.

Additionally, Brunsma and Rockquemore (2001) have examined the manner by which multiracial individuals conceive of their racial identities. Rockquemore (1999) proposed a four-category identity typology that is different from Root's earlier conceptualization. Individuals with a *singular identity* choose to identify with a single racial group—most commonly (though not always) the minority group. Brunsma and Rockquemore (2001) attributed this to social treatment of hypodescent (e.g., the "one-drop" rule for Blackness in America). Individuals with a *border identity* tend to identify with two distinct racial groups: They choose labels such as "mixed," "biracial," and "half-and-half." Brunsma and Rockquemore viewed this group as merging and respecting multiple perspectives simultaneously. Nevertheless, in 2001, Brunsma and Rockquemore revised Rockquemore's (1999) original typology, adding the notion of *validated* versus *unvalidated* border identities. An individual of mixed heritage who chooses to self-identify as biracial implicitly requests that others accept that identity as well.

In contrast to *border identity*, individuals who possess a *protean identity* may identify themselves differently

depending on the social context. Finally, individuals with a *transcendental identity* attempt to defy racial labels or identification by race: For example, they may abstain from responding to self-report race questions or choose “Other.”

Given the increasingly diverse and complex nature of America’s racial landscape, and the continuing salience of racial identity, models of racial identity need to be further tested for their validity on future populations. Factors in need of integration and consideration include colorism relevant themes.

Skin Color. Perceptions and stereotypes related to skin color can influence self-appraisal in conjunction with racial identity. Skin color biases pose another risk for youth of color (and particularly African American youth). Skin color is probably the most visible and salient phenotypic feature associated with racial categorization and related biases. Colorism can be defined as systematic bias and inequality on the basis of skin color (usually privileging lighter skin tones over darker ones). Color consciousness and attitudes begin at an early age. Much of the early literature regarding skin color preference involved preschool populations (e.g., Clark & Clark, 1940). Clark and Clark found that Black children as young as 3 years old had knowledge of skin color differences and that they could identify their own skin color. In later work, young Black children were given a Black and a White doll and were asked questions such as which one they would “like to play with” or “which one is the nice doll?” (Clark & Clark, 1947). The majority of the participants in that study demonstrated White preferences. The Clarks concluded that this is an indication of Black self-hatred, a finding that was cited in the U.S. Supreme Court’s 1954 landmark decision in *Brown v. Board of Education*.

However, later work illustrated that these studies involved inaccurate interpretations or methodological flaws (Baldwin, 1979; Brand, Ruiz, & Padilla, 1974; Cross, 1991; Spencer & Horowitz, 1973; Spencer & Markstrom-Adams, 1990; Swanson et al., 2009), and that color preferences during early childhood are not related to self-esteem: Despite having a White preference (for dolls, pictures, or other objects), Black children display positive self-esteem and self-concept (Banks, 1984; McAdoo, 1985; Spencer, 1984). Young Black children do not internalize pro-White/anti-Black messages, due to their cognitive egocentrism (Piaget, 1932). Spencer (1984) noted that such young children do not project their preferences inward; they have a protective level of egocentrism that generally precludes low self-esteem. Cross (1991) noted that, even in the Clarks’ data, it was not clear that Black children

systematically preferred White dolls, and in any case, their preference shifted with age (see Harpalani, Qadafi, & Spencer, 2013).

Self-appraisal processes are key to understanding the development of self-esteem in relation to color. As children mature, they shed this protective egocentrism and become more aware of how society views Blackness. Data indicate that Black preschool children demonstrate Eurocentric attitudes, preferences and color-connotations, with increased Eurocentricity through age nine (Spencer, 1999). These attitudes and preferences reflect the fact that children learn at an early age that all things “White” are more valued in society. However, *children do not internalize these attitudes because of their egocentrism*. The onset of concrete operational thought marks a shift in attitudes and preference toward a more Afrocentric orientation. Another risk factor then emerges: the end of egocentric thinking and the emergence of self-appraisal in relation to others. Once Black children have the “veil of protective egocentrism” lifted, they begin not only to understand societal attitudes and stereotypes of color, but to view themselves in light of them. Many Black children react to this dissonance by shifting preference behavior rather than acquiring low self-esteem; nonetheless, this shift itself diverts energy from other developmental tasks such as academic engagement.

Of course, such risks may be offset by protective factors: Black parents can, and often do, socialize their children to understand the importance and implication of their skin color. Racial socialization can be a protective factor by decreasing the psychological impact of hostilities based on color and race. Proactive racial socialization strategies encourage racial and cultural pride, while protective strategies emphasize awareness of racism and related biases such as colorism (H. C. Stevenson, 1994).

As children transition into early adolescence, there are well-defined stereotypes about skin color related to social valuation of lighter skin over darker skin. These stereotypes exacerbate the already significant stress during adolescence that is related to body image and physical appearance. Color biases can also exacerbate stress in the realm of interpersonal relationships, where skin color can be a source of acceptance or rejection. According to Porter (1991), children prefer honey brown tones to darker ones, independent of gender or age. Porter found different gender- and age-related rationales for preferences, rooted in cognitive development, and linked with intergroup social experiences. Children between the ages of 9 and 11 offered reasons related to desire for sameness and desire to be liked

by others (e.g., “her friends are that color” and “wants to be like everyone else”). Older children (12- to 13-year-olds) explained their preference based on physical attractiveness (e.g., “probably thinks she’s ugly with that color”) and the possibility that people are discriminated against on the basis of skin tone (e.g., “could get more jobs and people would talk to her more”). These findings underscore the significance of normative developmental tasks, such as forming peer relationships, in mediating the impact of skin color. Affective processes become increasingly salient.

On the psychosocial level, researchers have found that skin color is related to feelings of attractiveness, self-esteem, and satisfaction. Stress related to body image and physical appearance is the most prominent developmental manifestation of skin color bias. Early researchers assumed that, because light skin was valued more than dark skin, there would be a negative effect on self-esteem related to this bias, especially in children (Clark & Clark, 1940). However, as with the doll studies, such assumptions can be erroneous: Coping responses to stress vary significantly within groups. Fegley, Spencer, Goss, Harpalani, and Charles (2008) found that skin color consonance (satisfaction with one’s own skin tone) and dissonance (dissatisfaction with one’s own skin tone) were related more significantly to a variety of measures of psychosocial well-being, including body image, than was skin tone itself. In their multiethnic sample of adolescents, darker skinned individuals were more likely to be dissonant than lighter skinned individuals, although individuals rating their skin tone in the middle showed the greatest amount of satisfaction. Fegley et al. (2008) also found Asian and Asian American youth to be the most dissonant with respect to skin tone, and that lighter skinned individuals (of all racial/ethnic groups combined) had lower overall body image and less positive general attitudes. These findings indicate that the relationship between colorism, coping, and psychological well-being is more complex than one might predict based strictly on societal biases. Other factors, such as cultural upbringing, may also play a role: For example, Montalvo and Codina (2001) found that relatively dark-skinned Mexican Americans (born in the United States) had lower self-esteem scores than dark-skinned Mexicans born in Mexico. Quiros and Dawson (2013) found similar evidence of stigma and privilege associated with colorism among native Caribbean Latinas. These findings reflect the needs of individuals negotiating societal expectations based on physical characteristics. Gender continues to be high on the list of characteristics exacerbating the processes noted.

Gender. In addition to race and the effect of colorism, gender socialization plays a large role in self appraisal, particularly as children grow into gender roles and receive gender-specific feedback on their behaviors. Parents provide different socialization experiences for males and females, and there has been much emphasis on analyzing the impact of father-absence and female-headed households. Males are encouraged to be physical and allowed significant independence while females are frequently assisted rather than encouraged toward independence and mastery. For example, boys who are reared in female-headed homes without a positive male figure may lack adequate identification with a male role model; these youth may compensate for their sense of masculinity by demonstrating excessively aggressive, assertive and often antisocial behavior patterns (see Cunningham, 1993; Ketterlinus & Lamb, 1994).

Of course, such behavior has consequences for coping and identity processes and for educational and life outcomes (Spencer, 1995). According to the gender intensification hypothesis (J. P. Hill & Lynch, 1983), observed sex differences between adolescent males and females are largely due to accelerated gender-based expectations resulting in youth behaving in stereotypically masculine and feminine ways. This “intensification” occurs as youth seek acceptance in social groups. For minorities and low-resource youth, efforts toward acceptability, and the development of greater independence expected of developing adolescents are often confounded by their experiences within the broader society, with its stereotypes and expectations.

The demand and demonstration of independence and responsibility occur early and are recognized in particular microsystems such as family, school, and church. Many low-resource minority youth find themselves moving into positions that demand responsible and independent behavior, but lacking the necessary provisional tools and support.

These challenges are manifested differently for males and females. As reported by Swanson and Spencer (1997), traditional masculinity as experienced in Western societies includes engaging in certain behaviors that are not socially sanctioned, but nevertheless validate masculinity. Male adolescents, in seeking to demonstrate their masculinity, may believe that others will perceive them as masculine if they engage in risk-taking behaviors, which may include involvement in premarital sex, alcohol and drugs, and participating in delinquent activities (Swanson, Cunningham, & Spencer, 2005).

For Black male youth, who feel frequently challenged due to myriad expressions of structural racism, risk-taking behavioral patterns may be viewed as more salient for guaranteeing their view of self as a man. Black males are probably the most highly stigmatized and stereotyped group in America—as illustrated by the recent, vast media coverage of Trayvon Martin’s killing and subsequent accusations of racial profiling. The even more recent Summer 2014 Ferguson, Missouri, residents’ reactions to a police officer’s killing of another unarmed Black male youth dramatically illustrate the dilemma. Whether it is with images of the super-athlete, criminal, gangster, or hypersexed male, it seems that most of society’s views of African Americans are defined by these stereotypes. The Black male has, in one way or another, captured the imagination of the media to such a wide extent that media representations create his image far more than reality does. Most of the images of the Black male denote physical prowess or aggression and downplay other characteristics. For example, stereotypes of Black athletic prowess can be used to promote the notion that Blacks are unintelligent (Harpalani, 2005). These societal stereotypes, in conjunction with numerous social, political, and economic forces, interact to place African American males at extreme risk for adverse outcomes and behaviors.

H. S. Stevenson (1997) has described how African American youth are “missed” and “dissed” by mainstream American society, and how this treatment in conjunction with neighborhood factors relates to African American youth becoming “pissed” and managing their anger. Black youth are “missed” as stereotypical media-based images distort, usually in negative terms, the meanings of their social and affective displays. Hence, these unique cultural displays are devalued and viewed with insolence—“dissed.” In conjunction with these misrepresentations, many Black youth reside in high-risk contexts where anger displays may be appropriate coping mechanisms. Anger may indeed become a form of competence for social and emotional viability in certain high-risk contexts. Thus, misrepresentation, disrespect, and hazardous contextual factors interact in creating the anger of Black youth (i.e., “pissed”).

Additionally, African American parents often describe anecdotally the additional developmental task of having to instruct their male children on how to respond to police officers while insuring that their behavior is not misconstrued as threatening or aggressive. This childrearing strategy reduces the probability that their Black sons become victim to police brutality at worse or simple harassment at best (see Cunningham, Hurley, Foney, &

Hayes, 2002). It is not surprising, then, that girls and boys perceive neighborhood police presence as having very different meanings, serving quite different potential sources of stress and self-definition (see Spencer, 1999, 2001). For minority parents, childrearing efforts require the provision of explicit explanations of minority status and its meaning and significance relative to race, gender, body type, physical size, and responses to authority. American culture and the minority experience are themes explained by some parents to their sons as cultural socialization. However, such explicit socialization is not typically the norm, although its protective function in support of positive youth development has been established (see Spencer, 1983; Spencer, Harpalani, et al., 2006). Yet the differential experiences of Black males and the related stress remain present even when not made explicit. In the context of such a culture, youth having similar experiences can exhibit either resiliency and school adjustment or problem behavior and academic disengagement. Unfortunately, the complexities of these processes are not well understood for youth who chronically struggle with difficult conditions. Too frequently, these youth are stereotyped as lacking appropriate moral fabric (see Spencer, 1999).

For example, many Black males believe that their behaviors are misinterpreted and their academic efforts are not respected by the school system. Whether it is hostile encounters with law enforcement, lukewarm everyday interactions with strangers, or negative teacher perceptions (Spencer, 1999), Black male youth experience and develop within stress-filled contexts. Not only through numerous structural and economic inequities, but even for middle class Black males, there exists a societal ethos that defines them as dangerous, threatening, and unintelligent. All of these factors, in addition to normative developmental processes encountered by adolescents, affect identity formation among African American adolescent males (Cunningham, 1993).

Stereotypes and social expectations can affect self-appraisal for various groups: For example, Asian American males are stereotyped as weak and unmasculine, and females are portrayed as submissive. These stereotypes, in conjunction with other factors, can render these youth vulnerable to mental health and social adjustment problems. Nevertheless, stereotypes can affect identity formation in complex ways. Von Hippel, Hawkins, and Schooler (2001) proposed a different and interesting take on the impact of racial stereotypes. Their study found that, among both Black and White Americans, counter-stereotypic performance was more salient to self-concept. Of the participants in their study who performed well

academically, Black Americans were more likely than White Americans to define their sense of self around intelligence, whereas among high-performing athletes, White Americans were more likely to define their sense of self around athletics. Harpalani (2005) examined athletic identity and academic resilience among low-income urban youth from various racial groups. He found that, while there were no differences in sports participation by race or achievement level, high-achieving Black adolescent males placed less importance on sports as part of their identity than either marginally achieving Black males or high-achieving non-Black males. These effects were not present among females, for whom sports participation does not have the same salience overall at school during adolescence. Harpalani (2005) also found that high-achieving Black students viewed intelligence as a more flexible entity and also emphasized the importance of being smart or intelligent as a means to success more than either marginally achieving Black students or high-achieving non-Black students. All of these findings are consistent with Von Hippel et al.'s (2001) argument, and, building on their work, Harpalani proposed the counter-stereotypic identity hypothesis: When an individual excels in a domain that runs counter to stereotypes of his/her racial group, that domain takes on particular salience for identity.

Adolescent females face a different array of issues related to social expectations of femininity, power dynamics related to gender, and the relationship between these and other factors and racism, family structures, and other forms of inequality. Physical maturation is an even more significant stressor, given the particular societal emphasis on female appearance. Moreover, maturation may be related to family structure and socialization. Ellis, McFadyen-Ketchem, Dodge, Petit, and Bates (1999) found that early sexual maturation is related to father absence. Analyzing data from a longitudinal study of 173 girls, the authors concluded that quality of father's relationships with daughters delayed the onset of puberty. Also, Spencer and Dornbusch (1990) noted that single parenthood may create additional stress by giving children autonomy earlier. While this may facilitate the development of coping skills, it can also be associated with negative outcomes. Adolescents dealing with normative developmental issues may not have the supports available to deal with the challenges of additional autonomy; this depends on the quality of resources and relationships available in school, community, and other contextual settings. Developmental stressors also compound identity development for adolescent females. This effect may be pronounced when fathers are absent. Fathers often serve as an initial "safe male"

figure (Hetherington, Cox, & Cox, 1985), whose male feedback plays a role for girls in gender socialization. It may be from this feedback that girls understand and refine a sense of their own femininity.

When the father is not present, girls may seek this feedback from their peers, which is not as "safe" an interaction. Moreover, this risk is increasing as girls are physically maturing at much younger ages. The average age of menarche has fallen from 17 to 13 between the mid-1800s and the mid-1900s. One out of seven White girls starts to develop breasts or pubic hair by the age of 8; for Black girls, nearly half start showing such signs of sexual maturity at this early age (Lemonick, 2000). By drawing more attention from older males, early maturation can increase the risk for earlier sexual activity and teen pregnancy, and this effect is more pronounced for Black girls.

Harris, Gold, and Henderson (1991) studied the influence of father-absence on gender-role orientation and achievement in a sample of Black and White older female adolescents. Harris et al. expected females without fathers to exhibit greater masculine-linked attributes and have higher achievement motives: Their findings indicated that Black girls (although not girls in general) with fathers exhibited significantly higher achievement needs and higher masculinity and androgynous attributes. One critical question here is the extent to which this finding reflected a characteristic of female-headed (father "absence") outcomes versus cultural socialization experience associated with the multiple roles of Black females. Ladner's classic (1972) research on sex-role development indicated that positive characteristics of adulthood, including strength and independence, were less sex-role differentiated among poor African American adolescents than among their European American, middle-class counterparts. Ladner suggested that multiple gender roles have been a reality for African American women for generations.

Adolescent females experience greater emotional barriers, greater anxiety, and have a greater inclination to regressive reactions when confronting problem-solving situations (Jung, 1993). Adolescents who generally demonstrate higher self-confidence show higher heuristic competence and lower accompanying emotions, greater social cognition, and a more active or proactive adaptation to stress.

Gender-typed characteristics, specifically female's level of masculinity, reflect a sense of efficacy and control that has been linked to depressive symptomatology. Females with low levels of masculinity score higher on measures of depression than their female counterparts with high levels of masculinity. There is a need to more actively assist

adolescent females in translating their positive academic experiences into positive youth outcomes and life-course attributes. This is particularly relevant when considering that multiple gender roles have been a reality for ethnic minority women for generations with less sex-role differentiation among them than among their Anglo counterparts. This is a trend that is not expected to drastically change in the near future and for which adolescent females need preparation and support to embrace.

It is assumed that, because females do not exhibit behavioral problems to the same extent or magnitude as males, they are experiencing successful transitions into adulthood, barring such social problems as pregnancy or drug abuse; however, complexities exist (see Spencer, Fegley, & Dupree, 2006). Although adolescent females fare better than males more generally, there remains the need for more active assistance in translating positive attributes during the transition to adulthood into broader life course opportunities. As long as females feel positive about their school experiences and behave responsibly at home, they appear to possess the attributes necessary for pursuing life goals (Swanson & Spencer, 1997). The potential concerns, however, are whether there are certain attitudes and behaviors that "mask" stressful experiences and whether structural barriers and societal expectations related to gender that emerge in later stages of development (i.e., getting married, having children, etc.) may pose additional coping challenges for females. A key task is determining how to prepare young females for these challenges.

There is also a need to examine gender identity in interaction with race. Research findings have suggested differences in body image perceptions between Black and White adolescent girls. Studies of gender identity often yield significant racial and ethnic differences; for example, Parker et al. (1995) showed how Black and White adolescent girls perceive body image ideals in very different ways. Parker et al. (1995) found that, unlike White adolescent females, Black adolescent females typically do not aspire to an "ideal" body image. Rather, they tend to emphasize the individually desirable features that they already have. In contrast to the so-called Barbie doll ideal that many White girls aspire to, the Black girls in Parker et al.'s study emphasized making one's own physical features "work for you." These different concepts of body image have implications for gender identity, and they illustrate how proactive cultural socialization can serve as a buffer against the stresses that adolescent girls face regarding beauty ideals.

Nevertheless, color bias is also related to body image and has different implications for males and females.

For Black females, concerns about skin tone exacerbate the normative challenges of body image and appearance (Fegley et al., 2008); these occur because of the greater importance placed on physical attractiveness for females generally. Moreover, developmental period also plays a significant role, as concerns about appearance grow for all youth during adolescence. Thus, risks associated with colorism vary with gender, context, and development, and resultant stress, coping, and self-appraisal also vary based on this plethora of factors.

In addition to race and gender, issues of sexual orientation and transgender status and identity development have become more visible and prominent in the last decade. Much of the attention has focused on gaining legal rights and reducing prejudice based on sexual orientation. These are important efforts that can help reduce the risk and stress faced by gay, lesbian, and transgender youth, but there is still the need to study coping, identity, and outcomes, given that these statuses are still marginalized. Although there has been some important work on self-appraisal and identity development in gay and lesbian youth (e.g., Savin-Williams, 1990, 2005), this is a prominent area for future research. The same is true for transgender youth (Grossman & D'Augelli, 2006; <http://srlp.org/resources/fact-sheet-transgender-gender-nonconforming-youth-school/>).

Body Awareness: The Special Experiences of Girls. An important issue that is helpful to consider involves the evolution of the relationship young girls develop with their physical bodies. Especially salient questions include why they begin dressing provocatively and when they begin to place such a significant emphasis on how their bodies appear to other people.

Useful evidence can be derived from studies that examine individuals suffering from clinically identified body-related disorders. These types of studies help identify maladaptive perspectives that individuals develop regarding their bodies and the reasons youth develop them. A central theme from many published studies suggests that individuals come to associate positive and valued *internal* characteristics with specific physical characteristics. One clinically identified body-related disorder is called body dysmorphic disorder (BDD). Individuals challenged with this disorder have recurrent, negative thoughts about a specific body part, and do so often to the point that they stay at home or avoid contact with other people. One theory for the cause of BDD involves the development of maladaptive thought patterns (Buhlmann et al., 2009). Individuals who suffer from BDD have maladaptive beliefs

about the *importance of attractiveness*. They come to believe that beauty is highly important and, critically, start to associate beauty with other positive attributes, such as social and intellectual competence (Buhlmann et al., 2009). Many of these studies utilize measures that assess implicit associations. In other words, they try to target the underlying, perhaps unconscious, associations that individuals make between physical qualities and internal qualities. These automatic associations are important, because they often go unchallenged and may be more influential than explicit and logical thoughts that are available to conscious awareness.

The Implicit Associations Test (IAT) and the Beliefs About Appearances Scales (BAAS) are two empirically validated tests that are commonly used to determine whether individuals have maladaptive beliefs about physical beauty (Buhlmann et al., 2009). When taking the IAT, participants classify words into categories using a computer program. One example of an IAT task is asking participants to classify words that relate to beauty into the category "good." Two words representing the categories will remain on the screen (such as "good" and "bad"). Then the participant will be shown different adjectives and must classify words that relate to beauty in the "good" category as quickly as possible. The program records reaction time. The shorter the reaction time required to classify a word into a particular category, the more likely the classification represents the participants' automatic associations.

The BAAS is a self-report survey that asks participants to answer questions about attractiveness. It is intended to identify dysfunctional beliefs about external appearances (Spangler & Stice, 2001). Participants are asked to report the extent to which they agree with statements that link appearances with other valued qualities. For example, one question asks participants to rate the extent to which they agree with the statement, "The opinion others have of me is based on my appearance" (Spangler & Stice, 2001). This scale investigates a range of domains that are potentially affected by implicit beliefs about appearances.

It is likely that the same types of implicit thought patterns underlie problematic behaviors of young girls, such as dressing provocatively to get attention. Young girls begin to believe that their value is based on their appearance. They begin to develop these implicit associations between characteristics that they value (i.e., intelligence, agency, social competence, etc.) and the positive reactions they receive for their bodies. As a result, they shape their behaviors to continue to receive positive feedback for their bodies. These behaviors may eventually become

stable aspects of identity, which continue to feed into the negative beliefs and automatic thoughts about the importance of appearance. In other words, when considered from a particular theoretical perspective which focuses on recursive processes (see phenomenological variant of ecological systems theory, Spencer, 1995, 2008b), the redundant thoughts may be internalized into "stable ways" of conceptualizing the self in relation to body awareness beliefs. It is critical to identify the sources of these associations between the physical body and internal characteristics as well as to examine ethnically diverse groups of girls given their unequal representation in media portrayals.

Of course, another significant influence is the family unit. From a very young age, girls learn that they are evaluated based on their looks, rather than based on their character, feelings, or potential (McKinley, 1999). They receive direct feedback from their family members. They are also very observant of the types of feedback their mothers receive about their bodies from their fathers and other members of society (McKinley, 1999). Young women are also highly susceptible to feedback from their peers (Kichler & Crowther, 2009). Negative communication from family and friends, defined as repeated negative comments about physical appearance, significantly and adversely affect levels of experienced body satisfaction (Kichler & Crowther, 2009).

These types of implicit associations are primarily formed in the cognitive domain. However, the socioemotional and physiological domains of development play significant roles in the formation of these associations. There is significant overlap and critical influence between these three domains. For example, emotional reactions can come from unconsciously (but cognitively) equating physical characteristics with internal qualities that matter to the individual. However, the resulting emotional and behavioral *reactions* to the same types of influences can differ based on temperament and social support. For example, a physically large woman equating small physical size with being less "needy" is more likely to be negatively affected by this implicit association if she has a more sensitive, shy, or internalizing temperament, particularly if this temperament is combined with few social supports. On the other hand, a resilient temperament or strong emotional supports could mediate the effects of these negative associations. Thus, context is critical, and it is imperative to examine the influence of all three of these domains of development. All would have potential for ultimate self-appraisal processes independent of gender.

NEGOTIATING SELF IN CONTEXT

A range of literature addresses relationships with family, peers, and adult mentors which affect self and identity development during adolescence (see Swanson et al., 2010). These relationships provide stability and offer support for enhancing resilience and protective factors (Benard, 2004; Garmezy, 1994; Masten et al., 1999; Waller, 2001). According to literature on positive youth development and asset building, relationships are central to identity processes (Damon, 2004; Lerner, Almerigi, Theokas, & Lerner, 2005; Small & Memmo, 2004), and critical to the meaning making youth engage in when interpreting the world around them and their place in it (Spencer, 2008b). However, the nature of relationships with safe, trusting adults is particularly instrumental in the self-appraisal processes of youth as the adults are positioned to engage youth with interpersonal feedback and experiential opportunities relevant to preparing for, and successfully negotiating, early adulthood expectations.

All families experience some level of vulnerability but those requiring out-of-home placement for children suggest a high level of vulnerability too frequently ignored in the literature on normal youth development. Accordingly, the following section explores the implications for youth in families with significant levels of vulnerability as a result of unstable or disruptive family conditions. The section also notes the impact of key cultural socialization practices for youth in these highly vulnerable conditions.

Family Socializing Efforts and Positions of Vulnerability

Stability

Multiple changes during the course of childhood and adolescence contribute to inconsistencies in lived experiences that can compromise self-development processes. Frequent residential moves are stressful but have the potential benefit of predictable family relations and expectations. While the impact on self-processes can vary depending on the reasons for multiple moves, consistent relationships within the family are particularly relevant for identity exploration within a supportive context. Youth experiencing multiple moves as a result of being placed with families outside their kinship network experience heightened vulnerability for identity development (Swanson, 2010).

In interviewing 12- to 19-year-olds about their perceived status as foster children, Kools (1997) found high levels of

insecurity, with approximately half of all youth in foster care moving to three or more different placements. Other sources of instability include memories of birth families as well as both positive and negative experiences in foster care (Upshur & Demick, 2006). Mediators of insecurity include adoption and kinship care, since “children placed with relatives average fewer placements than those in non-kinship care, are more likely to remain in their first foster care placement, and exhibit lower reentry rates” (Schwartz, 2007, p. 1203).

Some research suggests that youth experiencing long-term instability seek stability or continuity in other contexts or relationships. Given the process of identity development occurring during adolescence, seeking stability in relationships during this period provides a short-term solution with long-term implications. Some youth, for example, can demonstrate the academic potential expected in an educational system and are able to find stability within the school setting, thus allowing the exploration of an identity associated with post high school educational opportunities. In contrast, others find stability in peer relationships, sometimes outside of socially sanctioned contexts, but often within relationships that offer “support necessary to withstand emotionally challenging circumstances (i.e., school-related problems) and to cope in appropriate and effective ways” (Stanton-Salazar & Spina, 2005, p. 380). Instability leads to challenges in efforts by youth to create a coherent sense of self by contributing to the complexity of youth’s experiences while negotiating self (Surrey, Smith, & Watkins, 2006).

Complexity

The extended contexts, physiological transitions, and greater cognitive differentiation that occur during adolescence contribute to the complexity of developmental factors to negotiate. Living in an out-of-home placement exacerbates the difficulties youth can experience in developing a coherent sense of self (Surrey et al., 2006). Some children may experience discontinuity in their experience of selfhood. Some also experience more discontinuity in identity when placed in kinship placements (with relatives) than participants placed with nonrelatives (Schwartz, 2007). Additionally, youth in adoptive families that understand their uniqueness have more opportunities to discuss where the youth came from than those that insist they are no different from biological families (Upshur & Demick, 2006). Therefore, the degree of openness within families about a youth’s past appears to be a resource for youth. This is comparable to the research, discussed in the next section,

on racial and cultural socialization, which provides youth with a source of pride based on the history of one's group. Without openness, youth may feel as though they have a hidden self (i.e., connection to birth family) and a false self (i.e., connection to adoptive family). As summarized and reported by Surrey et al. (2006), Watkins and Fisher suggested that "the fact that children must knit together the various pieces of a complex identity neither means that they will fail this task nor that this task handicaps them in any way" (quoted in Surrey et al., 2006, p. 155). Whether or not a child is given the opportunity to process questions of origin and self is a seemingly important resource for creating a unified understanding of self.

Despite having such complex histories by the time they reach adolescence, as with all youth, foster youth continue to participate in and be shaped by their social environments (Cole, 1996; Lave & Wenger, 1991; Wortham, 2006); therefore, foster caregivers play a key role in the child's ongoing self-development. Generally, as caregivers form relationships with youth, norms and patterns of interaction emerge that reinforce and/or undermine various selves (Wortham, 2006). Some aspects of self will be more formative, evolving, and perhaps even undiscovered (e.g., perception of self or perception of others), while others will be somewhat stable by adolescence (e.g., ways of relating to others). For example, when a youth moves into a new foster home, the youth's perception of self will be influenced by her or his perception of the foster parents (cf. Cooley, 1902; James, 1892/1961). The ways in which youth have learned to relate to others, particularly adults, are likely to be more stable, though not unchangeable. Research has shown that children develop models for relating to adults based on their normative interactions with significant caregivers (Bretherton & Munholland, 1999), such as expectations around rules, discipline, communication, affection, and so on. Even with the complexity of a youth's history, both the unification of past selves and the development of future selves remain open to possibilities since youth can learn new models for relating to adults over time, models based on consistent interactions with significant caregivers (Swanson et al., 2002).

Ethnic Identity and Socialization

Beyond attending to basic needs, parents provide the socialization they perceive necessary for their children's success from their early developing years into adulthood. The processes and unique requirements of cultural socialization are significant aspects of self-appraisal processes for youth. Parental cultural socialization varies significantly and often may be emotionally unavailable as a source of protection

to buffer the impact of discrimination and stigma. Minority parents, however, seldom raise issues regarding race concerns with their adolescent children unless it is in response to an injustice or request by the youth. N. E. Hill's (2006) research supports these long-standing findings, noting that the majority of parents consider racial and ethnic socialization as important, although most nevertheless adopt reactive positions in discussing race with their children. Youth in families explicitly promoting cultural socialization (i.e., knowledge and celebration of one's ethnic pride, history, and heritage) and preparation for discriminatory bias, report more attention to these during adolescence than during childhood (Hughes, 2003). To support positive self-appraisals, parents provide both cultural socialization and preparation for bias to assist youth in coping with discriminating messages and behaviors (see Hughes et al., 2006, for a comprehensive review). Much of the research on the impact of racial and cultural socialization has focused on understanding these processes within intact families with generational experiences addressing discrimination. Youth in families that struggle to meet the basic physical and emotional needs are subjected to negotiating self-development in unstable and complex systems.

Initially intended as a temporary respite for families in a time of need, foster care has become a long-term living situation for many youth, who average 5 years in foster care (Kools, 1997). Theorists and researchers have paid considerable attention to the development of self among children, but in most cases, studies have focused primarily on biological families and mostly middle class, Caucasian participants (Schwartz, 2007). As indicated, it is our view that all humans are vulnerable (i.e., have varying levels of both protective factors and challenges). The same applies to families. Accordingly, like contextual factors that facilitate resilience in heavily researched impoverished youth, the following discussion highlights self-development under varying levels of vulnerable family circumstances.

Out-of-home placements induce a high level of vulnerability. However, despite limited research, there are different views on the impact foster care and adoption has on self. The most prominent view is that it has a negative impact (Kools, 1997; Wegar, 2006; Yancey, 1992); thus, it suggests a high level of vulnerability (i.e., many more challenges than objective supports experienced). A wealth of evidence suggests that children in foster care suffer severe impairment, including unhealthy identity outcomes, poor academic achievement, early educational discontinuation, substance abuse, and even homelessness (Pinderhughes, Harden, & Guyer, 2007; Wegar, 2006; Yancey, 1992).

Unique aspects of foster care with implications for positive selfhood comparable to other vulnerable conditions for youth include provisions for stability, facilitating an integration of increasing complexity due to interactions in a wider range of contexts, enhancing ethnic identity, and strategies for negating or offsetting stigmatizing assumptions regarding one's personal status or social position. Strategies promoting positive youth development particularly for those in special circumstances are available.

Child welfare agencies have increasingly focused on enhancing ethnic identity among children in foster care (Schwartz, 2007). It is commonly accepted that "adolescents seek a sense of belonging in the larger sociocultural world and a sense of connection to traditions that precede them and will outlive them" (Levy-Warren, 1996, p. 131). According to Levy-Warren, developing a mature ethnocultural identity satisfies this need; however, several factors are known to affect a child's ethnic identity while in foster care. These factors include racial distinctiveness or dissimilarity with foster or adoptive families, inability of foster families to assist youth in participation of ethnic traditions and rituals, and inability of foster or adoptive parents to prepare a youth for the negative views of minorities by the dominant culture. The majority of factors are related to minority youth, as "research suggests that the development of ethnic identity is more of an issue for minority than majority children" (Schwartz, 2007, p. 1202). Youth placed with relatives engage in more rituals and practices related to their ethnicity, while those placed with nonrelatives displayed more art and information about the foster child's ethnicity. Yancey (1992), in a meta-analysis, contended that social maladaptation of minority youth in foster care signifies identity disturbances caused by negative perceptions of African Americans and Latinos perpetuated by dominant society that are unmediated by foster parents. It is, in essence, insufficient to primarily educate youth about their ethnic background; it is also important to assist them in maintaining a connection to their ethnic background through rituals and practices (Schwartz, 2007). Accordingly, those youth "living" ethnicity and experiencing its legitimacy as positive cultural representations enjoy psychological protection which then lowers their level of vulnerability. As a source of support, it serves to undermine the potential effects of stereotyping and stigmatizing experiences.

Stigmatization

Youth who are prepared to recognize and negotiate biases associated with an aspect of self-identification exhibit

fewer problem behaviors and mental health instabilities than those unprepared. This is consistent for youth facing stigmatizing attitudes as a result of their racial, ethnic, gender, religious, or sexual orientation identification. It is not only a matter of being "socialized" for bias but also for having the necessary supports to assist youth in coping with them. Youth in foster care experience stigma in a form of isolation from peers in addition to the separation from close family. This ongoing experience of stigma, reminders of their "differentness," also reinforces the experiences of instability that limits their opportunities for identity exploration. Upshur and Demick (2006) noted that foster children face the challenge of balancing a "true self" and a "public self," which is characterized by the views of others outside the family. Unfortunately, these views are often permeated by myths about foster children and families. Such myths are that: (a) foster and/or adoptive mothers are defective or depressed and contribute to the psychiatric symptoms in their children; (b) adoption and foster care comprise a lifelong grieving process for all members; (c) the only way to have true attachment is to bond with a child in its first hours of life; and (d) the psychological health of a child is entirely dependent upon relationships within the nuclear family (Surrey et al., 2006). Foster children have also reported feeling stigmatized by either direct or indirect negative stereotypes about being in foster care.

Kools (1997) identified the outcomes of the stigmatized self-identity as being low self-confidence, lack of future orientation, and a focus on "what I cannot do," rather than "what I can do" (p. 268). The findings, generated from the perspectives of participants, highlight the association between stigma and an imposed self with negative expectations consistent with other youth who identify as members of a stigmatized group. These negative expectations are a major factor for the possible future selves toward which youth are directed. This form of identity foreclosure, as suggested by J. Marcia (1991), represents the classification of an individual who is socialized into a particular identity with "goals and expectations determined by others or defined by group membership" (Kools, 1997, p. 269).

Due to the influence of families and the family context in self-development processes for youth, young people developing in highly vulnerable family contexts encounter greater instability and complexity in negotiating these processes. Having safe places and relationships from which to explore and develop remain critical throughout this developmental period. In the following section, these attributes are explored within relationships between adults and adolescents in relation to educational experiences

with the school as a context for self-development. Factors related to stability, contextual and developmental complexity, ethnic identity, and stigma also shape the educational and nonfamilial relationships, particularly in schools, thus affecting the academic outcomes of all youth. In addition, challenges of relationships within schools and the impact of unacknowledged privileges in shaping supportive contexts are discussed.

Schooling and Competence

Various factors contribute to students' academic achievement and success. These include teacher expectations, parental involvement, and changing demographics (e.g., family composition, neighborhood conditions, and national economics which influence social economic status). These factors, however, vary in the extent to which they influence achievement. As such, identity formation is determined or influenced by the level of cognitive maturation, the quality of ego defenses, existing situational factors, and prior socialization (Spencer, Dupree, & Hartmann, 1997).

Students with low evaluations of their academic competence and general self-worth generally perform poorly in school, loose interest in academic activities and are also likely to be truant. For African American adolescents, academic self-esteem is a better predictor of achievement than general self-esteem (Hare, 1977; T. J. Jordan, 1981; Mboya, 1986; Swanson & Spencer, 2011). Studies have shown that self-esteem emerges from feelings of competence in domains of greatest significance to the individual, namely, academic, social, or athletic domains (see Harter, 2003). Older children can find sources of support and gratification in the peer group, school, neighborhood, and work place that can help to counter the negative effects of adverse situations.

Assessing links between social and cognitive functioning is especially relevant during the middle and high school years (i.e., adolescence). Relationships between identity processes and academic performance influence the development of individual coping strategies and a personal sense of competence. For example, although boys are considered at higher risk of displaying specific types of reading delays, a large percentage of boys referred for learning difficulties reflect biases in teacher identification procedures (Hinshaw, 1992; Swanson et al., 2009).

The presence of coping skills, social supports, and positive self-esteem mitigates the risk of emotional and social problems posed by high stress and/or physical vulnerability in children and adolescents. The absence

of these coping mechanisms increases the likelihood that emotional or behavioral disorders will occur even under conditions of moderate stress and no physical vulnerability (Spencer, 1995).

Identity Processes and Academic Experiences

Resilient youth demonstrate positive outcomes in their academic trajectories and psychosocial processes (Luthar, 2006). Resilience is defined as "a dynamic process encompassing positive adaptation within the context of significant adversity" (Luthar, Cicchetti, & Becker, 2000, p. 543). Outcomes associated with resilience are broadly identified as factors contributing to success under adverse conditions and are subsequently explored to understand the processes. The concept has drawn attention as being domain-specific, such that youth can demonstrate resilience in one domain while remaining vulnerable in another (see Luthar, 2003; Wang & Gordon, 1994). In recognizing multiple components of resilience, educational resilience represents a specific domain where youth have positive educational adaptations and outcomes within the context of significant adversity (Wang & Gordon, 1994). As demonstrated by seminal research by Werner (1995, 2005), familial relationships are important in facilitating resilient outcomes. Werner also emphasized the importance of the roles of "substitute parents," such as grandparents or older siblings. These significant adults enhanced students' potential for adaptive outcomes by buffering students from negative circumstances. Cunningham and Swanson (2010) extended the concept of "substitute parents" to examine the roles of significant adults within the school context.

Slaughter-Defoe and Rubin (2001) pointed out that school officials have tremendous influence during the adolescent years. The researchers followed 56 African American children and their families from Head Start to 12th grade and the results of their longitudinal study demonstrated that the magnitude of influence changes from elementary to middle school. While parental influences were evident in the early grades, the authors found that, as children grow older, teachers have more influence on achievement patterns and educational outcomes than parents. However, the most significant findings of this study were associated with the students' early indicators of academic success (i.e., grades obtained before 7 years of age). Slaughter-Defoe and Rubin found that these early grades predicted the educational goals of students in their 13th year of formal schooling when they were around 17–18 years old. The ideal aspirations of these students appeared to have been largely influenced by early indicators of

school success (accounting for 31.4% of the variance in level of goal setting).

For many African American students, educational resilience is associated with achievement within school systems that have numerous social and economic challenges. Many urban African American adolescents, while negotiating the normative challenges associated with development during this period, are also faced with exposure to community violence, poverty, and racism. An important point to emphasize is that students can be educationally resilient and still face challenges in other areas. As Luthar and colleagues (2000) suggested, unevenness in functioning is expected in all humans.

There are two factors particularly relevant to educational resilience: students' exposure to significant adversity (e.g., negative life events, low teacher expectations, or race-related stressors) and the influences of their home environment, teacher expectations, and classroom climate (see Cunningham & Swanson, 2010; Wang, Haertel, & Walberg, 1997). These students are more likely to report high teacher or school support, high expectations from parents and significant adults (i.e., teachers), high academic self-esteem, and high parent involvement or parental monitoring.

Youth vulnerability is heightened when overall disadvantage or challenge increases their levels of stress. Some students experience greater vulnerability to adversity associated with the increased stress than their counterparts. For example, Cunningham, Corpew, and Becker (2009) reported that vulnerability increased among students with friends who engaged in antisocial behaviors. Their assessment of vulnerability acknowledged that all youth experience challenges and stressors, but the outcomes for some youth are associated with maladaptive outcomes consistent with being "vulnerable and reactive" (Luthar et al., 2000, pp. 547–548).

Education is viewed as a primary impetus toward social and economic mobility as well as a mechanism for redressing inequalities (J. Jordan, 1999). Nevertheless, the difficulties some youth face in educational systems contribute to disengagement from the educational process. According to Swanson et al. (1999), disengagement is displayed in the form of poor academic performance with little or no educational goals. Academically disengaged youth withdraw both socially and emotionally from the school climate, interact minimally with others, fail to find a place of belonging in the academic system, and do not develop adequate levels of commitment to the institution of learning (Kelly, 2003). This is consistent with others who have

compared Black males to other groups and found higher suspension rates, lower attendance, and lower standardized test scores, all of which are predictive of high dropout rates (Ford, Grantham, & Whiting, 2008; Gibbs, 1998; Noguera, 2003, 2008).

Some researchers contend that part of the solution lies within the connection between youth and influential adults. Swanson and associates (2002) claimed that the extent to which adolescents are able to demonstrate competence is dependent on their access to a range of legitimate opportunities and long-term support from caring adults. Furthermore, they suggest that relationships provide a context in which adolescents can grow by being exposed to the values of others, which frequently includes adults in their community and their school.

Teachers and Classroom Climate

As previously noted, teacher relationship and the school environment are critical protective factors for fostering educational resilience. These factors include (a) developing caring relationships that teach social skills while providing positive regard and a culture of care, respect and support; (b) setting high, achievable, and explicit expectations for academic performance and classroom behavior; and (c) providing opportunities to actively engage in meaningful learning experiences (see Benard, 2004; Henderson & Milstein, 1996).

Patrick, Turner, Meyer and Midgley (2003) identified supportive classroom environments as encompassing these school-based factors that foster resilience. They studied teachers and their students to distinguish between supportive, ambiguous, and nonsupportive environments. In contrast to supportive classes, teachers who created nonsupportive environments were authoritarian in that they stressed teacher power and control, conveyed low expectations, and used extrinsic motivation to engage students. Ambiguous environments reflected teachers who were generally supportive but did not connect with students in a personal way. They may have set high expectations but were inconsistent in demanding effort and respect and thereby undercut their own efforts.

In differentiating between resilient and nonresilient students, Waxman, Huang, and Padron (1997) examined the classroom context and individual attributes of Latino middle school students in math classes. Resilient students had significantly higher perceptions of academic involvement, satisfaction, self-concept, and aspirations than nonresilient students. Although nonresilient students were comparable to national levels of academic aspirations, the resilient

youth were significantly higher. No difference was found between the two groups' perspectives on parental involvement (i.e., interest and expectations). In fact, both groups reported average amounts of parental involvement.

Historically, schools have focused on their role as a conduit for transferring knowledge without consideration of cultural factors in learning (Spencer et al., 2006). This prevailing position, while explicitly challenged in contemporary reviews, still poses an obstacle to thinking contrarily (and therefore responding differently) about what a safe, inclusive and positive school environment should be for students. It impedes discussions that consider how to mitigate exclusionary practices in serving all youth and how to provide access to various levels of intervention. Mainstream teaching practices remain intact as well as the argument that disruptive students need to be removed from the class to preserve teaching and the experience of the better resourced and self-regulated students (Advancement Project, 2010; Skiba, Shure, Middelberg, & Baker, 2012). Morris (2012) described further the breadth of school's influence on the trajectory of minority youth:

According to the theory of social reproduction, educational institutions in their pedagogy, design, structure and practice, serve to reproduce social hierarchies. Using this lens, institutions that are not intentionally "learning organizations" or evolving in the context of their intentional quest for knowledge and social change are those that continue their reproductive role in churning out children trained to maintain racial and social stratification. (Morris 2012, p. 8)

Based on these ideas, schools not only exclude but replicate through their specific contexts and practices negative school experiences, which potentially initiate or exacerbate negative trajectories for youth of color. What is also coupled as an effect from the lack of school flexibility and advancement is the transmission of negative understandings of the self to minority youth. Skiba et al. (2012) and others who are against the use of zero tolerance practices in schools underscore the marginalization process disadvantaged youth of color experience. Regarding the conditioning minority youth receive as a result of zero tolerance practices, Noguera (2003) observes that, "by sorting children on the basis of their presumed academic ability or behavior, children learn whether they are in on the educational pipeline and develop expectations regarding where they will end up on the social hierarchy" (p. 118). How youth are treated and related to informs their self-understanding and feelings about their own potential. It is evident that the process of physically and publicly

removing students of color from classrooms, and in some cases school grounds, is traumatizing. This type of discipline reinforces negative stereotypes and low academic engagement.

Students classified for special education services are most at risk for negative outcomes associated with zero tolerance as they have typically been identified as those most often suspended or expelled from school (Chin, Dowdy, Jimerson, & Rime, 2012). Those suspended from school are more likely to continue to repeat negative behaviors, fall behind in school, or drop out (Rausch & Skiba, 2006; Sharkey & Fenning, 2012). Specific references in the literature identify higher rates of engagement by youth with poor role models, risky behavior, and difficulty with re-entry into the school system (Casella 2003; Michail, 2013; Noguera, 2003; Skiba et al., 2012).

There is a cumulative effect of negative stigmas resulting from being suspended or expelled and identified as a special education student. Black males represent a large majority of the students who are identified as needing special education and were often susceptible to punitive measures under zero-tolerance policies (Advancement Project, 2010; Fenning & Rose, 2007; Noguera, 2003; Raffaele Mendez & Knoff, 2003). Student removal, suspension or expulsion resulting from punitively based policies trigger a series of negative emotions in children and youth, which is compounded in marginalized groups. Feelings ranging from anger and sadness to frustration and shame occur (Schulz & Rubel, 2011). Some youth, due to the lack of alternative supports, engage in maladaptive behaviors as a coping outcome (Michail, 2013; Schulz & Rubel, 2011; Spencer & Tinsley, 2008). Recognized and accessible supports as well as meaning making of particular feedback and events can offset the adverse impact.

Significant Others and Educational Aspirations

Social status research consistently identifies interpersonal relationships as significant correlates of educational aspirations and educational achievement (Buchman & Dalton, 2002). In the earliest discussions of interpersonal influences, Cooley (1902) and Mead (1934) referred to social interactions with significant others as major sources of information, guidance, and support for youth. Additionally, research on productive or unproductive responses of youth to normative challenges encountered emphasize the importance of significant others as a "mediating variable for educational aspirations" (Scratchfield & Picou, 1982, p. 22).

Davies and Kandel (1981) suggest that causal models of educational and occupational attainment identify

interpersonal influences as a vital link to educational and occupational aspirations. Research supports interpersonal influences as critical in shaping educational aspirations of children more profoundly than their scholastic aptitude or previous academic achievement (Cunningham & Swanson, 2010).

Social psychologists have defined significant others as “persons who exercise major influences over the attitudes of individuals” (Woelfel & Haller, 1971, p. 75). They explain that significant others exercise a major influence on the attitudes of individuals by: (a) communicating the norms, values, and expectations of the culture or society in which they live; (b) defining the behavior that is considered to be appropriate to the culture or society in which the individual resides; (c) modeling appropriate attitudes and behaviors; and (d) providing necessary information about the environment to the individuals under their influence. The formation of attitudes, according to Woelfel and Haller (1971) and consistent with a phenomenological orientation, requires the processing of information through self-reflection and daily interaction with others. For example, youth may conceptualize an event or experience through perceptions and the internalization of information provided by his or her significant other through daily communication. Thus, in an educational context, significant others are instrumental in shaping students’ expectations through the youth’s perceptions of how those significant others distinguish educational goals and communicate academic expectations (Cunningham & Swanson, 2010; Entwistle, Alexander, Pallas, & Cadigan, 1988; Picou & Carter, 1976; Woelfel & Haller, 1971).

Early perspectives exploring the process by which significant others are influential suggests that change in youth’s behavior and attitudes occur through two modes of interpersonal influence. One describes significant others as models who serve as a basis for emulation and the other suggest they are definers whose expectations set the standard for appropriate behavior (Kelley, 1979). Theoretically, these constructs, referred to as models and definers, are dominating frameworks in methodological and theoretical approaches of early studies on the influence of interpersonal relationships and significant others.

Recognizing that these two modes of influence (definers and models) are not mutually exclusive, Cohen (1987) posited that “significant others can be both definers and models of educational aspirations” (p. 339). In his study to determine how parents influence their children’s educational aspirations, Cohen (1987) found that parents influence their adolescent children through both modeling

and defining. Modeling was defined as the emulation of parents’ education, exemplifying either college-educated or non-college-educated people and life styles. Definers, on the other hand, communicate expectations for appropriate behavior, stressing one level of education over another (p. 339). The researchers drew on the earlier assumptions of Woelfel and Haller (1971) indicating that: (a) Attitudes are relationships between a person and an object or set of objects; (b) humans’ perceptions of an object are mediated by symbolic structure; and (c) relationships are conceptual in that they are based on one’s conception of the self and the conception of the object at hand. These earlier assumptions, now empirically validated, support the significant impact of relationships on youth development within varied contexts (Cunningham & Swanson, 2010; Spencer, Harpalani, et al., 2006).

Several key points are drawn from methodological and theoretical approaches to research on significant other influence: (a) Significant others influence adolescents’ attitudes and behavior by acting as models or definers or both; (b) significant others influence acts as mediating variables for educational aspirations; (c) significant others are often identified as parents, peers, teachers, extended family and adult friends; (d) parents have a more powerful influence on the formation of educational goals than peers; and (e) influence of significant others mediates the effect of socioeconomic status and ability on educational aspirations. This foundational work remains instrumental in research examining students’ academic trajectories and relationships supportive of the academic experiences of youth. Nonetheless, how children and youth cope when significant supports are unavailable or inadequate is relevant to understanding the impact of interpersonal relations on developmental outcomes and the impact on policy decisions.

Bullying and “Drama”

In recent years, the issue of school bullying has become a focus of law and public policy—following highly publicized instances of suicide related to bullying (Hanks, 2012). In August 2010, several federal executive departments, including the U.S. Department of Education, and the U.S. Department of Health and Human Services, held the first ever National Summit on Bullying, and the following March, president Barack Obama, along with first lady Michelle Obama, held the White House Conference on Bullying Prevention (Hanks, 2012). In *Kowalski v. Berkeley County School District* (2011), the U.S. Court of Appeals for the Fourth Circuit held that a school’s decision

to protect students from bullying and harassment trumps any free speech concerns. Other Circuit Courts have ruled similarly: the Sixth Circuit in *Lowery v. Euverard* (2007), and the Ninth Circuit in *LaVine v. Blaine School District* (2001).

However, the Third Circuit ruled, in *Morrow v. Balaski* (2013), that a school district has no affirmative constitutional duty, absent very particular circumstances, to protect students from bullying. This is consistent with the U.S. Supreme Court's ruling in *DeShaney v. Winnebago County Department of Social Services* (1989) that, unless there is a specific custodial relationship (such as with prisoners), state government agencies do not have an affirmative constitutional duty to protect individuals from private harm.

Nevertheless, most of the legal and political response to bullying has come at the level of state and local government—implemented through school and school district policy rather than through the federal courts. While the vast majority of states have passed some form of anti-bullying legislation, different states have taken different approaches; for example, eight states (Arkansas, Connecticut, Louisiana, Massachusetts, New Hampshire, New Jersey, New York, and South Dakota) include off-campus behavior in their anti-bullying legislation (Hanks, 2012). While federal case law suggests that schools have to meet a high standard to punish off-campus behavior (demonstration that off-campus conduct adversely affected school operations), the U.S. Supreme Court has not yet ruled on whether the scope of anti-bullying legislation intrudes on the First Amendment's protection of free speech.

Anti-bullying laws typically have several elements: a statement of the conduct prohibited; whether the conduct constitutes a single act or repeated actions; classes of students who are protected; coverage of cyber-bullying or electronic communication; and the scope of prohibition (on- versus off-campus). States have taken various approaches to these issues, which may implicate several federal Constitutional issues besides free speech, such as the Fourth Amendment (school administrative searches) and procedural due process (Hanks, 2012).

Future cases will likely address these issues. Additionally, school bullying is an international issue: According to the World Health Organization (WHO), it is a worse problem in some countries than in the United States (Currie et al., 2008). According to WHO, Turkey, Lithuania, and Greenland have higher levels of bullying among preadolescent and early adolescent youth than the United States, while Spain and Sweden have less (Currie et al., 2008).

Thus, bullying is garnering global attention, with many initiatives designed to address the problem.

Nevertheless, Weddle (2004) contends that, at least in the United States, most of these initiatives address individual conduct of bullies rather than root cause of bullying, which is school climate and culture. He identifies "social control" and "social cohesion" as characteristics of schools that most effectively address bullying (Weddle, 2004, p. 653). Others have also supported this notion; for example, the American Educational Research Association (AERA) report on prevention of bullying also notes that schools with "fair discipline" and a "supportive atmosphere" have less bullying (AERA Report, 2013, p. 38). However, Weddle (2004) notes that the focus on individual perpetrators, as opposed to school climate, is problematic. For example, it is very difficult to find school administrators and teachers legally liable for individual incidents of bullying, because such events are usually not individually foreseeable. Also, as noted earlier, schools do not have an affirmative duty, under most circumstances, to prevent such harms against students. Even if school administrators are generally aware of bullying in the schools, they are rarely aware in advance of specific incidents that will occur or are likely to occur. Weddle (2004) recommends greater focus on changing school climate to foster bullying prevention, and on creating legal accountability for schools that fail to do so.

The emphasis on school climate is particularly salient for racial minority and LGBT youth, both of whom already face hostile school environments. As noted earlier, H. S. Stevenson (1997) discussed how Black males face hostile school and neighborhood environments; in these environments, superficial displays of prowess and aggression may be necessary to mitigate bullying and victimization. Additionally, behaviors such as the "acting White" epithets discussed by Fordham and Ogbu (1986) and their critics (e.g., see Spencer & Harpalani, 2008) also represent conduct that could fall under the rubric of "bullying." Tyson, Darity, and Castellino (2005) have discussed how school climate is related to "acting White" epithets, noting that these are more likely when Black students perceive the school to be a hostile environment, and when there is gross underrepresentation of Black students in higher level classes. Also, as Spencer and Harpalani (2008) note, identity formation and racial identity development, along with related coping strategies, are all intricately related to perceptions of the school environment. Thus, while a focus on school climate is necessary for bullying prevention, such an approach must also be contextually

and developmentally sensitive—taking into account the particular challenges that diverse groups of youth face in negotiating school, home, and neighborhood climates (Phelan, Davidson, & Cao, 1991).

Further complicating the conceptual framing of bullying interventions is the fact that researchers' definitions have not expanded with the social changes of a technological era; during middle and late adolescence, youth define and identify bullying behaviors differently from the definitions used to study the behavior and develop interventions. To explain the disconnect, researchers have suggested that *how students understand bullying* is a function of development and their perceptions of bullying change during adolescence (see Allen, 2013, for a review). Similarly, research exploring adolescents' understanding of privacy in socially mediated communication finds youth often dismiss current conceptualizations of bullying referring to it, in contrast, as "drama" (Allen, 2010). Marwick and Boyd (2011) found that adolescents often view bullying as childish and immature and doing so may be a "protective mechanism" (p. 1) that allows adolescents to avoid seeing themselves as powerless (e.g., a "victim") or having to acknowledge that they are guilty of bullying. While still preliminary, this work supports the notion that adolescents may understand bullying quite differently than researchers or even school officials and those conceptualizations may be affected by the context, development, and interpretive or meaning-making processes of youth.

Allen (2013), in examining social interactions and developmental shifts, identified four themes linking bullying behavior and drama: (1) elitism, (2) drama and the social milieu, (3) developmental change, and (4) norms, status, and hierarchy. These are each uniquely connected to the nature of social interactions and developmental change during adolescence. For example, elitism is connected to drama and the social milieu because elitism affects the social interactions among students. Likewise, drama and the social milieu are affected by how students develop and change socially over the course of middle and high school (i.e., from ages 10 to 18). "Developmental change affects [how] students create norms and negotiate status and hierarchy" (p. 428). In synthesizing the themes, norms, status, and hierarchy are connected to the elitist attitudes that permeate the social culture of the school environment; while each emergent theme is an entity within itself, they are also interconnected. Allen's findings are based on work with suburban youth from economically affluent families. Elitism as a theme, however, represents only one type of

status that privileges some youth over others, creating and heightening experiences of vulnerability and risk.

While social hierarchies and contexts are central to addressing bullying, one should also not exclude individual psychological approaches. Memory and cognitive-based therapy (CBT) models may be useful for individuals who have been victims of bullying and related forms of stress. Bullying experiences can have a long-term impact, and without positive supports and necessary interventions, negative thoughts and maladaptive coping mechanisms may become implicit, automatic, stable thought patterns (Brewin, 2006). The impact of bullying on self-processes and identities derives from social climate and hierarchies, and these are the root causes of the problem; nevertheless, it is important to explore interventions such as CBT, which may help individuals who have already been victims.

Social Privilege and Stigma

Apparent from the history of colorism, as reported in global accounts and its continuation in 21st-century life, power disparities are a part of the human experience given the under-acknowledged problem of color bias. These disparities are also prevalent as a part of the experiences of youth, given the challenges of family vulnerabilities, academic opportunities, and relationships in school contexts. Various forms of privilege, including colorism, have consequences for the broadly reported life course outcomes and differences in social status.

Black and Stone (2005) suggested that the concept of privilege communicates the various ways that opportunity is made possible for some in a society while, at the same time, denied to others. They caution that most academic discussions of privilege have centered upon race and gender, thus they wish to expand this conceptual framing to include other frequently marginalized groups. In doing so, they hope to pull readers away from a dichotomous view of privilege and unpack the various factors that shape and complicate one's identity and thus one's ability to access different forms of privilege. The authors affirmed that a more sophisticated perspective indicates that the concept of privilege communicates the various ways opportunity is made possible for some in a society while denying it to others. The authors suggested that an understanding of human identity and its many aspects of privilege and oppression may help us to identify each individual's unique needs. The forms of privilege addressed note their budding presence in scholarly literature and the authors' argument that they are

granted social privilege rather than just “preference” (which they see as less well-defined and pervasive).

People with social privilege often deny the fact that they enjoy unearned advantages at the expense of others and maintain that they are truly more intelligent, hardworking, determined, and so on, than the groups they dominate. To avoid the dissonance and confusion that results from being confronted with one’s social privilege, they must uphold distorted or inflated views of their own innate value and justify their oppression (either overt and hostile or subtle and indirect) of others. To become aware of one’s social privilege is to accept one’s responsibility to surrender unfair advantages and entitlements, recognize one’s role in the oppression of others, and fight against the system that reinforces injustice—a feat that proves challenging for some.

Meanwhile, people who identify partly or entirely with an underprivileged group experience many mental and physical consequences. Membership in multiple oppressed groups means that one experiences various kinds of oppression, and persons with conflicting identities (i.e., partly privileged and partly underprivileged, as in the case of a Black male, a rich woman, a gay White person, etc.) can feel confused, angry, and cynical about their standing in society. The experiences that come as a result of an underprivileged identity often have a highly negative effect on the overall well-being of the individual (Swanson, 2010). Members of disadvantaged groups may internalize their oppression and view themselves as inferior to others. They also may develop antisocial or maladaptive behaviors to cope with their oppression and gain some of the advantages that they lose by virtue of their identity.

With regard to counselors, counselor educators, and their patients, privilege studies can greatly enhance the effectiveness of the counseling relationship. Counselors are in a unique position that enables them to help clients understand their experiences of privilege and the way they are negatively affected by it. Black and Stone (2005) affirmed that it is the counselor’s responsibility to engage in meaningful self-exploration, internal reflection, and processing of their various identities—counselors cannot afford to retain the privilege-blindness of some members of dominant groups. They must also examine the ways in which their individual identities influence their relationships with their supervisors (or supervisees) and clients. For example, a counselor who occupies a socially powerful position may be more likely to place exclusive blame on the client, or the family (in the case of school counselors), for circumstances that result from the client’s underprivileged status. Black and Stone believe that counselors

must be trained with an eye to their social identities and that a failure to do so will only strengthen unfair social hierarchies and reduce the effectiveness of counseling.

Along the same lines, the perspective on privilege provided by Case (2007) examines college students’ attitudes toward various feminist issues before and after taking courses with and without gender content. The study measured students’ awareness of male privilege, prejudice against women, support for affirmative action, and identification with feminism. Findings provided insights regarding the complexities of the relationships and processes. In general, the women’s studies and diversity courses examined seemed to be effective in raising students’ awareness of men’s systemic advantages in society, lowering their endorsement of various forms of sexism, and increasing their support for affirmative action measures. These findings are important because previous studies have indicated that greater awareness of White privilege can lead to direct action (speaking out to friends and family about racial stereotypes, challenging racism, etc.), thus diversity courses that address issues of gender may also help motivate students to oppose various forms of sexism and identify with feminist values. However, these results may have been influenced by the students’ own self-selection into courses—it may be that students who chose to take a course with gender content were already predisposed to show a change in their attitudes toward women over a period of time, regardless of whether they had taken that specific course.

Despite reinforcing other studies’ findings that courses entirely devoted to gender content can encourage students to develop a feminist identity, Case’s (2007) study found that self-identification with feminism remained stable in the courses that addressed both race and gender. This indicated that the amount of gender content that a course contains really did influence its effectiveness in advancing feminist identification. However, general diversity courses provide students with more opportunities to consider intersections of oppression and make connections across different types of human identity and privilege. It may be that the benefits accrued by learning about various forms of privilege (rather than focusing on just one) are greater than the potential loss of feminist self-identification.

Future research on diversity courses’ influence on the attitudes discussed in this article would help to reinforce or repudiate these conclusions. Some new directions for this research that the author suggested would be to examine the effectiveness of courses that address other kinds of social inequality (race, sexuality, disability, socioeconomic

status, etc.). It would also be valuable to observe how or if diversity courses actually affect the behavior and practices of students in addition to their self-reported mental positions. Finally, because random assignment to college courses is rarely possible, this research requires further inquiry into student interest in diversity courses as predictors of the change in their levels of sexism and male privilege awareness.

Coston and Kimmel (2012) used Erving Goffman's study of stigma to examine three potential sites of marginalization (disability, homosexuality, and working-class status) within a group that is generally recognized as privileged: men. According to Goffman, there exist at least three strategies by which a marginalized group can react to the stigma against them and reduce the amount of distress they experience. These strategies were identified as (1) minstrelization—exaggerating the differences between yourself and members of the dominant group, overconforming to the stereotypes they have that portray you as inferior in strength, intellect, and so on; (2) normification—minimizing the differences between both groups to undermine or eliminate the basis of any possible discrimination; (3) militant chauvinism—highlighting the differences between the groups for the purpose of claiming that your marginalized group is truly superior to the dominant group, and thus attempting to assert power over the dominant group.

For Coston and Kimmel, the marginalization of men who are disabled, gay, or working class is rooted in their perceived failures to embody some aspect of hegemonic masculinity and thus complicates their ability to access the male privilege we expect them to have. Although they are men, the site of their privilege also provides the basis for the discrimination they face, thus they often do not feel (very) privileged at all. Coston and Kimmel discussed how each group may react to society's problematization of their masculinity with either or both overconformity to hegemonic masculinity and/or resistance to it. In doing so, the authors provided a complex view of male privilege and the inflexible standards required to access it. Males can also be denied access due to their deviation from other standards. The approach extends research on intersectionality and how various forms of privilege and marginalization can exist within a single person.

Pratto and Stewart (2012) observed that social privilege exists in a "half-blind" state within the members of socially dominant groups. This means that, although the dominant group is capable of recognizing the inequality and problematized identity of the disadvantaged group,

they are not always capable of recognizing their own social dominance as a privilege (as opposed to the normal or unmarked position). They referenced other studies' findings that people can be aware of the disadvantages that come with certain other social identities but fail to see or to acknowledge that privileges accompanies their own identity. Pratto and Stewart also pointed out that members of a subordinate group are more likely to perceive themselves as members of that group and to recognize that their identity has been stigmatized, whereas members of a dominant group do not necessarily see themselves as members of a social group or as having a distinct social identity. The study drew upon two theories to account for these discrepancies. The first is norm theory, which posits that people implicitly view certain (dominant) groups as the default setting such that other groups are viewed as a deviation from the norm. The second is social dominance theory, which explains how the psychology of one's unique group position accounts for one's (in)ability to recognize social privilege. Their theorizing and findings suggest four hypotheses: (1) group membership is more prominently perceived by members of a subordinated groups than by members of dominant groups, (2) dominant groups generally have higher levels of social dominance orientation (SDO) than subordinated groups, (3) SDO will be more positively associated with differential group identification in privileged groups than it is in underprivileged groups, and (4) overt measures promoting the power of one's own group will be more associated with SDO in dominant groups than in subordinated groups.

As suggested, their survey results confirmed the authors' four hypotheses for each sample group and across each type of group distinction (sexual orientation, social class, gender, and race). Interpreting the results, the authors noted how low identity salience helps dominant groups to remain blind to their role in an unfair social hierarchy and their responsibility to fight against it. Similarly, other privilege studies show advantages associated with any socially dominant group similar to the association between being American and being White (Devos & Banaji, 2005). In essence, privileged status allows the privileged person to experience (usually blindly) their daily life and identity as routine, all encompassing, normal, neutral, and universal. Pratto and Stewart (2012) affirmed that it would be interesting to extend their analysis to see how the processes discussed in their article translate into real-life behaviors and practices. They noted that policies designed to treat all groups equally and neutrally (e.g. "color-blind" policies) are likely to maintain group dominance because they are

(perhaps implicitly) designed to suit the dominant group best. These biased policies result in material advantage for dominant groups, and other studies have found that those with privilege react with anger and opposition toward policies that acknowledge and attempt to counteract their unfair advantages. On the other hand, opinion polls often find that women and racial minorities support measures to eliminate institutional discrimination and privileges. Thus this study ultimately suggests that dominants will oppose group-sensitive policies unless they come to endorse greater group equality, relate to the subordinated groups, and recognize the innumerable obstacles faced by people who do not have the social privileges the dominants take for granted. Most studies of privilege focus on the disadvantaged group. An impressive aspect of this perspective is the acknowledgment that dominant groups are in fact cognizant of social inequality. While gay and lesbian support groups are common in high schools in providing supportive relationships, they do not mitigate the marginalization prevalent in a heterosexual dominant context. This latter point also reflects the experiences of youth who are members of a religious minority.

Schlosser (2003) concurred with others in noting that the majority of conversations about diversity or multiculturalism are concerned with race-based issues and affirms the importance of ensuring that discussions include other minorities whose experiences have been neglected by dominant society and researchers alike. Schlosser explicitly discussed religion and the privileges afforded to Christians in agreement with McIntosh's (1988) claim that the subtle unearned advantages that White people possess (referred to as White privilege) are mimicked in the dynamics between all dominant groups and those who they oppress. His list of 28 privileges afforded to Christians in the United States, however, varied from others in its attention to those that have no perfect equivalent in other forms of oppression, such as seeing knowledgeable celebrations of your holidays across the media, receiving time off from school or work on your holy days, being greeted in public places according to your holiday season, having ready access to places where you can worship, feeling comfortable displaying items of religious significance, and so on. He suggested that, in order to understand how power operates, all types of dominant groups must be identified as privileged, and these silent advantages must be articulated and discussed.

In his discussion of religious groups in the United States, Schlosser emphasized that the majority of Americans practice Christianity and are thus positioned as members

of the dominant religion. Christians are identified as those who believe in Jesus Christ as their Lord and savior and the teachings of the Old and New Testaments. Other criteria are that Christians take communion and celebrate holidays congruent with their religious beliefs (e.g., Easter and Christmas). In addition to the advantages of being members of the dominant religion, their greater numbers and historical control in political realms provide Christians with significant power in creating policies and laws. One way in which this power makes itself known is in the common concept of "separation of church and state," which presumes both that the word "church" means something to all people and that the meaning of "church" is singular and stable. In a society where Christianity was not the dominant religion, we might think of this as the separation of "temple and state," "mosque and state," or more inclusively as "religion and state." Another example of religious bias emerged in the 2000 presidential election, during which the press frequently ignored Joseph Lieberman's political qualifications and instead focused on the fact that he (the Democratic Party's vice presidential candidate) was an Orthodox Jew. One more example can be found in George W. Bush's declaration of June 10, 2000, as "Jesus Day" in the state of Texas, where he served as the governor. Each of these phenomena displayed a lack of consideration of minority religious groups.

Continuing his comparison of Christian privilege to White and male privilege, Schlosser suggested that the feminist concept of "nonconscious ideology" might also help to explain the existence of Christian privilege. To Schlosser, it seems that Christians are not likely to interpret their environment as religiously hostile or discriminatory because there are no significant pressures on them to imagine how it feels to be a person who does not share their own (dominant) religious beliefs. They cannot share the perspective of the oppressed groups and thus they do not perceive their surroundings as oppressive, at least in that particular way. Nevertheless, Schlosser states that it is the responsibility of any dominant group to become familiar with their unearned advantages and welcome a discussion of the power they possess. Schlosser also briefly made a case in favor of religion being viewed as an ethnic group and thus a legitimate variable of research in power and privilege studies. Schlosser's approach was novel for its strong introduction to the concept of Christian privilege. Schlosser noted that his list of Christian privileges was not at all complete but was intended to spark further dialogue about Christian privilege and help bring society closer to including all religions in dominant discourse. Moreover,

Schlosser insisted that all people should strive to cherish rather than merely tolerate the existence of religions that differ from our own. Particularly for youth who are members of a religious minority, acknowledgement of their beliefs and related practices reduces the stressors associated with maladaptive coping outcomes (see Swanson et al., 2010).

Although attention to the issue of privilege is relatively recent, what the various approaches have in common relative to their implications is that someone benefits by denying access and opportunity to others. The outcomes are significant not only for individuals victimized by the socially constructed conditions but, in fact, there are implicit psychological costs for those objectively benefiting from the untoward practices.

IDENTITY AND COPING

Within a developmental framework, juxtaposed against the concept of privilege, stereotypic messages related to domains of the self and experiences of discrimination have implications for educational experiences and mental health outcomes, particularly during adolescence (García Coll et al., 1996; Spencer, 1995; Swanson, 2010). In synthesizing several theoretical perspectives on depressive symptomology for youth, including cognitive and socio-ecologic factors, Hammack (2003) identified oppression as the primary catalyst contributing to adolescent depression. The following section elaborates on (a) significant social and developmental factors associated with the etiology of depression during adolescence and (b) the significance of a positive reference group in identity development and in mitigating depressive symptoms.

In response to the uncertainties of their environment, many marginalized or stigmatized youth develop coping skills and adaptive behaviors to compensate for their status as minority group members. Anxiety for these youth may be triggered by academic problems, family conflict, community violence, interpersonal relationships, or employment and career issues. Behaviors such as hyperactivity, acting out, and aggression in younger adolescents suggest the presence of unaddressed anxiety, while delinquent activity, substance abuse, and sexual promiscuity may be responses to underlying anxiety or depression in older adolescents (Gibbs, 1982; Kauh, 2010; Swanson, 2010). These behaviors reflect coping responses that enable youth to adapt to impoverished or oppressive lifestyles, but

are yet maladaptive for success in mainstream society (see Gibbs, 1989; Spencer et al., 2006).

These strategies can result in positive resolutions that contribute to the development of an effective repertoire of responses. Adaptive strategies, however, are important independent of the developmental period (Taylor, 2010). The possible negative or problematic consequences are particularly relevant during adolescence as these early-developed coping responses are utilized in facing future stressors, with implications that extend into adulthood (Luthar, 2006; Swanson, Cunningham, & Spencer, 2003). The extent to which youth experience competence in their efforts to change their circumstances is critical for establishing a foundational framework for future challenges. Some stressors that challenge competence are adolescent-dependent, in that they are events unique to adolescence (i.e., pubertal changes, school transitions). Most normative stress that adolescents encounter is inevitable and uncontrollable: They are encountered by most youth and include day-to-day hassles found in different social environments. Life-event stressors in impoverished urban communities are often associated with exposure to violence as well as typical adolescent stressors (e.g., puberty and increased conflicts with parents).

While students may perceive typical stressors as a hassle, research over the past decade has demonstrated that the perceived hassles are good indicators of parental monitoring (see Cunningham et al., 2002; Spencer, Dupree, Swanson, & Cunningham, 1996, 1998). Parental monitoring is generally referenced as parents' awareness of their children's activities. Specifically, parental monitoring is defined as parents' knowledge, supervision, and control of their children's daily activities and peer relationships in an attempt to minimize the potential risks to which their children are exposed (Barber, Olsen, & Shagle, 1994; Cottrell et al., 2003; Gray & Steinberg, 1999; Parker & Benson, 2004; Spencer et al., 1996, 1998). For example, families that show moderate to high parental monitoring may include parents who are familiar with their children's friends, extracurricular activities, and express concern about where their children spend time away from home and school (Spencer et al., 1996). Even some single-parent families manage to exhibit high parental monitoring, although they may experience more difficulties than parents in two-parent households (Gutman & Eccles, 1999; Spencer et al., 1996). Single parents may have more challenges to exhibit high parental monitoring because they are often the sole providers for their families. Single parents have various constraints that compromise the

availability of resources needed to manage their children's activities and relationship. Factors such as financial strains, restrictive social supports, psychological distress, and time constraints interfere with consistent levels of parental monitoring (McLoyd, 1998).

Explicit strategies for addressing adversities at home or school that are communicated and modeled shape the perspectives of youth on the challenges they encounter and actions required to mitigate them. O'Connor (1997) explored the characteristics of six African American students who were a subsample of a study examining 46 students' perceptions of American opportunity structures and the impact of their optimism on future aspirations. Resilient students had (a) strong evidence of their personal competence, (b) concrete experiences which conveyed that individuals could defy racial barriers, and (c) social interactions that communicated strategies that would allow them to negotiate the financial limitations of their households in their pursuit of upward mobility (p. 622).

These attributes, however, were considered insufficient to account for the optimism expressed by the educationally resilient youth. O'Connor found that most of these students recognized systemic challenges, relative to their status as minority members, associated with race, class, and, at times, gender that could potentially frame their perspectives that life opportunities were limited. Some students defied odds and demonstrate defiance against the perceived limitations. Gordon (2004) defined defiance as "acts of active resistance to a challenge and pushing against obstacles standing in the way of personal achievement" (p. 124). As such, in contrast to students who recognized systemic challenges, those students identified as academically resilient also recognized and explicitly responded to social injustices; they were not resolved to accept systemic challenges without struggle or action. The social experiences of the resilient students, while having heightening awareness of structural constraints, did not represent indomitable structures that could not be defied, negotiated, or altered. This acknowledged potential for change may have additionally created the space for these youths to be optimistic about their futures and exhibit continued effort in school (O'Connor, 1997, p. 623).

As stated earlier, systemic challenges (i.e., stressful contextual and life experiences) may compromise the academic success and transition into adulthood of youth (Cunningham et al., 2009). Impoverished youth are more likely not to graduate from high school than their peers from more economically stable homes and communities. Youth caring for siblings or helping parents with

addictions, mental health problems, or physical disabilities are also at increased risk of poor academic outcomes. These outcomes are often attributed to absences or lack of focus when able to attend school (Slaughter-Defoe & Rubin, 2001). To mitigate these vulnerabilities, sufficient supports are required to enhance academic competence leading to academic resilience (Trask-Tate & Cunningham, 2010). The supports reduce risks in areas that are most likely to directly affect academic performance and intellectual curiosity. For example, in a sample of urban African American adolescents, Trask-Tate and Cunningham (2010) examined students' reports of parental "school-based" involvement, perceptions of social support from school officials, and students' expectations for how long they intended to go to school (e.g., drop-out, graduate high school, finish college, or attain a graduate or professional degree after college). The results indicated that perceptions of support from school officials accounted for the most variance associated with academic future expectations. Although the home environment is a critical context for developmental outcomes, the supports provided by other socializing agents can significantly mitigate the limitations of a vulnerable family.

Vulnerability and Depression

Racial and gender differences in rates of depression have been attributed to several factors, including socioeconomic status, experiences of racism and discrimination, gender socialization, and societal attitudes about physical beauty (Boyd-Franklin, 1995; García Coll et al., 1996; Kohn-Wood, Hudson, & Graham, 2008; Nolen-Hoeksema, 1990; Smolak, Levine, & Gralen, 1993). Although reporting similar rates in perceived discriminatory experiences, males and females may differentially internalize these encounters (L. D. Scott, 2004; Sellers, Caldwell, Schmeelk, Karen, & Zimmerman, 2003).

Gender differences

J. L. Rushton, Forcier, and Schectman (2002) found that, among a national sample of adolescents, females and ethnic minority youth were most likely to report baseline depressive symptoms with females reporting persistent symptoms at follow-up. Theorists suggest that such gender differences in the prevalence of depression in the United States are associated with both psychological and societal factors. Nolen-Hoeksema (1990) suggested that boys and girls differ in their ruminative styles. As youth progress from childhood through adolescence, they gain the ability

to think more abstractly and to think in more sophisticated ways (Piaget, 1972). As a result, they apply the ability to reflect on different thoughts and actions. Females, in particular, tend to mull over their negative self-appraisals, which leads to bouts of depression and anxiety. In contrast, boys' gender socialization toward a performance orientation encourages them to utilize distraction strategies (i.e., acting out) when experiencing perceived threats to their sense of self (Carlson & Grant, 2008; Cunningham, 1999).

Pubertal development for both boys and girls contribute to immense physical changes to their bodies that include an increase in body weight associated with growing muscle and fat (Susman & Dorn, 2013). Girls are particularly sensitive to these physical changes, as they decline significantly in self-esteem and increase in depressive state around the onset of puberty (Rosenblum & Lewis, 1999). Researchers suggest that the negative impact of pubertal development on girls' mental health can be attributed to societal appreciation for and definitions of physical beauty that favors tall, thin women. The onset of pubertal development, consequently, leads to a sudden increase in body fat, which as previously noted can exacerbate an adolescent female's tendency to be overly concerned about her body weight and physical appearance (Smolak et al., 1993). As such, their psychological well-being—in the form of higher body dissatisfaction, lower self-esteem, and higher depression—declines (Rosenblum & Lewis, 1999).

Research notes, however, that these same trends in depression as they relate to pubertal development do not emerge among African American females. In contrast, although African Americans are at greater risk for obesity than Whites (Ogden, Flegal, Carroll, & Johnson, 2002), their sense of well-being seems less vulnerable to the physical changes that accompany pubertal development, which many theorists believe can be attributed to cultural differences in the ideal body. Numerous studies have found, for instance, that the ideal female body type among both African American males and females is heavier than that of Whites (Freedman, Carter, Sbrocco, & Gray, 2004; Gluck & Geliebter, 2002). As such, sudden increases in body fat and body weight associated with pubertal development may not have as negative consequences on the mental health and well-being of African American females as is evident among their White female peers. This relationship may depend, however, on the extent to which African American girls identify with their racial group. Girls, for example, who weakly identify with African American culture may not share the same attitudes about body image. As such, they are more susceptible to societal attitudes

regarding weight and this contributes to relatively higher depression during adolescence. In examining psychosocial correlates of obesity, Asthana (2012) found that obesity among adolescent girls in Delhi significantly predicted self-esteem, depression and social anxiety. The relationship between weight and mental health are attributed to weight stigma—the negative cultural attitudes and discrimination associated with weight.

Racial Differences

Overwhelming evidence suggests that lower socioeconomic status (SES) is strongly linked to poorer physical and mental health (Adler et al., 1994; Schreier & Chen, 2013). In fact, individuals from the lowest SES backgrounds experience higher psychological distress (Eaton & Muntaner, 1999) and are 2 to 3 times as likely to have mental disorders (Muntaner, Eaton, Diala, Kessler, & Sorlie, 1998) as those from the highest SES. Disadvantaged communities often lack resources that promote well-being (e.g., high levels of supervision for teenagers) and, instead, possess high rates of unemployment, homelessness, substance abuse, crime, and violence (Bowen & Chapman, 1996; Brody et al., 2001). Exposure to neighborhood crime and violence puts individuals at greater risk for experiencing immediate, as well as, long-term psychological distress (Cunningham et al., 2009; Gorman-Smith & Tolan, 1998; Miller, Wasserman, Neugebauer, Gorman-Smith, & Kamboukos, 1999). Further, African Americans and other ethnic minority groups are overrepresented among the lowest income brackets; 24% of Africans Americans live in poverty compared to 8% of Whites. As a result, African Americans are at particularly high risk of experiencing mental health problems.

In addition, ethnic and racial minority individuals' experiences with racism and discrimination can negatively affect their mental health by increasing depression and anxiety (Kessler, Mickelson, & Williams, 1999; L. D. Scott, 2004). Simons et al. (2002) investigated the correlates of childhood depressive symptoms in preadolescent African American children and found that racial discrimination was positively related to their depressive symptoms. The impact of such experiences can become increasingly negative during the transition into adolescence when a shift from concrete to more formal cognitive abilities occurs. Specifically, the decline in egocentric thinking allows for the emergence of perspective-taking abilities (Grusec & Lytton, 1988). In the context of ethnic minority youth, increased abilities to consider the perspectives of others may leave them more susceptible to the negative effects

of societal stereotypes and discrimination. Some youth, for instance, internalize negative stereotypes about their racial group, leading to poorer self-esteem and psychological functioning (Cross, Strauss, & Phagen-Smith, 1999). Moreover, the negotiation of these experiences becomes a part of the process of racial identity development, which involves the restructuring of individuals' cognitive schemas in response to changes in their maturational level *and* interactions within their environment (Spencer, Swanson, & Cunningham, 1991). Further, depression may represent individuals' responses to perceived lack of power or efficacy to effectively influence their environment. Racism and discrimination further contribute to poorer mental health through its relationship to discriminatory hiring and housing practices that force racial minority individuals to live in lower SES neighborhoods and work lower paying jobs.

Implications of Ethnic Identity

Racial identity encompasses many psychological and behavioral components ranging from feelings of belonging, commitment and attitudes toward one's group to shared language, behaviors, and values (Cross et al., 1999). It represents an important psychological characteristic that may protect racial minority youth from developing depressive symptoms caused by various risk factors. Mumford (1994) stated that identification with the dominant White culture (Eurocentricity) has a positive correlation with depression, while having a positive Black identity is negatively correlated with depression.

Theorists suggest that individuals' racial identity represents a source of strength. Cross et al. (1999) suggested that a strong racial identity instills positive images and attributes of in-group members and the ethnic culture, thereby instilling pride in the ethnic group and in an individual's affiliation with that group. Similarly, Kulis, Napoli, and Marsiglia (2002) argued that being embedded in an ethnic or racial culture "[enhances] pride, self-esteem, and interpersonal skills" (p. 103). According to Scheier, Botvin, Diaz, and Ifill-Williams (1997), the lack of a strong racial identity leads to "feelings of inadequacy, marginality, and role confusion, all of which [may lead to negative behaviors] as a means of coping with internal psychological pressures" (pp. 23–24). As such, much research focusing on the implications of racial identity for the mental health of African American youth emphasizes the importance of their ability to identify specifically with Black culture. Results of numerous other studies support these theories and findings; racial identity has been

positively related to self-esteem and negatively related to depression (McMahon & Watts, 2002; Roberts et al., 1999; Sellers et al., 2003; Sellers, Copeland-Linder, Martin, & Lewis, 2006).

Although research has primarily focused on how the need for African American youths to identify with Black culture contributes to their overall sense of self-worth and identity development, some suggest that ethnic and racial minority youth must successfully negotiate identification with *both* their ethnic culture as well as the dominant White culture (LaFromboise, Coleman, & Gerton, 1995). Du Bois (1989), however, described the African American experience as a duality, in which, an individual is American but not completely accepted in American society. Along similar lines, Cross' stages of psychological Nigrescence for Black Americans consist of two dimensions, which Cross argued were in direct conflict with each other: (1) individuals' orientation toward Black culture and (2) individuals' orientation toward mainstream White society. As such, positive Black identity has been assumed to have a direct negative relationship with perceived White precedence (i.e., having Eurocentric values). In as much as past research has suggested that both of these dimensions are important for the sense of self and mental health of youth (Pyant & Yanico, 1991; Ward & Braun, 1972), few studies have simultaneously examined the relative contribution of each of the dimensions for adolescent well-being. Rather, the majority of studies examine either identification with Black culture alone or in combination with identification with the dominant White culture. Swanson et al. (2009), however, argued that these dimensions of identity are unique and should be independently assessed. Work by Sellers and colleagues (2006) expanded the conceptualization of racial identity to include public and private regard but also national identity in examining the impact on mental health outcomes.

Significant conceptual and empirical work has focused on the impact of negotiating challenges to salient areas or domains of self during adolescence. The positive relationships between racial identity and positive outcomes suggest the need for youth to have a positive reference group as an orienting aspect of identity development (e.g., high centrality buffers the effect of school discrimination; Sellers et al., 2006). Research, for example, with Mexican youth confirm the salience of cultural values in mitigating anxiety, depression and behavioral problems by providing opportunities for defining and interpreting societal expectations (Berkel et al., 2010). The concept of a reference group orientation is attributed to work by Cross (1971, 1985) in his early

conceptualization of identity development processes for African Americans. This conceptualization of a reference group orientation, however, has not been explicitly framed or extended in understanding identity development based on other referent groups within developmental science. Significant research contributions in recent decades have provided and contributed to understanding the impact of group affiliations on self-appraisal processes. Attention has appropriately focused on the sense of belonging or affiliations to a referent group of youth, but there has been less attention to the factors within referent groups which create the foundation needed to support development, particularly under adverse conditions.

Given the wealth of research showing how positive affiliations and referent group orientations support self-appraisals, studies on cultural identity among Native Americans have not consistently shown the same pattern of outcomes. Hamill, Scott, Dearing, and Pepper (2009) examined depressive symptoms and the moderating effect of cultural identity among 12–18-year-old Native American youth. They found cultural identity significantly reduced depressive symptoms, which was moderated by age (assessed as students' grade in school). W. D. Scott and Dearing (2012), however, later found lower depressive symptoms among the younger participants (ages 12–15) within the same sample reporting high self-efficacy; this relationship was not moderated by cultural identity. Whitesell, Mitchell, and Spicer (2009) examined developmental trajectories of self-esteem and culture in relation to personal resources, problem behaviors and academic performance as part of a 3-year longitudinal study on Native American youth. The positive relationship between self-esteem and academic achievement was consistent with previous literature but cultural identity had no direct effect. The discrepancies may reflect early exploration of identity processes that contribute to inconsistencies in findings over time, different criteria used for assessing problem outcomes, and different assessments of cultural identity.

In addition to culture providing a reference group for identity exploration and development, faith communities may also contribute to the self-appraisal processes of youth. The sense of connection associated with belonging to a religious group can have a positive impact on mental health. This relationship is contributed to factors that include social cohesion, family support, and consistent values (Dabbagh, Johnson, King, & Blizzard, 2012). There have also been inconsistent findings related to the influence of faith communities on identity development.

Some studies differentiate spirituality from religiosity, with spirituality reflecting a commitment to faith principles in contrast to practicing the traditions and expectations of a religious community. Butler-Barnes, Williams, and Chavous (2012) explored racial pride, educational utility beliefs, and religiosity. They found an interaction between high educational attributions and low religious beliefs. Reported beliefs in religious practices, often the focus of religiosity assessments, did not represent the attributes associated with positive outcomes (i.e., cohesion). Nevertheless, it was also noted that a faith community can contribute to, or exacerbate, experiences of stigma and adaptive challenges (see Bridges & Snarey, 2010).

Methodological Considerations

Early research on Black children did not differentiate between personal and group identity, and nondevelopmental interpretations of negative self-concept were attributed to racial self-hatred for decades thereafter (see Swanson et al., 2009, for a review). While focusing on one or both constructs, the research frequently ignored developmental transitions, parental racial socialization, and societal and historical traditions that stress racial membership as a determinant of group and individual experiences. Phenomenological approaches (i.e., PVEST) are consistent with understanding the meaning-making processes of individuals from diverse backgrounds and experiences. Emergent contextualized perspectives offer greater conceptual and analytic sophistication for examining developmental processes. These, however, still require a phenomenological orientation to mitigate the implicit biases of oversubscribed, presumably objective assessments. While efforts to create valid and reliable measures are necessary for large-scale studies, it is misleading to suggest that the selection of measures and the associated constructs are diversely representative without exploring the meaning-making processes of those being studied.

In addition to considering assessment approaches, recent advances in theoretical applications have contributed to complexities in analytic strategies. Studies examining the influence of various contexts (e.g., multilevel models) and that promise broad ranging impact, have gained in popularity over recent decades (Raudenbush, 2005). When designing and conducting studies that examine contextual factors, it is critical to address any differences in units of analysis.

Similarly, it can be misleading to assume that constructs such as "self" and "identity" share the same

meanings across cultures. It is important to understand and examine culturally salient factors contributing to self-appraisals in non-Western societies. Much of this current review has focused on research with global implications but drawing largely from research conducted in the U.S. Examining philosophically different perspectives on how self-processes are defined and on factors influencing the meaning-making processes associated with self-appraisals facilitate an enhanced understanding of self development processes. Additionally, examining cultural influences on these processes can contribute to understanding how they may differ over time, thus identifying developmental trajectories from childhood through adolescence.

Mixed methods, path modeling, and hierarchical linear modeling relevant to multilevel modeling provide greater support for using this perspective. In studies that use an ecological perspective, the context should be adequately described to provide information about the contextual level being examined (i.e., meso versus exo, degree of embeddedness), and, in the case of a developmental focus, individual factors should be provided to situate the person (i.e., child, parent) within a specific context at a given period in time.

A final note regarding methodological trends is the rising prominence of mixed-methods research designs. Cross (2005) provided a historical review of the use of mixed methods when studying identity among African Americans. He noted that, although valuable new constructs were added over time in the research on Black identity, self-report questionnaires were the primary method of assessment. Multiple ethnic identities and situational and developmental changes in identity are clearly important, and therefore the use of mixed methods extends knowledge of identity processes across contexts. There remains value in utilizing a clearly focused research method that continues, for example, to explain processes, predict trajectories, and identify critical developmental periods and influences. The strength of mixed methods is its potential for addressing complex phenomenon but a major challenge is that the strengths and limitations of each method must be addressed. Sensitivity to issues of reliability and credibility are necessary in the initial design and in the analytic decisions. While using the strengths of quantitative and qualitative methods, it is important to address potential pitfalls by adopting greater vigilance in design and implementation of the research that is appropriate for the research question and implications for the population being studied.

FUTURE IMPLICATIONS FOR CONCEPTUALIZING SELF

Several relevant issues for future conceptual considerations and research studies are presented throughout this chapter. The following are some highlights and additional directions for research on self-development and self-processes:

- Explore in greater depth the impact of self-efficacy or an agentic perspective on self-processes: importance of feeling like you matter; importance of effectance motivation (classic perspectives by theorists such as Albert Bandura, Robert White) on self-development and experiences that further shape it. There is very little research on these processes during middle childhood, which has implications for adolescence and later development.
- Broaden and examine reference groups that are salient for the identity formation of youth. Particularly salient for understanding societal references they draw on (i.e., cultural factors or faith-based values) during self-appraisal processes.
- Explore memory and cognitive-based therapy (CBT) model. Individuals form an initial memory that then competes to be remembered. According to this model, if the individual does not have positive supports and does not learn to identify the negative thoughts before they become implicit and automatic, they can become stable thought patterns (Brewin, 2006).
- It is also critical to take into account how young individuals make sense of the world. Currently, when scaled measures are applied to young children, they are not adapted to the minds of younger individuals (for example, see Kichler & Crowther, 2009).
- Examine the noted considerations through the lens of different human development models. For example in using a PVEST perspective, meanings eventually become stable coping patterns: “I get meaning from my body.”

CONCLUSION

Early and ongoing self-processes facilitate later identity formation and contribute to the development of positive efficacy under supportive conditions. Positive academic experiences and social competence are associated with adolescents’ ability to adapt. These, however, are frequently compromised for youth of color and other marginalized youth by a variety of challenges related to

the contexts of their development. During a time when peer relations become significantly more relevant to an adolescent's self-esteem, the role of adults in ensuring continued positive efficacy is expected to provide a sustaining impact.

Adolescence, as a time of normal exploration and unavoidable cognitive transformations, provides opportunities for further growth and positive development that can be facilitated through integrated services and programs directed toward youth. Among diverse youth, positive identity formation, safe interpersonal relationships, and development of skills and interpersonal competencies in conjunction with available supports are vital for experiencing and transitioning the adolescent years.

CHAPTER 19

Aggressive and Violent Behavior

MANUEL P. EISNER and TINA MALTI

ORGANIZATION OF THE CHAPTER	795
WHAT IS AGGRESSION?	795
WHERE DOES AGGRESSION COME FROM?	796
Aggression as Adaptive Behavior	796
Aggression as Psychopathology	797
Conclusions	798
THE DEVELOPMENT OF AGGRESSION AND VIOLENCE: CROSS-CUTTING THEMES	799
Population Heterogeneity and State Dependence	799
Turning Points	800
Developmental Taxonomies	800
Situational and Developmental Time	800
Causality and Reciprocal Processes	801
Right and Wrong	801
Conclusions	802
SUBTYPES OF AGGRESSION, CLINICAL CLASSIFICATION, AND MEASUREMENT	802
Subtypes of Aggression	802
Clinical Classification and Comorbidity	804
Measurement	805
Conclusions	806
THE EPIDEMIOLOGY OF AGGRESSION FROM INFANCY TO LATE ADOLESCENCE	806
Normative Age Curves	806
Developmental Stability of Aggression	807
Trajectories	808
Age-Specific Behavioral Manifestations of Aggression	809
Sex Differences in Aggression	810
Conclusions	811
THE BIOLOGY OF AGGRESSIVE BEHAVIOR	811
Behavior Genetics	812
Genetic Polymorphisms	813
Brain Regions	813
Psychophysiological Correlates of Aggression	814
Conclusions	814
COGNITIVE AND EMOTIONAL FUNCTIONING AND AGGRESSION	815
Cognitive Functioning	815
Social-Cognitive and Emotional Functioning	816
Conclusions	817
MORAL DEVELOPMENT AND AGGRESSION	817
Moral Reasoning	818
Moral Disengagement	819
Moral Emotions	819
“Moralistic” Aggression	820
Conclusions	821
FAMILY FUNCTIONING AND AGGRESSION	821
Attachment to Parents and Significant Others	821
Parenting Styles and Practices	822
Conclusions	823
PEER RELATIONS	824
Social Networks and Aggression	824
Friendship and Aggression	824

The authors are grateful to Michael Lamb, Rolf Loeber, John Archer, and Aaron Sell for their insightful comments on earlier drafts of this chapter, and to members of the Laboratory for Social-Emotional Development and Intervention at the University of Toronto for assembling references. The first author is grateful

for the support by the Jacobs Foundation and the Swiss National Science Foundation for the support of work related to this study. The second author is grateful for the support by the Canadian Institutes of Health Research (CIHR).

Generations of students have been taught to think about the nature of human aggression as a choice between two alternatives. Was Thomas Hobbes (1968/1660) right in assuming a natural “omnipresent danger of violent death” in the absence of the monopolizing power of the state? Or was Jean-Jacques Rousseau’s (2002/1762) vision of a natural peace among humans in the absence of evil brought about by manmade injustice more adequate? According to primatologist Frans de Waal, thinking about human aggression in relation to these alternatives is a waste of time (de Waal, 2005, p. 215). Humans are a bipolar species: We have an unparalleled capacity for cruelty, hatred, and brute use of force, but we also have a matchless sense of compassion, care, and moral obligation. The real question, therefore, is under which conditions either of these capacities prevails. Variation occurs at different levels: Whole societies can quickly move from a state of peace to outright civil war, where young men rape and kill, and societies ridden by extreme violence can experience massive declines in a matter of just a few decades. At the same time, variation occurs within individuals: Despite considerable stability of aggression over the life-course, humans move in and out of periods of temper tantrums, fights with classmates, and involvement in youth gangs during the growth from infancy to adulthood. In this chapter, we review current knowledge of the mechanisms that bring forth stability and change, and examine research on how developmental change is connected to societal conditions and biological mechanisms.

ORGANIZATION OF THE CHAPTER

We begin the chapter with three sections that outline the framework of our review. We first briefly define the terms *aggression* and *violence* (first section), then discuss the phylogenetic and ontogenetic origins of aggression (second section), and continue to identify six general crosscutting themes in developmental analyses of aggression (third section). The subsequent two sections discuss

epidemiological aspects of aggression. Specifically, the fourth section examines subtypes of aggression, the role of aggression in clinical diagnoses, and comorbidities with other mental health problems and behaviors; the fifth section provides an overview of different perspectives on the epidemiological description of aggression over the life-course. The remaining five sections review current research in a selection of domains implicated in the causation of aggressive behavior over the life course, namely genetic and biological factors (sixth section), cognitive and emotional development (seventh section), moral development (eighth section), family and peer dynamics (ninth section) and the link between macro-level processes and individual differences in aggression (tenth section). Across these sections we link current research to the six cross-cutting issues identified. We conclude with an integrative discussion of future strategies in developmental aggression and violence research.

WHAT IS AGGRESSION?

Aggressive behavior has been defined as behavior through which individuals intentionally cause physical or psychological harm to others (Krahé, 2013). This definition comprises many different behaviors. The English language, for example, probably contains several hundred verbs that describe acts that fall under this definition. Table 19.1 lists a selection of these verbs grouped into eight heuristic categories, namely inflicting physical injuries (bite, hit, rape, wound), engaging in confrontational conflicts (argue, fight, quarrel), using coercive power (abuse, coerce, intimidate, terrorize), using group-level coercive power (conquer, raid, battle), withdrawing support from dependents (abandon, neglect, starve), inflicting reputational losses (disregard, insult, tease, provoke), retaliating (avenge, retaliate), and inflicting personal harm by taking or destroying somebody’s property (burn, destroy, rob, vandalize).

TABLE 19.1 English verbs that express aggression

Heuristic Category	Examples
Inflict physical injury	Abort, assault, attack, batter, beat, bite, cut, drown, hit, hurt, injure, fight, punch, push, kick, kill, lash out, mutilate, rape, shoot, slaughter, slap, stab, strangle, strike, torture, wound
Confrontational conflicts	Argue, battle, clash, compete, fight, quarrel
Use coercive power	Abduct, abuse, arrest, bully, coerce, compel, force, frighten, intimidate, pressurize, punish, scare, terrify, terrorize, threaten
Use group-level coercive power	Attack, conquer, invade, raid, battle
Withdraw support for dependents	Abandon, maltreat, neglect, starve
Inflict reputational losses	Annoy, disregard, exclude, frustrate, harass, insult, offend, reject, slight, tease, enrage, infuriate, provoke, upset
Retaliate	Avenge, retaliate, revenge
Inflict losses on a person’s property	Burn, damage, destroy, mug, ravage, rob, steal, vandalize

We note three issues with this definition: First, some items used in common psychometric instruments of aggression do not fulfill the criteria of this definition. The aggression subscale of the Achenbach Child Behavior Checklist (CBCL/6-18), for example, comprises items such as “talks too much,” “showing off or clowning,” and “easily jealous” (Achenbach & Rescorla, 2001). These behaviors would not constitute aggression according to the proposed definition. Second, aggressive acts vary widely in the level of “intentionality.” Items like “reacting aggressively when teased” involve little intent. However, they probably belong to the construct of aggression as they imply a goal-directed antagonistic response aimed at countering a primary hostile act. Third, the definition does not limit aggression to norm-breaking or morally wrongful behaviors. For example, acts of self-defense in reaction to a threat, punitive action, and coercive acts by legitimate agents of state control are aggressions by the terms of this definition.

In developmental research, aggression is usually interpreted as a subdomain of the broader category of *externalizing behaviors*, an umbrella term for all antagonistic behaviors directed at the external environment. It comprises aggressive, defiant and disruptive, as well as hyperactive and impulsive, behaviors (Liu, 2004). The notion of *antisocial behavior* refers to aggressive and nonaggressive behaviors that break social and legal norms but not to the spectrum of ADHD-related behaviors. For adolescents, the term *antisocial behavior* is often used interchangeably with *delinquency* or *crime*, although it covers behaviors such as bullying that are not subject to criminal law sanctions. When used for children, the notion of antisocial behavior usually refers to a group of behaviors that includes aggression, oppositional behavior, and status violations.

Violence comprises acts of physical force intended to cause physical pain. Specifically, the 2002 *World Report on Violence and Health* by the World Health Organization defined violence as “the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation” (Krug, Dahlberg, Mercy, Zwi, & Lozano, 2002, p. 5). This definition combines three domains, namely *self-directed violence* such as suicide, *interpersonal violence* defined by criminal law, and *collective violence* including war, genocide, torture, or terrorism. The present review is limited to interpersonal violence, that is, behaviors that involve the use or threat of use of physical force to hurt or damage other persons.

WHERE DOES AGGRESSION COME FROM?

Where do aggression and violence come from? Much developmental research interprets this question as a question about the ontogenetic origins of differences between individuals. Empirically, this perspective leads to an emphasis on factors such as brain dysfunction, the learning of aggressive scripts, inadequate socialization, moral deficits, or exposure to aversive life-events. Theoretically, it results in a “violence-as-pathology” model, whereby non-normative characteristics of the individual or the environment explain the aggressive behavior. However, it does not answer the phylogenetic question about the species-wide roots of aggressive behaviors and the astonishing similarities in the mechanisms that trigger aggressive behavior patterns across cultures and over time.

Aggression as Adaptive Behavior

Questions about the phylogenetic roots of aggression and violence require a framework that examines the universal mechanisms associated with violence among all humans, in all cultures, at all times (Eisner, 2009). Its general questions are: What is the function of aggression among human beings? What problems is aggression designed to solve? And where do the neurological and psychological mechanisms involved in aggressive responding come from?

One approach to these questions is evolutionary theory and evolutionary developmental psychology (Archer, 2009b; Buss & Duntley, 2006; Ellis & Bjorklund, 2005). Within an evolutionary framework, aggression is seen as a facultative adaptation, that is, the result of interlocked domain-specific mechanisms (e.g., neurocognitive problem-solving mechanisms such as anger, arousal, or fear) whose activation depends on the environment. These mechanisms are assumed to have evolved during the environment of evolutionary adaptation (Bowlby, 1958). For example, the psychological mechanisms associated with, for example, being a good fighter or effectively deterring a potential attacker through convincing anger displays probabilistically conferred bearers of these abilities greater chances for reproduction over the millions of years during which the neurocognitive and physical characteristics of humans were being shaped. The notion that the neurocognitive mechanisms involved in the aggressive behavior of children, adolescents, and adults have an evolutionary basis does not presume a primordial war of all against all. Rather, it assumes a complex interrelation between evolved

mechanisms that support executive control, cooperation, compassion, and friendship, and mechanisms that bring forth jealousy, revenge, hatred, anger, and rage.

Arguments in support of an adaptationist perspective on aggression come from several sides: Evidence from anthropological, historical, and archaeological research indicates that intraspecific violence was an important selective force throughout the history of the human species until very recently (Eisner, 2003; Pinker, 2011). The incidence of intentional killings varied wildly over time and between places, but reviews suggest that a rate of some 10%–20% of male deaths due to intraspecific violence may have been fairly typical (Pinker, 2011, p. 49). Anthropological research also shows that, in many prestate societies, high social status and access to women is associated with a reputation for being good fighters and warriors (Patton, 2000), and that women find men more attractive who appear to be good warriors and hunters (Escasa, Gray, & Patton, 2010). Furthermore, some fundamental developmental patterns associated with aggression among humans look surprisingly similar to those among nonhuman primates, especially our closest relatives, the chimpanzees: This includes rough and tumble play during childhood (Flanders et al., 2010), the peak of serious physical aggression after the start of sexual maturation (Walsh, 2009), the early emergence of sex differences in physical aggression (Archer, 2004), and individual-level risk factors such as impulsivity, risk-seeking, preferences for alcohol, or exposure to poor child rearing (Higley, Suomi, & Chaffin, 2011).

Buss and Duntley (2006) distinguished among several adaptive problems for which aggression may have evolved as a solution. One is *co-opting the resources* of others. Humans stockpile considerable amounts of attractive goods including toys, food, weapons, and land. Gaining access to these scarce goods is an important goal, and humans use several strategies such as trickery or cooperative exchange to achieve it. But one of the options is aggression, especially if the owners appear weaker than the protagonists. Proactive aggression to co-opt attractive goods can be observed during the second year of life, and raids on owners of toys, food, jackets, or mobile telephones remain a core element of bullying from early to late childhood (Tremblay, 2010). A second function of aggression is *defense against attack*. The assumption here is that, in the presence of conspecifics interested in co-opting one's goods or taking one's life, the chance for survival depends on defensive abilities. Such abilities may be supported by emotional mechanisms such as intense anger and irascibility in the face of threats to the owners'

goods and reputation, as they help to fend off potential attackers (Sell, Tooby, & Cosmides, 2009). A third hypothesis proposed by Buss (Buss & Duntley, 2009) is that aggression serves to increase status and power within social hierarchies. Aggression is not always a successful strategy. But especially in contexts characterized by the absence of central authority or contested hierarchy the use of force is a promising avenue for dominance, which is associated, in turn, with access to valuable resources (Pellegrini, 2008). In this vein, Guerra (2012, p. 105) observed that, for inner-city youths in Jamaica, violence "is one of the few available currencies they have to get ahead. It is relatively easy to learn and can be 'traded' for power, control, resources, respect, status, and other desired outcomes." Fourth, aggression can serve to *inflict costs on same-sex rivals*. Access to valuable members of the other sex is a valuable resource, and aggression against competitors can yield benefits. Aggression against same-sex competitors can include attempts to lower the others' reputation, for example, by spreading damaging rumors about their characters or making detrimental remarks about their ability to control their partners' sexual behavior (McMaster, Connolly, Pepler, & Craig, 2002). It may also involve the public staging of fights which make differences in "formidability" (Sell et al., 2009) visible to members of the other sex.

Aggression as Psychopathology

The dominant perspective in the developmental science literature is that aggression is primarily maladaptive. Especially more extreme and persistent manifestations of aggressive behavior are interpreted as part of a broader set of mental disorders such as oppositional-defiant disorder or conduct disorder (see below, section 4). Extensive evidence shows that persistent aggression is dysfunctional under peaceful social conditions: For example, aggressive children are more likely to be rejected by other children, they do less well at school, and they are more likely to suffer from symptoms of mental disorder including depression, ADHD, and schizophrenia (Connor, 2002). Furthermore, aggressive and antisocial youth are less likely to find stable jobs, are more likely to suffer from a range of health problems, are more likely to have concurrent substance-abuse problems, and have shorter life expectancies (Piquero, Farrington, Nagin, & Moffitt, 2010).

Within this framework, the origins of aggression are generally traced back to various risk and resilience influences that increase or decrease the likelihood of aggression.

Risk factor research has identified hundreds of factors that are probabilistically associated with differences in aggressive behavior over the life-course (Farrington, 1998; Farrington & Loeber, 2000; Ribeaud & Eisner, 2010). Using the ecological framework proposed by Bronfenbrenner (1979), these risk factors are often grouped into individual, family, school, peer, neighborhood, and wider societal categories (Farrington, 1998; Krug et al., 2002; Loeber & Hay, 1997; Lipsey & Derzon, 1998; Loeber & Hay, 1997). Widely accepted individual risk factors include genetic risks, impulsivity, low intelligence, low arousal, antisocial beliefs, and low empathy. Biological risk factors associated with external influences include exposure to pathogens such as lead, birth complications, or child malnutrition. Family-related risk factors replicated across studies comprise, for example, parental criminality, child abuse and neglect, poor emotional bonds with parents or caregivers, low parental involvement, and poor family functioning. School-related individual risk factors comprise truancy, low academic motivation, and poor relationships with teachers, while school-level risk factors include high levels of classroom disruption and poor school functioning. At the level of peers, violent behavior is associated with antisocial peers, gang membership, and rejection by more prosocial children. Neighborhood level characteristics implied in an increased likelihood of aggressive behavior include high concentrated social disadvantage, low social cohesion, and high levels of crime. Finally, at the level of whole societies, associations have been found between violence and characteristics such as high social inequality, social cleavages associated with a lack of interdependence, and poor state functioning, including a lack of state legitimacy (Eisner, 2013).

Recently researchers have increasingly become interested in protective factors (Hall, Catalano, Loeber, & Farrington, 2012). There is not yet a consistent terminology for use when discussing protective factors but most authors conceptualize direct protective factors as antecedent characteristics that predict a low probability of violence or aggression (Herrenkohl, Lee, & Hawkins, 2012). If their effect is linear, they can be seen as the inverse of risk factors. In contrast, the notion of buffering protective factors refers to characteristics that mainly operate in the presence of risk factors (Lösel & Farrington, 2012). For example, Lösel and Farrington (2012) found that individual characteristics such as above-average intelligence and an easy temperament (i.e., emotional stability, positive emotionality, low impulsivity) had buffering effects on aggressive behavior even in the presence of

various environmental risk factors. Moreover, Loeber and Farrington (2012) have drawn attention to the possibility of nonlinear effects, whereby only the “protective” or the “risk” tail of predictor variables may be associated with variations in aggressive behavior.

A recent special issue in the *Journal of Preventive Medicine* reviewed the current state of knowledge (Hall, Catalano, et al., 2012). Among others, it presented findings from four separate longitudinal studies on the effects of presumed protective factors measured at Ages 10–14 on violence during adolescence (Ages 13–18). Of the 92 tests for associations with violence perpetration conducted across the four studies, authors identified fewer direct (i.e., having effects only at the “positive” tail) protective factors (12%) than risk (i.e., having effects only at the “negative” tail) factors (23%). Mixed factors (i.e., those that have both protective and risk effects) were identified in 18% of the tests. However, findings were only partly consistent across studies (Hall, Simon, Mercy, Lee, & Mercy, 2012): For example, in the Pittsburgh Youth Study, high academic achievement was found to be a protective factor. In contrast, in the Seattle Social Development Project study, youth-reported low grades were a risk factor; and in the National Longitudinal Study of Adolescent Health, the grade point average was found to be both a protective and a risk factor.

Generally, approaches that interpret aggression as maladaptive behavior rest on three normative pillars. The first is the broad consensus that children should develop to be socially competent, empathetic, and morally responsible individuals who have good chances to lead fulfilled and contented lives. The second is that, according to the Universal Declaration of Human Rights (1948), humans have a universal right to be protected from harm and victimization by others, meaning that aggression is considered wrong. Third, many risk factors associated with aggression are in themselves widely held to be undesirable conditions that reduce the welfare and well-being of individuals at all stages of the life course, meaning that efforts to eliminate or reduce them are desirable.

Conclusions

At first sight, the adaptationist perspective offered by work premised on evolutionary psychology and the more widely held view of aggression as a maladaptive phenomenon seem to be at odds with each other. However, an increasing number of researchers recognize the possibility of integrating views of aggression as adaptive and as

maladaptive behavior. We outline two areas where such integration may be fruitful: First, the majority of processes and risk factors associated with individual differences in aggressiveness and the prompting of aggressive action in specific situations appear to be cross-culturally universal. We thus need to explain why children and adolescents are more likely to behave aggressively in circumstances such as being teased or treated unfairly, why high fearlessness and risk-seeking are associated with higher risk of aggressiveness, or why homicide peaks among men at around Ages 18–25 across the world. Evolutionary theory, as Bjorklund and Pellegrini (2000, p. 1703) have argued, provides a possible theoretical framework for answering such questions, while it may also help to better understand the extent to which mechanisms leading to aggression are culture-bound.

Second, neurobiological work increasingly identifies specific areas in the brain implicated in aggression-related emotions such as anger and rage as well as in the cognitive mechanisms that control impulses, allow long-term rational planning, and bring forth complex abilities such as compassion and conscience (Raine, 2013). The unfolding of these mechanisms in each individual is critically shaped by the exposure to risk and protective factors as the child grows up. But a theory of how the phylogenetic architecture of the underlying neurocognitive processes (e.g., anger processing in the amygdala) has evolved, and how the cognitive, emotional, and moral development from infancy to adolescence follow patterns that were shaped by the adaptive pressures over the human past may help to organize otherwise disparate findings. Moreover, understanding the universal mechanisms—individual, social, and political—that promote justice, fairness, and compassion rather than anger and aggression in human beings can help to inform strategies aimed at effectively reducing aggression and violence (Guerra, 2012).

THE DEVELOPMENT OF AGGRESSION AND VIOLENCE: CROSS-CUTTING THEMES

The volume of research on human aggression makes it increasingly difficult to organize empirical evidence and theoretical perspectives. In the following section, we propose six cross-cutting questions that can help to structure current developmental aggression research: Is the rank-order stability of aggressive tendencies over time due to latent underlying traits or to external influences? Are there developmental turning points where aggressive behavior

can change its direction? Are there different groups of individuals to whom different explanations of aggression apply? What is the relationship between the long-term development of aggressive potential and the situational dynamics that give rise to aggressive action? How can we simultaneously model causal mechanisms that influence children's behavior as well as the influence that children's behavior has on their environment? And how can questions about right and wrong inform and guide current theorizing and empirical research on aggression?

Population Heterogeneity and State Dependence

Probably the most salient question in developmental research relates to the causes of stability and change in aggression over the life course. In the early 1990s, Nagin and Paternoster (1991) introduced a distinction that helped to organize the main theoretical perspectives. Following work by the economist James Heckmann (1981), they argued that two major groups of developmental theories of crime can be distinguished: *population heterogeneity* and *state dependence* approaches (Nagin & Paternoster, 2000): Population heterogeneity theories explain the continuity of aggression over time—and the stability of differences between individuals at any moment in time—as the result of durable underlying characteristics that differ between individuals and that influence a broad range of different behavior manifestations. This includes theories that emphasize lasting effects of time-invariant genetic differences, neurocognitive impairments incurred in the first years of life, or highly stable personality characteristics such as psychopathy or callous-unemotional traits (Frick, Ray, Thornton, & Kahn, 2013; Van Goozen, Fairchild, Snoek, & Harold, 2007).

State-dependence theories, in contrast, assume behavioral plasticity in that individuals' behaviors change in response to external forces: Hence the continuity of aggression is seen as the result of the stability of the social context, which keeps generating the causal mechanisms that lead to aggressive behavior. State-dependence theories do not deny the lasting influence of early risk factors. But these "pre-specified constraints" (Granic & Patterson, 2006) are seen as relatively subordinate to contingencies in the developmental process. Four major causal mechanisms dominate in state-dependence models: ongoing social learning processes across the life course (Huesmann & Taylor, 2006), stability and change in social bonds with prosocial as opposed to antisocial others (Catalano & Hawkins, 1996; Sampson & Laub, 2005), strains and negative life events

(Agnew, 2001), and “snares” or cascading constraints that result from prior problem behavior (Thornberry, 1987). State-dependence theories also tend to emphasize agency and decision-making—they examine acts of violence or aggression as a result of situational triggers, opportunities, and/or recent life-events (Fontaine & Dodge, 2006).

Turning Points

Population heterogeneity and state dependence are not necessarily mutually exclusive assumptions. Opportunities for turning points may arise in specific developmental transitions (e.g., from childhood to adolescence) or due to major life-events (e.g., failing/passing an important exam), while development is guided by stable latent traits through other periods. The *dynamic systems model of antisocial behavior* by Granic and Patterson (2006) assumes such a mix of processes: It identifies phase transitions where children’s developmental trajectories are especially open to external influences. In particular, entry into day care or school between Ages 3 and 6, the transition to more autonomy from parents during adolescence, and the transition to adulthood constitute such phase transitions in which seemingly minor incidents can act as bifurcations and shift aggressive trajectories in new directions (Granic & Patterson, 2006). This view echoes arguments by Dodge and Pettit (2003) in their *bio-psychosocial model of antisocial behavior*, where the beginning of primary school is also seen as a major “switch-point” that offers an opportunity to change chronic behavior problems caused by dispositional factors and prior adverse experiences in the family. Sampson and Laub’s (2005) *age-graded theory of informal social control*, in contrast, emphasizes individual biographical events rather than developmental periods. It holds that critical events such as moving home, marriage, or employment increase the contingency of the developmental process, offering opportunities for changes in routine activities, friendship networks, and self-identities associated with antisocial behavior.

Developmental Taxonomies

A third question is whether there exist subgroups to which different causal mechanisms apply. In her *dual developmental taxonomy of crime*, Terrie Moffitt (1993) suggested that adolescent offending is caused by two groups of individuals with different developmental trajectories and different etiologies: The life-course persistent trajectory starts early in life and is caused by the combination of

biological (genetic and neurocognitive) and environmental risk factors at an early age. These children show early signs of serious aggressive and nonaggressive conduct problems, and they have a high probability of long criminal careers well into adulthood. Adolescence-limited offenders, in contrast, have few, if any, early developmental risk factors. Their offending during adolescence is “state-dependent,” that is, driven by age-specific tensions (the “maturity gap”), opportunities that emerge through life-style, and routine activities (e.g., Vazsonyi, Pickering, Belliston, Hessing, & Junger, 2002), and the side-effects of reactions to their problem behavior (e.g., school exclusions) on their future life-chances (Berridge, Brodie, Pitts, & Tarling, 2001). Similarly, Frick and White (2008) have presented evidence that there exists a subgroup of children with callous-unemotional traits (lacking empathy, absence of guilt, callous use of others) that can be identified early in life (Dinolfo & Malti, 2013) and who are at risk for later antisocial and delinquent behavior. They are believed to have common genetic and neural characteristics (e.g., deficits in amygdala functioning), which lower the reactivity to environmental influences (Frick et al., 2013). Among others, they are less responsive to distress cues, less able to recognize sad and fearful emotional expressions, less reactive to negative emotional words, and more fearless (Frick & White, 2008, p. 363). In a study of 3,687 7-year-old twins, Viding, Blair, Moffitt, and Plomin (2005) examined the heritability of conduct problems in this group. They found that, for those who also had high levels of callous-unemotional traits, the heritable component was very high (.81), and that it was much lower among those without callous-unemotional traits (.30). The same pattern was confirmed at Age 9. Frick and White (2008) have, therefore, argued that the distinction between aggressive youths with and without callous-unemotional traits could make a substantial contribution to the development of a *taxonomy* of groups of antisocial youths.

Researchers have proposed varying numbers of distinct groups with different trajectories and etiologies (Jennings & Reingle, 2012), but disagreement persists over the number of groups that need to be distinguished, whether such groups are real or pragmatic groupings of essentially continuous characteristics, and whether preventive interventions need to be tailored to distinct groups.

Situational and Developmental Time

From the 1970s onwards, psychological research shifted from analyzing the aggressive act to examining the

aggressive individual (Hartup, 2005). Much current research is therefore more concerned with explaining stable between-individual differences than in examining the dynamics of conflictive episodes. But there is increasing recognition that the *real-time* affective, cognitive, and deliberative processes represented in the operations of the brain need to be part of developmental aggression research. For example, Granic and Patterson (2006) have proposed a distinction between the microsocial (moment-to-moment or "real") time and the macrosocial (developmental) time. They note that, not only must long-term developmental predictors be mediated through the thread-needle of real-time neurocognitive processing of information in order to result in actions that lead to violence, but also that "micro-social interactions [are] the proximal causal generators of development" (Granic & Patterson, 2006, p. 120).

One theory that models the relationship between long-term risk factors and the proximal mechanisms is the *general aggression model* by Anderson and Bushman (2002). It primarily builds on earlier learning and social information processing theories (Bandura, 1973; Crick & Dodge, 1996) and views conflictive episodes as the result of the interaction between individual and situational influences. Person-related factors mainly include the knowledge structures manifested in beliefs, attitudes, and scripts, whereas situational factors comprise aggressive cues, provocations, or frustrations. In a judgment and decision-making process that is influenced by situational cues and the internal state of the individuals (e.g., arousal), choices are then made between thoughtful nonviolent actions and impulsive aggressive options.

There is disagreement about whether the general aggression model, with its emphasis on social learning, adequately captures the mechanisms that link developmental time and moment-to-moment time (Ferguson & Dyck, 2012), and we currently have limited knowledge about how processes at different time scales (from split seconds to days, weeks, and years) interact to create sequences of aggressive behavior throughout development.

Causality and Reciprocal Processes

A fifth problem in developmental aggression research is the disentangling of correlates, causes, and consequences of aggressive behavior. In particular, the past 10 years have seen a growth of interest in models that examine what are variously called reciprocal, bidirectional, or transactional dynamics between children's behavior and their environment. Such issues have arisen, for example, regarding

child-parent relationships (Lansford et al., 2011), child peer-group relationships (Rubin, Bukowski, & Laursen, 2009), teacher-child relationships (Doumen et al., 2008), or the dynamics between violent perpetration and victimization (Hanish & Guerra, 2002). Theoretically, research on reciprocal dynamics is rooted in the transactional models developed by Sameroff (2009). Accordingly, children's present developmental state is the result of a series of reciprocal processes whereby various ecological layers of environment influences, while children also influence their social environments. In aggression research, the *coercion theory* developed by Patterson (1982) is a transactional model. It assumes that children learn aggressive behavior through iterated cycles of reinforcement whereby children adopt aggressive scripts as the mothers' reactions unintentionally signal to children that aggression is successful, while mothers learn that giving in to demands ends conflict.

In the past decade, new conceptual approaches to the reciprocal dynamics involved in the development of aggression and violence have evolved (i.e., developmental cascades) which take into account the timing of events in the emergence, or development of, aggression and violence from childhood to adolescence. Developmental cascades have been described as chain reactions, snowballs, spillovers, or progressive effects in the literature (Masten & Cicchetti, 2010). They describe processes by which antecedent conditions, such as harsh parenting, may be related with varying probabilities to specified outcomes, such as increases in aggression. Thus, cascades are processes by which functions at one level or in one domain of behavior affect the organization of competency in later developing domains of general adaptation (Cox, Mills-Koonce, Propper, & Gariépy, 2010). Theoretically, these effects reflect the transactions by which interactions predict development in complex living systems (Masten & Cicchetti, 2010, p. 491). Whether they are direct and unidirectional, direct and bidirectional, or indirect through various pathways, developmental cascades are believed to alter the course of development in positive or negative ways (Masten & Cicchetti, 2010).

Right and Wrong

The last cross-cutting theme relates to the question of the role of morality in the conceptualization of aggression and its development (e.g., Wikström, Oberwittler, Treber, & Hardie, 2012). As mentioned in the second section, work in evolutionary psychology conceptualizes aggression as adaptive. In contrast, much developmental work

conceptualizes aggressive and antisocial behaviors as disorders or as mental health problems similar to ADHD, depression, or autism spectrum disorders (e.g., Loeber, Burke, Lahey, Winters, & Zera, 2000). But intentional aggression differs from mental health disorders in that it is situated in a broader framework of (violations of) universally valid norms, rules, and obligations that underlie the functioning of societies and regulate social interactions and relationships (e.g., Sen, 2009). Understanding the what and why in how humans apply norms of justice, fairness, and care to the conflicts that inevitably occur in everyday life and how this adaptational process develops throughout the life-span may help to understand why some children behave more aggressively than others, why aggression increases or decreases over time and/or in specific situations, and why and when aggression is considered (mal)adaptive and/or “immoral” (i.e., violating moral norms of justice, fairness, or care).

Reflecting this perspective, theoretical models of the development of morality and aggression in childhood and adolescence have developed relatively independently. Yet, both domains focus on moral decision-making, intentional harm, injustice, and victimization (Arsenio, 2014). Developmental scientists have, therefore, increasingly felt a need to integrate these two domains conceptually. Arsenio and Lemerise’s (2004) seminal *Child Development* paper provided a first attempt to systematically integrate models of moral development and developmental theories of aggression. We believe that these recent integrative developmental frameworks may greatly help us understand and investigate developmental antecedents, causal risk and resilience factors, and consequences of aggression and violence for individuals, groups, and society because they transform questions about the adaptive and maladaptive nature and consequences of aggression to broader questions concerning universal norms of fairness, justice, and care.

Conclusions

Researchers differ with respect to what they consider the most important general questions that any developmental aggression research must address. In the present section, we have presented six cross-cutting questions or issues that we consider relevant for most ongoing research. For example, the extensive body of work on the association between parenting and aggression can be examined by asking whether scholars assume that the association reflects shared genetic factors (i.e., population heterogeneity) or genuine causal mechanisms (i.e., state dependence) (Pettit & Arsiwalla, 2008); whether the parenting behavior

of caregivers is believed to have particularly important causal effects in some developmental periods such as early childhood; whether researchers assume the existence of discrete groups of children that differ in the extent to which abusive parenting has a detrimental effect on their subsequent behavior (e.g., Caspi et al., 2002); how researchers link the real-time sequence of parent-child interactions to the developmental time of slow changes in aggressive behavior tendencies (Granic & Patterson, 2006); whether there are reciprocal causal associations between parenting and child problem behavior (e.g., Stattin & Kerr, 2000); and whether parenting is assumed to affect child aggression by changing moral beliefs about whether inflicting harm is justifiable.

SUBTYPES OF AGGRESSION, CLINICAL CLASSIFICATION, AND MEASUREMENT

Aggression is not a homogenous phenomenon. It comprises a variety of acts with different motivations (e.g., greed, revenge, self-defense, jealousy) and behavior patterns (e.g., hit, insult, ostracize). Recent research has, therefore, turned to distinguishing several subtypes that might have different etiologies and developmental trajectories over the life-course. At the same time, aggressive behavior is associated with a wide range of other behavior problems and mental health issues, suggesting that it belongs to a broadband syndrome of behaviors. In the following section, we selectively review recent proposals to systematize subtypes of aggressive behavior, the role of aggression in clinical diagnoses of mental disorders, and the evidence for co-morbidity with related behaviors and mental health problems.

Subtypes of Aggression

The past 20 years have seen increasing efforts to distinguish several subtypes of aggression (Vitaro, Bredgen, & Barker, 2006). Little, Henrich, Jones, and Hawley (2003) have proposed organizing the literature with focus on two main dimensions: The first relates to the forms (the “whats”) and the second to the functions (the “whys”) of aggression: The first dimension distinguishes *overt aggression* from *relational aggression*. Overt or direct aggression refers to behaviors that are openly directed at others with the intention of causing physical or psychological harm, or coercing them to do things they would not otherwise do (e.g., pushing, kicking, threatening). Relational aggression,

in contrast, refers to acts that intend to damage the social status, friendships, or interpersonal relations of other people (Crick & Grotpeter, 1995). It comprises behaviors such as spreading rumors, malicious gossiping, and social exclusion. Similar terms with a considerable overlap are *indirect* or *social* aggression (Underwood, 2003). The two forms of aggressive behavior are highly correlated with a mean attenuation-corrected correlation of $r = .76$ across 98 studies (Card, Stucky, Sawalani, & Little, 2008). However, they are differentially related to a series of covariates: For example, relational aggression is more strongly associated with internalizing problems than overt aggression, but less strongly associated with ADHD symptoms, delinquency, and the lack of prosocial behaviors (Card et al., 2008).

The second dimension relates to the difference between reactive and proactive aggression (Dodge, 1991; Hubbard, McAuliffe, Morrow, & Romano, 2010). Reactive aggression involves responses to provocations or threats and is usually accompanied by emotions of fear and anger. It is defensive and retaliatory. Proactive or instrumental aggression is the purposeful and goal-directed attack or threat of attack against people. Goals of proactive aggression include co-opting the goods of other individuals (robbery), controlling other peoples' behavior (coercion), or inflicting punishment for perceived prior wrongdoing (revenge). Instrumental aggression is only occasionally accompanied by autonomic arousal and is planned with goals in mind. Proactive and reactive forms of aggression are strongly correlated, although the association may be inflated due to poor differential sensitivity of conventional survey instruments. A meta-analysis of 36 studies suggested a correlation of $r = .68$ (Card et al., 2008). Still, proactive and reactive aggression differ with respect to a range of characteristics (Cima, Raine, Meesters, & Popma, 2013): Reactive aggression is linked to displays of anger under stress, high physiological arousal, and deficits in social problem solving. Proactive aggression, in contrast, is associated with a low level of physiological arousal, callous-unemotional traits, and little sign of rejection by peers (e.g., Arsenio, Adams, & Gold, 2009).

Aggressive and Nonaggressive Antisocial Behavior

Despite the trend to distinguish subtypes of aggression, there is disagreement about whether the high-order distinction between aggressive and nonaggressive antisocial behaviors is analytically fruitful. In particular, violent behavior among youth is consistently associated with a range of nonaggressive behaviors including truancy, lying, sexual promiscuity, binge drinking, gambling, substance

use, and property offenses (Farrington, 1998). Arguments in favor of more encompassing constructs come from criminological work that has found adolescent criminals to be generalists rather than specialists: Capaldi and Patterson (1996), for example, found little evidence of violent specialization in that violent adolescent offenders could barely be distinguished from general frequent offenders with respect to their demographic or risk-factor characteristics. Similar results were found in epidemiological research on mental health disorders. For example, Kessler et al. (2011) examined the comorbidity among 18 *DSM-IV* anxiety, mood, behavior, and substance disorders in 14 developed and developing countries, using the World Mental Health Survey data. In all studied countries, "overt conduct disorder"—which mainly comprised bullying, fighting, and being cruel—was part of a syndrome of externalizing disorders that includes oppositional defiant disorder, substance abuse, covert conduct disorder, hyperactivity disorder, and intermittent explosive disorder (Kessler et al., 2011, p. 94).

Others find analytically meaningful differences: For example, the two behavior domains follow different normative trajectories over the life-course (Loeber et al., 1993; Tremblay, 2010). Overt physical aggression peaks at Ages 2–4 and then declines, while covert behaviors become more frequent as children grow older. This could signal that overt and covert pathways of antisocial behavior are shaped by partly separate mechanisms (e.g., Burt, 2009) but it could also reflect the heterotypic continuity of a broader syndrome of antisociality, the behavior manifestations of which shift from more overt to more covert behaviors with age (as suggested by Patterson, 1993).

Burt (2009) argued that overt/aggressive and nonaggressive or covert forms of antisocial behavior represent correlated, but meaningfully distinct clinical phenomena, although she also noted considerable gaps in consolidated knowledge. Differences included a higher rank-order stability across development for aggression, a higher overrepresentation of boys in physically aggressive behaviors than in nonaggressive rule breaking, a more important role of genetic influences for aggressive as compared to nonaggressive antisocial behaviors, and differential association with personality characteristics such as negative emotionality, which seem more characteristic of aggressive than of nonaggressive behaviors. This suggests that overt physical aggression may be more strongly influenced by developmentally invariant factors than other types of rule-breaking behavior, which are more strongly influenced by contextual mechanisms.

Clinical Classification and Comorbidity

In the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*; American Psychiatric Association [APA], 2013), a new chapter titled "Disruptive, Impulse-Control, and Conduct Disorders" has been added. All disorders in this chapter are characterized by problems in emotional and/or behavioral self-control. Interestingly, because it is developmentally related to conduct disorder, antisocial personality disorder is listed twice in the *DSM-5*: once in this chapter, and once in the chapter on personality disorders. Also of particular interest, the commonly comorbid ADHD is not listed in this chapter, but instead with neurodevelopmental disorders. Two diagnoses are most relevant for the classification of aggressive symptoms in childhood and adolescence: *Oppositional defiant disorder* (ODD), which consists of symptoms that are grouped into three types: angry/irritable mood, argumentative/defiant behavior, and vindictiveness; and *conduct disorder* (CD), which consists of symptoms that are largely unchanged from the *DSM-4-TR* and are described by reference to prolonged patterns of antisocial behavior, such as serious violations of social and moral norms and rules. However, a specifier has been added for children who show callous and unemotional interpersonal (CU) styles across multiple settings and relationships. This is particularly interesting because of the independently developed body of empirical work on the role of various moral emotions, such as empathy and guilt, in the development of aggression (Arsenio, 2014; J. Blair, Mitchell, & Blair, 2005; Malti & Krettenauer, 2013). Children with the CU specifier are thought to have a more severe form of conduct disorder, making them less responsive to treatment. In a recent study by Kahn, Frick, Youngstrom, Findling, and Youngstrom (2012), a large community sample of children was compared to a clinical sample of 5- to 18-year-olds. In the community sample, 10%–32% of those with CD and 2%–7% of those without CD met criteria for CU specifier. In contrast, in the clinical sample, 21%–50% of those with CD and 14%–32% of those without CD met criteria for CU specifier. Overall, between 10% and 50% of those with CD also had the CU specifier. Importantly, children with CU were rated higher on CD symptoms, especially aggression/cruelty.

Comorbidity

There is strong evidence that aggressive behavior is associated with a range of mental health problems including

ADHD symptoms, autism spectrum disorders, and internalizing symptoms including depression and anxiety (Loeber et al., 2000). Across Western and non-Western societies, studies find a substantial correlation between aggression and ADHD symptoms (Beauchaine, Hinshaw, & Pang, 2010). Also, children with mental health problems in the autism syndrome spectrum have been found to have a higher rate of aggressive behavior, although a substantial part of this association may be mediated by other disorders, especially concurrent ADHD/ADD disorders (Bronsard, Botbol, & Tordjman, 2010). For example, according to analyses of the 2003 National Survey of Children's Health (NSCH)—a study of over 100,000 parents and their children in the United States—44% of children with autism were involved in active bullying as compared to 24% in the general population of children Ages 6–17 (Montes & Halterman, 2007, p. 255). However, the same study also found that bullying was only elevated among children with autism who also had concurrent ADHD/ADD disorders. Furthermore, research suggests a small to moderate correlation between depressive symptoms and aggression from childhood onwards. For example, in the Dutch TRAILS (TRacking Adolescents' Individual Lives Survey) study, a large prospective population study of adolescents, the concurrent association between aggressive and depressive problems ranged between $r = .34$ and $.56$ across four waves from Age 11 to Age 20 (Sijtsema, Oldehinkel, Veenstra, Verhulst, & Ormel, 2014).

Three processes have been implied in the correlation between aggression and other forms of poor mental functioning: First, evidence shows that genetic factors account for a part of the overlap: For example, a substantial proportion of the association between ADHD symptoms and ODD/CD are attributable to genetic factors (Nadler, Silberg, Eaves, Maes, & Meyer, 1998). Second, there is evidence suggesting that the association between different manifestations of poor psychosocial functioning is partly due to shared environmental risk factors, suggesting broadband causal mechanisms that affect a wide range of behavioral outcomes. For example, early childhood adversity has been implicated in the development of neurobiological deficits and cognitive-emotional problems, which affect a range of behavior and emotional problems (Van Goozen et al., 2007). Finally, there is evidence suggesting unidirectional and bidirectional causal links between different behavior domains. For example, researchers have asked whether there is a causal relationship between depressive symptoms and aggressive behavior. Aggression may lead to chain reactions

of failures such as peer exclusion, coercive reactions by parents, and academic failures, all of which may result in an increased vulnerability to depressive symptoms (Capaldi & Stoolmiller, 1999). Alternatively, depression may developmentally precede and cause aggression. In particular, problems with regulating negative affect and irritability may contribute to more conflicts with others and aggressive acting out (Wolff & Ollendick, 2006, p. 208). Recent research has found more support for a causal pathway from externalizing behaviors to poor emotional health, mediated through the effects of disruptive behavior on poor academic functioning (Masten et al., 2005), inconsistent parental discipline (Lengua & Kovacs, 2005), and peer victimization (Leadbeater & Hoglund, 2009).

Measurement

The valid and reliable measurement of aggression has remained a major challenge. The most important instruments for measuring aggression are informant ratings by means of item batteries, self-reports, observer ratings, and experimental estimates of aggressiveness. In high-quality developmental research, it is standard that researchers collect data on aggressive behavior from multiple sources. This may include peers, teachers, mothers, fathers, target individuals, and observations. The idea is that combining information from different informants results in more valid and more reliable estimates of the underlying behavior. Despite the usefulness of multi-informant measurement approaches, worrying discrepancies exist between different informants (Rescorla et al., 2013). The causes for these discrepancies are still unclear although recent work has returned to this important issue (de los Reyes, 2011). Different informants may observe different parts of children's lives (e.g., at school, at home), they may differ in the extent to which they have access to pertinent information, or their response behavior may be biased in systematic ways. Direct observational measures of aggressive behavior can overcome some limitations of survey instruments (Pellegrini, 2008). Although this approach has long been known, it is used surprisingly rarely, probably due to the high costs of collecting this kind of data. Observational measures are based on real-life observations of ongoing interactions, either by trained observers or via technical means such as videotaping, and the subsequent systematic coding of the observations. Another important methodological innovation involves use of the space-time budgets developed by Wikström et al. (2012) to accurately measure the social and spatial environments in which young people

spend their time, to track the kinds of activities they choose in these contexts, to observe how their interactions with others develops over space and time, and to relate incidents of rule-breaking (including violence) to the movement of adolescents through space and time.

Irrespective of how aggression is measured, observational (i.e., nonexperimental) longitudinal studies have limited ability to determine whether risk or protective factors are effectively causal. Jaffee, Strait, and Odgers (2012) identified four main challenges: First, the association between risk factors and outcomes may be confounded by third variables or sets of variables. This *omitted variable* problem can lead to inflated estimates of causal effects. For example, it is difficult to determine whether the association between poor parenting and antisocial child outcomes is causal if important variables such as shared genetic factors are not taken into consideration. The second problem is *reverse causation*. Thus, many studies find that maternal depression is associated with the development of child problem behaviors. But, while low maternal psychological well-being may predict child aggression, disruptive child behavior may also reduce maternal well-being. Unless all potential causal relationships can be explicitly excluded, it is impossible to conclude with confidence that causal effects in either direction have been demonstrated. A third challenge is *social selection*: We may find statistical associations between presumed risk factors and aggression because individuals have chosen exposure to given environments that fit their preferences, interests, and abilities. For example, individuals with aggressive tendencies who lack social skills may prefer aggressive media contents. This would result in positive associations even if the media contents themselves did not influence behavior. The fourth challenge is *misidentification*. This means that presumed risk factors may be associated with other risks, making it difficult to identify true causal agents responsible for associations. For example, parental separation is associated with children's problem behavior; but separation is often accompanied by high partner conflict and lacking attention to children's needs—each of which implies a different causal mechanism. Identifying the active causal ingredient requires the identification of confounders, but it also requires the identification of causal mechanisms that can be operationalized as mediators. However, it is rarely possible to establish the temporal and causal relationships between such intercorrelated factors. One tool to assess the quality of causal inferences based on observational data is the Cambridge Quality Checklist (Murray, Farrington, & Eisner, 2009).

Conclusions

Over the past 10 years, increasing attention has been paid to different subtypes of aggression. In particular, the distinction between two main functional types, namely goal-directed and instrumental proactive aggression as opposed to defensive and impulsive reactive aggression, appears to be analytically useful. Emerging findings (some of which we discuss further on) suggest that they are associated with different neurocognitive mechanisms and varying developmental risk factors. However, there is currently limited knowledge about the age at which a distinction between different motivational complexes becomes meaningful. Also, scholars have noted that the measurement of intentionality in conventional psychometric scales may be problematic, meaning that new empirical strategies to assessing proactive and reactive aggression may be required (Little et al., 2003).

On the other hand, aggression is part of a broader spectrum of externalizing behaviors whose manifestations change over the life-course, but whose components may be differentially susceptible to environmental influences (Burt, 2009). Although much evidence suggests that shared underlying personality characteristics and environmental influences are largely responsible for behavioral syndromes, there is also evidence for causal and reciprocal processes between subdimensions of externalizing behavior. For example, excessive alcohol consumption is known to be a short-term causal mechanism associated with increases in the probability of aggressive behavior. However, separating symptomatic comorbidity from possible causal mechanisms between subdomains of antisocial behavior has proven difficult in part because the typical time-intervals between assessments in longitudinal studies (between one and several years) make it difficult to examine more short-term mechanisms. Emerging research that integrates measurement of short-term variations in problem behavior (for example diaries or space-time budgets) into longitudinal studies may help to shed more light on these issues (e.g., Wikström et al., 2012).

THE EPIDEMIOLOGY OF AGGRESSION FROM INFANCY TO LATE ADOLESCENCE

Extensive work has reviewed the epidemiology of aggression over the life-course (Connor, 2002; Farrington & Loeber, 2000; Krahé, 2013). In our view, four different approaches are particularly useful in shedding light on distinct aspects of the developmental epidemiology of aggression: work that describes normative age curves for

subtypes of aggression, analyses of the relative (between-individual) stability of aggressive tendencies over time, trajectory analyses that group individuals by similar pathways over time, and qualitative descriptions of age-specific manifestations of aggression.

Normative Age Curves

A first perspective describes the prevalence of aggression over the life-course. Current research suggests that distinct age curves exist for physical aggression (Tremblay, 2000), relational aggression (Côté, Vaillancourt, Barker, Nagin, & Tremblay, 2007), bullying perpetration (Scheithauer, Hayer, Petermann, & Jugert, 2006), and violent offending (Loeber & Farrington, 2012). The two empirically most robust and theoretically most relevant normative patterns probably are the *age curve for physical aggression* and the *age-crime curve* for violent crimes.

Knowledge of the developmental epidemiology of physical aggression has mostly been drawn from Richard Tremblay's pioneering scholarship (Tremblay, 2000). Combining the findings from various longitudinal studies, Tremblay found that the prevalence of physical aggression increases steeply from birth until about Ages 24–36 months and gradually declines thereafter along a continuous path (see Figure 19.1). This normative pattern can be found in different societies and seems to be a cross-culturally universal pattern (e.g., Alink et al., 2006). In a recent extension, Tremblay (2010) suggested that the pattern applied not only to physical aggression, but also to oppositional behavior, defiance, and disregard for rules. For more covert behaviors such as vandalism, indirect aggression, and theft, in contrast, findings suggest low levels in early childhood and an increasing trend from childhood to early adolescence.

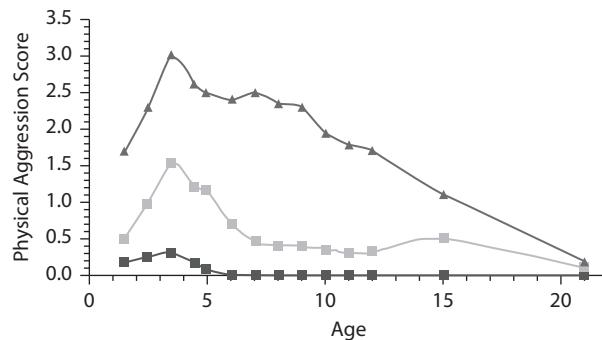

Figure 19.1 Three developmental trajectories of physical aggression from 17 months to 21 years.

Source: From "Development of Sex Differences in Physical Aggression: The Maternal Link to Epigenetic Mechanisms [Comment]," by R. E. Tremblay and S. M. Côté, 2009, *Behavioral and Brain Sciences*, 32, 290–291.

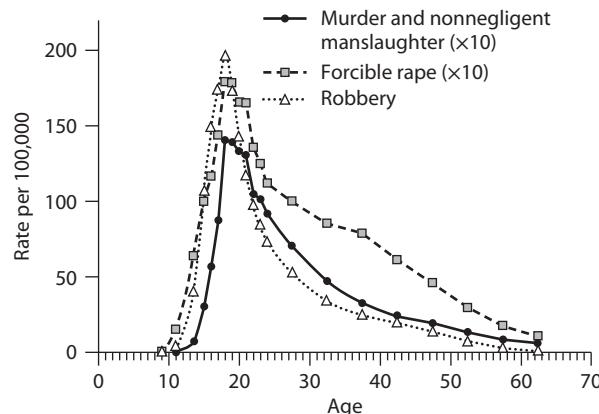

Figure 19.2 Age curve of violent crime in the United States, 2009–2011.

The second normative age pattern is the age-crime curve. It was first discovered in the 1830s by the Belgian statistician, Adolphe Quetelet, who found that the age distribution of criminal offenders followed a curve with a steep increase between Ages 10 and 18, a peak around Age 20, and a subsequent decline as age progressed (Quetelet, 1835). Figure 19.2 shows the age distribution of perpetrators of rape, robbery, and murder/manslaughter in the United States in the years 2009–2011. Both the overall age pattern as well as the differences between types of violence—robbery peaks earliest, assault tends to have a slower decline with growing age—are very similar across many societies (Farrington, 1986).

Interestingly, the steep increasing flank of recorded violent crime between Ages 12 and 17 is not found in the broader survey measures of physical aggression used by Tremblay (2000). The apparent contradiction might reflect the increased official recording following the transition to the age of criminal responsibility. But this is not the case. Data on the age distribution of perpetrators of, for example, homicide or armed robbery demonstrate that the ability to inflict serious physical harm on others indeed increases between Ages 12 and 17. Furthermore, the age curve for serious violent offending resembles the age distribution of other behaviors that index physical strength, recklessness, and high risk-seeking. This includes, for example, involvement in organized intragroup fighting (war) or high-risk sports activities (Rosen, 2005).

Developmental Stability of Aggression

A second approach answers questions about the extent to which between-individual differences in aggression are

stable over different time spans. Generally, findings are in line with what Caspi and Roberts (2001) have called the “twin laws” of longitudinal correlations in personality research. First, the correlations are high over short periods of 1–2 years and decrease as the time intervals between measurements increase. In a now classical review of longitudinal studies on boys, Olweus (1979) found that, over periods of 1–2 years, the (attenuation-corrected) correlations for the same aggression measures were typically in the range of $r = .65–.80$. For longer time intervals, the correlations declined linearly: Over 10 years the average correlations were $r = .60$, and over 20 years they were $r = .40$.

Second, the correlations between subsequent measures of aggression become larger as the age of the participants increase. A recent study suggested that this increase in the stability of aggressive behavior began in the first four years of life. Alink et al. (2006) found that 1-year stability of parent-reported aggression increased between the first year (age 12–24 months) and the third year (age 36–48 months) from $r = .49$ to $r = .72$. In an oft-cited interpretation of this pattern, Olweus (1979) concluded that the developmental stability of aggression is almost as high as that of intelligence. Unfortunately, no new review of the evidence has been conducted, but recent work suggests three qualifications: First, newer studies tend to report smaller stability estimates than those found by Olweus (1979). For example, in a study of children between Ages 10 and 15, Cillessen and Mayeux (2004) found 5-year stabilities for physical aggression of $r = .34$ and $r = .48$ for girls and boys respectively, while stability coefficients for relational aggression were .37 and .39. Also, a study of 205 boys between Grades 1 and 7 found that the stability of aggression fell from $r = .49$ to $.63$ over a 1-year period to $r = .21$ over 6 years (Schaeffer, Petras, Ialongo, Poduska, & Kellam, 2003). Second, stability estimates tend to be highest if they rely on the same informants over time. However, they are considerably lower when different informants assess children in the same environment and even lower if different informants assess children in different environments over time (Frick, Kimonis, Dandreaux, & Farell, 2003). Finally, stability estimates are considerably affected by changes in the social context. For example, a longitudinal study of 664 16- and 17-year-old students in Long Island, New York, examined the stability of physical and psychological dating aggression over 4 months and 12 months (Timmons Fritz & Smith Slep, 2009). Adolescents who stayed with the same partners over the study period were compared to adolescents who changed partners. The 4-month and

12-month stability coefficients for both physical and psychological dating aggression were significantly affected by changes in the dyadic situation: For example, the 4-month stability when staying with the same partners was $r = .40$ (physical aggression) and $r = .71$ (relational aggression), but only $r = .23$ and $.38$ respectively among those who had changed partners.

Trajectories

A third approach uses *trajectory analysis* to answer questions about whether there exist different groups of people with different behavioral trends over age. *Trajectory analysis* (Nagin, 1999) or *group-based modeling of development* (Nagin, 2005) has become increasingly influential over the past 20 years. It uses longitudinal data to identify groups of individuals whose behavior follows a shared trajectory over time. It has an affinity with taxonomic models, such as the dual taxonomy proposed by Moffitt (1993), but it can also be seen as an heuristic device to describe a much more complex reality (Nagin & Tremblay, 2005). Over 100 studies have used group-based modeling techniques to study aggression, violence, or broader constructs of anti-social behavior from childhood to adulthood (Jennings & Reingle, 2012). Findings are not always consistent: Across studies, the number of identified trajectories varies between 2 and 7, and the number and shape of trajectories partly seems to depend on the measurement strategy, the behavior domain, the developmental phase captured, and the length of observation (Martino, Ellickson, Klein, McCaffrey, & Edelen, 2008).

Beyond these inconsistencies, which require further investigation, four important patterns are evident in multiple studies (Odgers et al., 2008). First, most studies find a subgroup of “life-course persistent” children whose physically aggressive behavior remains high over long developmental time-spans. In this comparatively small group, aggression is usually combined with various other age-specific types of antisocial behavior. In the *Montreal Longitudinal Study*, 4% of boys Ages 6 to 15 had such “chronic” trajectories (Nagin & Tremblay, 2005), and more recent studies similarly find that 4%–10% of male children follow this trajectory (Piquero, Carriaga, Diamond, Kazemian, & Farrington, 2012). In mixed-gender studies, boys typically account for over 70% of the children in this category. Second, most studies identify a “persistent low” group. Children in this group start with low levels of aggressive behavior during early childhood and

consistently remain unaggressive throughout their lives (Broidy et al., 2003). The estimates for the size of this group vary widely between 20% and 70%, depending on the examined age span and the measurements used (Broidy et al., 2003), with girls overrepresented. Third, varying proportions of children tend to be classified into one or two “declining” or “childhood-limited” trajectory groups. Both start with high or medium levels of aggressive behavior at the beginning of childhood, but the behavior follows a declining trend across early and middle childhood. These children are the ones who drive the overall decline in physical aggression described in the previous section. Finally, some evidence suggests a distinct additional group of “adolescence onset” aggressive children with an escalating trajectory between Ages 11 and 17 (Jennings & Reingle, 2012; Odgers et al., 2008). For example, Martino et al. (2008) found that 23% of their sample showed increasing physical aggression between Ages 12 and 14. Similarly, in the *Montreal Longitudinal Study*, 17% of the boys were found to be in one of the rising trajectory groups between Ages 12 and 17 (Brame, Nagin, & Tremblay, 2001) and data from the longitudinal *Project Northland Chicago* found that 19% and 22% of the adolescents of African American and Hispanic origin, respectively, were on escalating trajectories between Ages 11 and 13 (Reingle, Maldonado-Molina, Jennings, & Komro, 2012).

From early childhood to early adulthood, the distinction among four major trajectory groups (“life-course persistent,” “childhood limited,” “persistent low,” and “adolescence onset”) emerges as an analytically useful and empirically supported classification. It has helped researchers in their search for early risk factors that predict membership in any given trajectory. For example, socioeconomic adversity, hostile and abusive parenting, poor prosocial skills, and low trust and trustworthiness predict membership in the ‘life course persistent’ trajectory (e.g., Malti, Averdijk, Ribeaud, Rotenberg, & Eisner, 2013). The distinction has also proven useful when analyzing the effects of life-events such as joining or leaving youth gangs, which change the probability of following particular probabilistic pathways (Haviland, Nagin, & Rosenbaum, 2007). Thus, as two of the developers of trajectory analysis emphasize, “It is important for users and consumers of the analyses to remember that individuals do not actually belong to a trajectory group, that the number of trajectory groups in a sample is not immutable, and that individuals do not follow the group-level trajectory in lock step” (Nagin & Tremblay, 2005, p. 898).

Age-Specific Behavioral Manifestations of Aggression

A fourth perspective answers questions relating to the age-specific manifestations of aggression and the situational contexts in which they occur. It entails descriptions of what children and adolescents actually do when behaving aggressively.

Infancy

The selective use of physical force often emerges toward the end of the first year of life (Tremblay et al., 1999). At the age of 12 months, infants show focused protest and self-defense, for example if toys are taken away from them (Hay, 2005). At 14 or 15 months of age, physical aggression against peers or siblings such as pushing, hitting, pulling hair, or biting is evident, and by the age of 17 months, almost 80% of children show some physical aggression, with “taking things from others,” “pushing to get what he/she wants,” “biting,” “kicking,” and “fighting” being the most frequently observed behaviors (Tremblay et al., 1999). Sex differences in physical aggression also emerge during the second year of life. The Québec Longitudinal Study of Child Development, with about 2,000 first-born children, showed substantial sex differences in physical aggression at Age 17 months, where about 5% of boys and 1% of girls were found to belong to the “high aggressive” latent class (Baillargeon et al., 2007). Results from the Dutch Screening and Intervention of Problem Behavior in Toddlerhood study suggested marginally significant sex-differences in physical aggression at Age 12 months according to mothers, but not fathers. By Ages 24 and 36 months, however, reported sex differences were in the range of $d = 0.30\text{--}0.36$ (Alink et al., 2006).

Early Childhood

Some noncompliance, physical aggression toward peers, and poor regulation of impulses are widespread during toddlerhood. For example, temper tantrums tend to occur among children between Ages 18 months and 4 years. In a normative sample of 1219 families with children aged between 18 and 60 months, 81% were reported to have at least one temper tantrum per month; these ranged from short responses to extensive episodes involving screaming, kicking, and dropping to the floor (Potegal & Davidson, 2003). The prevalence was found to increase from 87% at 18–24 months to 91% at 30–36 months before falling to 59% at 42–48 months.

The broader normative decline between Ages 2 and 5 in physical aggression as a strategy to solve conflicts over toys

or territories during dyadic play has been amply described (Hay, 2005; Rubin, Burgess, Dwyer, & Hastings, 2003). It is generally associated with the growth in social, cognitive, and verbal skills. At the same time, verbally mediated forms of aggression become more important (Ostrov, Ries, Stauffacher, Godleski, & Mullins, 2008). As children become older, its manifestations shift from more direct forms during early childhood (e.g., telling a peer that one doesn’t want to play with the peer unless the peer gives him or her a toy) to more indirect forms in middle childhood (e.g., spreading rumors and lies about a peer). Rough and tumble play emerges as a distinct form of playful aggression, which develops into highly sophisticated role-play during the primary school years (Flanders, Leo, Paquette, Pihl, & Séguin, 2009). It seems to contribute to the acquisition of social and emotional skills, the practicing of social rules, and the negotiation of dominance hierarchies, but can slide into antagonistic aggression among rejected or less skilled children (Smith & Boulton, 1990).

Middle to Late Childhood

During middle childhood (6–10 years), the establishment of stable and trusted friendships and wider acceptance by peers become a core concern, while peer rejection becomes a major source of frustration. Physical aggression generally continues to decline, but a small group of children with multiple behavioral difficulties continue to be involved in fights with others, destruction of possessions, or the robbing of valuable objects. Indirect aggression increases, reflecting the growing importance of friendships as well as children’s increasing cognitive skills (Côté et al., 2007). Parent and teacher assessments tend to show low correlations, possibly suggesting that, in middle childhood, aggression is still largely context-specific (Achenbach, McConaughy, & Howell, 1987).

By the beginning of primary school, aggressive children have a clear tendency to select friendships with peers who also show antisocial behaviors. They become increasingly rejected by more social competent children, although children who combine aggression with social skills can be admired and acquire dominant roles. Situations where new groups are formed (such as the beginning of kindergarten or school) or where new children enter groups seem to be particularly prone to trigger aggression. For example, Roseth, Pellegrini, Bohn, Van Ryzin, and Vance (2007) observed 61 children in a preschool child-care setting using seven waves of measurement over a year. They found that levels of aggression increased at the beginning of the

year and then declined as the year progressed. The authors argued that these patterns may reflect initial conflict over dominance hierarchies, which eventually stabilize and allow for more cooperative strategies.

A specific type of aggression that develops in the context of school settings is school bullying. Bullying has been defined as the use or threat of force to intimidate, coerce, and exclude others. Forms of bullying include physical and verbal bullying, being threatened or forced to act, being excluded or gossiped about, having property taken or damaged, and racial, sexual, and cyber bullying (Olweus, 1993). There is disagreement about the development of bullying during primary school. Some authors find that bullying increases between Ages 7 and 12 (Hanish & Guerra, 2004), while others find a general decline through primary school years (Boulton, Trueman, & Flemington, 2002). Solberg and Olweus (2003) reported decreased victimization rates between Ages 11 and 15, but increases in self-reported perpetration rates, probably suggesting that older children tend to bully their younger peers.

Early to Late Adolescence

During adolescence, behaviors associated with intense authority conflict such as truancy or running away from home become more frequent. Alcohol and substance use also begin during these years, and the early onset of substance use is associated with a greater risk of serious and violent offending (Schulenberg & Maggs, 2002). Puberty is also associated with a rapid increase in physical strength, which in turn leads to more serious types of physical aggression including robbery, serious assault, and homicide. According to self-report studies, the 1-year prevalence of serious violent offending (carrying weapons, threatening for money, fighting, beating up family/nonfamily members, hurting with weapons) is around 15%–30% in Western societies, although a small minority of about 3%–5% of adolescents commit most of the violent acts reported (Elliott, Hatot, Sirovatka, & Potter, 2001).

The situational context of aggression and violence during this stage shifts away from conflicts with schoolmates, siblings, or parents and into public space and unsupervised leisure time activities. Across the globe, adolescence is also the age at which delinquent peer associations can turn into criminal gangs (O'Brien, Daffern, Chu, & Thomas, 2013). Such groups are predominantly male, share particular codes of dress and behavior, control territories, and engage in confrontational dominance plays that can lead to serious violence with neighboring groups. Adolescent

girls are considerably less likely to be involved in physical violence than boys.

This period is also characterized by an increase in sexual aggression. In a Canadian longitudinal study, McMaster et al. (2002) found that sexual harassment (homophobic name-calling, making sexual jokes, and making comments or rating sexual body parts) increased substantially between Ages 12 and 14. By Age 15, a considerable amount of sexual and nonsexual violence is committed within adolescent romantic couples (e.g., Averdijk, Mueller-Johnson, & Eisner, 2011). For example, a study of 15-year-olds found that 34% of Italian and 32% of Canadian adolescents reported having used physical aggression against boyfriends/girlfriends (Connolly et al., 2010). Girls reported slightly less physical aggression, but the differences were small and most aggression was bidirectional.

Sex Differences in Aggression

Sex differences in aggressive behavior are among the most robust and stable findings in aggression research (Archer, 2004; Nivette, Eisner, Malti, & Ribeaud, in press). These differences universally follow a similar pattern: Indirect aggression is similarly frequent among both sexes, and possibly somewhat more frequent among girls. Direct verbal and confrontational aggression is more frequent among boys, and sex differences increase further the more they involve escalated physical violence. Among perpetrators of homicide, robbery or assault, men outnumber women by a factor of at least 1:5 in virtually all known human societies, although there is some variation over historical time and between societies (Campbell, 2007). Until recently, the dominant theory for explaining these sex differences was social role theory. This theory focused on the process of socialization and gender roles in forming sex differences in aggressive behavior and posited that the societal division of labor created stereotypical gender roles that socialize women into domestic roles that emphasize nurturing and compassion, whereas men are socialized into “breadwinner” roles that encourage dominance and competition (Eagly, Wood, & Diekman, 2000). This theoretical framework predicted that the sex difference in aggression would be greater in societies where girls are socialized into compliant, subordinate and gentle roles while boys are socialized to be dominant, competitive and aggressive. Also, sex differences should gradually emerge during childhood as the effects of gender-specific socialization accumulate.

Archer (2009a) has argued that the relative cross-cultural stability of sex differences in physical aggression, the similarity with sex differences in physical aggression in the animal kingdom, and the early emergence of sex differences are difficult to reconcile with a social learning perspective. Rather, he argued that sex differences in aggression are due to the greater evolutionary pressure on males to engage in overt competition for reproductive success (Archer, 2009a). For females, long internal gestation periods and higher parental investment lead to higher costs for risky and direct aggressive behaviors. For males, in contrast, greater variance in reproductive success leads to greater incentives for aggressive same-sex competition. These evolutionary processes are assumed to have shaped a number of proximal neurocognitive mechanisms: They include sex differences in the fear system as well as the greater ability of females to engage in reactive inhibition (controlling aggressive responses to fear), effortful control (the general ability to manage attention and actively regulate behavior), and general self-control (Archer, 2009a).

Empirical research on the developmental origins of sex differences bears on this debate between social learning and evolutionary theories (Hay, 2007). Earlier accounts reported that sex differences in physical aggression gradually emerge in the first 4–6 years, leaving ample room for social learning explanations (Loeber & Hay, 1997). Increasingly, however, studies of early child development suggest that sex differences in physical aggression can already be found much earlier. Baillargeon et al. (2007) examined physical aggression among almost 3,000 infants at Ages 17 and 29 months as part of the Québec Longitudinal Study of Child Development. They found that, even at 17 months, male infants were 5 times more likely to display frequent physical aggression than female infants. Also, the sex-ratio of aggressive behavior did not change between Ages 17 and 29 months. The authors argued that these findings are not compatible with the expectations of gender role theory (Baillargeon et al., 2007).

Conclusions

The five descriptive perspectives highlighted in this chapter illuminate a number of conceptually important issues and suggest a number of possible avenues for further research.

First, they suggest that the dominant feature of normative child development is an increasing ability to control aggression with age, experience, and brain maturation, whereby the use of force is supplanted by more effective, more cooperative and more complex strategies for

achieving goals. As Tremblay put it, “Rather than learn how to physically aggress [children] learn not to physically aggress” (Tremblay, 2009, p. 373). Accordingly, learning theories that assume the active acquisition of physically aggressive behavior during the life course seem implausible as a general explanatory framework, although learning processes are likely involved in reinforcing and activating existing trait aggressiveness (Huesmann & Eron, 1989). This suggests that preventive efforts are most likely to be effective if they intervene at the developmental roots of aggression during pregnancy and the first years of life and if they reinforce the normative unfolding of cognitive, social and moral skills as children grow older (Tremblay, 2010).

Findings regarding the rank-order stability of aggression over time suggest a stochastic process that is characterized by decreasing rank-order stability as time intervals become larger and increasing stability as children grow older. Despite the importance of relatively stable between-individual differences, it is worth pointing out that a maximum of about 20% of the variation in aggression at adolescence can be reliably predicted by measures of aggression at, say, the beginning of primary school. Furthermore, little is currently known about whether there exist, as suggested by Granic and Patterson (2006), distinct developmental phases where pathways are more open. Supportive evidence would probably require a decline in the rank-order stability of aggression in specific developmental phases (e.g., at entry into school). Also, systematic reviews of evidence comparing groups with and without change in external circumstances (e.g., moving home, changing partner) could shed light on the extent to which stability in aggression is state-dependent. Furthermore, the emerging evidence for similar trajectories in different societies has enriched the field. At the same time, we note that the evidence for early characteristics that reliably predict membership in the various groups is still limited, although there is clear evidence that the life-course persistent trajectory includes a large proportion of individuals with multiple early risk factors. Probably a fruitful area for further research would combine trajectory analysis techniques with the examination of life events that are hypothesized to change the developmental trajectories of aggressive behavior.

THE BIOLOGY OF AGGRESSIVE BEHAVIOR

Work on the biological underpinnings of aggressive behavior has been among the most dynamic areas of research

over the past 20 years. Four main interlocking strands of research must be distinguished (Portnoy et al., 2013): Behavioral geneticists have used designs such as longitudinal twin and adoption studies to understand the overall contribution of genetic factors to the development of aggression; molecular geneticists have examined the impact of polymorphisms in individual genes, and their interaction with environmental conditions, on aggressive behavior; laboratory neuroscientists have elucidated the real-time neurological processes involved in generating aggressive actions, and the more lasting characteristics of brain functioning that contribute to trait aggression; and neuropsychologists have developed methods that are increasingly embedded in longitudinal studies and that assess the extent to which components of brain functioning are associated with externalizing behaviors.

Behavior Genetics

Behavior genetic studies examine the relative influence of genes and the social environment by comparing the similarity of phenotypic characteristics, such as aggression, in monozygotic and dizygotic twins or in twins growing up with their biological parents as opposed to foster parents (Rhee & Waldman, 2002). They typically distinguish between three main sources of variation (Plomin, 2011): The genetic effect, which is usually measured as the extent to which monozygotic twins are more similar than dizygotic twins; the effect of the shared environment, which is estimated as the extent to which monozygotic twins are more similar than would be expected on the basis of the genetic effect only; and the effect of the nonshared environment, which comprises all remaining variance components. Recent meta-analyses of behavior-genetic studies show high contributions of heritable characteristics to variations in aggression. A review by Moffitt (2005) of over 100 studies concluded that, regardless of the design (twins reared together, adoption, twins reared apart), the heritability estimates for aggressive behavior converged to about 50%. Burt (2009) compared the influence of genetic factors on physical aggression as opposed to nonaggressive rule breaking and, like Moffitt (2005), concluded that the propensity for aggression is highly heritable, with genetic factors accounting for about 65% of the variance. Moreover, the heritability component was substantially lower for nonaggressive rule-breaking, which follows a trajectory over time that only peaks during the adolescent years.

A new line of research has begun examining whether genetic influences may not only account for developmentally

stable between-individual differences in aggression, but may also be responsible for changes over the life-course. For example, a recent study examined parent data from the University of Southern California (USC) Risk Factors for Antisocial Behavior (RFAB) twin study at Ages 9–10 and 14–15. Findings suggested that change in aggressive behavior during the transition to adolescence may be due to genetic factors that are activated during puberty (Niv, Tuvblad, Raine, & Baker, 2013).

Some evidence suggests that the effect of genetic factors varies between contexts (Burt, 2009, p. 612). For example, Tuvblad, Grann, and Lichtenstein (2006) found that, in disadvantaged high-risk neighborhoods, adolescent aggression was mostly due to shared environmental influences, with relatively little variance due to genetic factors. If confirmed by further research, these findings may suggest that genetic factors which index biological malfunctioning could be more important in protected and stable environments, while social factors may be more influential in settings where high levels of disadvantage and threat make aggression more adaptive.

Also, ongoing research is examining the extent to which established associations between social risk factors and antisocial behavior are effectively due to shared genetic influences. This work is important because, until very recently, genetic influences were entirely unaccounted for when exploring the relationship between social factors and aggressive behaviors. For example, Trzesniewski, Moffitt, Caspi, Taylor, and Maughan (2006) tested three hypotheses about the mechanism responsible for the association between reading achievement and aggressive behavior. The first hypothesis was that the association between reading achievement and aggressive behavior was attributable to genetic influences that influence both aggressive behavior and poor reading abilities. The second hypothesis was that the empirical association could be explained by shared environmental antecedents such as child neglect. The third hypothesis was that reading skills and aggressive behavior were causally interrelated, meaning that poor reading skills led to more aggressive behavior and/or that antisocial behavior led to more reading difficulties. Comparing the strength of the correlations for both monozygotic and dizygotic twins, the researchers concluded that a small proportion (21%) of the association was due to additive genetic factors, while most (71%) of the phenotypic association reflected shared environmental effects such as shared family experiences. Finally, the authors found support for a reciprocal dynamic relationship whereby reading skills influenced aggressive behavior and vice versa.

Genetic Polymorphisms

Findings from behavioral genetics likely reflect the combined influence of a large number of genetically influenced characteristics ranging from body weight and size to intelligence or more specific disorders such as ADHD (Portnoy et al., 2013). They are, therefore, commonly interpreted as initial evidence that a search for polymorphisms in specific genes would be worthwhile.

There now exists several lists of possible genes that may be implicated in between-individual differences in aggression (e.g., Ferguson & Beaver, 2009). Recent research has focused on three groups of genes that influence the functioning of two main neurotransmitter systems in the brain, the *dopaminergic system* and the *serotonin system*. The first group is involved in the production of dopamines, neurotransmitters that send signals between cells. They are distributed in the brain through dopaminergic pathways, neural pathways that send dopamine to the different brain regions. Dopamine has been described as a reward system. It plays an important role in motivation, attention, arousal and pleasurable reward. Several genes are involved in dopamine functioning and geneticists have examined the extent to which different polymorphisms (i.e., versions) of these genes are correlated with aggression. For example, in some studies, allele variants of the two dopamine receptor genes DAT2 and DAT4 were correlated with child aggression (Zai et al., 2012).

A second important group of suspects are genes that code for the neurotransmitter *serotonin*. Serotonin is a mood stabilizer, and low levels of serotonin are associated with higher irritability, depression, and impulsiveness. The most widely studied gene is the serotonin transporter 5HTT, a gene that regulates the availability of synaptic serotonin (5-HT). In particular, it is suspected that the polymorphism 5HTTLPR may be implied in a series of affective disorders and behavior problems. For example, in some studies, carriers of the low expressing alleles were at-risk for childhood conduct disorder (Cadoret et al., 2003), and aggression (Haberstick, Andrew, & Hewitt, 2006). A third group of genes that have received much attention are genes that are involved in regulating the metabolism of neurotransmitters, especially the gene MAOA (monoamine oxidase A), which is responsible for metabolizing serotonin and dopamine. Besides possible main effects of MAOA, the gene has also been found to interact with environmental conditions. Caspi et al. (2002) found that exposure to maltreatment predicted subsequent antisocial behavior among men with the short allele of the

MAOA gene, while it had little impact on men with the long allele. The most recent meta-analysis on this G×E interaction (Byrd & Manuck, in press) included 27 studies and showed that the MAOA × maltreatment interaction was robustly replicated in 20 male cohorts, but was not evident in 11 female cohorts (although maltreatment had a main effect on antisocial and aggressive behaviors).

G×E interaction effects suggest developmental models that distinguish different groups of children with varying vulnerability to environmental conditions. In particular, Belsky and Pluess (2009) have argued that various polymorphisms index broader variations in the susceptibility to environmental influences. The implication is that children with higher susceptibility do worse under detrimental conditions, but better under supportive conditions. This also implies that intervention effects are moderated by genetic differences.

Despite the impressive growth in pertinent research, the field remains characterized by inconsistencies. A meta-analysis by Vassos, Collier, and Fazel (2013) reviewed 185 studies involving over 60,000 participants on relationships between genetic polymorphisms and aggression, examining 277 independent associations related to 31 genes. The authors found no replicable significant main effects (G×E interactions were not examined in that study), arguing "that it is unlikely that few candidate genes explain a complex behavior like aggression and many hundreds or thousands of genes probably interact in a complex manner" (Vassos et al., 2013, p. 4). Another recent meta-analysis (Duke, Bègue, Bell, & Eisenlohr-Moul, 2013) arrived at a similarly sobering conclusion regarding the link between serotonin and aggression: It examined 175 independent samples in 144 studies. There was a small relationship between serotonin and aggression, anger and hostility of $r = -.12$, suggesting that about 1% of the variation in human aggression might be related to levels of serotonin. Moreover, the authors noted that the reported effect sizes significantly declined with the publication year, possibly suggesting a systematic bias in earlier publications. They concluded that "contradictory findings, unreliable measurement, and a high degree of complexity leave our overall finding of a small inverse correlation between serotonin and human aggression open to multiple, equally plausible interpretations" (Duke et al., 2013, p. 1165).

Brain Regions

In a recent overview, Raine (2013, p. 267) has summarized research on the various brain regions believed to be

involved in the biology of violence. He broadly distinguished three broad domains, namely *cognitive processes* (thinking), *affective processes* (emotions), and *motoric processes* (behavior).

With respect to cognitive processes, the main relevant brain regions are the *ventromedial prefrontal cortex* (involved in the processing of risk and fear, inhibition, and decision making), the *medial polar regions*, the *angular gyrus* (involved in attention and theory of mind), and the *anterior and posterior cingulate* (emotion formation and processing, learning, and memory). Raine (2013) argued that impairments of these regions result in poor planning, reduced ability for sustained attention, a poor ability to evaluate emotions, poor decision making, impaired self-reflection and a reduced ability to process rewards and punishments. These deficits are, in turn, associated with poor control over aggressive thoughts and feeling, overreaction to minor irritations, lack of insight and a poor response to punishments and rewards.

Among the brain areas associated with deficits in affective processing, Raine (2013) highlighted the *amygdala/hippocampal* complex (processing of emotional reactions), the *insula* (subjective emotional experiences, i.e., feelings and desires/cravings), the *anterior cingulate* (emotional stability, motivation, anxiety), and the *superior temporal gyrus* (perception of emotional stimuli, social cognition). Impairments in these regions are associated with the inability to understand the mental states of others, learning impairments, lack of guilt and empathy, poor fear conditioning, poor emotion regulation, and a reduction in negative emotions associated with moral transgression (Raine, 2013, p. 269). More specifically, the amygdala appears to be critically involved in forming links between conditioned stimuli and unconditional responses; it enables individuals to sense the badness and goodness of actions. According to R. J. Blair (2007), the underactive amygdala fails to signal the full value of aversive stimuli. Psychopathic children therefore fail to fully perceive facial expressions of distress, which normally act as a control mechanism.

For example, a recent meta-analysis by Gavita, Capris, Bolno, and David (2012) has examined the link between anomalies in the anterior cingulate cortex—an area associated with emotional stability and anxiety—and the aggressive behavior of male children aged 11–15. The review of eight brain imaging studies showed a strong overall effect of $d = -.98$. The authors concluded that functional abnormalities of the anterior cingulate cortex are strongly associated with aggressive behavior disorders.

At the level of the regulation of motoric processes, the main potentially involved areas of the brain are the *dorsolateral prefrontal cortex* (motor planning, organization, and regulation), the *orbitofrontal cortex* (correction of inappropriate behavioral reactions), and the *inferior frontal cortex* (response inhibition). Impairments in these areas are associated with response perseveration, impulsivity, failure to avoid punishments, and motoric excess (Raine, 2013, p. 269).

Psychophysiological Correlates of Aggression

Various psychophysiological characteristics are believed to be associated with aggression (Lorber, 2004). Probably the best-replicated correlate is a low heart rate. In a meta-analysis of 45 studies, Ortiz and Raine (2004) found an average effect size for the correlate with aggression of $d = -.44$ for resting heart rate and $d = -.76$ for the heart rate under stress. Moreover, a low heart rate during childhood predicts adolescent violence and life-course persistent offending. Two hypotheses have been developed to explain the link between heart rate and aggressive behavior. The hypoarousal hypothesis argues that children with low resting heart rates have atypically low arousal levels. Aggressive behavior could, therefore, constitute a strategy to stimulate their arousal levels to optimal levels. The fearlessness hypothesis assumes that low resting heart rates are markers for the lack of fear or anxiety, which in turn increases the willingness to engage in attacks, despite the risk of retaliation, and reduces the fear of punishment.

A second well-researched correlate of antisocial behavior is poor skin conductance fear conditioning. Fear conditioning relates to the process by which organisms learn to predict aversive events. It is typically assessed by means of experiments that combine aversive stimuli (e.g., noxious loud noises) with neutral stimuli. Individuals who are high on fear conditioning quickly learn to react with fear (measured by means of skin conductance) to the neutral stimulus even if the noxious stimulus does not occur. Gao, Raine, Venables, Dawson, and Mednick (2010) showed that poor fear conditioning at Ages 3 to 8 predicted aggressive behavior at Age 8 in a sample of male and female children in Mauritius. This finding held after controlling for measures of anxiety and fearfulness.

Conclusions

Research about the links between genes, brain functioning, and violence has recently been described as having “a very long way to go” by a leading specialist in the field

(Raine, 2013, p. 260). At the same time, we increasingly understand how different regions of the brain are involved in the complex cognitive, emotional, and moral processes whereby aggressive behavior is either adopted or rejected in favor of action alternatives. Specifically, genetic and environmental influences interact in the maturation of the neural systems that regulate complex moral emotions (e.g., empathy and guilt), executive functioning, and the display of social skills associated with the gradual replacement of aggressive behavior by more sophisticated strategies of conflict resolution and goal attainment.

Until very recently, almost all research in developmental psychology on aggression was genetically and neurologically “blind,” meaning that a potentially important source of variation was ignored. Moreover, much of the biological research that has been conducted in the past decades tended to treat aggression as a stable trait characteristic rather than as a dynamic phenomenon (Loeber & Pardini, 2008). Genetically informed longitudinal studies that comprise repeated neurological assessments and repeat measures of aggression can overcome such limitations.

COGNITIVE AND EMOTIONAL FUNCTIONING AND AGGRESSION

The role of social-cognitive and emotional functioning in the development of aggressive behavior has been extensively studied (Bandura, 1973; Crick & Dodge, 1996). Below we provide a selective review of central issues that have emerged in this literature. These issues are closely linked to the relationship between moment-to-moment processes and developmental time: Cognitive, evaluative and emotional processes are the core proximal elements of real-time judgment and decision-making (Fontaine & Dodge, 2006). But the way in which they function is influenced by the normative maturation process of the human body, the latent personality structures of individuals, as well as their accumulated experiences and knowledge structures.

Cognitive Functioning

It is well established in the developmental literature that low cognitive ability is related to higher levels of aggressive behavior across development (Lösel & Farrington, 2012). Recent studies have shown that the association between low cognitive ability, especially verbal aspects of intelligence, and aggressive behavior can be found at an early age. For example, Dionne, Tremblay, Boivin,

Laplante, and Pérusse (2003) tested the relations between expressive vocabulary and physical aggression in late infancy with a study that involved 562 19-month-old twins in Canada. They found a small correlation ($r = -.20$) in the expected direction. This association was not due to genetic influences, although a substantial proportion of the total variation in aggression (58%) was accounted for by heritable factors. The authors suggest that delays in language development may increase the likelihood of persistent physical aggression. Research in a different Canadian longitudinal sample similarly showed that physical aggression in early childhood (3.5 years) is associated with receptive vocabulary deficits (Séguin, Parent, Tremblay, & Zelazo, 2009). Also, verbal reasoning predicted physical and verbal aggression negatively in a sample of 11- to 16-year-old Estonian children (Kikas, Peets, Tropp, & Hinn, 2009). Barker and colleagues (2011) found that verbal IQ was negatively related to physical aggression in adolescence. In addition, a study by Giancola and Mezzich (2000) revealed that conduct-disordered female adolescents had poorer language skills than peers without conduct disorders. Lastly, Kennedy, Burnett, and Edmonds (2011) documented lower reading and vocabulary skills in violent offenders than in nonviolent offenders. In a study using a longitudinal birth cohort design, Liu, Raine, Wuerker, Venables, and Mednick (2009) showed that low IQ (as assessed by a composite of verbal and performance IQ scores) was associated with birth complications, and it was found to mediate the link between early predictors and later externalizing behavior.

One of the most commonly studied aspects of neurocognitive development is children’s executive functioning. Executive functioning is the ability of humans to regulate and adapt behavior in the most varied environments, to plan and anticipate consequences of alternative actions, to override spontaneous impulses, and to oversee their working memory. It has long been assumed that there exists a link between aggressive behavior and executive functioning. For example, low inhibitory control is assumed to be associated with a tendency for reactive aggression while a low ability for gratification delay is likely associated with fast discounting of future costs and a tendency for confrontational actions that seem to provide immediate solutions (Raijmakers et al., 2008). The neural system coordinated by the frontal lobe that maintains executive functioning develops gradually and only matures fully in early adulthood (Zelazo, Carlson, & Kesek, 2008). But links between poor executive functioning and aggression can already be found at an early age. Raijmakers et al. (2008) matched

4-year-old high-aggressive and low-aggressive children on intelligence and administered a series of neuropsychological tasks. A factor analysis suggested one main dimension of executive functioning that represents inhibitory control. The study found substantial associations between lacking inhibition and aggression, after controlling for sex and differences in ADHD symptoms.

Separating different subdomains of executive functioning has remained difficult. A rare exception is a longitudinal study of children at Ages 17 to 41 months by Séguin et al. (2009). They examined whether different dimensions of neurocognitive functioning regulate aggression and hyperactivity. The authors found evidence that aggression was specifically associated with measures of poor language functioning while hyperactivity shared unique variance with poor performance on visuo-spatial abilities. The specific role of deficits in language skills at this age suggests that advances in linguistically mediated executive functions play an important role in the increasing regulation of physical aggression and the growth of social problem-solving skills at this age.

Increasingly, it has also become possible to distinguish the trajectories of different subdomains of executive functioning over the life-course. For example, it appears that executive functioning in more abstract “cool” situations develops earlier in life than executive functioning in “hot” situations; this suggests that significant motivational and emotional components develop more gradually and significantly later than those that are less affectively engaging. Such differences in the maturation of “cool” and “hot” executive functioning may be partly responsible for the rise in risky behaviors during adolescence (Prencipe et al., 2011).

Executive functioning has also been shown to vary as a function of external influences. For example, alcohol consumption has been found to negatively affect inhibition, emotional control, flexible thinking, and self-monitoring, all of which increase the likelihood of aggressive behavior (see Eisenberg, Spinrad, & Eggum, 2010).

Social-Cognitive and Emotional Functioning

A significant amount of work has investigated the social-cognitive skills of children with and without aggressive behavior. This research has been conducted in the tradition of the social information processing (SIP) model (Crick & Dodge, 1996). In a nutshell, the SIP model states that individuals first have to encode information about social situations accurately. Second, the encoded information has

to be represented appropriately. Third, this representation has to enact specific goals, which lead in a fourth step to the generation of action strategies. Fifth, individuals have to evaluate the different action responses and lastly, at the sixth step, enact the selected responses. Each of these six steps requires individuals to process information about social situations accurately. The model assumes that children’s information processing about social events changes based both on moment-to-moment experiences in everyday life as well as due to normative developmental changes. In this theoretical framework, numerous studies have documented links between children’s SIP skills and aggressive behavior (for a review, see Dodge, Coie, & Lynam, 2006). According to the SIP model, children with aggressive problem behavior show biases and/or deficits at all steps in the social information processing cycle and this is indeed the case (Crick & Dodge, 1996). A meta-analytic review with 41 studies and over 6,000 participants revealed a robust association between the attribution of hostile intent and aggression, although the effect sizes varied considerably across studies (de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002).

Research on the SIP model has contributed valuable information about the social-cognitive deficits associated with aggression. However, many studies have focused on hypothetical stimuli (such as video, picture or audio stimuli presented in the research laboratory) rather than real-life situations. It is less clear whether the SIP patterns of aggressive children generalize to real-life interactions, such as multifaceted situations of social exclusion and inclusion in school settings. One extension of the SIP approach involves the application of elaborate models of on-line social decision-making and antisocial behavior in youth (Fontaine & Dodge, 2006). For example, Fontaine, Yang, Dodge, Pettit, and Bates (2009) investigated the development of social response evaluation and decision-making across childhood and adolescence. They found no relations between aggressive response evaluations and aggression between 5 and 7 years of age. But between Ages 13 and 17, aggressive response evaluations, nonaggressive response evaluations, and aggressive behavior were strongly interrelated. The authors concluded that social response evaluation mechanisms become increasingly linked to aggressive behavior during adolescence.

Since 2005, developmental theorists have increasingly emphasized the *role of emotions* in the SIP approach to aggression (Lemerise & Arsenio, 2000). This emphasis reflects the renewed recognition of the role of (moral) emotions in motivating aggression (Malti & Latzko, 2012).

Lemerise and Arsenio (2000) introduced a model that added emotions to each of the steps of the SIP model. This was followed by the suggestions of a dual-processing model of information processing. Accordingly, interactions between cognitive functioning, emotional development, and social experiences may cause differences in SIP and related aggression (de Castro, 2010). The introduction of these models was accompanied by empirical research on emotional information processing in children with aggressive problem behavior. In a comprehensive review of the literature on emotions, SIP, and aggressive behavior, Lemerise and Maulden (2010) stressed that one key feature underlying SIP biases in children with aggressive behavior includes poor emotion regulation skills and/or negative emotionality (e.g., Olson, Lopez-Duran, Lunkenhimer, Chang, & Sameroff, 2011). For example, research has provided ample evidence that children with aggressive behavior report more anger than nonaggressive children and are less able to control their anger (Arsenio, 2014; see Hubbard, McAuliffe, Rubin, & Morrow, 2007). Some studies have also revealed that rejected-aggressive children generate less constructive problem-solving responses when presented with stimuli in which provocateurs were angry (Lemerise, Fredstrom, Kelley, Bowersox, & Waford, 2006). In a meta-analytic review, a negative relation between emotion knowledge and externalizing symptoms was documented, although the effect size was small (Trentacosta & Fine, 2010).

Conclusions

In summary, the literature review has revealed evidence for a negative causal link between cognitive functioning, specifically verbal skills, and both aggressive behavior and its development across childhood and adolescence. Thus, one of the most robust correlates of severe conduct problems is impaired verbal ability. Verbal deficits have been found in aggressive toddlers, conduct-disordered children, serious adolescent delinquents, and adult criminals. The evidence on the effectiveness of cognitive-behavioral and social-skills approaches for reducing antisocial and aggressive behavior supports the notion that cognitive biases are causally implied in aggressive behavior (Lösel & Beelmann, 2003). Also, studies on the links between social information processing, emotional processes, and aggression have shown that children with aggressive problem behavior do not only show biases at each of the six steps of the SIP model, but they also display difficulties in a broad range of emotion processes, such as emotion recognition

skills, or perceptions and expression of anger. This is important for the conceptualization of preventive strategies because an array of social-cognitive and emotional skills may be needed to effectively prevent and/or treat aggressive behavior problems. This idea was supported in a recent meta-analytic review of 213 school-based, universal social and emotional learning (SEL) programs involving 270,034 school-age students of all ages. The study documented the positive effects of participation in SEL programs that teach children various social and emotional skills to promote their social-emotional and behavioral development (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011). What remains less clear is the relative contribution of specific skills, such as empathy or self-regulation, and if they are being promoted in developmentally appropriate ways, for reducing aggressive behavior. Future research in this area may provide valuable information for the design and/or refinement of aggression intervention strategies and may inform current interventions about where to continue targeting their efforts (Malti & Chaparro, 2014).

Much of the large body of research in this area has remained cross-sectional. Future research on the developmental processes involved in the associations between social information processing, emotional skills, aggression and violence is therefore warranted. In addition, integrative empirical work utilizing various innovative methodologies, such as observations of emotion regulation skills and aggressive behavior in real time, and physiological responding to emotion-evoking stimuli, may further contribute to our understanding of the multifaceted social-cognitive and emotional processes involved in the developmental course of aggression from childhood to adolescence.

MORAL DEVELOPMENT AND AGGRESSION

Developmental theories on children's and adolescents' morality date back almost 100 years, with Piaget's classic book on children's moral judgment published in 1932. Piaget described cognitive moral development as a process involving the active construction of moral knowledge and increasingly autonomous reasoning about norms of fairness and justice. Although links between cognitive moral development and morally relevant behavior, such as aggression and the (dis)approval of violence, were conceptualized early in the cognitive-developmental theoretical tradition, relatively little empirical evidence was available until about 2000. Since then, there has been significant

growth in research on links between different dimensions of children's moral development (such as moral cognition, moral emotion, and moral motivation) and aggressive behavior and violence (Wikström et al., 2012; Arsenio & Lemerise, 2004). Conceptually, this is hardly surprising given that moral development concerns the same domain as aggression, inflicting or preventing harm, maintaining or breaking norms of fairness, and (not) showing care. This new research was also prompted by increasing recognition in the bullying literature that we need to understand why children and adolescents engage in bullying in everyday moral conflicts. For example, one perplexing finding was that bullies do not necessarily lack perspective-taking skills, but rather use their social knowledge strategically to reach their goals (Gasser & Keller, 2009). This has led bullying and aggression researchers to pay closer attention to aggressive children's cognitions, emotions, and motivations about moral issues, such as in situations involving justice, fairness, and care (Arsenio, 2014; Malti & Krettenauer, 2013; Malti & Ongley, 2014). By corollary, there may be important turning points in moral development, such that children acquire the capacity to anticipate guilt feelings, which may change their respective aggression pathway by highlighting the negative consequences of their behavior both for victims and themselves (i.e., feeling guilty and sad about not living up to one's own moral standards).

Next we provide a selective review of this literature, highlight central issues, and identify areas in need of future research.

Moral Reasoning

Research on moral reasoning and aggression was rooted in the notion that moral cognition can motivate morally relevant behavior, such as prosocial behavior or aggression. However, empirical research on the relations between moral reasoning and aggressive behavior has been scarce in the past decade. The existing research points to moral reasoning deficits associated with aggressive behavior. For example, Manning and Bear (2011) documented concurrent and longitudinal relations between moral reasoning and aggression in elementary school children. More recently, the literature has shifted to examining the potential role of social and individual moderators. For example, a study by Gasser and Malti (2012) pointed to the effects that best friends' moral reasoning has on the relation between the friends' aggression and children's aggressive behavior. Other studies have investigated individual

variables that may explain links between moral reasoning and antisocial behavior, such as cognitive distortions (Arsenio & Lemerise, 2004) and egocentric biases (Gibbs, 2014). These cognitive processes have been described in more detail in the related literature on social information processing (see previous section) and the literature on moral disengagement (see next section). In a nutshell, these studies emphasized that cognitive distortions lead to differences in the moral judgments of children with aggressive behavior. Lastly, later work also suggested that aggression and violence is in part due to impairments in specific brain regions (particularly the dorsal and ventral PFC) that subserve moral cognition (Raine & Yang, 2006).

A different, recent line of research has focused on the moral reasoning of children who were exposed to violence. Studying the effects of violence on children's aggression and related moral reasoning development is important as it can reveal if and how being immersed in violent social contexts may affect children's normative development. This research revealed that these children's moral reasoning development remained similar to that of children who were not exposed to violence, although there were context-specific differences. For example, Posada and Wainryb (2008) investigated 8- and 15-year-old Colombian children's judgments about stealing and physical harm in the abstract and in the context of survival and revenge. While considerations of justice led all participants to judge it wrong to steal or hurt others, their judgments in the context of revenge were more mixed, with a sizable proportion endorsing stealing and hurting in that condition. Furthermore, the majority expected that people would steal and hurt others in most situations. In a study by Ardila-Rey, Killen, and Brenick (2009), Colombian children who were exposed to violence, in contrast to those with minimum exposure, judged it more legitimate to inflict harm or deny resources when provoked, and judged it more reasonable to retaliate for reasons of retribution. These findings point to the role of political violence in moral development and the related endorsement of aggression as a justified means of retaliation. There is also evidence that adolescents who are exposed to contexts that allow for interpersonal aggression show different attitudes toward the legitimacy of aggression and violence. For example, one study has shown that adolescents who neutralized the harmful effects of aggressive behavior and who endorsed patriarchal and traditional world-views were more likely to support honor killings in Jordan (Eisner & Ghuneim, 2013). In a study comparing children with violent and nonviolent behavior, Astor (1994) showed that all children condemned unprovoked

violence for moral reasons. Yet, under provocation, children with violent behavior perceived aggression as a form of reciprocal justice. Barber (2008) also provided evidence that a minority of Palestinian and Bosnian adolescents exposed to political violence had different perspectives on their own aggressive behavior, for example, by agreeing to statement such as, "I am more violent." Specifically, data from the Adolescents and Political Violence Project (APVP) revealed that 49% and 38% of Bosnian males and females, respectively, agreed with the statement "I am more violent," as did 17% and 12% of Palestinian males and females, respectively. These findings suggest that experiences of violence, social injustice, and inequality undermine concern for others and facilitate beliefs that promote unfairness, harm and victimization (Arsenio, 2014). But this is only one part of the story. The findings also show that children and adolescents who are affected by war, violence, and aggression also display moral knowledge in spite of having been exposed to these traumatic experiences. This points to the importance of studying how children think and reason about morality in general and in specific, morally relevant situations that are related to their trauma.

Moral Disengagement

The notion of moral disengagement (MD) was developed by Albert Bandura to describe mechanisms that neutralize moral self-sanctions and allow individuals to commit harmful acts by justifying actions in ways that prevent them from feeling guilty or ashamed (Bandura, Barbaranelli, Caprara, & Pastorelli, 1996; for a review on mechanisms of MD, see Hymel, Schonert-Reichl, Bonanno, Vaillancourt, & Rocke Henderson, 2010). It was initially conceptualized to explain how otherwise normal adult people can commit atrocities, but has become increasingly relevant in research about everyday aggression and its development over the life-course. Contemporary research has found robust links between aggressive behavior and MD. For example, one of the first empirical studies was conducted among 799 adolescents aged 10–15 in Rome, Italy. The study found that higher levels of moral disengagement were associated with parent, peer, and self-assessed physical and verbal aggression. Moreover, there was suggestive evidence that the effects of moral disengagement on aggression were partly mediated through hostile ruminations irascibility (e.g., Bandura et al., 1996). One longitudinal study showed that adolescents who maintained higher levels of MD were more likely to engage in

frequent aggressive and violent acts in late adolescence (Paciello, Fida, Tramontano, Lupinetti, & Caprara, 2008). Researchers have extensively investigated the role that MD plays in both traditional and cyber-bullying. Many have shown that traditional bullies have higher levels of MD (e.g., Perren & Gutzwiller-Helfenfinger, 2012), and that a reduction in MD is associated with a reduction in antisocial behavior (Shulman, Cauffman, Piquero, & Fagan, 2011). The findings on MD and cyber-bullying are somewhat inconsistent although a positive link between MD and cyber-bullying has been documented (Thornberg & Jungert, 2013). Children and adolescents who engage in delinquent behavior exhibit high levels of MD as well (Bandura et al., 1996). The directionality of the relation between MD and aggression remains to be determined, but the most convincing model assumes a bi-directional process whereby children retrospectively justify their acts of aggression using techniques of moral neutralization, but moral disengagement also prospectively serves to facilitate future harm-doing against others (Ribeaud & Eisner, 2010). Thus far, however, researchers have not systematically studied if and when mechanisms of MD occur in childhood, although some evidence suggests that early patterns of dysfunctional family- and community contexts, and low empathy contribute to later MD and aggression (Hyde, Shaw, & Moilanen, 2010).

Moral Emotions

In the past decade, moral developmental researchers have increasingly begun to study the role of emotions in children's emerging morality and aggressive behavior. This focus was partially established in order to overcome the strong focus on moral cognition and to identify the factors that prevent children from acting in accord with moral principles of fairness, justice, and care. Emotions were a prominent candidate for further investigation as they matter to us and may therefore serve as important motives for moral action tendencies and impede amoral, aggressive acts (Malti, Gummerum, Keller, & Buchmann, 2009). In developmental research, moral emotions have been defined as self-conscious or self-evaluative emotions because they require an evaluation of one's own action in relation to others in morally relevant conflict situations (Eisenberg, 2000; Malti & Ongley, 2014). Prototypical moral emotions are guilt and shame, as well as the morally relevant process of empathy. Traditionally, research on moral emotions and aggression has had a strong focus on empathy/sympathy and aggression. Overall, there is

evidence that aggression is negatively associated with empathy, particularly the affective component of empathy or sympathy (Jolliffe & Farrington, 2006). In fact, some researchers have argued that empathic dysfunction is one of the major features of clinical symptoms of aggression, such as psychopathic tendencies (J. Blair, 2008). There is also evidence of impaired affective empathy in bullying (Caravita, Di Blasio, & Salmivalli, 2009). This deficit is related to impairments associated with amygdala dysfunction. However, the overall relation between empathy and aggression appears to be only modest in strength, and depends on the type of aggression, age period (i.e., overall, the findings appear more consistent in adolescence than in childhood), and the empathy component (with stronger effects for affective empathy than for cognitive empathy, see P. A. Miller & Eisenberg, 1988). Because of these inconsistencies, future work is needed to disentangle how the different components of empathy, such as affective arousal, emotion understanding, and emotion regulation, are associated with aggression (Decety, 2010).

Another line of work has focused on the role of feelings of guilt in aggression. Guilt feelings indicate that moral norms have been internalized and that individuals accept responsibility for their wrongdoing. For this reason, it is thought that guilt may inhibit aggression (Malti et al., 2009). Developmental research suggests that early precursors and forms of guilt feelings are negatively associated with the development of aggression (e.g., Kochanksa, Barry, Jimenez, Hollatz, & Woodard, 2009). A prominent line of work on the role of guilt in aggression has been conducted in the happy-victimizer paradigm, which has studied the emotions that children expect moral wrongdoers or the self in the role of the moral wrongdoer to feel. These emotion attributions have been interpreted as guilt feelings (Malti & Ongley, 2014). Taken together, this line of research shows that aggressive behavior is negatively related to guilt feelings, both in childhood and adolescence (for a review, see Arsenio, 2014). In a recent meta-analytic review with more than 8,000 participants, Malti and Krettenauer (2013) found that guilt feelings, as operationalized by self-attributed negative emotions following wrongdoing, were negatively associated with aggression, with a medium-size effect (Cohen's $d = .47$). Recent research has begun to assess spontaneous emotions (also known as microexpressions) in response to transgressions using emotion recognition technology (Dys & Malti, 2014). As these emotions are rapid and often unconscious emotional expressions, they can provide insights into children's automatic emotional processes and the ways in which they

influence children's aggression. As such, these kinds of analyses can provide answers to state and trait components of aggression antecedents. There is also evidence that these self-attributed happy emotions are more consistently related to proactively aggressive tendencies than to reactive forms of aggression (Arsenio et al., 2009). Related research on bullying and guilt feelings has revealed a similar lack of guilt in bullies (Thornberg & Jungert, 2013).

In conclusion, this research has shown important links between the moral emotions of guilt and empathy-related responding to aggression. Future work is needed to disentangle how different components of these complex emotions, such as arousal versus emotion understanding, are associated with overt aggression and different subtypes of aggression across development. It would also be beneficial to extend the research on children's narrative construals to assess their emotional experiences of their own interpersonal conflicts, as these may reveal the emotional subtleties involved in experiences of harm and moral transgression (Gutzwiller-Helfenfinger, Gasser, & Malti 2010).

“Moralistic” Aggression

An argument that follows from evolutionary theory is that aggression plays a critical role in maintaining cooperation among humans (Eisner, 2009). Thus, evolutionary theory and game theory alike maintain that cooperation (i.e., the expenditure of resources for someone else's benefit) among genetically unrelated individuals should be selected against, because self-interested actors benefit from not adhering to rules (“cheating”) and reaping the benefits of group efforts without contributing themselves. In game-theoretic terms, in the absence of sanctions, cheating is a dominant strategy. Trivers (1971) therefore argued that, in a cooperative species like homo sapiens, psychological mechanisms must have evolved that overcame this “free-rider” problem. The most important such mechanism is “moralistic aggression”; the process whereby members of a group inflict costs on individuals who choose non-cooperative or “cheating” strategies (Kurzban, DeScioli, & O'Brien, 2007). Such exacted costs can take different forms such as social exclusion, the infliction of physical pain, or murder. If imposed by specialized agencies they are referred to as “punishments,” if carried out by individuals they are described as revenge or reactive aggression. Experimental evidence suggests that moralistic aggression can be reliably elicited in situations predicted by evolutionary theory: Thus, large proportions of individuals are prepared to incur costs for themselves when faced

with violations of social norms, and, when presented with scenarios that indicate different levels of free-riding by other players, respondents express more anger the less the other players adhere to fairness norms (Fehr & Gächter, 2002). Brain-scans suggest that humans derive emotional satisfaction from punishing defectors, and that individuals are more likely to inflict higher punishments on defective (self-interested) players if they are observed by others (Kurzban et al., 2007, p.13). In other words, perceived disrespect, injustice and unfair treatment are important drivers of the anger that leads to aggression motivated by the moralistic aim of restoring balance (D. T. Miller, 2001). This process of intervening, with either physical or verbal aggression, in the case of deviations or violations of fairness norms begins as early as Age 3, and has been interpreted as reflecting an emerging sense of reciprocity and fairness during toddlerhood (Tomasello & Vaish, 2013).

Conclusions

Taken together, integrative research on moral development and aggression has contributed to an increasing understanding of the moral antecedents of aggressive behavior in children and adolescents. We believe that future research systematically integrating these two domains further will be informative, both for the development of theory as well as for applications. While the former has made good progress in recent years, there is still much need to translate moral developmental research into effective strategies that prevent aggression and violence in childhood and adolescence. Collectively, these studies reveal several implications for future research and developmental theory. Clearly, one area for future work is the systematic study of developmental processes involved in the associations between moral cognition, moral emotions, and beliefs about morality, on the one hand, and aggression and violence on the other. A developmental approach to the study of moral emotions, cognitions, and attitudes toward aggression will further elucidate the independent and combined effects of various dimensions of moral development on aggression and violence. This requires longitudinal designs and comprehensive assessments of morality as well as aggression.

Furthermore, future work should combine different levels of analysis, such as trait-based measures and experience sampled measures of empathy and related moral emotions, to yield better understanding of the role of moral emotions in the development of children's and adolescents' aggressive tendencies. This would involve

an analysis of verbal and expressive components of emotion, physiological arousal, brain activity, and observed components of emotions. Lastly, developmental research on real-life experiences of social inequality and injustice, such as social exclusion or exposure to war, is warranted to further elucidate the role of moral reasoning and moral emotions in the development of aggression. Multifaceted social contexts often involve conflicting moral and amoral concerns, such as group functioning or traditions, which may interfere with morality and prompt aggression to be used as a means to reach specific goals or to maintain group functioning (Malti, Killen, & Gasser, 2012). Research on morality in real-life social conflict situations will help to explain how these experiences affect children's and adolescents' morality, aggression, and violence.

FAMILY FUNCTIONING AND AGGRESSION

The links between socialization in the family and the development of aggression and violence have been extensively studied. In the next sections, we provide a selective summary of this literature, identify strengths and challenges, and provide suggestions for future research. Regarding the role of family processes in the genesis and development of aggression, various components, such as marital conflict, domestic violence, family SES, parent characteristics, and sibling relations, have been studied. Given the limited space, we focus on two of the most well-researched dimensions of family functioning: Attachment and parenting (see Bowlby, 1958; Grusec & Davidov, 2010).

Attachment to Parents and Significant Others

The bond between children and parents has long been recognized as important for children's social-emotional and behavioral development. John Bowlby's theory of parent-child attachment integrated evolutionary, biological, developmental, and cognitive concepts into a coherent model of human behavior (Bowlby, 1958). It postulated that the quality of the attachment between mothers and children during infancy has a lasting influence on socioemotional development, including both internalizing and externalizing problems. A recent meta-analysis examined the evidence for the developmental link between insecure attachment and subsequent externalizing behaviors (Fearon, Bakermans-Kranenburg, Van IJzendoorn, Lapsley, & Roisman, 2010). It found substantial support for the hypothesized link, but the average effect size was small

($d = 0.31$) over an average period of 25 months between the measurement of attachment and the assessment of children's externalizing behaviors. The authors also noted a clear lack of studies on father-child attachment. The few existing findings suggest that positive bonds between children and their fathers play important roles in the socialization of children. For example, in an analysis of the National Longitudinal Study on Youth, 1997 wave, Bronte-Tinkew, Moore, and Carrano (2006) found that positive father-child relationships were associated with less property crime, violence and substance abuse at Age 15. These effects were found after controlling for various aspects of the mother-child relationships and other well-known developmental risk factors. Evidence showing the importance of supportive bonds with adults other than the parents also comes from experimental research on the effectiveness of mentoring programs (Dubois & Karcher, 2013).

Parenting Styles and Practices

Current parenting research has been inspired by Diana Baumrind's seminal parenting typology (Baumrind, 1966) with considerable research examining different components of parenting styles (Morris, Cui, & Steinberg, 2013). In the current literature, three dimensions have been consistently identified: parental warmth versus rejection and hostility, structure or behavioral control versus chaotic and inconsistent parenting, and autonomy support versus strict coercion and emphasis on obedience (Skinner, Johnson, & Snyder, 2005). One of the most consistent findings in developmental research on externalizing behavior problems is the correlation between ineffective parenting practices and the onset and continuation of aggressive and antisocial behaviors (e.g., Beyers, Bates, Pettit, & Dodge, 2003). A growing number of studies have revealed links between parenting and aggression in children and adolescents. Several groups of parenting risk factors have been identified: They include inconsistent and harsh parental discipline, low parental involvement in children's activities, poor supervision, and lack of parental warmth or emotional support (e.g., Loeber and Hay, 1997; Olson et al., 2011). Parental warmth may be a protective factor because it promotes the development of empathy, which is known to be associated with a lower likelihood of aggression (Malti, Eisenberg, et al., 2013). A recent meta-analysis examined the strength of the association between parenting and delinquency (Hoeve et al., 2009). Examining 161 studies, the meta-analysis found the strongest associations between delinquency and poor parental monitoring,

parental rejection, hostility and neglect, as well as psychological control (i.e., intrusions in the development of the child). By and large, these findings confirmed the results of over 50 years of research on the topic; namely that poor supervision and harsh and hostile parenting are among the best-replicated and strongest correlates of aggression and violence in children and adolescents. Longitudinal studies provided even stronger evidence of parenting effects on aggression. For example, mothers' spanking at Age 3 has been found to be associated with Age 5 aggressive behavior even after controlling for initial levels of aggressive behavior and other confounding variables such as parents' characteristics, family demographics, and functioning in a population-based U.S. sample (Taylor, Manganello, Lee, & Rice, 2010). Harsh parenting can be transmitted from one generation (i.e., grandparents) to the next (i.e., parents), with the latter predicting child externalizing behavior (Bailey, Hill, Oesterle, & Hawkins, 2009), though it remains unclear if this is, in part, an effect of unmeasured genetic commonalities.

Mechanisms of Parental Influence on Aggression

Several studies have investigated the mechanisms whereby harsh parenting affects externalizing problems. Specifically, poor emotion regulation skills may explain how parenting contributes to adjustment (Morris, Silk, Steinberg, Myers, & Robinson, 2007). Indeed, harsh and intrusive parenting is associated with poor emotion regulation of the child, which is, in turn, associated with aggressive behavior from an early age onwards. For example, Age 3 self-regulation mediated the link between Age 2 low maternal warmth/sensitivity and child externalizing behavior problems at 4 to 5 years in alcoholic families (Eiden, Edwards, & Leonard, 2007). Similarly, self-control mediated the relation between harsh parenting in the preschool years and Age 11 externalizing behavior (Bradley & Corwyn, 2007). Burnette, Oshri, Lax, Richards, and Ragbeer (2012) examined mediators of the effects of harsh discipline on externalizing behavior during early to late adolescence. They found that the effects on externalizing behavior were partly mediated by their effect on emotional reactivity (i.e., being easily aroused) and disinhibition (i.e., self-control and sensation seeking), although in this study harsh parenting only had a significant effect on externalizing behavior for girls, but not for boys. Another link between harsh parenting and aggressive behavior outcomes is through social and cognitive skills. For example, in a study by Dodge, Greenberg, Mallone, and the Conduct

Problems Prevention Research Group (2009), an early social context of disadvantage in kindergarten predicted harsh-inconsistent parenting. This in turn predicted social and cognitive deficits, which predicted conduct problem behavior. High levels of conduct problem behavior in children predicted elementary school social and academic failure, which in turn predicted parental withdrawal from supervision and monitoring. Finally, low parental supervision was associated with deviant peer associations, which ultimately predicted adolescent violence.

Current Themes and Future Directions

The size and importance of causal effects of parenting on children's aggressive behavior is still a source of controversy, for at least three reasons (see Morris et al., 2013, for a review): First, the connection between parenting and child behavior is increasingly viewed as a bidirectional process where parenting is as much influenced by child behavior as the other way round (Rothbaum & Weisz, 1994). For example, Stattin and Kerr (2000) criticized popular assumptions about the association between parental monitoring and aggression. They showed that this well-known association reflected the effect of children's evasiveness rather than a genuine product of parental surveillance (Stattin & Kerr, 2000). Kerr, Stattin, and Özdemir (2012) later re-examined the relationship between parental monitoring and adolescents' maladjustment, reporting that the effects of adolescent adjustment on the changes in parenting styles were more robust than the effects of parenting styles on changes in adolescent adjustment. Similarly, a longitudinal study by Huh, Trastan, Wade, and Stice (2006) of 496 adolescent girls found more support for the hypothesis that externalizing problem behavior had a detrimental impact on subsequent parental support and control than for the reverse. Finally, Burke, Pardini, and Loeber (2008) examined the bidirectional relationship between parenting and disruptive psychopathology in a clinic-referred sample of 177 boys assessed at 10 time-points between Ages 7 and 17. They found limited evidence of parenting effects on child behavior, but substantial support for the notion that child problem behavior affects parenting. In particular, children's oppositional defiant disorder symptoms predicted timid parental discipline, lower parental involvement, and poor communication.

Increasingly, the social mold or socialization model is being criticized, with relatively consistent evidence of reciprocal processes emerging (Pettit & Arsikawa, 2008). In line with the notion of turning points and their role

on trajectories of aggression, it is also possible that the direction of effects changes with age, in that parents may have a greater influence on child behavior at earlier stages, while child behavior has more effects on parenting in later years. In addition, there might be many other confounding variables. For example, poor parenting often comes with a number of other environmental risk factors such as poor parental health, parental conflict, and economic stress. Isolating the effects of parenting from these processes has been difficult. Each parenting dimension also does not stand-alone, so future research on their joint effects is warranted. Third, there is increasing evidence that the effects of parenting on externalizing problems may be moderated by various other individual-level variables such as temperament and emotion regulation (Rubin et al., 2003) or biological reactivity to context (Erath, El-Sheikh, Hinnant, & Cummings, 2011). For example, children with dopamine D4 receptor (DRD4) 7-repeat polymorphism showed increased externalizing behaviors when they were exposed to insensitive parenting (Bakermans-Kranenburg & van IJzendoorn, 2006). Biological indicators of self-regulation, such as respiratory sinus arrhythmia (RSA), and biological sensitivity to context, such as skin conductance reactivity (SCLR), also moderate the association between harsh parenting and the development of externalizing behavior. For example, Erath et al. (2011) found that boys with lower SCLR and harsh parenting maintained high and stable externalizing behavior from Age 8 to Age 10 while externalizing behavior increased from Age 8 to Age 10 in boys with higher SCLR and harsh parenting. Finally, a considerable part of the shared variance in poor parenting and poor child outcomes is likely due to shared genetic factors (Moffitt, 2005). Notably, aggressive children may be at risk of having abusive or neglectful parents, not because poor parenting is the cause of aggression, but because harsh and unresponsive parenting and aggressive child behavior have the same genetic roots.

Conclusions

In summary, the relationship between family functioning and children's and adolescents' aggression is one of the best-researched areas of developmental psychology. Yet, research since 2000 suggests that some accepted answers are now being challenged. In future, bidirectional and nonlinear models need to be investigated to understand both parent and child effects better. Potential confounding variables also need to be controlled for, and biological and genetic characteristics of both children and parents need

to be considered in research on the roles of parent-child relationships and parenting styles on the development of aggression and violence.

PEER RELATIONS

Peer relationships become increasingly important during middle childhood, and developmental research has long suggested a link between peer relations and the development of aggressive behavior in childhood and adolescence. For example, aggressive behavior leads to peer rejection, which in turn predicts subsequent aggression (Lansford, Malone, Dodge, Pettit, & Bates, 2010). Below we provide a selective review of central findings in this area of research, outline strengths and gaps in the current research on peer relations and aggressive behavior, and highlight areas for future research. We differentiate between broader social network variables, on the one hand, and friendship relationships, on the other hand, to characterize children's relationships with peers.

Social Networks and Aggression

There are various relations between social networks and the development of aggression. In this literature, children's and adolescents' social networks are often assessed using measures of social preference (i.e., being accepted/rejected by peers), popularity (i.e., perceived centrality in the peer group), social impact (visibility in the peer group), and social centrality (social status within the network). Social network variables have frequently been measured using peer nomination techniques. For example, social preference is often calculated by counting the number of peer-like nominations, and subtracting the number of peer-dislike nominations. While some studies have also utilized peer nominations of aggression and bullying, many studies also include self- and other reports of aggressive problem behavior (see Rubin et al., 2009).

One main area of research has focused on relations between social preference and aggressive behavior in children and adolescents. Overall, social preference is related rather consistently and negatively to various forms of aggression across childhood and adolescence, both cross-sectionally and longitudinally (Lansford et al., 2010; van Lier & Koot, 2010). The moderators and mediators of this relation are less well-understood. However, peer rejection may relate differentially to aggression depending on the form of aggression. In a meta-analytic review,

Hubbard et al. (2010) showed that reactive aggression, but not proactive aggression, was positively associated with peer rejection.

Another line of work has investigated links between aggressive behavior and different components of peer networks such as popularity, likeability, and peer reputation. The literature shows, in part, differential relations to aggression. For example, a study by Prinstein and Cillessen (2003) has shown that high peer-perceived popularity and low social preference was associated with increases in overt and relationally aggressive behavior in adolescence over a 17-month interval. Because there is consensus in the literature that various social network variables are associated with the emergence, maintenance, and decrease in levels of aggression from early childhood to adolescence, the field has moved toward examining the causal mechanisms and investigating moderators and mediators of this relation, as well as effects on subsequent mental health outcomes.

Friendship and Aggression

Aggression and children's friendship relations have frequently been related conceptually. One of the reasons is that friendships are considered to be among the most central contexts for children's behavioral adjustment and assumed to yield emotional and social benefits for children (Berndt, 2002; Rubin, Malti, & McDonald, 2012). As such, they may help children and adolescents with aggression to overcome these behavior problems. In support of this notion, some researchers have shown that children with aggressive behavioral problems who experience warm and supportive friendships may become less aggressive over time as a result of their positive experiences with friends (Poulin, Dishion, & Haas, 1999). However, friendships that are characterized by negative interactions may not yield socioemotional benefits for children, but may instead promote maladjustment. Furthermore, some researchers have found that children with aggressive behavior problems may have trouble forming and maintaining constructive friendships (Cillessen, Jiang, West, & Laszkowski, 2005). For example, Bagwell and Coie (2004) examined 48 dyads of 11-year-old boys. While they found no differences in self-reported friendship quality between aggressive and nonaggressive youth, they observed more positive engagement and reciprocity in nonaggressive boys and their friends compared with aggressive boys and their friends. Still others have documented that associations between aggression and friendship quality are moderated

by other behavioral and emotional characteristics, such as prosocial behavior (McDonald, Wang, Menzer, Rubin, & Booth-LaForce, 2011). Children with aggressive behavior also have biased cognitions about friendship relations and display low levels of guilt (Malti & Keller, 2009).

Another line of work has investigated selection and influence effects of affiliating with deviant peers on aggressive behavior (for a review, see Dishion & Pihler, 2009). Selection effects are effects whereby previously aggressive children prefer peer relationships with those who are similar in their behavior tendencies. Influence effects relate to the notion that aggressive peers influence the behavior of children who were previously less aggressive. There is substantial support for selection effects (i.e., "birds of a feather flock together"). For example, children choose friends similar to themselves in aggression, controlling for between-friends influence (Berger & Rodkin, 2012). There is also much evidence for influence effects in the literature. Accordingly, although many children may be aggressive before affiliating with deviant peers, peer groups can influence and exacerbate these tendencies (for a review, see Salmivalli, 2010). For example, a study by Weerman (2011) found support for the notion that joining or leaving a street-oriented youth group has substantial effects on delinquency. Haynie (2001) examined the effects of peer networks on delinquency and documented that not all adolescents are influenced to the same degree by their peer networks. Rather, when more of the youths are delinquent or the network is very cohesive, peer delinquency plays a more significant role in the target individual's delinquency.

The development of statistical models to estimate stochastic actor-based models of network dynamics has had a major impact on research exploring the link between peer networks and the development of aggressive behavior (e.g., Veenstra, Dijkstra, Steglich, & van Zalk, 2013). Specifically, longitudinal network analysis involves repeatedly measuring a person's network (e.g., Snijders & Baerveldt, 2003), allowing researchers to disentangle selection and influence effects. A study by Sijtsema et al. (2010) suggested that instrumental, reactive and relational aggression were more likely to be adopted from friends in a sample of 12- to 14-year-olds, but also that adolescents tended to select their friends on the basis of similarity, and that friends reinforced each other's aggressive behavior. A study by Dijkstra et al. (2010) also used network analysis to examine the dynamics of weapon carrying among adolescents in three American high schools that primarily served low-income minority students. Dijkstra found strong influence effects, suggesting that adolescents who

befriended peers who carry weapons subsequently carried weapons, too. Additionally, carrying weapons was associated with aggressiveness rather than vulnerability. The authors argued that this reflected status dynamics whereby low-status peers tried to imitate the behavior of high-status peers (Dijkstra et al., 2010, p. 207). In a similar vein, it has been suggested that friends who are similarly aggressive may reinforce each other's aggressive behaviors (Dishion & Pihler, 2009). Furthermore, if children have friendships with peers who are aggressive, their own aggressive behaviors may remain stable or increase over time (e.g., Adams, Bukowski, & Bagwell, 2005). However, peer influences may also be positive. For example, aggressive children who are friends with nonaggressive peers become less aggressive over time (Warman & Cohen, 2000).

Bullying and Social Dominance

Bullying among adolescents is found in all human societies. Its conceptual association with social dominance within the peer group has led several scholars to examine hypotheses derived from evolutionary theory (Hawley, 2003; Prinstein & Cillessen, 2003). For example, among primary-school children, aggression was associated with high dominance status in peer groups, especially for a "Machiavellian" subgroup of children who strategically mixed coercive/aggressive with more prosocial strategies (Roseth et al., 2007). Pellegrini and Long (2002) examined the functions of boys' social dominance during the transition from primary school to middle school. They argued that boys use a mix of strategies to achieve social dominance, including agonistic (e.g., bullying) and more affiliative (e.g., having a network of peers) strategies. They interpreted the transition from primary to middle school as a change in children's ecology that disrupted established dominance structures, and therefore increased the probability that agonistic strategies would be adopted until new hierarchies were established. In line with their expectations, they found that dominance in the new school environment was initially associated with aggressive behaviors. Five months later, in contrast, teacher-assessed dominance in the class was associated with more affiliative skills.

Along similar lines, Vaillancourt (2005) has proposed an evolutionary theoretical framework to understand indirect aggression among females, which has been observed in many cultures. She suggested that indirect female aggression is an evolved pattern that represents a strategy for securing access to mates and reducing the value of

competitors. According to this perspective, indirect aggression should peak at the age of maximum reproductive value (i.e., Ages 11 to 15), early-maturing girls should be more likely to engage in indirect aggression, and a large proportion of female indirect aggression should entail accusing other females of being unattractive sexual partners.

Bystanders and Aggression

A recent research perspective that emphasizes the episodic character of aggressive acts has focused on the role of bystanders in bullying incidents (Salmivalli, 2010). Starting from the observation that peer witnesses are present in most bullying incidents, Salmivalli's research team examined their reactions and the ways in which these reactions contribute to or resolve the problem. Using peer-nomination data, the researchers identified four roles: assistants of bullies, reinforcers of bullies, outsiders, and defenders of the victim. They hypothesized that the behavior of these bystander groups significantly affects the behavior of the bullies: If others join in the bullying or give even subtle positive feedback they should reinforce the aggression, whereas challenging bullies by taking sides with the victim was expected to help end bullying episodes. A series of empirical studies supported the expectation that the behavior of bystanders acted as a moderator: Depending on their action the likelihood of bullying was either reinforced or reduced (Salmivalli, 2010). Additionally, interventions in support of victims positively influenced the victims' well being.

Salmivalli and colleagues' findings (e.g., Kärnä et al., 2011) regarding the situational dynamics of bullying and the role that bystanders play have led to the development of a Finnish bullying prevention program, KiVa. In addition to the indicated interventions for bullies and victims, the program specifically focuses on changing school-wide norms and changing the behavior of pupil bystanders within a framework of support by schools. The effectiveness of the program has been evaluated in a randomized controlled field trial in which pupils in years 4–6 (10–12 years) in 78 schools were randomly assigned to intervention and control conditions. Findings suggested that the intervention had consistent beneficial effects on seven out of 11 outcomes 9 months after the intervention. This included self-reported and peer-reported victimization and self-reported bullying.

Mechanisms of Peers' Influence on Aggression

To go beyond mere correlational findings, research has investigated potential mechanisms that underlie the

associations between peer relations (i.e., social networks and friendship relations) and aggression. Mechanisms at the social level (e.g., norms of aggression in the peer group) and at the individual level (e.g., holding specific values or affiliating with friends with specific characteristics) are distinguished. At the social level, one mechanism is the acceptability of aggression as a group norm that can make aggression more legitimate and thus make those using it socially accepted and popular (see the previous section on moral disengagement and aggression). In accord with this notion, individuals behaved more aggressively when the group norms favored aggression, especially at 6 rather than 9 years of age (Nesdale, Durkin, Maass, Kiesner, & Griffiths, 2008). At the individual level, research has shown that a wide range of psychological factors moderate and mediate associations between peer networks and aggression. For example, it has been suggested that aggression can promote popularity, particularly when it is accompanied by peer respect (Kuryluk, Cohen, & Audley-Piotrowski, 2011). It has also been shown that high-status peers are particularly likely to influence social aggression in the peer group (Shi & Xie, 2012).

Conclusions

In summary, important research on the role of peer relations in aggression has been undertaken. Affiliation with deviant peers and friends clearly exacerbates aggressive behavior although research on the moderators and mediators of these associations is still relatively sparse. Future research thus needs to determine if and how variation in the features of children's peer and friendship relationships relate to their aggressive behavior trajectories. In other words, who are the friends and peers of children and adolescents with aggressive behavior, what are their developmental and social backgrounds, and how do these features help shape the development of aggression in children and youths. Furthermore, although there is now considerable research on the mechanisms that underlie the various associations between peer relations and aggression, models that test dynamic relations between these variables over time are still sparse. Therefore, longitudinal network analysis is needed to shed further light on the causal mechanisms that underlie stability and change in children's peer relations and aggression. Lastly, researchers have stressed the role of culture in children's peer and friendship relationships (Chen, Chung, & Hsiao, 2009), and there is some limited research on peer relations and aggression outside of North America and Europe (e.g., for a study on popularity and

aggression in India, see Bowker, Ostrov, & Raja, 2012). For example, one study found that Chinese peer groups were homogeneous on aggression (Chen, Chang, & He, 2003). Chen et al. (2009) concluded that children appear to form peer groups on the basis of similar behavioral characteristics that are culturally embedded. However, few cross-cultural research studies on peer relations and aggressive behavior have been published, and more research on the way in which cultural norms, values, and expectations influence children's peer relations and aggression is needed.

MACRO-LEVEL DYNAMICS AND INDIVIDUAL DEVELOPMENT

Most developmental aggression research emphasizes proximal data tracking the unfolding of individual characteristics and life-circumstances. It emphasizes the influence of factors like deficits in executive functioning, parental maltreatment, or associations with delinquent peers. Macro-level comparative research on violence, in contrast, usually relies on aggregated data to examine cross-national, regional, or neighborhood level differences in violence. In its explanatory framework, macro-level research tends to examine factors such as social inequality, the quality of governance, social disorganization, or alcohol and firearm availability (e.g., Nivette, 2011). Bringing these two perspectives together has been a continuing challenge. Although most developmental models of aggressive behavior incorporate cascade models of how contextual (neighborhood, city, country) influences shape individual development, the nature of the causal chains linking macro and micro-level variation has remained elusive.

Cross-National Differences

Social contexts differ widely with respect to levels of violence (United Nations Office on Drugs and Crime [UNODC], 2011). Homicide rates, for example, vary between countries by a ratio of about 1:100, and worldwide differences between cities vary by factors of a thousand (e.g., in the early 1990s between about 350 per 100,000 in Medellin, Colombia, and about 0.4 per 100,000 in Tokyo, Japan). The 2011 UNODC *Global Study on Homicide* showed that the burden of youth violence was very unequally distributed across regions and countries: Latin America had the highest average rates of homicides committed by young people at Ages 15–24 with a rate of 36.6 per 100,000 inhabitants. In Europe, the average youth

TABLE 19.2 Homicide rates by youth and adults across WHO regions

	Youth (15–24)	Adults	Total
Africa	16.1	8.5	10.1
North America	12.0	4.6	5.6
Latin America	36.6	16.1	19.9
Asia	2.4	2.1	2.1
Caribbean	31.6	13.2	16.3
Europe	1.2	1.3	1.2
Oceania	1.6	1.2	1.3

Source: From *Global Study on Homicide: Trends, Context, Data*, by United Nations Office on Drugs and Crime, 2011, New York, NY: Author.

homicide rate was about 30 times lower, at 1.2 per 100,000 (Table 19.2).

Large-level differences between societies raise a number of questions for developmental research, many of which cannot currently be answered convincingly. We highlight three issues: First, from a developmental perspective, one would want to know the age at which these differences emerge. Do countries with high rates of homicide or robbery also have higher rates of ODD and CD in middle and late childhood? Recent work suggests that this may not be the case. For example, Murray, Anselmi, Gallo, Fleitlich-Bilyk, and Bordin (2013) conducted a systematic review of studies on the prevalence of conduct disorders in Brazil, a country with one of the world's highest homicide rates (about 30 per 100,000) and a large proportion of children living in poverty, being exposed to multiple environmental risk factors. They identified four studies of 7- to 14-year-olds that used the Development and Well-Being Assessment (DAWBA) as a diagnostic instrument. The studies showed average rates of 1.4% (CD) and 2.4% (ODD) in Brazil, rates that were remarkably similar to those found in high-income countries like Britain (1.5% and 2.3%) and Norway (0.5% and 2.3%), where the homicide rates were 30 times lower than in Brazil. Similarly, Canino, Polanczyk, Bauermeister, Rohde, and Frick (2010) conducted a worldwide review of studies on the prevalence of CD and ODD among children 18 years or younger. Their analysis included 25 studies from some of the least and most murderous social contexts in the world (e.g., Puerto Rico and Norway). There was no cross-cultural variation in the prevalence estimates of ODD and CD once methodological variations were taken into account. If corroborated by further evidence, this lack of meaningful cross-cultural differences in the prevalence of conduct disorders would suggest that macro-level variation in criminal violence is due to adolescent-specific risk factors rather than early developmental problems. For example, youth

violence may be a more adaptive behavior in contexts characterized by illegal drug markets, gangs, poor state functioning, or ethnic cleavages. Developmentally, this would imply that the near universal individual differences in aggressive potential in childhood are amplified during adolescence as a function of opportunity structures specific to adolescence.

Second, little is known about which of the many proximal risk factors are responsible for societal differences in violence. Emerging cross-cultural comparative work shows that the major developmental individual, family, and peer risk factors are broadly similar across cultures (e.g., Chen & Astor, 2010), although the effect sizes are unlikely to be invariant cross-culturally. Cross-national differences in youth violence may therefore emerge from several different processes: The exposure to one or several risk factors may vary between societies; the presence and combination of protective factors may differ between nation states; the effect size of any one risk or protective factors may itself be variable, possibly as a result of its cultural meaning or as a consequence of interactions with other risk factors. For example, high impulsivity is universally associated with youth aggressive behavior (Vazsonyi & Belliston, 2007), but it is currently very difficult to say whether the vast differences in lethal youth violence between, for example, Honduras and Chile can in any way be attributed to differences in self-control or some other developmental factor. Moreover, different processes are involved in different places. For example, early malnutrition increased the likelihood of externalizing behavior up to Age 17 in Mauritius, while exposure to war, especially when combined with poor parenting, predicted aggressive behavior in Palestine.

Third, we know little about how macro-level characteristics that account for variation in violence rates are linked to more proximal developmental dynamics. For example, Nivette and Eisner (2012) found that beliefs in the legitimacy of the state (i.e., that the state is fair and that its rules should be obeyed) is a highly significant predictor of cross-national variation in homicide rates. But how do findings that weak, failing, and illegitimate states have increased amounts of violence relate to questions about individual development? Empirical research on the causal cascades that may explain such links is only emerging. Thus, increasing evidence suggests that manifestations of organized violence such as vigilante groups, youth gangs, or drug cartels emerge when states fail to provide protection, the police are seen to be unfair, and criminal justice agencies are seen as inefficient or corrupt. In Ghana, for

example, Tankebe (2009) showed that citizens were more willing to engage in vigilante self-justice if they perceived the police as unfair and untrustworthy. Similarly, youth in Jamaica were more willing to cooperate with the police when they felt the police were fair and legitimate (Reisig & Lloyd, 2009). Such findings suggest that the functioning of state institutions has repercussions for the legal socialization of children and adolescents (Fagan & Tyler, 2005). In particular, the likelihood of violent self-help seems to depend, among other factors, on the extent to which a central authority is believed to provide protection, enforcing legitimate rules that reflect shared moral values fairly.

Emerging experimental research suggests that the legitimacy of social institutions is a direct causal force, and that preventive interventions can successfully promote cooperation by improving legitimacy. A meta-analysis by Mazerolle, Bennett, Davis, Sargeant, and Manning (2013) for the Campbell Collaboration examined 28 studies with experimental or quasi-experimental designs that had examined the effects of interventions aimed at improving police legitimacy and procedural justice. There was a highly significant average effect of this type of intervention on citizens' compliance with the law ($OR = 1.62$).

Trends in Violence

There is also significant gap between developmental research and macro-level scholarship in relation to trends in violence rates over time. Over the past 50 years, many macro-level indicators of violence show two main periods of change in many Western societies (United Nations Office on Drugs and Crime, 2011): The first involved a steep increase in serious interpersonal violence concentrated in the period between the early 1960s and the early 1980s and the second a sustained decrease in homicide and other manifestations of violence since the early 1990s (Zimring, 2006). In the United States, the homicide rate has declined by 60% from a peak of about 10 per 100,000 in 1991 to about 4 per 100,000 in 2012. Evidence for the decline can be found in all major indicators of violence including robbery, rape, assault, and child abuse (Blumstein & Wallman, 2006). Moreover, the decline extended to other indicators of teenage problem behaviors including teenage pregnancies, substance abuse, and binge drinking (Finkelhor & Jones, 2006).

An extensive literature has proposed various explanations for the later decline. They include economic prosperity, demographic changes, the end of the crack-cocaine epidemic, the legalization of abortion, increases in the

number of police officers, higher imprisonment rates, more effective pharmacological treatment, fewer environmental neurotoxins, and broad socio-cultural change (for discussions see, Finkelhor & Jones, 2006; Blumstein & Wallman, 2006).

Many of these explanations remain contested, in part due to the lack of convincing evidence linking macro-level variation to changes in individual-level behavior. A study by Collishaw, Gardner, Maughan, Scott, and Pickles (2012) illustrated the dilemma: This study used two national samples of British adolescents in 1986 and 2006 to examine whether trends in youth antisocial behavior could be explained by changes in parent-child relationships. The authors found that, in both waves, poor parental monitoring, low youth disclosure to the parents, low parental interest, and low quality time with parents were significantly associated with more conduct problems. This is in line with the wider literature on parenting and antisocial behavior. However, there was no evidence that the increased incidence of conduct problems was associated with a secular decline in parenting quality over time. In fact, initial descriptive trend analyses showed significant increases in parental monitoring and normative parental expectations. Furthermore, analyses suggested that the increase in conduct problems might even have been bigger if parenting had remained unchanged over the period. The authors argued that, while some parenting interventions have been shown to be effective in altering youth problem behavior trajectories, there was no evidence that population-level changes in parenting were associated with any major change in the incidence of conduct problems.

Period or Cohort Effects?

An important step toward understanding the American decline in interpersonal violence would involve clarifying whether it was due to a cohort effect or a period effect. A cohort effect would imply that younger cohorts had a consistently lower propensity for antisocial behavior. This would suggest that factors early in their lives influenced their long-term trajectories. A period effect would mean that, in the mid-1990s, the likelihood of committing crimes declined simultaneously in different cohorts. Fabio et al. (2006) addressed this question by comparing the youngest and the oldest birth cohorts of the Pittsburgh Youth Study. A comparison of these two cohorts is particularly salient because the older cohort was aged 15 in 1989, a period of steep increases in homicide rates nationally, while the younger cohort was aged 15 in 1995, when national

homicide rates had started a steep decline. The two cohorts differed significantly in their violent offending, with the younger generation having lower levels of violence than the older generation. However, the lower rate of the younger cohort could not be explained by differences in the exposure to individual and neighborhood-level risk factors, including gang membership and hard drug use. The authors also found little evidence of a cohort effect, as there was no consistent tendency for the younger cohort to have lower violence rates than the older cohort at the same age. Rather, the lower violence rates of the younger cohort were entirely due to period effects—social forces that influence different age groups at the same time. The authors were not able to identify the relevant period factors, but mention factors such as the waning of the crack-cocaine epidemic as potential explanatory candidates (Fabio et al. 2006, p. 158). These findings suggested that social factors can operate simultaneously on the behavior of young people of different ages. What these factors are and how they interact with developmental processes is currently poorly understood. It could be, for example, that shifts in moral beliefs and cultural values affected the behavior of different age groups in similar ways. Alternatively, changes in economic incentive structures such as illicit drug markets may have had ripple effects over an age range far broader than that of the young people directly involved in drug dealing (for a discussion of approaches see, e.g., Blumstein & Wallman, 2006).

Conclusions

There are huge differences between regions, states, cities, and neighborhoods in the extent to which young people are involved in violence. There is also compelling evidence that societal levels of interpersonal violence are subject to change, with the crime drop in the United States over the past two decades providing a particularly impressive example. But despite the tradition of ecological theories in developmental psychology, only limited progress has been made in our understanding of exactly how macro-dynamics are linked to individual development. The recent growth in mainly cross-sectional studies on child aggression and youth violence in various non-Western contexts has added significantly to our understanding of the extent to which the relevant causal mechanisms are universal. Also, important lessons on developmental cascades that link social context to individual development have been learned from longitudinal research examining neighborhood effects on the development of conduct problems (e.g., Leventhal &

Brooks-Gunn, 2000), although many causal mechanisms remain unclear (Galster, 2012). Clarification of the link between individual development and macro-level variation in violence may require cross-culturally comparative longitudinal studies. Ideally, such studies would comprise several sites that reflect theoretically meaningful variation, for example, in levels of violence or specific combinations of risk and protective factors. While expensive, such studies would yield unique data clarifying the link between macro-level characteristics and micro-level developmental dynamics.

CHALLENGES AND FUTURE DIRECTIONS

Research on the developmental dynamics of aggression and related manifestations of antisocial behavior is one of the oldest areas of developmental psychology. Over the past decade considerable progress has been made in several substantive areas: Overall, there has been a continued increase in genetic, neuropsychological and neurocognitive studies that have contributed to a better understanding of the biological mechanisms associated with aggressive behavior; the introduction of trajectory analysis has made a significant contribution to understanding normative trends in types of aggressive behavior over the life course, with an emerging consensus about the distinction of at least four main developmental patterns; the wider availability of high-quality longitudinal studies has helped to move beyond lists of risk and protective factors, and toward more sophisticated models of causal mechanisms that include reciprocal effects and cascades across different layers of a child's ecological environment; a still small but quickly growing body of research is based on data outside highly developed Western countries, leading to a growth in knowledge about the cross-cultural replicability of empirical findings; and the growth of research on effective prevention and intervention strategies has contributed to a better understanding of how aggression and violence can be reduced in various settings. Also, several new lines of empirical and theoretical inquiry have been opened. This includes, for example, work on the link between the development of moral and prosocial capacities and aggression (Malti & Krettenauer, 2013; Tomasello & Vaish, 2013), research on the interaction of genetic and environmental variables in the causation of antisocial behavior (Byrd & Manuck, *in press*), and studies on differential risk factors for subtypes of aggressive behavior (Cima et al., 2013).

While we have tried to review some of these new developments in developmental aggression research, we acknowledge major gaps in our discussion. To name just a few: We hardly covered the substantial volume of work on media consumption and aggression, we only briefly touched on the emerging field of developmental victimology and the links between victimization and aggression, and we were unable to discuss the body of work on neighborhood effects on the development of aggressive behavior and violence.

This chapter concludes by highlighting some of the areas where future research is needed.

- *Methodological challenges.* The valid and reliable measurement of aggression from infancy to adulthood remains a challenge: Multi-informant studies continue to show low to medium informant agreement, the causes of which have remained unclear (de los Reyes, 2011); associations between risk factors and aggression are often measurement-dependent, leading to a lack of confidence in the robustness of findings and difficulties for replication across studies; and attempts to identify different etiologies for various subtypes of aggression are hampered by the limited sensitivity of existing instruments (Little et al., 2003). Together these issues suggest a need for better measures of aggression that are sensitive to theoretically relevant subtypes of behavior (Vitaro et al., 2006). Recent innovations that can contribute to new insight include repeated administration of space-time budgets (Wikström, 2012), computerized experience-sampling tools in natural settings, and mixed-method strategies that combine multiple informants with behavioral observations in natural settings (Pellegrini & Long, 2002).
- *Time lag between cause and effects.* In developmental research the frame rate (i.e. the number of measurements taken per time period) determines the resolution at which causal mechanisms can be reliably discovered. For most studies on aggression this frame-rate is currently set at one picture per year, the most common cadence of data collections in longitudinal studies. If causal mechanisms exist with a cause-effect delay of minutes, hours, days, weeks or months, then conventional longitudinal designs don't have the capacity to discover them. Future research should pay more attention to designs that allow for causal dynamics at different time spans between cause and effect. Studies with multiple measurements during the year are still

rare, but can illuminate important medium-term processes (Roseth et al., 2007). Such studies with a high frame rates would be particularly important around life events (e.g., school entry, moving home) that are hypothesized to act as potential ‘turning points’ of problem behavior. Similarly important are fine-grained analyses of children’s real-time natural movements through action contexts in which aggression is an option, especially if embedded into longitudinal analyses (Wikström et al., 2012). Integrating the “long view” of slow developmental change of latent trait-like characteristics with the “short view” on recurrent patterns of interactions and conflicts and the real-time decision making dynamics remains an important challenge for future research (Anderson & Bushman, 2002; Granic & Patterson, 2006).

- *Genetic and biological research.* The neuroscience revolution has made it clear that explaining the development of aggression requires an understanding of the brain, the information-processing organ structured phylogenetically by human evolution and shaped ontogenetically by genetic and environmental influences (Raine, 2013). There are robust findings for a genetic component in between-individual differences in aggression and a link with psychophysiological and cognitive-emotional characteristics. But many findings on effects of specific gene polymorphisms, gene-environment interactions, and functional deficits have remained partly contradictory. For a developmental perspective on aggression and violence, we believe that much future research will need to be genetically and biologically informed. For example, more robust evidence is needed on the ways in which environmental experiences over the life course (e.g., malnutrition, victimization, poor attachment) have effects on brain functioning, which in turn influences aggressive behavior (Portnoy et al., 2013). Epigenetic research on the effects of the environment (e.g., child abuse) on the expression of specific genes will likely play an important role here (Tremblay, 2010). Also, emerging knowledge about how different components of brain functioning (e.g., “hot” versus “cold” executive functioning, moral emotions) normatively develop at different speeds will likely enrich our understanding of the age-specific manifestations of aggressive behavior (Prencipe et al., 2011).
- *Universal mechanisms involved in the causation of aggression.* Emerging evidence suggests that many mechanisms associated with the formation of aggressive

behaviors may be cross-culturally universal rather than culturally specific (Murray et al., 2013). But there are still large gaps in current knowledge, and we note an almost complete lack of longitudinal data in most societies outside the West. More robust evidence from diverse cultures is needed on, for example, the situational triggers for anger, the information processing mechanisms associated with aggressive problem solving, the peer and family risk factors associated with antisocial propensities, the individual cognitive and biological characteristics associated with violence, and the normative age-specific manifestations of aggression. Also, the focus on what causes aggression and violence has partly led to a neglect of the question of what causes desistance from aggression and violence. Better knowledge about why desistance from aggression is the normative pattern during much of childhood (Brame et al., 2001), how this process interacts with developing social, cognitive, and emotional competencies, and why a small group of children follows a persistent high trajectory (Frick & White, 2008) will be highly useful for developing better prevention strategies.

- *Morality and aggression.* Until rather recently, psychologists and criminologists have either shied away from including morality into models of antisocial behavior, or have simply equated aggression with evil, making a normative judgment that adds little to the scientific understanding of the causes of aggression. For about 10 years morality has become increasingly established on the landscape of aggression research. One reason is the growing volume of work that shows the importance of evolving notions of fairness, justice, and compassion in the development of children (Eisenberg, 2000; Malti & Ongley, 2014). This trend is echoed in the more sociologically informed work that emphasizes the importance of a legitimate—that is, fair, effective, and protecting—social order as a motivational basis for cooperation rather than fighting (Reisig & Lloyd, 2009). Both suggest developmental links between aspects of morality and aggression (Malti & Krettenauer, 2013). Future research in this area needs to better identify the developmental periods in which moral beliefs and emotions related to different types of aggressive behavior emerge. It also requires that investigators examine reciprocal dynamics between components of morality such as moral disengagement and aggression, as effects between both domains are likely bi-directional. Furthermore, it is important that comparative research

- better understands the link between structural, cultural and political characteristics of a social context and the normative development of moral beliefs about aggression and aggressive fantasies (Guerra, Huesmann, & Spindler, 2003).
- **Developmental research and experiments.** We note a continuing cleavage between developmental aggression research that mainly uses observational data and prevention and intervention research that relies on randomized controlled experiments. This gap is detrimental because experiments are the best instrument to test causal hypotheses about aggression and because good observational research is the best basis for making interventions more effective (Eisner & Malti, 2012). An exception is the work by Salmivalli and others (e.g., Salmivalli, 2010) on the dynamics of bullying within peer networks at schools. It demonstrates how innovative basic research on the influence of bystanders and other actors on bullying can help to develop research-based prevention programs, the evaluations of which in turn can act as a testing ground for the tenability of the original theory. Further progress along these lines requires more high-quality prevention and intervention research that is explicitly designed to test hypotheses about specific causal mechanisms and that is integrated into longitudinal studies so that, for example, hypotheses derived from developmental taxonomies can be tested empirically (Moffitt, 2005). Research has clearly shown that research-based family and school-based interventions can help reduce aggression in children and adolescents (Webster-Stratton, & Taylor, 2001). But we believe that more can be done to translate current state-of-the-art knowledge systematically into the design of interventions that aim to reduce aggression and violence.
 - **The micro–macro divide.** Lastly, we have emphasized that developmental research tends to focus on individual or proximal contextual factors that affect aggression and violence. Yet, macro-level comparative research suggests that cross-national or broad contextual differences help explain variations in aggression and violence. Interdisciplinary research is needed in order to determine which developmental mechanisms cause macro-level variations in levels of aggression and violence. For example, research should determine at what age reliable cross-national differences in serious violence emerge, as such knowledge can inform targets for prevention policy (Krug et al., 2002). Also, more work is needed about how illegal opportunities provided by protection

entrepreneurs, drug markets, distrust in state institutions and a sense of injustice interact during adolescence with early developmental risk factors such as poor cognitive functioning or parental abuse and neglect (Guerra, 2012; Tankebe, 2009). In particular, more progress should be made to understand the mechanisms of legal socialization from childhood to adulthood including attitudes toward legal authorities and perceptions about the legitimacy of the law (Fagan & Tyler, 2005).

THEORETICAL OVERVIEW

The study of gendered development is the study of how gendered behavioral and psychological characteristics arise and remain stable or change over time. This topic is important in part because society views gender as an important category. For instance, we are often asked to indicate our gender, suggesting that gender conveys important information. In everyday life, people also typically like to know if they are dealing with men or women, and most of us are happy to provide this information, for example by wearing our hair and dressing in ways to indicate our gender. In addition, many psychiatric disorders are more common in one sex than the other, and understanding gendered development could aid in designing interventions to prevent or treat them. Many people also think that psychological or behavioral differences between males and females make

men or women particularly suitable for different jobs or social roles, or explain economic disparities between men and women. But how accurate are these beliefs? And, in those areas where men and women differ, how does this come to be the case, and how does it remain stable or change over time?

In this chapter, I attempt to answer these questions. I begin by framing the question of gendered development, and by defining some terms, such as sex and gender. Following this introductory material, the empirical evidence regarding the nature and sizes of behavioral and psychological differences between men and women, and boys and girls, is summarized. These are the gendered outcomes whose development we wish to understand. I then critically evaluate the evidence regarding the factors involved in the development of these gendered behaviors and psychological characteristics, focusing initially on influences as they unfold chronologically, beginning at conception. Where the available information allows, this discussion includes information on how different types of influences interact with one another, how they vary with

The author's research described in this chapter was funded by the United States Public Health Services, National Institutes of Health, HD24542, and by the Wellcome Trust.

context, and how they change or remain stable over time. In those instances where cross-cultural evidence is available, that too is described. It is worth noting at the start, however, that most of the available research is from North America and Western Europe, and its broader cross-cultural validity is often unknown. Following the review of behavioral research, research on gender differences in brain structure and function is evaluated. The chapter ends by outlining specific areas that are likely to be particularly productive for future research.

Current thinking on psychological development in general, and on the development of gendered characteristics in particular, is that developmental systems approaches will ultimately provide the most complete understanding of the factors producing stability and change over time, and the thinking behind this chapter is rooted in this perspective. In practice, however, there are few studies that have used developmental systems approaches to study gendered development. Where such studies exist, they are described in some detail. (For more information on developmental systems approaches, see Lickliter and Honeycutt, Chapter 5, and Witherington, Chapter 3, both in this *Handbook*, Volume 1.)

The gendering process involves many different types of influences, beginning at the moment of conception and continuing across the lifespan. These influences include genetic information on the sex chromosomes; fetal and neonatal concentrations of testosterone and perhaps other hormones; socialization by parents, peers, teachers and others; and self-socialization based on cognitive developmental processes associated with gender. Although discussions of gendered behavior often ask whether nature or nurture has the more important influence, this view of a primary force—either nature or nurture—driving gendered development is mistaken. As the developmental systems perspective suggests, not only are many different types of influences involved, but these influences interact with one another over time to produce stability and change in gendered characteristics. Gendered behavior can differ for a single individual in different contexts, and the factors that contribute to gendered development and their interactions can differ from one individual to another and from one time to another. The current state of knowledge is such that the elements of the developmental systems governing gender development are still being identified, but enough is known to be confident that these elements include some that would typically be classified as nature, such as genes, some that would typically be classified as nurture, such as socialization by parents, and some that do not fit clearly

into either of these two categories, such as the prenatal and neonatal hormone environment. Thus, not only is it unhelpful to try to choose between nature and nurture in understanding gender development, it is not even possible to clearly separate nature and nurture in this context.

Given the complexity of gendered development, it would not be possible for a single chapter in this *Handbook* to cover the topic in sufficient detail. In light of this, the *Handbook* includes two chapters that focus on gendered development. One of these includes in-depth information about social and cognitive factors involved in gendered development (see Leaper, Chapter 19, this *Handbook*, Volume 2), whereas the current chapter includes in-depth information about hormonal factors involved in gendered development. The current chapter also includes some discussion of social and cognitive factors, and how they work together with other types of factors, such as the early hormone environment, but interested readers are referred to the chapter by Leaper for a more detailed treatment of the social and cognitive processes involved in gendered development.

WHICH BEHAVIORS ARE GENDERED AND HOW LARGE ARE THE DIFFERENCES BETWEEN THE SEXES?

In this chapter, the term *gendered* is used to describe psychological characteristics or behaviors that differ on the average for groups of men and women or groups of girls and boys. Historically, sex and gender have been distinguished, with sex referring to a person's biological sex, as defined by characteristics such as whether the gonads are ovaries or testes or whether the 23rd pair of chromosomes is two Xs or an X and a Y, and gender referring to other differences. In keeping with this tradition, I use the terms *gender* and *gendered* to describe psychological and behavioral differences between males and females. I do not, however, use the term *gender* to imply that any particular type of factor, such as social or cultural influences, explains the difference between the sexes. In discussing gender differences, it is also important to remember that they are average differences between groups of males and females, and that there is typically a great deal of individual variability within each sex, as well as overlap between the sexes. In this respect, psychological and behavioral gender differences are similar to the gender difference in height. On the average, men are taller than women, but some women are taller than some men. In fact, the overlap

for the sexes is generally larger for gendered behavior than it is for height. So, although some sex differences in gendered behavior are larger than the sex difference in height, most are smaller. The next section of this chapter describes the nature and magnitude of sex differences in gendered behavior, in order of magnitude, beginning with those that show the largest differences.

The sizes of differences between the sexes can be quantified using “ d ” (d = the mean for one sex minus the mean for the other sex, this value divided by the pooled standard deviation). In terms of d , the size of the gender difference in height is about 2.0 for men and women in the United States (US) and in Great Britain (International Committee on Radiological Protection, 1975; Tanner, Whitehouse, & Takaishi, 1966). In the behavioral sciences, group differences with d values of 0.8 or larger are considered large, those of 0.5 are considered medium, those of 0.2, small, and those of 0.1 or less, negligible (Cohen, 1988). Put into a familiar context—group differences in IQ scores—a large difference ($d = .8$) corresponds to a group difference in IQ of about 12 points, a medium difference ($d = .5$) to an IQ difference of about 8 points and a small difference ($d = .2$) to an IQ difference of about 3 points.

Meta-analytic reviews have attempted to determine the size of behavioral and psychological differences between males and females, and have concluded that most differences fall in the small to negligible range (Hyde, 2005). In addition, the size of gender differences can depend on the context. For instance, a meta-analysis of helping behavior found that, when people knew that they were being watched, men were more helpful than women, and the effect size was substantial ($d = .74$). In contrast, when people clearly were not being watched, the gender difference was of negligible size ($d = .02$) (Eagly & Crowley, 1986). For some other characteristics, group differences vary with age. Vocabulary is a good example of this pattern. Girls acquire language earlier than boys, and from about 18 to 60 months of age, girls have larger vocabularies than boys do (Bornstein, Hahn, & Haynes, 2004). Earlier and later in life, however, there are negligible gender differences in vocabulary.

Gender Identity

Despite the overall pattern of similarity, there are some areas where large and consistent differences in the behavior or psychology of males and females are seen. The largest psychological difference between men and women, as well as between girls and boys, is in gender identity, or the

sense of self as male or female. Most men and boys have a male gender identity and most women and girls do not. The d value for this difference appears to be greater than 10.0 (Hines, Ahmed, & Hughes, 2003; Hines, Brook, & Conway, 2004).

Sexual Orientation

The second largest difference between the sexes is in sexual orientation. Most men have their primary erotic interest in women, whereas most women do not. The d value for this difference is about 6.0 (Hines, Ahmed, et al., 2003; Hines et al., 2004; Meyer-Bahlburg, Dolezal, Baker, & New, 2008).

Childhood Play

Another area of substantial difference between males and females is in childhood play. Most notably, girls and boys tend to prefer different toys. Boys prefer vehicles and weapons, whereas girls prefer dolls and tea sets (Maccoby & Jacklin, 1974; Pasterski et al., 2005; Sutton-Smith, Rosenberg, & Morgan, 1963). These differences emerge early in life, beginning to be apparent by the age of 12 months (Jadva, Golombok, & Hines, 2010; Snow, Jacklin, & Maccoby, 1983), and perhaps as early as 3 to 8 months (Alexander, Wilcox, & Woods, 2009), and they grow larger as children grow into toddlerhood and middle childhood (Golombok & Hines, 2002). In children aged 4 to 10 years, the gender differences for toys like vehicles and weapons (preferred by boys) and dolls and tea sets (preferred by girls) can be very large ($d = 2.0$) (Pasterski et al., 2005).

Children also sex-segregate in their play, and this difference grows larger as childhood progresses too. At age 4.5 years, children spend about 3 times as much time with same-sexed than other-sexed playmates, and at age 6.5 years, this difference has increased to about 10 times as much (Maccoby & Jacklin, 1987). The tendency of children to play with others of the same sex is seen in a range of cultures (Whiting & Edwards, 1975). Boys also are more physically active, and tend to engage in more rough-and-tumble play (playful aggression involving overall body contact) than girls; these gender differences are of moderate size ($d = 0.5$) (DiPietro, 1981; Eaton & Enns, 1986; Hines & Kaufman, 1994; Maccoby, 1988). Composite measures of toy, playmate and activity preferences can show very large gender differences ($d > 2.5$) (Hines, 2010).

Personality

For other psychological and behavioral characteristics, including personality characteristics, meta-analytic findings suggest that gender differences are smaller than those seen in height. For instance, males and females differ in the likelihood that they will show physically aggressive behavior, and this difference is manifested dramatically in the numbers of convictions for violent crime—over 90% of those incarcerated for violent crimes are men. Meta-analytic results (Hyde, 1984), however, suggest that, within the general population, the gender difference in tendencies to engage in physical aggression is of moderate size ($d = .5$). These meta-analyses also suggest that the gender difference in aggression is larger when assessed by direct behavioral observation, by peer report, or by projective tests, than when assessed by self-report or by parent or teacher report. The gender difference is also larger in children ($d = .58$) than in college students ($d = .27$).

Some questionnaire measures of other personality characteristics also show substantial differences between males and females. A meta-analysis of a broad range of personality inventories (Feingold, 1994) found that the largest gender differences were seen for traits labeled as Dominance—higher in males—and Empathy—higher in females. The Dominance construct includes measures of dominance, assertiveness and ascendancy and shows a gender difference of moderate size ($d = .50$). The Empathy construct includes measures of empathy, nurturance, and tender-mindedness, and shows a large gender difference ($d = .97$). The same meta-analysis also showed small gender differences in anxiety ($d = .28$) and trust ($d = .25$), with both higher in females. Other constructs, including impulsiveness, activity, openness to ideas, gregariousness, and order, showed negligible gender differences favoring males ($d = .03$ to $.15$).

Another conceptualization of personality includes 30 traits that contribute to five broad personality factors: Neuroticism (N), Extraversion (E), Openness to Experience (O), Agreeableness (A) and Conscientiousness (C). A meta-analysis using this approach examined gender differences in the United States and in 25 other cultural settings (Costa, Terracciano, & McCrae, 2001). This study found smaller gender differences in Dominance ($d = .19$ in the United States; $d = .27$ in other cultures) and Empathy ($d = .43$ in the United States; $d = .22$ in other cultures) than the Feingold meta-analysis, which was based on a broader range of personality assessment tools. The Feingold meta-analysis also included Cattell's 16 Personality

Factors Inventory, which shows large gender differences in Dominance and Empathy. Gender differences on other personality facets were small to negligible in Costa et al.'s cross-cultural study. This study also found that gender differences in personality were larger in North America and Western Europe than in Africa and Asia. The authors interpreted this result in the context of individuality versus communalism, suggesting that people in individualistic cultures attribute their behavior to personal characteristics, like personality traits, whereas people in communal cultures are more likely to make attributions to their social roles.

Interest in infants and in parenting is another area where males and females differ, but life stage is also important (Feldman & Nash, 1978, 1979; Nash & Feldman, 1981). Women who have infants respond more to infants in general than do other women, including mothers of older children, pregnant women, married women without children and single women. Similarly, grandmothers of infants respond more to infants than do women who have children who are adolescent or older, but who do not yet have grandchildren. Among men, those who are expecting a child or a grandchild are more interested in pictures of babies than men who are not expecting. Demand characteristics also influence expressions of interest in infants. For instance, males and females show similar psychophysiological responses, such as blood pressure and heart rate changes, to babies crying or smiling, but females show more behavioral responses than males do, a result interpreted to reflect female responses to the social expectation that they are interested in babies (Frodi & Lamb, 1978; Frodi, Lamb, Leavitt, & Donovan, 1978). Similarly, males and females show smaller differences in their self-report of interest in infants when they are in mixed sex groups or in private than when they are in single sex groups (P. W. Berman, 1976). Gender differences in interest in infants are also more obvious when the infants are relatives than when they are not, and when people are instructed to care for the infants (P. A. Berman, 1980).

Cognition

Based on meta-analytic findings, the largest cognitive gender difference documented to date appears to be that in mental rotation performance; males outperform females on speeded measures of the ability to mentally rotate visual stimuli (Linn & Petersen, 1985; Voyer, Voyer, & Bryden, 1995). This difference appears to be larger for rotation of three-dimensional (3D) than two-dimensional (2D)

objects, perhaps because tasks using 2D objects are easier. The difference is also larger in adults than in children, perhaps in part because different tasks are used at different ages. For example, children are almost always assessed using 2D tasks. For mental rotation of 3D depictions of objects in adults, the gender difference is large when strict scoring criteria are used ($d = .92$), though still less than half the size of the gender difference in height.

Meta-analytic results also suggest that another aspect of spatial ability, spatial perception, shows a difference favoring males. Spatial perception tasks require individuals to accurately position a stimulus (e.g., a line) within a distracting array (e.g., a tilted frame). The gender difference on measures of spatial perception, like that on mental rotations, appears to be larger in adults ($d = .56$) than in children ($d = 0.38$) (Voyer et al., 1995), although the use of different tasks at different ages may again be an issue. Also, one particular spatial perception task, adapted from the Benton Judgment of Line Orientation to increase its difficulty, may show a gender difference in college students that is similar in size to that seen for 3D mental rotations (Collaer, Reimers, & Manning, 2007).

For a third type of spatial ability, spatial visualization, meta-analytic results suggest only small to negligible differences between males and females ($d < .20$) (Linn & Petersen, 1985; Voyer et al., 1995). These types of tasks involve complex, sequential manipulations of spatial information and typically can be solved in more than one way. Individual measures require identification of simple figures within complex designs (e.g., Embedded Figures, Hidden Patterns), construction of specified shapes from three dimensional blocks (e.g., Block Design), and imagining what unfolded shapes would look like when folded to form three-dimensional objects (e.g., Paper Folding, Surface Development).

As for spatial ability, the mathematical performance of males and females has been compared using meta-analysis, with results suggesting that the several subcategories of ability differ with respect to the nature and magnitude of gender differences (Hyde, 2005; Hyde, Fennema, & Lamon, 1990). Measures of mathematical problem solving show small gender differences favoring males, at least among older, highly selected samples, such as college students ($d = .32$). Tests used to select students for admission to university in the United States also favor males. The Math subtest of the Scholastic Aptitude Tests (SAT Math) shows a small gender difference ($d = .38$), and the Math subtest of the Graduate Record Exam (GRE Math) shows a larger gender difference ($d = .77$). Individuals

taking these tests are self-selected, however, and more males than females drop out of education. Thus, these effect sizes may be inflated, because a smaller proportion of low achieving males than females are likely to take the tests. In childhood, girls show a small advantage on tests of computational skills ($d = .21$), although this advantage appears to be gone by adulthood ($d = .00$), perhaps again partly because the lowest scoring boys are more likely to drop out of education and testing. There also appears to be no appreciable gender difference in the understanding of mathematical concepts across the age range, although females score negligibly better than males ($d = .06$). In regard to scores on mathematics achievement tests, there is a negligible male advantage ($d = .06$) in Grades 4 and 8 (about Age 10 and 14 years) in the United States, though not necessarily in other nations (Lee, Grigg, & Dion, 2007) and NAEDP data explorer). Some of the implications of these cross-cultural differences will be discussed later in this chapter, where evidence regarding the causes of gendered behavior is evaluated.

Meta-analytic results (Hyde & Linn, 1988) suggest that verbal ability shows a negligible female advantage ($d = .11$) in both children and adults, but that some specific verbal tasks show larger gender differences. There is a small female advantage for speech production ($d = .33$) and a smaller male advantage for analogies ($d = .16$). There also is a moderate female advantage on measures of verbal fluency, such as the ability to list words that begin with a specific letter ($d = .53$) (Kolb & Whishaw, 1985; Spreen & Strauss, 1991). Girls appear to have greater writing proficiency than boys from about ages 10 to 18, and these gender differences are of moderate size ($d = .53$ to $.63$) (Salahu-Din, Persky, & Miller, 2007) and NAEDP data explorer). Vocabulary shows a negligible female advantage in adults ($d = .02$), although, as mentioned before, girls develop language earlier than boys, and know more words up until about Age 5.

Girls also excel on measures of perceptual speed. According to meta-analytic findings this difference, as assessed with the Differential Aptitudes Test (DAT), is of moderate size ($d = .48$) (Feingold, 1988). Similar measures from the Educational Testing Service show female advantages of similar size ($d = .49$) (Ekstrom, French, & Harman, 1976). The magnitude of the sex difference in perceptual speed, at least as assessed using the DAT, appears to have declined over the years, however, from $.62$ in 1947 to $.34$ in 1980 (Feingold, 1988).

Some other cognitive gender differences also appear to have declined from the 1940s to the 1980s (Feingold,

1988). The changes were linear rather than stepwise, so appear not to reflect changes in the tests (Feingold, 1988). One exception to this trend in Feingold's study was the SAT Math, which continued to favor males, especially at the upper end of the distribution. Other research suggests that even this gender difference is reducing, however. In 1982, the ratio of boys to girls scoring over 700 on the SAT Math at the age of 13 years was 13:1, whereas more recently it has been about 3:1 (Halpern et al., 2007). As noted above, the size of the observed gender difference on this type of test also is influenced to an unknown extent by more low scoring boys than girls leaving education, and so not taking the test.

The male advantage on 3D mental rotation tasks appears not to have changed from the 1970s to the 1990s (Sanders, Soares, & D'Aquila, 1982; Voyer et al., 1995). A gender difference in mental rotation performance also has been seen in infants as young as 3 to 5 months of age (Moore & Johnson, 2008; Quinn & Liben, 2008). In these studies, more male infants than female infants showed looking preferences suggesting the ability to distinguish rotated, identical objects from objects that are rotated and different.

Psychiatric Diagnoses

Another important area of gender difference involves the likelihood of being diagnosed with specific psychiatric disorders (American Psychiatric Association [APA], 2000; Rutter, Caspi, & Moffitt, 2003). Females are more likely to be diagnosed with depression than males are, at least from adolescence onwards. Males and females appear to be similarly likely to be diagnosed with schizophrenia, considered across the lifespan, but the age of diagnosis tends to differ. Males are diagnosed at a younger age on average than females are. Some psychological disorders appear to show dramatically skewed sex ratios. Classic autism is diagnosed 4 times more often in boys than in girls, and Asperger syndrome is diagnosed 9 times more often in boys than in girls (Rutter et al., 2003; Wing, 1981). Tourette syndrome, attention-deficit/hyperactivity disorder, and conduct disorder are also more likely to be diagnosed in males than in females (Alexander & Peterson, 2004; APA, 2000; Froehlich et al., 2007; Moffitt, Caspi, Rutter, & Silva, 2001). In contrast, females are more likely than males to be diagnosed with eating disorders, in addition, as mentioned above, to being more likely to be diagnosed with depression beginning in adolescence (APA, 2000). It has been suggested that, in general, males are more likely than females to be diagnosed with early-onset

disorders involving neurodevelopmental impairment, such as autism, whereas females are more likely to be diagnosed with emotional disorders that begin at or after adolescence, such as depression (Rutter et al., 2003). Understanding the developmental systems involved in gendered behavior more generally could inform understanding of these disorders that vary by sex.

INFLUENCES ON GENDERED DEVELOPMENT

Gendering begins before birth. Socially, expectant parents typically prepare somewhat differently for babies depending on whether they anticipate girls or boys. Different, largely nonoverlapping, pools of possible names are viewed as appropriate for each sex, and different clothes, toys and bedroom furnishings are selected based on the sex of the anticipated children. Physiologically, gendering begins early too, at conception, with fertilization of the ova by sperm carrying X or Y chromosomes. These chromosomes then influence gonadal development and gonadal hormone production, and even before birth, these hormones appear to influence neurobehavioral processes related to gendered behavior. Gendering continues postnatally, when social factors are even more prominent than they were before birth. External agents, including parents, peers, teachers, and strangers, encourage gender-typical behavior, and sometimes discourage gender-atypical behavior, particularly in boys. Children also self-socialize into gendered behavior. Once they understand that they are girls or boys, they learn what behaviors are expected of those of each sex and come to value complying with these expectations. Across the lifespan, our genes, our hormones, our social interactions, our context and our values continue to influence our gendered behavior.

This chapter discusses the evidence of these influences chronologically, beginning at conception. Gendered behavior in childhood has been studied most extensively in regard to the full range of factors that are thought to be important for gendered development, and children's play behavior will be discussed first in the context of describing each of these factors. Discussions of other gendered behaviors will follow, again in order of the magnitude of the gender differences. The aim is to elucidate the processes involved, not only in the development of psychological and behavioral differences between the sexes, but also those involved in individual differences in gendered behavior within each sex—in other words, why some of us are more gender-typical than others. In reviewing this information,

it is often necessary to discuss different types of influences in isolation, because this is the nature of the available research evidence. It should be kept in mind, however, that these influences are likely to interact in complex ways, that the nature of these interactions may differ at different life stages, and that these interactions remain largely unstudied.

Children's Gendered Behavior

As noted earlier, children's gendered behavior has been studied extensively and so is discussed first in regard to the various factors that are thought to play a role in human gendered development including genes on the sex chromosomes, gonadal steroids, particularly during prenatal and neonatal development, socialization by parents, peers and others, and self-socialization based on cognitive understanding of gender. In addition, the theoretical background that has led to interest in each type of factor in relation to gender development is introduced in the context of describing research on children's gendered behavior. This background is relevant to subsequent sections discussing the same factors in relation to other gendered outcomes, but is not repeated there.

Genetics and Gender

A person's sex is typically determined by the 23rd pair of chromosomes, sometimes called the sex chromosomes. This pair is generally either two X chromosomes, leading to the development of a female phenotype, including ovaries, or one X and one Y chromosome, leading to the development of a male phenotype, including testes. These chromosomes, and the physical phenotypes they produce, are important in part because they influence how the social environment responds to the individual. They are also important for other reasons, some of which occur before birth. Prominent among these are the different fetal hormone environments produced by testes as opposed to ovaries, and the influences of these hormone environments on gendered behavior are described more fully below.

There is as yet no evidence for direct genetic effects on gendered human behavior. In rodents, however, there are some gender differences in the brain very early in life, prior to gonadal differentiation, and so before the developing fetus can be identified as male or female other than by the sex chromosomes, suggesting a direct genetic effect on the brain and potentially on behavior (Arnold, 2009; Gatewood et al., 2005). There also appear to be direct effects of the sex chromosome genes on some aspects of aggressive behavior that are seen more often in male

than in female animals, and on some parenting behaviors that are seen more often in female than in male rodents (Gatewood et al., 2005). The study suggesting these effects used transgenic mice, with the phenotype of one sex but the genotype of the other, to separate direct genetic effects from hormonal effects and other gendered aspects of the phenotype. The results suggested direct involvement of information on the Y chromosome in the development of physically aggressive behavior and parenting behavior in mice. No comparable information is available for humans, however, and so possible direct effects of sex chromosome genes on human gendered development are not discussed further in this chapter.

Gonadal Hormones and Gender

Another, less direct, way in which the sex chromosomes influence gender development is by determining gonadal development. The primordial gonads have the potential to develop into ovaries or testes. The sex-determining gene on the Y chromosome (SRY), however, generally causes these bi-potential gonads to become testes, whereas in the absence of SRY, they typically become ovaries. By Week 8 of human gestation, the testes have begun to produce testosterone and other androgens, so that concentrations of these hormones appear to be higher in male fetuses than in female fetuses throughout gestation, but most markedly from about Week 8 to Week 24 (Smail, Reyes, Winter, & Faiman, 1981). These androgens act through receptors on cells in the tissues that become the external genitalia causing them to develop as penis and scrotum, whereas, in the absence of these hormones, the same tissues develop as clitoris and labia. The ovaries do not appear to produce large amounts of estradiol or other hormones prenatally, and the development of phenotypically female external genitalia—clitoris and labia—does not appear to require ovarian hormones before birth (Wilson, George, & Griffin, 1981).

Some neural cells also can respond to androgens, such as testosterone, or to hormones produced from testosterone. In addition, literally thousands of studies of nonhuman mammals, ranging from rodents to nonhuman primates, show that these hormones influence neural development during sensitive periods of prenatal and neonatal life (Arnold, 2009). For example, injecting testosterone into newborn female rats produces animals that later show increased potential for male-typical behavior and decreased potential for female-typical behavior. Similarly, removing testosterone from male rats shortly after birth produces animals that later show reduced potential for male-typical

behavior and increased potential for female-typical behavior. The behaviors that are influenced include reproductive behaviors, such as mounting of estrus females, as well as nonreproductive behaviors that differ on the average for male and female animals, such as rough-and-tumble play, which is more common in male than in female animals.

The same early hormonal manipulations also influence brain development, including brain anatomy. Several areas of the brain that have receptors for gonadal steroids show volumetric sex differences. The best known of these is perhaps the sexually dimorphic nucleus of the preoptic area (SDN-POA), a region of the hypothalamus that is larger in male than in female rats (Gorski, Harlan, Jacobson, Shryne, & Southam, 1980). Treating female rats with testosterone early in life enlarges the SDN-POA, whereas removing testosterone from male rats early in life reduces it (Jacobson, Csernus, Shryne, & Gorski, 1981). These effects occur in part because hormones produced from testosterone rescue cells in the SDN-POA from programmed cell death (Davis, Popper, & Gorski, 1996). A different neural region, the antero-ventral periventricular nucleus (AVPV), is larger in female than in male rats, and testosterone treatment during early development reduces the size of the AVPV, apparently by causing cell death (Forger, 2006). Thus, treatment with androgenic hormones early in life acts in several different ways to shape sex-related neural and behavioral development. Removal of the ovaries during early development appears to have little or no influence on gender related neurobehavioral development (Goy & McEwen, 1980), in contrast to removal of the testes.

An important and surprising detail regarding the influences of gonadal steroids on neural sexual differentiation is that male-typical development is accomplished, at least in rodents, largely by estrogen, produced from testosterone. Testosterone from the male gonads, the testes, enters the brain, where it is converted to estradiol by the enzyme, aromatase. Estradiol then acts through estrogen receptors to initiate cellular processes that produce male-typical neural and behavioral development (Hines, 2004; McCarthy, 2008). As a consequence, treatment of developing female animals with estrogenic hormones, including the synthetic estrogen, diethylstilbestrol (DES), has similar effects to early treatment with testosterone (Hines, 2004). It increases later potential for male-typical behavior and reduces later potential for female-typical behavior.

Although our understanding of gonadal hormone influences on mammalian neurobehavioral development has come largely from studies of rodents, the outcomes have been similar when nonhuman primates have been

studied. For instance, treating developing female rhesus macaques with testosterone increases their later potential for male-typical behavior, including juvenile rough-and-tumble play behavior, as well as male-typical sexual behavior, and reduces their later potential for female-typical sexual behavior (Goy & McEwen, 1980). Despite this general consistency of effects, there are areas of species difference, however, and similar effects on human behavior cannot be assumed. Instead, the possibility of similar effects must be evaluated directly in humans. The thousands of studies of nonhuman mammals have revealed some general principles that can guide these evaluations, including:

- The early programming influences of testosterone occur during sensitive periods of prenatal or neonatal life, meaning that the hormone does not have the same effect if exposure occurs before or after this period.
- The timing of these sensitive periods varies somewhat from one species to another, but generally corresponds to times when testosterone is higher in developing male than in developing female animals.
- Within these overall critical periods, there are subperiods when specific behavioral outcomes are influenced. For instance, in rhesus macaques, testosterone influences sex-typed grooming behavior early in gestation, but rough-and-tumble play later in gestation (Goy, Bercovitch, & McBrair, 1988). Because of these separable critical periods, a brief hormonal alteration could have effects limited to systems that were developing at the time of the alteration.
- Hormonal influences are graded and linear, so when more hormone is administered, there is a more dramatic effect.
- Hormones influence not only behavioral differences between the sexes, but also differences within each sex. For instance, some female rodents show more male-typical behavior than others do, and the animals who show more male-typical behavior tend to be those whose location in utero was such that they would have been exposed to hormones from their male littermates (Clark & Galef, Jr., 1998; Meisel & Ward, 1981).
- The behaviors that are influenced by the early hormonal environment are those that differ on the average for males and females of the species.

As noted above, there is a prenatal sex difference in testosterone in humans, most markedly from about Week 8 to Week 24 of gestation, although testosterone seems to

be less dramatically higher in male than in female fetuses later in gestation, as well (Constantinescu & Hines, 2012). In addition, there is a second period, neonatally, when testosterone appears to be higher in boys than in girls. This gender difference in testosterone is largest at about the first to the second month postnatally, with testosterone levels tapering off to baseline in both sexes by about 6 months of age (Lamminmaki et al., 2012; Smail et al., 1981). These two periods, gestation and the early neonatal period, are the most likely early sensitive periods for gonadal hormones to influence human gender development.

It is not easy to study the influences of early testosterone exposure on human behavior. Rigorous experiments similar to those conducted in other species, where animals are randomly assigned to have either a hormonal manipulation or a placebo procedure, are generally not possible because of ethical considerations. Some information has come, however, from clinical situations in which the early hormonal environment is atypical, either because of a genetic condition, or because a woman was prescribed hormones for medical reasons during pregnancy. In addition, information has come from studies where testosterone has been measured in typically developing individuals and related to later behavior.

Several genetic conditions cause abnormalities of testosterone beginning early in life. The most thoroughly studied of these conditions, in regard to gendered behavior, is classic congenital adrenal hyperplasia (CAH). CAH refers to a group of autosomal recessive disorders that involve an enzymatic deficiency, usually of 21-hydroxylase (21-OH). The enzymatic deficiency results in an inability to produce cortisol and a consequent overproduction of adrenal androgens. In classic CAH, these hormonal abnormalities begin very early in gestation.

Classic CAH with 21-OH deficiency is estimated to occur in 1 in 5,000 to 1 in 20,000 births in the United States and Europe (New, 1998; Speiser et al., 2010). Female fetuses with CAH show markedly elevated levels of androgens (Pang et al., 1980; Wudy, Dörr, Solleder, Djalali, & Homoki, 1999), and they are usually born with some degree of virilization of the external genitalia (e.g., clitoral hypertrophy, partial fusion of the labia), caused by the androgen elevation prenatally. The virilization is sometimes so severe that a girl with CAH is initially assigned as a boy, but in most cases the genitalia are ambiguous. This ambiguous genital appearance at birth typically leads to rapid diagnosis and female sex assignment. Male fetuses with CAH appear to have testosterone concentrations in the normal male range, but elevated levels of a weaker

androgen, androstenedione, at least at mid-gestation (Pang et al., 1980; Wudy et al., 1999). Assumedly, adrenal androgens are initially elevated in male fetuses with CAH, but feedback mechanisms reduce testicular androgen production, resulting in the largely normal levels at mid-gestation in males. Boys with CAH are born with unremarkable male external genitalia, and in areas without universal screening they generally are not diagnosed until they experience medical problems, such as salt-losing crises, or precocious puberty. Once diagnosed, both girls and boys with CAH are treated with glucocorticoids to regulate their hormone levels. Girls with the disorder also usually have surgery to feminize their external genitalia.

There are two forms of classic CAH, a salt-wasting form and a simple-virilizing form. The salt-wasting form is more severe and is associated with greater androgen production. The salt-wasting form is also associated with aldosterone deficiency and, if untreated or poorly treated, can cause salt-losing crises that can result in severe dehydration, and even death. There is also a third, nonclassic, form of the disorder, late onset CAH. Late onset CAH, unlike the classic forms of CAH, is thought to involve minimal prenatal androgen elevation and becomes evident only later in life.

Androgen insensitivity syndrome (AIS) is a second disorder that involves atypical androgen exposure during early development. Individuals with AIS have deficient androgen receptor responses (Grumbach, Hughes, & Conte, 2003), either complete (CAIS) or partial (PAIS). Both forms are transmitted as X-linked, recessive traits and so are seen almost always in XY individuals. An XY infant with CAIS typically has normal appearing female external genitalia, and is typically assigned and reared as female with no awareness of the underlying disorder. Breast development occurs at puberty, because the individual has undescended testes, and the testosterone that the testes produce is converted to estradiol, with feminizing physical effects at puberty. CAIS is often diagnosed when menstruation fails to occur, because of the lack of ovaries and other female internal reproductive structures. The physical phenotype in PAIS is highly variable. It can be similar to that in CAIS, can involve external genital ambiguity, or can involve even more subtle manifestations, such as hypospadias or infertility. CAIS is far rarer than CAH, but exact figures are unknown. The incidence of PAIS is also unknown, and in its milder forms, it may go undetected.

A third category of disorders causing early hormonal abnormality are androgen biosynthetic deficiencies in XY individuals. Deficiencies in either 5-alpha-reductase

(5-aRD) or in 17-hydroxysteroid dehydrogenase (17-HSD) in XY individuals typically produce female appearing external genitalia at birth. The disorder is often not detected until puberty, when masculine secondary sexual characteristics (e.g., phallic enlargement, broad shoulders, facial hair, low voice) emerge, caused by rising levels of androgens. These disorders, like CAIS, are extremely rare, but are seen with increased frequency in some cultural groups where consanguinity is not unusual. For instance, groups of individuals with 5-aRD have been identified in a village in the Dominican Republic (Imperato-McGinley, Peterson, Gautier, & Sturla, 1979) and in Papua New Guinea (Herdt & Davidson, 1988; Imperato-McGinley et al., 1991). Similarly a group of individuals with 17-HSD has been identified in Gaza (Rosler & Kohn, 1983).

There are also conditions that involve early hormonal abnormality, without ambiguous genitalia. One of these is idiopathic hypogonadotropic hypogonadism (IHH) in XY individuals. In this syndrome, hypothalamic hormones that induce testicular hormone production are deficient. At birth, the genitalia appear to be those of a healthy male infant, presumably because maternal hypothalamic hormones have stimulated testicular hormone production in the fetus. Individuals with IHH, therefore, are thought to experience androgen deficiency beginning at birth. A second condition involving early hormone abnormality, but unremarkable appearance of the external genitalia at birth, is Turner Syndrome. Individuals with Turner Syndrome have one intact X chromosome, but the second is absent or imperfect. This syndrome causes ovarian regression, usually prenatally, and so many girls with Turner Syndrome experience reduced concentrations of ovarian hormones beginning prenatally. Because ovarian hormones are not needed for prenatal differentiation of the external genitalia, however, girls with Turner Syndrome are born with normal-appearing female external genitalia.

A final set of very rare abnormalities involves XY infants who were assigned as female because of abnormalities of their external genitalia, despite apparently normal prenatal androgen production. Some such conditions are penile agenesis (aphallia), cloacal exstrophy, and ablation of the penis. In the first condition, the child is born with testes, but no phallus. In the second condition, the child has exposed abdominal organs (e.g., bladder, intestines) and the penis is typically small and split into two parts, one on either side of the body. Historically, most XY infants with either of these conditions have been surgically feminized and reared as girls. The third condition has occurred when typically developing male infants have lost their penis, for instance

in a surgical accident, and then been reassigned and reared as girls.

Information about hormonal influences on human gender development has also come from people whose mothers took hormones for medical reasons during pregnancy. The hormones that have been prescribed during pregnancy include some synthetic progestins that mimic the actions of androgens (androgenic progestins), some that interfere with the action of androgens (anti-androgenic progestins), and some that are estrogens or that mimic the actions of estrogen. Notable in this last category is DES, a synthetic estrogen that was prescribed to millions of pregnant women in the 1950s and 1960s (Heinonen, 1973; Noller & Fish, 1974).

Researchers have also related normal variability in the early hormonal environment to later gendered behavior. These studies have measured testosterone in maternal blood collected during pregnancy, in amniotic fluid collected during pregnancy, in umbilical cord blood at birth, or in urine samples collected from infants during the neonatal androgen surge in the first several months after birth.

Other approaches have not measured hormones directly, but instead have looked at characteristics assumed to correlate with early exposure to androgenic hormones. The most common of these approaches involves assessing the ratio of the second digit of the hand to the fourth digit (2D:4D), a ratio that is larger in females than in males (Manning, 2002). Consistent with an androgenic influence, two studies have found that this ratio is smaller in individuals with CAH than in typically developing controls (Brown, Hines, Fane, & Breedlove, 2002; Okten, Kalyonku, & Yaris, 2002), although a third did not find this result (Buck, Williams, Hughes, & Acerini, 2003). The ratio is also reportedly larger in XY individuals with CAIS than in other XY individuals (Berenbaum, Bryk, Nowak, Quigley, & Moffat, 2009), again suggesting a role for androgen. These studies all involved dramatic variability in the early hormonal environment due to disorder. In contrast, the 2D:4D ratio is typically used to measure small amounts of variability in androgen exposure among typically developing individuals. The evidence that it does so is not convincing. One study (Manning, Bundred, Newton, & Flanagan, 2003) reported that the 2D:4D ratio in 50 healthy men related as predicted to a repeat polymorphism in the gene that encodes the androgen receptor, a polymorphism that relates inversely to the ability of the androgen receptor to act. Others have failed to replicate this association, however, including a study of 152 men (Hampson & Sanker, 2012), and a study of 188 men (Hurd, Vaillancourt,

& Dinsdale, 2011). Another study sometimes interpreted to support a link between normal variability in androgen and the 2D:4D ratio correlated testosterone measured in amniotic fluid with finger ratios in a sample of 29 girls and boys (Lutchmaya, Baron-Cohen, Raggatt, Knickmeyer, & Manning, 2004). This correlation was not significant, but the authors found a significant correlation between the 2D:4D ratio and the ratio of testosterone to estradiol. Several considerations suggest that this finding is spurious, including the small sample size, the analysis of males and females together, instead of separately, the failure of the original predicted relationship to be significant, and the lack of an empirical basis for predicting the relationship that was significant.

The 2D:4D approach to measuring early androgen exposure is highly accessible and appears simple. Consequently, hundreds of published studies have looked at relationships between 2D:4D and gendered behavior (Voracek, 2011). The results of these studies have been inconsistent, however (Hines, 2011). For instance, many studies have related 2D:4D to sexual orientation. One of these studies involved more than 20,000 participants who measured their own 2D:4D and reported this and their sexual orientation online (Collaer et al., 2007). This study found that 2D:4D showed the predicted relationship to sexual orientation in males, but not in females. In contrast, a meta-analytic report on numerous studies, that did not include this large on-line study, found a somewhat different result (Grimbos, Dawood, Burriss, Zucker, & Puts, 2010). This time 2D:4D showed the predicted relationship to sexual orientation in women, but not men. This inconsistency, and similarly inconsistent results for other gendered behaviors, suggest that the gender difference in 2D:4D is too small, or its measurement contains too much error, to provide a useful assessment of individual differences in early androgen exposure. Consequently, studies using the 2D:4D approach are not discussed further in this chapter.

As noted above, gender differences begin to emerge during the first year of life, and include a gender difference in the ability to mentally rotate objects that has been documented by two independent research teams in infants as young as 3–5 months of age. There are occasional individual reports of earlier gender differences, such as in looking at a mechanical object as opposed to a human face (Connellan, Baron-Cohen, Wheelwright, Batki, & Ahluwalia, 2007), but these have yet to be replicated. In addition, the report on the preference for a mechanical object has been suggested to be of questionable reliability, because of weak

scientific control, demand characteristics, a lack of coder blinding, and similar studies that suggest a different conclusion (Escudero, Robbins, & Johnson, 2013; Spelke, 2005). There is as yet no information regarding the factors that contribute to the early emerging gender difference in performance on mental rotation tasks.

Early infancy is characterized by rapid behavioral change, and the brain continues to develop rapidly during the first 2 years after birth, providing much scope for the social environment to interact with other factors involved in gender development at this particular time. Two reports have studied parent-child interactions during this important period of early development using a developmental systems approach. One study assessed characteristics related to language development in 30 mothers and their 30 infants, half male and half female, on numerous occasions between the ages of 3 and 11 months (Sung, Fausto-Sterling, García Coll, & Seifer, 2013). Boys and girls did not differ in the frequency or duration of their nondistressed vocalizations at any time period, nor did vocalization contingent on maternal speech differ for boys and girls. There was some evidence suggesting that boys and girls might differ in their patterns of change over time, however. Boys generally remained static, whereas girls and mothers of girls showed significant behavioral changes over time, although it is not clear that the data for girls and boys differed significantly from one another. The same research team also studied disciplinary interactions involving eight male and eight female infant–mother dyads from the age of 5 to 12 months (Ahl, Fausto-Sterling, García-Coll, & Seifer, 2013). Male infants were more likely to cry or whine during discipline than female infants, and their mothers used longer vocalizations, more words, and more affectionate terms than did the mothers of girls. Although these studies involved small samples, and their replicability and implications are as yet unclear, they suggest that there may be numerous subtle differences in the dynamical systems involved in the development of boys and girls during infancy.

Gender differences in toy preferences also emerge early in life. These gender differences are highly reliable and have been studied extensively. The empirical evidence suggests that they result from numerous influences, including the early hormonal environment, postnatal socialization by others, and processes of self-socialization based on gender cues in the environment. These influences are discussed initially in the chronological order in which they begin to occur, and, where available, evidence regarding how these influences might interact are discussed.

There is reliable evidence that prenatal androgen concentrations influence children's gender-typed toy preferences, as well as other gendered aspects of children's play. This evidence comes from studies of children with genetic disorders causing hormonal abnormalities before birth, from studies of children whose mothers took hormones for medical reasons during pregnancy, and from studies relating individual variability in hormone levels prenatally and neonatally to subsequent gendered play behavior. Studies of nonhuman primates also suggest an inborn influence on gendered toy interests.

Girls exposed to high concentrations of androgens before birth, because of CAH, have consistently been found to show increased male-typical childhood play behavior (Hines, 2011). There are over a dozen studies reporting this finding, and these studies come from research teams working in New York, Baltimore, Los Angeles, and Chicago in the United States, as well as in Sweden, the United Kingdom, the Netherlands, Germany, and Japan. Researchers have used parental report, child self-report and behavioral observations to measure gendered play, and have used same-sexed siblings as controls, as well as controls matched for background factors, such as age, sex and parental education. Thus, the result seems robust. The typical pattern is that girls with CAH show increased preferences for toys that boys usually prefer, and decreased preferences for toys that girls usually prefer. In addition, they show increased preferences for boys as playmates, and for male-typical play styles, such as rough, active play.

The severity of the disorder also predicts the degree of gender-typical behavior in girls with CAH (Nordenstrom, Servin, Bohlin, Larsson, & Wedell, 2002), as does the degree of genital virilization at birth (Hall et al., 2004). Girls with the salt-losing form of CAH show more male-typical behavior than those with the simple-virilizing form, and the amount of physical virilization relates positively to the amount of behavioral virilization. Both of these findings strengthen the argument that androgen exposure, rather than other aspects of the CAH disorder, is responsible for the increased male-typical behavior.

Studies of the daughters of women who took hormones during pregnancy also suggest androgenic influences on gendered play. Like girls with CAH, these girls show high levels of male-typical play (Ehrhardt & Money, 1967). Girls whose mothers took anti-androgenic progestins during pregnancy show the opposite pattern of behavior, reduced male-typical and increased female-typical play (Ehrhardt, Grisanti, & Meyer-Bahlburg, 1977). These findings provide convergent evidence of an androgenic

influence on gendered behavior. These girls did not have a disorder, and so their behavioral changes, unlike those seen in girls with CAH, cannot be attributed to the nonhormonal aspects of the CAH disorder.

Genital virilization at birth, however, rather than hormonal influences on brain development, have been suggested to explain the behavioral differences seen in girls exposed to high levels of androgens before birth. Specifically, it has been suggested that genital virilization could alter girls' perceptions of their own behavior or could alter their parents' treatment of them in ways that would produce more male-typical behavior (Fausto-Sterling, 1992). The influences of anti-androgenic progestins on male-typical childhood behavior, mentioned above, argue against this suggestion, however, since these girls are born with normal, feminine-appearing external genitalia, but show reduced male-typical behavior. Also, medical personnel instruct parents to treat their daughters with CAH like any other girls, and parents' responses on questionnaires and in interviews suggest that they do so (Berenbaum & Hines, 1992; Ehrhardt & Baker, 1974). One study (Pasterski et al., 2005) observed parents playing with their children in a playroom, and recorded parental responses to their children's gender-typical and gender-atypical behavior. Both mothers and fathers discouraged their sons from playing with girls' toys. In addition, they gave their daughters with CAH more positive responses for playing with girls' toys than they gave to their unaffected daughters. These results argue against suggestions that parents are causing their daughters' reduced interest in girls' toys, although it could be argued that parents act differently when they are in the research laboratory than at home, or that they treated their daughters differently earlier in life. Indeed, parents of girls with CAH report encouraging more male-typical behavior in their daughters with CAH than in their unaffected daughters, and this encouragement has been found to partially mediate sex-atypical play in these girls (Wong, Pasterski, Hindmarsh, Geffner, & Hines, 2013). There is other evidence suggesting that this is not the sole cause of the girls' increased male-typical behavior, however, and we will return to this evidence below. For now, it is worth noting that parents in general tend to encourage whatever activities interest their children, so it would not be surprising if parents reported encouraging male-typical play behavior in their daughters with CAH, given that their daughters' enjoy engaging in those behaviors. Nevertheless this parental encouragement could further increase the girls' engagement in male-typical behavior in their day-to-day life. At the same time, however, parents might

encourage female-typical behavior in situations, such as in our laboratory, where they have access to girls' toys and the opportunity to encourage their daughters to play with these toys.

Normal variability in early concentrations of testosterone has also been related to later gendered play. In one study (Hines et al., 2002), maternal testosterone and sex hormone binding globulin (SHBG) were measured in blood samples taken for clinical purposes at mid-pregnancy ($M =$ week 16 gestation, $SD = 8$) in a longitudinal, population study involving almost 15,000 children and their parents (SHBG was measured as well as testosterone because it limits testosterone's ability to act). Parents of about 8,000 of the children completed a measure of their children's gendered behavior at age 3.5 years. This measure, the Pre-School Activities Inventory (PSAI) (Golombok & Rust, 2009), assesses engagement in gender-typical behavior and activities, and is standardized for children aged 2 to 7 years. It is specifically designed to assess behavioral differences within each sex, and the scoring is such that higher scores indicate more male-typical behavior. Six groups, of about 110 children each, were selected for study: highly masculine, highly feminine, and medium girls; and highly masculine, highly feminine, and medium boys. Among girls, mothers of highly masculine girls had the highest levels of testosterone and mothers of highly feminine girls had the lowest, with mothers of medium girls having levels between these two groups, and the linear relationship between testosterone and gendered behavior was highly significant. There was no relationship between gendered behavior and SHBG and the results remained the same when testosterone was adjusted for SHBG. In contrast to the results for girls, there were no differences in testosterone concentrations in the mothers of the three groups of boys. A second study related maternal testosterone during pregnancy to children's gendered behavior and did not find a significant relationship in either girls or boys (van de Beek, Van Goozen, Buitelaar, & Cohen-Kettenis, 2009). This study may not have had sufficient power to see the predicted relationships, however. It used a relatively small sample (56 girls, 56 boys), and assessed gender-typed toy play at age 13 months, before this aspect of gendered behavior has fully emerged. The effect sizes for gender differences in toy play in the van de Beek study were small to moderate in size ($d = .53$ for boys' toys; $d = .35$ for girls' toys), whereas the effect size for the gender difference on the PSAI at age 3.5 years was very large ($d = 2.8$).

Another study found that testosterone measured in amniotic fluid between Week 15 and 25 of pregnancy

related to later gender-typed behavior, again assessed using the PSAI (Auyeung et al., 2009). This study included 112 girls and 100 boys. Two other studies relating testosterone in amniotic fluid to childhood gender-typed play behavior have not found similar results (Knickmeyer et al., 2005; van de Beek et al., 2009), but these studies both used substantially smaller samples and less sensitive behavioral measures than the study producing positive results.

A third study examined testosterone during the early postnatal surge and related it to later behavior, assessed using the PSAI as well as by observing children's toy choices in a playroom (Lamminmaki et al., 2012). This study measured testosterone in urine samples from infants at day 7 postnatally as well as monthly from the first to the sixth month after birth. The PSAI was completed by parents when children were 14 months of age, and children's interests in gender-typed toys were observed at the same age. Testosterone was higher in boys than in girls at all seven time points, but was highest in boys 1 month postnatally and declined to near the level seen in girls by 6 months. The area under the curve for testosterone predicted PSAI scores in boys. Also, significant gender differences were seen in play with a train and a baby doll, and the area under the curve for testosterone positively predicted play with the train for girls and negatively predicted play with the doll for boys. These relationships were seen in relatively small groups of children (15 boys for the PSAI, 20 boys for the doll, 22 girls for the train), however, and, as yet, there have been no replication attempts.

This evidence that testosterone during putative critical periods for gendered development predicts later gendered play behavior in typically developing children could provide important additional convergent evidence that testosterone plays a role in the development of gendered human behavior. None of these children had endocrine disorders, and none had atypical genitalia at birth. Parents were unaware of their children's testosterone levels. Thus, altered self-perceptions, or altered parental perceptions or treatment, based on awareness of abnormality or genital virilization, cannot explain the observed relationships between testosterone and behavior. In addition, these findings are important, because they suggest useful approaches to studying how hormones work together with other types of factors to shape gendered behavior. It is challenging to conduct studies of interactive effects in individuals exposed to atypical hormone environments prenatally, because such individuals are not numerous, and studies of interactive effects require large samples. None of these

findings linking normal variability in the early hormone environment to later gendered play has yet been replicated independently, however.

Studies of nonhuman primates suggest that they also show gendered toy preferences, similar to those seen in children. A study of vervet monkeys found that female monkeys spent more time contacting girls' toys than male monkeys did (Alexander & Hines, 2002). Similarly, male monkeys spent more time contacting boys' toys than female monkeys did. There was no difference in contact time with neutral toys. A subsequent study of rhesus macaques replicated the finding for boys' toys and neutral toys. This study (Hassett, Siebert, & Wallen, 2008) used wheeled toys, generally preferred by boys, and plush toys, which both boys and girls enjoy. Results showed that the male monkeys preferred the wheeled toys, and that there was no difference between male and female animals for the plush toys. These preference patterns again resembled those seen in children.

Thus, there is convergent evidence of an inborn contribution to the development of gendered childhood play behavior. Girls exposed to higher than normal levels of androgenic hormones prenatally, either because of a genetic disorder or because androgenic hormones were prescribed to their mothers during pregnancy, show increased male-typical play behavior and reduced female-typical play behavior. Also, children whose mothers took anti-androgenic hormones during pregnancy show reduced male-typical behavior. Among typically-developing children, individual variability in testosterone, measured in maternal blood samples during pregnancy, in amniotic fluid at mid-gestation or in urine shortly after birth, also have been reported to predict gender-typed childhood behavior. Although the individual studies of typically-developing children have not been independently replicated, at least as yet, they, along with the findings for children exposed to anti-androgenic hormones, suggest that testosterone can influence human behavior in the absence of external virilization. Finally nonhuman primates show gendered toy preferences similar to those seen in children. Taken together, the evidence suggests that individual girls and boys have different propensities to engage in gendered play, based to some extent on inborn factors, and these factors are likely to include their early exposures to androgenic hormones.

Socialization and Gender

It is also well established that the social environment begins to shape gendered behavior early in life. Even

before a child is born, parents typically select names, buy clothes, and decorate rooms in different ways depending on whether they are expecting a girl or a boy. To the world outside the immediate family, gender is also an important social category. Friends typically ask new parents "Is it a girl or a boy?" before they ask anything else. In one study, this question was the first to be asked in 80% of the cases, whereas first questions concerned the health of the baby or the mother only 18% of the time (Intons-Peterson & Reddel, 1984). The tendency to dress boys and girls differently, and to add gender cues, such as a ribbon or a bow to a bald baby's head, suggests that parents want other people to know whether their child is a girl or a boy.

In addition to these general ways in which girls and boys are treated differently, there are specific differences in the gender-related responses and information that girls and boys receive. For example, girls and boys receive different responses from their parents when they play with gendered toys. Although parents generally encourage their children to engage in the activities that interest them, gendered toy play can be an exception. A meta-analytic study of parental responses to boys and girls (Lyttton & Romney, 1991) found that parents encouraged boys and girls similarly in regard to most behaviors, including behaviors related to independence and achievement. A main area of difference, however, involved reactions to children's engagement with gendered toys. Others also have looked at parental responses to play with same-gender and other-gender toys (Fagot, 1978; Fagot & Hagan, 1991; Langlois & Downs, 1980; Pasterski et al., 2005). Findings from these studies suggest that girls get more positive responses when they play with girls' toys than boys do, and boys get more positive responses when they play with boys' toys than girls do. In addition, although negative responses are relatively rare, boys, but not girls, get negative responses when they play with gender-atypical toys. This use of negative responses is remarkable, given that at the age of 12 months parents give about 39 times as many positive as negative responses to their children's toy play (Fagot & Hagan, 1991). Parental socialization of toy choices appears to be at its peak during the second postnatal year (Fagot & Hagan, 1991; Lyttton & Romney, 1991).

Once children enter preschool and begin to interact with teachers and peers, these individuals also encourage gender-typical toy interests and discourage cross-gendered interests (Fagot, 1977; Fagot & Patterson, 1969; Lamb, Easterbrooks, & Holden, 1980; Lamb & Roopnarine, 1979; Langlois & Downs, 1980). In general, the encouragement to make gender-typical toy choices and avoid cross-gender

choices is stronger for boys than for girls (Fagot, 1977; Fagot & Hagan, 1991; Pasterski et al., 2005).

These different patterns of reinforcement for girls and boys are assumed to shape their behavior, just as patterns of reinforcement shape other types of behavior. One study investigated this effectiveness for toy choices by observing parents interacting with their children in a playroom (Pasterski et al., 2005). The study included typically developing children as well as girls and boys with CAH. For the typically developing children, parental reinforcement correlated as anticipated with the children's gendered toy play. For girls with CAH, however, this was not the case. For these girls, who had been exposed to high concentrations of androgen prenatally and who preferred boys' toys, toy choices did not correlate with parental reinforcement patterns.

Other parental characteristics also predict children's gendered behavior among typically developing children. In a longitudinal, population study of thousands of parents and children, measures of gendered parental behavior (e.g., who takes out the trash, who cooks dinner) correlated positively with gendered behavior in offspring (Hines et al., 2002). Parents who adhered to traditional gender roles in these activities had children with more gender-typical behavior than did less traditional parents. In addition, the children of mothers who are highly educated and who work outside the home show less gender-typical behavior than the children of less educated mothers or mothers who do not work outside the home (Hines et al., 2002; Ruble & Martin, 1998).

Parents are not the only people who shape children's gendered behavior. Peers, in particular, encourage children to engage in gender-typical, but not gender-atypical, play (Fagot, 1977; Fagot & Patterson, 1969; Frodi et al., 1978; Lamb et al., 1980; Lamb & Roopmarine, 1979; Langlois & Downs, 1980). Children's tendency to play with children of the same sex also provides the opportunity to learn more gendered behavior. By engaging largely with children of the same sex, it has been suggested that children spend the majority of their time observing, practicing and being encouraged to engage in gender-typical behavior, with little time spent observing, practicing or being encouraged to engage in gender-atypical behavior (Leaper, 1994; Maccoby & Jacklin, 1987). Evidence supporting the influences of playing with same sex or other sex peers comes from a study that related the amount of play with peers of the same sex early in the school year to the amount of increase in gender-typical behavior by the end of the year (C. L. Martin & Fabes, 2001). This study found that the

children who played with more same-sexed peers showed a bigger increase in gender-typical behavior by the end of the year than those who played with fewer same-sexed peers.

Even strangers encourage children to engage in gender-typical play. For instance, strangers left to interact with a baby dressed in gender-neutral clothes, but told that the child is a girl or a boy, are more likely to offer the child a doll if they have been told that the child is a girl (Seavey, Katz, & Zalk, 1975; Sidorowicz & Lunney, 1980).

Cognitive Development and Gender

Another way in which children acquire gendered behavior is through self-socialization. This self-socialization relies on children's cognitive understanding of gender and their acquisition of male or female gender identities. Basic gender identity understanding can be measured in children beginning at about the age of 2 years, when most children can correctly identify themselves as girls or boys. By the age of 2.5 years, about 75% of children can tell you that they are girls or boys, and they can sort their picture, and pictures of others, into piles of males and females; 95% of children can do this by the age of 3 years (Thompson, 1975). Gender identity understanding continues to develop until children are about 6 to 7 years of age, with children first acquiring the additional understanding that they have always been and will always be male or female, called gender stability, and finally the understanding that if they adopted the characteristics of the other sex, such as wearing their clothing or engaging in their activities, their gender would not change, called gender consistency (Ruble et al., 2007).

There is some evidence linking self-knowledge of gender identity to children's gendered behavior. Achievement of the first two levels of understanding, gender identity and gender stability, has been found to relate to gendered behavior. For example, understanding of gender stability relates positively to knowledge of gender stereotypes and to rigidity about gender-related behavior (Ruble, Martin, & Berenbaum, 2006), and to wearing gender-typical clothing (Halim et al., 2014). Similarly, acquiring an understanding of gender consistency relates to reduced rigidity about gender-appropriate behavior. This may occur because children then know that their gender will not change if they engage in gender-atypical behavior (Huston, 1983; Ruble et al., 2007).

Equipped with gender understanding, children can observe the world around them, see what girls and boys and women and men do, and then preferentially model the behavior of others of their own sex. One study (Bussey

& Bandura, 1992) explored this process by asking 2- to 4-year-old children if they would feel good or bad after playing with a gender-appropriate toy, and after playing with a gender-inappropriate toy. The children were also asked to predict how they thought another child would feel about the same behaviors. Finally, the children were observed in a playroom with the same toys. Children showed gender-typical toy play and they said that other children would feel good about playing with gender-typical toys, but bad about playing with gender-atypical toys, and this was the case across the age range. In regard to themselves, however, only the 4-year-old children said that they themselves would feel these ways. Additionally, the difference between feeling good about playing with a gender-typical toy and feeling bad about playing with a gender-atypical toy predicted behavior in the playroom. The larger this difference, the more gender-typical was the children's play. These findings were interpreted to suggest that, early in life, children play with gender-typical toys because they are reinforced for doing so, and that, between the ages of 2 and 4, they begin to incorporate social expectations and values and come to value engaging in gender-typical behavior and attach positive emotions to complying with gendered expectations. These then become self-evaluations that add additional motivation to behave as girls or boys should.

The acquisition of gender identity also underlies other mechanisms by which children self-socialize gendered behavior. One of these mechanisms is imitating or modeling the behavior of others of the same sex. If shown models of one sex engaging in a particular behavior or choosing a particular object and shown models of the other sex engaging in a different behavior or choosing a different object, children subsequently indicate greater interest in the behaviors or objects that were modeled by individuals of their own sex (Masters, Ford, Arend, Grotevant, & Clark, 1979; Perry & Bussey, 1979). Similarly, if children are told that items of one color, say green balloons, are for one sex, and that other similar items, say orange balloons, are for the other sex, they subsequently show more interest, both verbally and behaviorally, in the items that they have been told are for their own sex (Masters et al., 1979). They also show increased preferences for objects and activities that have been endorsed by children of their own sex over those that have been endorsed by children of the other sex (Shutts, Banaji, & Spelke, 2010).

Information about stability and instability of behavior is relevant to understanding its development. For instance, some researchers have argued that situational influences

on children's gendered behavior should lead to relative instability over time (Maccoby, 2002). Studies examining stability in children's gendered behavior over time have often been interpreted to suggest low stability, but this may have been the result of methodological limitations, such as small samples and few observations, as well as weak statistical approaches (C. L. Martin & Ruble, 2009). One study looked at over 300 samples of behavior for each of 61 preschool or kindergarten children over 6 months of a school year and found considerable temporal stability in choices of playmates of the same versus the other sex (stability coefficients ranged from about .6 to about .9 for data aggregated over 12 weeks) (C. L. Martin & Fabes, 2001). Similarly, another study found stability across 2 school years in playmate preferences of 5- to 12-year-old children, as indicated by the children's selecting pictures of peers with whom they would prefer to play (Serbin, Powlishta, & Gulka, 1993).

A developmental systems approach has been used to examine the origins of children's tendencies to play with others of the same sex (C. L. Martin et al., 2013). This study followed 230 preschool children over a school year, recording with whom they played and the activities in which they engaged. Results suggested that children played with others of the same sex in part because doing so facilitated engagement in gender-typical activities, but that sex segregation was explained to a greater degree by children affiliating with others of the same sex, regardless of the activity in which they were engaged.

Playmate preferences are not the only aspect of childhood behavior that has been studied over time. One study found impressive stability on a broad measure of gendered behavior over a long period of time. This longitudinal study used the PSAI to measure several thousand children's gendered behavior at the ages of 2.5, 3.5, and 5 years, and then used a similar measure, the Child Activities Inventory (CAI) to measure comparable gendered behaviors that were age appropriate at the age of 8 years (Golombok et al., 2008). Stability coefficients were high—for instance, 0.5 from the ages of age 2.5 to 5 years. Similarly, children who were the most gender typical at the age of 3.5 years were also the most gender-typical at the age of 8 years, whereas those who were the least gender-typical early on remained so later in development as well. This study also examined the trajectory of change in gendered behavior, and found that children who were the most gender-typical or gender-atypical at the earliest ages became progressively more so over the course of development. This acceleration may occur because highly gender-typical behavior leads to

engagement in highly gendered activities and to extensive play with same gendered peers who also enjoy highly gendered activities, whereas highly atypical gendered behavior leads to engagement in gender atypical activities and extensive play with peers, including other gender peers, who enjoy these gender-atypical activities. Thus, a particular child's degree of gendered behavior is likely to influence the environments he or she chooses, and these environments may then amplify the behavioral tendencies that led the child to choose them.

To summarize, individual differences in gendered childhood behavior, including toy, playmate, and activity preferences, are influenced by numerous factors. The gendering of these childhood behaviors begins at conception, when egg and sperm join to produce an XX or an XY individual. Information on the Y chromosome then causes the gonads to differentiate as testes, and testosterone, as well as other hormones produced by the testes, begin to affect the physical development of the XY fetus. The tissues that are influenced include regions of the brain, as well as the external genitalia. Several lines of inquiry suggest that androgenic hormones influence gendered childhood behavior. Over a dozen studies from a number of independent research groups have found that girls exposed to unusually high levels of androgens prenatally, because they have the genetic disorder, CAH, show increased male-typical play behavior in childhood. In addition, girls with more severe forms of CAH, involving the most dramatic androgen elevation, show the most male-typical play, as do girls with more severe genital virilization, which also reflects more androgen exposure or androgen response. In addition, girls with no genetic disorder, but exposed to high levels of androgenic hormones before birth because these hormones were prescribed to their pregnant mothers, also show increased male-typical play, and girls similarly exposed to anti-androgenic progestins during gestation show reduced male-typical play. Normal variability in testosterone prenatally, measured in maternal blood during pregnancy, or in amniotic fluid, predicts normal variability in male-typical childhood play, as does normal variability in testosterone measured in the urine of infants from birth to 6 months of age. Also, although parents report encouraging the interests of their androgen-exposed daughters in their everyday life, even though the interests are sex-atypical, observations of parents playing with their androgen-exposed daughters in a laboratory playroom suggest that they encourage these girls to play with girls' toys when given the opportunity to do so. None of these types of studies on their own is as persuasive as rigorous experiments, with random assignment

to receive hormones or placebos, would be. Each type of approach has its own limitations. For example, CAH is a disorder with consequences other than androgen exposure, including external genital virilization, mothers who take hormones during pregnancy or who undergo amniocentesis may not be representative of the population at large, and mothers who have high levels of testosterone may encourage more male-typical behavior in their children than do mothers who have low levels of testosterone. Each of these approaches thus has different types of limitations. Taken together, however, and considering also studies showing sex-typed toy preferences in nonhuman primates, the existing evidence converges on the conclusion that there is an inborn contribution to individual differences in children's gendered behavior, most probably from the early hormone environment.

Postnatally, the social environment and children's self-socialization, based on their cognitive development and gender identity understanding, further shape individual differences in these same gendered behaviors. Parents, teachers, peers, and strangers encourage children to engage in gender-typical behavior, and discourage boys from playing with girls' toys. Children also come to understand that they are boys or girls and that this will not change. They imitate the behavior of models of the same sex and respond to information that certain items or activities are for girls or for boys by showing increased interest in those that are for their own sex. They value doing so, and playing with gender appropriate toys comes to make them feel good about themselves. These processes activate additional mechanisms that further channel children into typical or atypical pathways. Children generally play with others of the same sex, providing them with more opportunities to learn sex-typical than atypical behavior. In addition, parents generally encourage their children to engage in the activities that they understand their children to enjoy, including encouraging girls with CAH to engage in male-typical behavior. At the same time, when given the opportunity to encourage more gender-typical behavior in their daughters with CAH, they do so. These daughters may be resistant to this socializing influence, however, given that parental socialization correlates as expected with gender-typical toy choices in girls without CAH, but not in girls with CAH (Pasterski et al., 2005). Consistent with these canalizing processes, children who are gender atypical early in development become increasingly so as they grow older, and this increasing trajectory occurs for those who are gender typical as well. Thus, inborn predispositions, as well as postnatal socialization, including

self-socialization, contribute to the acquisition of gendered behavior in childhood, and the effects of early androgen exposure may modify the impact of postnatal socialization by parents. These interacting and complementary processes combine to produce average differences between the sexes, as well as individual differences within each sex in gendered childhood behavior.

Gender Identity

Gender identity is involved in the acquisition of gendered behavior, but it is also a gendered aspect of human psychology on its own. In fact, it may be a uniquely human aspect of gendered psychology. As far as can be determined, individuals of no other species are consciously aware of their gender.

Gender identity differs dramatically for males and females. Almost all individuals who have the physical appearance of males acquire a male gender identity, whereas almost all individuals who have the physical appearance of females do not. This is not always the case, however. Some people who look like males identify as females, and some people who look like females identify as males. These people are gender dysphoric in their natal sex and may seek medical treatment (e.g., gonadal hormone treatment, genital surgery) to acquire the physical appearance corresponding to their gender identity. The incidence of this strong gender dysphoria is not known with certainty, because no rigorous epidemiological studies have been conducted. According to the *DSM-IV*, about 1 in 30,000 natal males and 1 in 100,000 natal females change their gender (APA, 2000). These estimates are old, however, and the numbers of children, adolescents and adults reporting gender dysphoria and seeking treatment have been rising (Zucker & Lawrence, 2009), perhaps because it has become more acceptable to seek help for this concern. Data from Belgium suggest that about 1 in 13,000 natal males and 1 in 34,000 natal females underwent sex reassignment surgery between 1985 and 2003, data from the Netherlands that about 1 in 12,000 natal males and 1 in 30,000 natal females received hormone therapy for gender dysphoria between 1986 and 1990, and data from Spain that about 1 in 21,000 natal males and 1 in 48,000 natal females received diagnoses of transsexualism between 1996 and 2004 (Zucker & Lawrence, 2009).

What factors contribute to individual differences in gender identity? People who choose to change gender in adulthood often recall feeling different from others and engaging in gender-atypical behavior, for their natal sex,

beginning in early childhood (Green, 1987). It is unlikely that these early cross-gendered interests are a major contributor to adult gender dysphoria, however, because most children who wish to change gender in childhood do not wish to change sex as adults. Across studies that have followed gender dysphoric children into adolescence, only 16% persisted in their dysphoria (range = 2% to 27%). Thus the great majority desist (Steensma, Biemond, de Boer, & Cohen-Kettenis, 2011). The period between Ages 10 and 13 years appears to be important for awareness of continuing dysphoric feelings, with individuals noting that changes in their social environment, their bodies and their first experiences of sexual attraction and love influenced their gender identification (Steensma et al., 2011). Although the early cross-gendered interests do not typically persist, they could provide a clue as to the causes of gender identity problems. Perhaps the same factors that influence cross-gendered interests in childhood influence gender identity.

Could the early hormone environment be involved? Gender dysphoric individuals are not typically born with ambiguous external genitalia, and rarely show any other physical evidence of exposure to unusual hormone environments. One might speculate, however, that localized hormonal differences within the brain could have influenced their development. For example, the mammalian nervous system, including the human fetal nervous system, can make testosterone and other gonadal steroids (King, 2012), and these hormones could act locally on neural circuitry involved in gender identity. This possibility is currently impossible to evaluate, however, because there are no techniques for assessing production of testosterone or other gonadal steroids in the living human brain, and the neural circuitry involved in gender identity is unknown.

Consistent with a role of early androgen exposure, XX individuals with CAH are more likely than other women to choose to change gender in adulthood. Although the vast majority of women with CAH develop a female gender identity, about 2% choose to live as men, despite having been assigned and reared as girls (Dessens, Slijper, & Drop, 2005; Meyer-Bahlburg et al., 1996; Zucker et al., 1996). This number is several hundredfold higher than the 1 in 30,000 or fewer who choose to live as men among women in general. Also, among women with CAH who are not gender dysphoric, identification with being female is reduced compared to other women, and the strength of identification as female correlates negatively with recalled cross-gendered behavior in childhood (Hines et al., 2004; Meyer-Bahlburg, Dolezal, Baker, Ehrhardt, & New, 2006).

Other evidence also suggests an association between CAH and reduced female gender identity. Self-reports of girls with CAH suggest reduced satisfaction with being girls (Ehrhardt, Epstein, & Money, 1968), and 10%–20% of girls exposed to high levels of androgen prenatally, because of CAH or other disorders of sex development, have been reported to be gender dysphoric (Sliper, Drop, Molenaar, & de Muinck Keizer-Schrama, 1998). Because most gender dysphoric individuals desist before adulthood, however, these figures may be higher than those for adults with similar conditions.

Individuals with CAIS almost always evolve female-typical gender identities (Hines, Ahmed, et al., 2003; Wisniewski et al., 2000), despite their Y chromosome, suggesting that the combination of no effective androgen exposure, feminine physical appearance, and sex assignment and rearing as girls are sufficient to produce female gender identities, despite the lack of a second X chromosome or ovaries. There is a report, however, of one individual with CAIS, who was assigned and reared as a girl, but chose to live as a man in adulthood (T'Sjoen et al., 2011).

Many XY individuals with enzymatic deficiencies in the pathway for testosterone production change from living as females to living as males following the appearance of male secondary sexual characteristics at puberty. One study reported on 18 XY individuals with 5-alpha-reductase deficiency in an isolated village in the Dominican Republic. These individuals were reported to have had undervirilized external genitalia at birth, to have been assigned and reared as girls, and to have been content as girls during childhood. However, 17 of the 18 were living as men following virilization at puberty (Imperato-McGinley, Guerrero, Gautier, & Peterson, 1974; Imperato-McGinley et al., 1979). A subsequent review of all available reports on XY individuals with 5-alpha-reductase deficiency found that 56% to 63% of those assigned and reared as girls lived as men in adulthood and that 39% to 64% of those with 17-HSD deficiency assigned and reared as girls lived as men in adulthood (Cohen-Kettenis, 2005). This review also concluded that the likelihood of making this change did not appear to relate to the severity of genital virilization at birth. Explanations for the variability in gender change include possible ambiguity in the sex of rearing (Herdt & Davidson, 1988; Money, 1976), or the advantages of being men rather than infertile women in the cultural settings where these disorders occur frequently—usually areas of high consanguinity (Herdt & Davidson, 1988; Wilson, 1979). In these cultural settings, medical treatment to prevent the emergence of masculine characteristics at puberty

is not always available, and to some extent the decision to live as men may be practical. If you look like a man, it could be easier to live as a man rather than as a woman. In the United States and most of Western Europe, individuals with these disorders are often assigned and reared as girls, and have their testes removed prior to puberty or before extensive masculinization has taken place. These individuals are more likely to remain living as women than those who experience physical masculinization (Wilson, Griffin, & Russell, 1993; Zucker, 2002). The available evidence does not support the idea that early androgen exposure is responsible for the changes in gender identity seen in some individuals with these disorders. Androgen exposure at puberty, perhaps by producing a masculine physical appearance, is a more likely explanation. The advantages of being a man in certain societies might also help some individuals with these disorders choose to live as men, particularly when they have virilized physically.

XY individuals assigned and reared as girls, because of conditions including penile agenesis or cloacal exstrophy, typically develop female gender identities (Meyer-Bahlburg, 2005). Although one research group reported a high incidence of gender dysphoria for XY individuals with cloacal exstrophy who had been assigned and reared as girls at one clinic (Reiner & Gearhart, 2004), this is not typical.

There are two well-documented cases where XY infants lost their penis in surgical accidents. In one case, the surgery took place when the child was 8 months of age, and he was reassigned as a girl by 17 months of age. The child was reported to be happy with this assignment in early childhood (Money & Ehrhardt, 1972), but in adulthood was living as a man and reported having been unhappy with the female sex assignment for many years (Diamond & Sigmundson, 1997). This case has been widely publicized as indicating that the Y chromosome and exposure to testicular hormones during early development made a male identity inevitable (Colapinto, 2000). A second, similar case argues against this interpretation, however. In this second case, the surgical accident occurred when the child was 2 months of age, and the reassignment as a girl was made by the age of 7 months. This individual was assessed at the ages of 16 and 26 years and had a female gender identity at both ages (Bradley, Oliver, Chernick, & Zucker, 1998). This second individual provides evidence of the power of socialization, accompanied by a feminine appearance, to shape gender identity. This XY infant was exposed to male-typical concentrations of testosterone and other testicular hormones prenatally and in early infancy,

was reared as a boy for at least the first 2 months of postnatal life, and then was reassigned as a girl. The success of this reassignment in producing a female gender identity in adulthood suggests that gender identity is not inevitably determined by the sex chromosomes or the early hormone environment, either singly or in combination. Instead, it points to powerful shaping by physical appearance or sex of rearing.

There are as yet no data examining normal variability in testosterone in amniotic fluid, maternal blood during pregnancy, or urine in infancy in relationship to gender identity. There are also no data showing that variability in social reinforcement of gender-typical or atypical behavior in the general population causes alterations in gender identity. One study found that children with gender dysphoria showed delayed cognitive understanding of gender compared to typically developing children or children with other psychiatric disorders (Zucker et al., 1999), but it is not possible to know if the gender dysphoria caused the delayed cognitive understanding of gender, or vice versa, or if a third factor caused both.

Another clue to the possible origins of individual variability in gender identity, comes from data suggesting that gender dysphoria and autistic spectrum conditions (ASC) co-occur more often than would be expected by chance. One study (A. L. C. de Vries, Noens, Cohen-Kettenis, Berckelaer-Onnes, & Doreleijers, 2010) of 204 children and adolescents who had been referred for evaluation of gender dysphoria found that 7.8% of the children also had an ASC, a figure that is much higher than the approximately 0.65% that would be expected to have an ASC in the population at large (Fombonne, 2009). Adults with gender dysphoria also have been found to show increased autistic traits (Pasterski, Gilligan, & Curtis, 2014). In both studies, the association between gender dysphoria and autistic traits applied to females as well as males with gender dysphoria. The findings might suggest that the reduced cognitive flexibility associated with autism, combined with feelings of gender atypicality, might lead individuals to think that they should be the other gender. Thus, the types of thinking patterns associated with ASC might predispose gender-atypical individuals to have difficulties with gender identity.

In summary, many types of factors appear to play a role in gender identity development. Information from studies of clinical syndromes involving androgen abnormalities suggests that androgen exposure during early development contributes to gender identity development. The risk of severe gender dysphoria in XX adults exposed to high

levels of androgens prenatally because of CAH is increased, although it is still rare (about 2%), and most XX and XY individuals who are assigned and reared as females develop female gender identities, even if they were exposed to high concentrations of androgens prenatally. XY individuals who cannot respond to androgens, because they have CAIS, almost always develop female gender identities, although their feminine appearance and unambiguous rearing as females could contribute to this outcome. There is a report of one individual with CAIS who chose to live as a man, despite having been reared as a girl, and having a feminine appearance, but, thus far, this is a single case. Many men with enzymatic disorders that impair androgen production choose to live as men after they acquire male secondary sexual characteristics at puberty, whereas many others remain living as females, especially if physical virilization at puberty is prevented. In addition, the change to living as a man may occur more frequently in cultures where being a man has social advantages, particularly in comparison with being an infertile woman. Evidence associating gender dysphoria and ASC suggests that psychological characteristics associated with ASC, such as reduced cognitive flexibility, might increase the likelihood of gender dysphoria in individuals with gender-atypical interests. Overall, the evidence suggests that the early hormone environment, gender-typical socialization, physical appearance, cultural differences, and personality variables all contribute to variability in gender identity, but little or no research has yet examined how these factors might interact to influence gender identity.

Sexual Orientation

Sexual orientation has also been reported on in the two cases where male infants were reassigned as girls following surgical accidents that damaged the penis. The child who was reassigned by the age of 7 months subsequently had erotic interest in both men and women (Bradley et al., 1998), whereas the child who was reassigned later, by the age of 18 months, appears to have been exclusively heterosexual in adulthood, and lived with a female partner (Diamond & Sigmundson, 1997). These two outcomes differ from one another to some extent—one individual has a bisexual orientation, whereas the other was interested in female and not male partners, but both differ from typical females, who have primary sexual interests in men. Thus, for both of these individuals, sexual orientation appears to have been influenced in the male-typical direction by their Y chromosomes, their early androgen exposure, their early

socialization as male infants, or some combination of these factors.

Women exposed to high levels of androgens prenatally, because of CAH, are also more likely than women in general to show erotic interest in women (Dittmann, Kappes, & Kappes, 1992; Frisén et al., 2009; Hines et al., 2004; Meyer-Bahlburg et al., 2008). These studies suggest that about 70% of women with classic CAH are exclusively or almost exclusively heterosexual, compared to over 95% of women without CAH. In addition, the likelihood of not being exclusively or almost exclusively heterosexual is greater for women with the more severe forms of classic CAH than in those with less severe forms (Dittmann, Kappes, Kappes, Börger, Meyer-Bahlburg, et al., 1990; Meyer-Bahlburg et al., 2008), and for women born with more severe genital virilization (Gastaud et al., 2007), suggesting that androgen contributes to the behavioral outcome.

The genital virilization in women with CAH, and surgeries to feminize the genitalia, could be particularly relevant to their sexual behavior, however. Even with surgical feminization, the genitalia are not identical to those of other women, and the surgical outcomes can produce problems, such as pain at intercourse (Schober, 1999). In light of these issues, convergent evidence is particularly important. Some convergent evidence has come from studies of XY females with CAIS. Almost all women with CAIS are erotically interested in men (Hines, Ahlmed, et al., 2003; Money, Schwartz, & Lewis, 1984; Wisniewski et al., 2000), suggesting that their lack of effective androgen exposure reduced their sexual interest in women, despite their Y chromosome. Women with CAIS are almost always reared as females, however. Socialization as females might, therefore, explain their female-typical erotic interest in men, although no specific socialization experiences have been linked to sexual orientation.

Sexual orientation in individuals with enzymatic deficiencies that prevent production of the full range of androgens has not been studied systematically. It is generally assumed, however, that those individuals who change to live as men following virilization at puberty, are sexually interested in women, and in many instances are known to live with or marry women (Wilson et al., 1993; Zucker, 2002). In contrast, individuals with the same disorders, who are surgically feminized and have their testes removed prior to physical virilization at puberty, are thought to be sexually interested in men, and in many instances they are known to live with or marry men (Wilson et al., 1993; Zucker, 2002). These findings suggest that

the cultural context, or physical appearance as a man or a woman, can influence sexual orientation in individuals with these disorders.

There is, as yet, no information relating normal variability in hormones in maternal blood during pregnancy, in amniotic fluid, or in infants' urine to sexual orientation, so it is not known if normal variability in the early hormone environment relates to subsequent sexual orientation. There is some information, however, on sexual orientation in the children of women treated with hormones during pregnancy. Men treated with progestins or estrogens do not appear to show altered sexual orientation (Kester, Green, Finch, & Williams, 1980; Meyer-Bahlburg, Ehrhardt, Whitehead, & Vann, 1987), and this is not surprising, because treatment of male animals with similar hormones does not influence their sexual behavior. In contrast, treatment of women with the synthetic estrogen, DES, during pregnancy has been linked to reduced heterosexual orientation in their adult daughters (Ehrhardt et al., 1985; Ehrhardt, Meyer-Bahlburg, & Veridiano, 1987; Meyer-Bahlburg et al., 1985; Meyer-Bahlburg et al., 1995). This outcome was seen in three studies including a total of about 100 DES-exposed women and matched and some sibling controls, and would be predicted based on findings in other species, where exposing female animals to DES during early development reduces subsequent female-typical behavior. In the three studies of women, 16%–35% of the DES-exposed women versus 0%–13% of the controls reported themselves to be homosexual or bisexual. The studies also included 20 sister pairs, where one sister was exposed to DES and the other was not, and 40% of the DES-exposed sisters reported a bisexual or homosexual orientation, compared to 10% of their unexposed sisters. A study of several thousand DES-exposed and unexposed women by a second research team (Titus-Ernstoff et al., 2003) did not provide evidence linking prenatal DES exposure to sexual orientation. This replication attempt relied on a single question about the sex of sexual partners, however, whereas the three studies finding a link between DES and sexual orientation used extensive interviews to assess sexual orientation, including sexual orientation in fantasy as well as in behavior. Thus, weak measurement reliability could explain the failure to replicate. The results suggesting reduced heterosexual orientation in women exposed prenatally to DES are important, because DES exposure would be hypothesized to masculinize neurobehavioral development, but would not cause virilization of the external genitalia. Thus, if replicable, these results would provide important

convergent evidence supporting hormonal influences on the development of human sexual orientation.

What other factors have been linked to variability in sexual orientation? Information from twin studies suggests a genetic contribution, particularly for men. Heritability estimates are higher for studies that specifically recruit nonheterosexual twin pairs (Bailey & Pillard, 1991; Bailey, Pillard, Neale, & Agyei, 1993; Whitam, Diamond, & Martin, 1993) than for those working with twin registers or population samples (Bailey, Dunne, & Martin, 2000; Kendler, Thornton, Gilman, & Kessler, 2000), but both approaches suggest some heritability. One concern about twin studies is that they confound genetic similarity and rearing similarity, so information on twins reared apart is valuable. For men, reports on four such pairs of identical twins found that two pairs were concordant for a non-heterosexual orientation, supporting the results of studies of twins reared together, and suggesting some degree of heritability for sexual orientation (Eckert, Bouchard, Bohlen, & Heston, 1986; Whitam et al., 1993). In contrast, reports on four pairs of identical female twin pairs reared apart appear to argue against substantial heritability in that, in all four pairs, only one of the two in the pair was not heterosexual (Eckert et al., 1986).

Researchers have also searched for specific genes that relate to variability in sexual orientation. These studies have looked at possible candidate genes, at genes on the X chromosome, and at the whole genome. Sequence variation in the androgen receptor gene appears to be unrelated to sexual orientation in men (Macke et al., 1993). Similarly, the gene regulating aromatase cytochrome, the enzyme that converts androgen to estrogen, does not appear to relate to variability in sexual orientation among men (DuPree, Mustanski, Bocklandt, Nievergelt, & Hamer, 2004). In an extended family, where there appeared to be maternal transmission of homosexuality in male offspring, genes on the X chromosome were examined and a linkage was found to markers on Xq28 (Hamer, Hu, Magnuson, Hu, & Pattatucci, 1993). The same research group subsequently replicated this finding for men, but found no such linkage for women (Hu et al., 1995). A second research group failed to replicate the finding for men (Rice, Anderson, Risch, & Ebers, 1999), although this failure to replicate could have resulted from methodological differences. For instance, the failed replication attempt did not focus on individuals with evidence of maternal transmission. Similarly, a genome-wide scan failed to replicate the linkage (Mustanski et al., 2005), but again, methodological differences prevent firm conclusions. In particular, the

genome-wide scan had poorer resolution for markers in the Xq28 region than the Hamer study. The genome-wide scan suggested possible linkage to other regions, including D7S798 in 7q36, D8S505 in 8p12, and D10S217 in 10q26, and the authors suggested that future research might use denser linkage maps in these regions and in the Xq28 region. There is also evidence that homosexual men, but not women, have fewer maternal uncles than aunts (Turner, 1995). These results suggest increased fetal mortality in the brothers of homosexual men's mothers. Other authors have attempted to explain these findings in terms of genomic imprinting (Green & Keverne, 2000).

The number of older brothers also has been related to sexual orientation in men, but not women (Blanchard & Bogaert, 1996). The probability of not being heterosexual has been observed to be 2% for men with no older brothers, and to increase to 2.6%, 3.5%, 4.6%, 6% and 7.8% with one, two, three, four, and five or more older brothers (Blanchard, 2001). The effect does not apply if the older brothers are not biologically related to the younger brother, suggesting an influence of prenatal factors (Bogaert, 2006). One suggested explanation of these findings is that mothers produce progressively more antibodies to male fetuses with each pregnancy involving male fetuses, and that these antibodies somehow alter sexual orientation (Blanchard, 2004). For unknown reasons, the effect of older brothers on sexual orientation is seen in right-handed, but not left-handed, men. Men and women who are not heterosexual are also less likely to be right-handed than are heterosexual men and women (Blanchard & Lippa, 2007; Lalumiere, Blanchard, & Zucker, 2000).

The causes of variability in sexual orientation have been suggested to differ for men and women (see also Diamond, Bonner, & Dickenson, Chapter 21, this *Handbook*, this volume). For instance, as noted above, evidence of a genetic contribution is stronger for men than for women, and the influence of older siblings does not appear to apply to women. In addition, sexual orientation appears to be more variable over the lifespan in women than it is in men (Baumeister, 2000). One study (Diamond, 2008) followed 79 lesbian, bisexual, and "unlabeled" women over 10 years and found that two thirds of the women changed their sexual orientation label over this period and one third changed their label more than once. It has been suggested (Diamond, 2007) that a dynamic systems approach is likely to be particularly informative in studying factors influencing sexual orientation in women, in part because women can show rapid shifts in their sexual orientation identity, and dynamic systems analysis are

particularly suited to examining stability and change in behavior. Dynamic systems analyses have not yet been used in studies of sexual orientation, however.

In summary, studies from several independent research groups suggest that exposure to high levels of androgenic hormones prenatally increases the likelihood of bisexuality or homosexuality in women. There is some support for a similar influence of estrogen exposure prenatally, although there is, as yet, no independent replication of this finding. Also, prenatal exposure to high levels of androgens does not lead to a nonheterosexual orientation in all individuals. For instance, among women exposed to high levels of androgens before birth, because of the genetic disorder, CAH, sexual orientation is typically heterosexual, although the likelihood of being bisexual or homosexual appears to be about 30%, well above the less than 5% that would be expected in the general population. There is limited systematic information on sexual orientation in men with enzymatic deficiencies that limit androgen production, but it appears that those who choose to live as men also have a sexual orientation toward women. These findings suggest that reduced androgen in males during early development does not necessarily lead to reduced heterosexual orientation. When the testes are removed prior to puberty in individuals with the same disorders, sexual identity and, apparently, sexual orientation often remain female-typical. These different outcomes suggest that the effects of uncorrected androgen exposure at puberty, particularly the development of a male phenotype at this time, might make it easier to adopt an identity and sexual orientation that matches physical appearance. Other possible explanations of the link between androgenization at puberty and sexual orientation toward women include social and cultural factors that might make it desirable to be a heterosexual male. The sexual orientation of men does not seem to be influenced by prenatal exposure to the synthetic estrogen, DES, or to progesterone or synthetic progestins, but it does appear to have some heritability. Reduced likelihood of sexual attraction to women has also been related to the number of older brothers, at least among right-handed men, although the reason for this relationship is unknown. A similar effect of older siblings is not seen in women, and women's sexual orientation is more changeable over the lifespan than is men's, suggesting influences of as-yet-unidentified life experiences.

Personality

Girls and women with CAH show increased propensities to behave in physically aggressive ways. This has been found

in two studies, one comparing girls with CAH to their unaffected female relatives (Pasterski et al., 2007), and one of female adolescents and adults with CAH, again compared to unaffected female relatives (Mathews, Fane, Conway, Brook, & Hines, 2009). The first study used a standardized questionnaire involving maternal reports about their children's aggressive behavior, and the second used retrospective reports by individuals about their own behavior in late childhood, again using a standardized instrument. In both studies, girls, but not boys, with CAH were found to show increased propensities for physical aggression. Other studies have not found increased aggression in girls with CAH (Erhardt & Baker, 1974; Ehrhardt, Evers, & Money, 1968), or have produced inconsistent findings (Berenbaum & Resnick, 1997), perhaps because the studies used relatively small samples or interviews with the girls' mothers, instead of standardized assessment instruments. Oddly, one review (Jordan-Young, 2010) suggested that studies assessing aggression directly in girls with CAH do not find increased aggression, but this is not the case, unless maternal interviews are viewed as direct assessments. Consistent with the findings of increased aggression in females with CAH, a study of children whose mothers took progestins, most of which were androgenic, during pregnancy, found increased propensities for physical aggression, assessed using a standardized instrument, in both progestin-exposed girls and boys compared to same-sexed siblings born of pregnancies where no hormones were taken (Reinisch, 1981). In this last study, potential confounding influences of genital virilization did not exist because all of the girls in the study had been born with unremarkable female external genitalia. There are no published reports on correlations between normal variability in testosterone prenatally or neonatally and subsequent physical aggression.

For both boys and girls, extreme maltreatment is associated with increased aggressive behavior. Also, although history of maltreatment has been found in some studies to interact with genetic factors in influencing maladaptive outcomes, it appears that high levels of trauma also produce maladaptive outcomes regardless of genotype (Weder et al., 2009). Parenting behaviors, such as harsh discipline, low warmth, and neglect also predict children's aggression (Sameroff, Peck, & Eccles, 2004; Serbin & Karp, 2004), and these effects can be mediated by altered cognitive biases, such as propensity for hostile thoughts and attributions, and by social learning, including the modeling of parental aggression (Chang, Schwartz, Dodge, & McBride-Chang, 2003; Serbin & Karp, 2004). Thus, there are powerful influences of adverse environments on

aggressive behavior, but these do not necessarily appear to be gender specific, and so are unlikely to explain differences between males and females in physically aggressive behavior. Negative peers and poor school success are also associated with increased aggressive behavior, however (Sameroff et al., 2004), and these characteristics tend to be more common in boys than in girls. Similarly, some activities that attract boys more than girls, such as aggressive computer games and drug use, are also associated with aggression. In addition, the same kinds of social and cognitive mechanisms that shape gendered toy choices could operate to shape gender differences in aggression (Bandura, 1973). Generally, aggressive behavior is not encouraged in boys or in girls but more men than women behave aggressively, and so boys might model aggression as a masculine behavior. The classic study (Bandura, Ross, & Ross, 1961) in which children watched male and female models behaving aggressively with a pop-up "Bobo" doll, concluded that both boys and girls modeled physically aggressive behavior, particularly in male models, but that boys modeled the physically aggressive behavior of male models more than girls did. Social cognitive approaches to understanding the gender difference in aggressive behavior have found that girls are more likely than boys to think that the victims of their aggression suffer, and to think that they themselves will be punished for aggressive behavior (Perry, Perry, & Rasmussen, 1986). Both of these beliefs would be expected to reduce aggressive behavior.

Levels of testosterone in adulthood are widely assumed to influence aggressive behavior. In particular, the use of androgenic steroids, for instance among body builders, is thought to increase aggressive behavior. Because men have more circulating testosterone than women, testosterone-induced enhancement of aggression could explain men's higher levels of aggression. It has not been possible to demonstrate this type of effect empirically in humans, however. Correlations between testosterone and aggressive behavior in men are small (Archer, Birring, & Wu, 1998; Book, Starzyk, & Quinsey, 2001). In addition, because testosterone is released in response to experience, including stress and the experience of winning a competition, the small correlation could reflect an effect of behavior on testosterone as easily as an effect of testosterone on behavior. Studies in which men were treated with testosterone generally do not find that the treatment increases anger or aggression (Alexander et al., 1997; O'Connor, Archer, Hair, & Wu, 2002; Tricker et al., 1996). These results contrast with data from other species, such as rats, where changes in testosterone alter the likelihood of

aggression (Simon, 2002). Perhaps the strong socialization to avoid physically aggressive behavior in contemporary life overrides a similar link in humans.

Empathy has also been studied in relation to the early hormone environment. Females with CAH have been found to score lower than unaffected female relatives on a standardized personality measure of empathy (Mathews et al., 2009). Because females typically score higher on this measure than males do, this would represent a masculinizing effect of early testosterone exposure. Empathy has also been related to prenatal testosterone exposure as measured in samples of amniotic fluid. There are several studies, from one research group, relating amniotic fluid testosterone to empathy and these studies have operationalized empathy in various ways. One study found a negative relationship between testosterone and empathy assessed by questionnaire in boys but not in girls (Chapman et al., 2006). In the same study, some participants were asked to judge emotions from pictures of eyes, and empathy assessed using this measure was related to amniotic fluid testosterone in boys and in girls. In another subsample, amniotic fluid testosterone related to the frequency of using intentional statements to describe interactions between cartoon images of moving triangles in boys but not in girls (Knickmeyer, Baron-Cohen, Raggatt, Taylor, & Hackett, 2006). In this subsample, girls also used more mental and affective state terms than boys did to describe the interactions between the triangles, but use of these terms was unrelated to amniotic fluid testosterone in either sex. These somewhat inconsistent results for relationships between empathy and amniotic fluid testosterone may reflect a lack of power. For instance, amniocentesis cannot be done for experimental purposes and clinical amniocentesis provides only a single sample for measuring testosterone. In addition, testosterone concentrations vary with time of day, and this was not controlled for in the studies.

Other approaches to understanding individual differences in empathy have examined social and cognitive influences. For instance, empathy is considered to be a feminine characteristic and so females might want to appear empathic. They also receive more socialization to show empathy and other caring behaviors than boys do (Eisenberg, Fabes, & Shea, 1989).

Like empathy, parenting interest is viewed as more important for females than for males, and in most countries, women are eligible for more parental leave than men. There is no evidence, however, that single male parents, or two male parents, have children who are less competent intellectually or emotionally than those in

comparable female-parented families (Golombok, 2000). Three studies, using a small number of interview questions, have reported that girls with CAH show reduced interest in babysitting and other aspects of childcare, including having children of their own, however (Dittmann, Kappes, Kappes, Börger, Stegner, et al., 1990; Ehrhardt & Baker, 1974; Ehrhardt et al., 1968). A study using a questionnaire to assess interest in infants produced equivocal results (Leveroni & Berenbaum, 1998), but a subsequent study using the same questionnaire in a larger sample found that females with CAH showed reduced interest in infants (Mathews et al., 2009). There are no studies relating normal variability in the early hormone environment to interest in infants or in parenting. As noted above, there are also influences of life stage on interest in infants in both men and women, suggesting influences of the environment or of experience on gender differences in this area.

In summary, there are powerful environmental influences on propensities for aggressive behavior, and boys may acquire aggressive behavior in part by imitating other boys and men. Also, boys and men who socialize largely with other boys and men might be at increased risk of both engaging in and receiving physical aggression, because boys and men engage in behaviors, such as drug use, that are risk factors for aggression, more than do girls and women. In addition, the early hormone environment appears to contribute to differences in aggressive behavior, with prenatal exposure to higher than normal concentrations of testosterone associated with increased aggressive behavior in females. Prenatal exposure to higher concentrations of androgens also increases the likelihood that individuals will choose to play with boys as opposed to girls (Hines & Kaufmann, 1994). Thus, the early hormone environment could initiate processes that alter the social environment, and self-socialization processes, in ways that increase the risk of physical aggression. The common belief that testosterone in adulthood increases human aggressive behavior has not been supported empirically. Empathy and interest in infants are also influenced both by environmental and hormonal factors, with early androgen exposure appearing to play a role in reducing empathy and interest in infants. Life stage also seems to be particularly important for interest in infants. There is as yet little or no work attempting to integrate understanding of how different types of factors interact to shape empathy or interest in infants and in parenting, however, nor is there research directly examining these types of interactions in the context of gendered aspects of aggressive behavior.

Cognition

Studies attempting to identify the causes of gender differences in human cognition have investigated the contributions of genetic factors, the early hormone environment, and postnatal socialization and social experiences, as well as possible contributions of hormonal differences between men and women at or after puberty. In regard to genetic influences, it was once thought that genes on the sex chromosomes explained the male advantage on visuospatial tasks (Maccoby & Jacklin, 1974). Subsequent research, on larger and more representative samples, did not support this conclusion, however.

More recently, it has been suggested that differences in androgen concentrations in male and female fetuses might explain gendered performance on spatial tasks. Some studies have reported enhanced mental rotations performance (Berenbaum, Korman Bryk, & Beltz, 2012; Resnick, Berenbaum, Gottesman, & Bouchard, 1986), or enhanced performance on other spatial tasks (Berenbaum et al., 2012; Hampson, Rovet, & Altmann, 1998; Mueller et al., 2008) in girls or women with CAH. Other studies have not produced similar findings, however (Baker & Ehrhardt, 1974; Helleday, Bartfai, Ritzen, & Forsman, 1994; Hines, Fane, et al., 2003; Malouf, Migeon, Carson, Pertrucci, & Wisniewski, 2006; McGuire, Ryan, & Omenn, 1975). The study investigating mental rotations performance in the largest sample studied to date used two mental rotation tasks that showed large gender differences, but found no significant difference between females with and without CAH (Hines, Fane, et al., 2003). One possibility is that the studies finding links between spatial abilities and CAH in females relied on small samples, truncated age ranges and selective reporting of measures, leading to spurious findings.

Studies relating testosterone measured in amniotic fluid to cognition have also produced mixed results. One study found an unpredicted negative relationship between amniotic testosterone and block building in girls, and no relationship between testosterone and any of 11 abilities measured in boys at age 4 years (Finegan, Niccols, & Sitarenios, 1992). At age 7 years, the same researchers found no relationship between amniotic testosterone and mental rotation scores (Grimshaw, Sitarenios, & Finegan, 1995). They reported a positive relationship between testosterone and speed of rotation in a subset of girls who used rotational strategies, but speed of rotation did not differ by gender. The authors also reported a negative correlation between testosterone and speed of rotation in boys, although this relationship was in the opposite direction to

that anticipated, and only significant when some data points were removed from the analysis. These researchers also reported on two variables that showed gender differences, spatial play experiences and mental rotation response times, but scores on these variables did not correlate with amniotic testosterone. A study of a separate sample of children also related testosterone measured in amniotic fluid to later performance on measures of spatial ability, including a mental rotations task and a disembedding task (Auyeung et al., 2012). Although the mental rotations task showed the expected gender difference, mental rotations performance did not relate to amniotic testosterone in either males or females. Performance on the disembedding task did relate to testosterone and this task showed a large gender difference in this particular study, although disembedding tasks typically show small to negligible gender differences.

Another approach to measuring normal variability in the early hormone environment has been to assay hormones in umbilical cord blood at birth. A study using this approach found no relationship between testosterone or other hormones and cognitive performance at 6.5 years of age in boys (Jacklin, Wilcox, & Maccoby, 1988). In the same study, two androgens, testosterone and androstenedione, each showed a negative relationship to performance on a spatial task in girls, findings contrary to prediction. None of the cognitive tasks used in this study showed significant gender differences, however, hampering interpretation of the findings.

Historically, researchers have sometimes been quick to conclude that inborn factors cause differences between males and females in overall intelligence or in spatial and mathematical potential. This history deserves mention, because remnants of it remain in scientific debates today. The attribution of gender differences in spatial abilities to genes on the sex chromosomes provides one example. The attribution of these same gender differences to differences in testosterone prenatally may be another. A third example of this historical pattern involves studies of general intelligence in individuals with CAH and in individuals exposed to androgenic progestins prenatally. Early reports suggested that intelligence scores in these groups were elevated compared to population norms, and led to the conclusion that early androgen exposure produced enhanced intelligence (Ehrhardt & Money, 1967; Money & Lewis, 1966). Later, however, this apparent effect of androgen on intelligence was shown to be unreliable—the result of comparing patients to outdated or otherwise inappropriate norms. When individuals with CAH were

compared to their relatives or to well-matched controls, their intelligence scores did not differ (Baker & Ehrhardt, 1974; McGuire et al., 1975; Wenzel et al., 1978). Research investigating intelligence test scores in individuals whose mothers took androgenic progestins, anti-androgenic progestins or the synthetic estrogen, diethylstilbestrol (DES) during pregnancy has also found no differences between them and relative or matched controls (Hines & Sandberg, 1996; Hines & Shipley, 1984; Reinisch & Karow, 1977). These results are unsurprising, because general intelligence shows no appreciable gender difference and so would not be expected to relate to exposure to gonadal hormones. Finally, some studies have reported reduced intelligence in individuals with CAH compared to matched controls (Helleday et al., 1994; Johannsen et al., 2006). These reports probably reflect different selection biases in individuals with CAH and their families as opposed to individuals recruited from the general population. Among the general population, more intelligent or educated people may be more likely to volunteer for research, whereas among patients and their families, people may be equally likely to volunteer across the full spectrum of education and intelligence. Consistent with the idea that selection biases differed in the two groups, both studies reporting reduced intelligence in individuals with CAH found that a far larger percent of the eligible CAH population than of the eligible control population agreed to participate.

Performance on tasks at which females outperform males, including verbal fluency and perceptual speed, might be expected to be impaired by prenatal exposure to androgens, and thus girls or women with CAH might be expected to show reduced performance on these types of tasks. Generally, however, girls and women with CAH have been found to perform like female controls in these areas (Baker & Ehrhardt, 1974; Helleday et al., 1994; Malouf et al., 2006; McGuire et al., 1975; Resnick et al., 1986; Sinforiani et al., 1994). In contrast to most findings, one study reported impaired performance on a measure of perceptual speed in girls with CAH (Hampson et al., 1998), but the sample in this study was very small (seven girls with CAH and six unaffected girls). Thus, the finding could be the product of chance.

Some have speculated that the male advantage on some standardized tests of mathematical ability, like the SAT, are caused by the sex difference in androgen concentrations during prenatal development (Benbow, 1988; Benbow & Stanley, 1983). However, there are no empirical findings supporting that conclusion, and the limited evidence from studies of individuals with CAH argues against it. Several

studies have reported decrements in arithmetic and mathematical performance in children of both sexes with CAH (Baker & Ehrhardt, 1974; Perlman, 1973; Sinforiani et al., 1994). Although this is not always found (Helleday et al., 1994), there are no reports of enhanced arithmetic or mathematical performance in girls or women with CAH, and no reports associating normal variability in early testosterone exposure with later performance in these areas.

Prenatal exposure to high levels of estrogenic hormones does not appear to influence the development of cognitive abilities that vary by gender. Women exposed to DES, for example, perform like their unexposed sisters on a range of gender-related abilities, including mental rotations, spatial perception, verbal fluency, and perceptual speed (Hines & Sandberg, 1996; Hines & Shipley, 1984). Additionally, a large, double-blind study found that females exposed to DES prenatally did not differ from placebo-treated females in performance on any of four American College Testing subtests that showed gender differences. Among males, those treated with DES scored higher than those treated with placebo on one of the four tests, a test that males excelled at. This difference had not been predicted, and the authors attributed it to chance (Wilcox, Maxey, & Herbst, 1992). A study of 10 pairs of brothers in which one was exposed to DES, and the other was not, reported reduced performance in the DES-exposed boys on a composite of three subtests from the Wechsler Intelligence Scales—Picture Completion, Object Assembly, and Block Design. The 10 pairs of brothers did not differ on composites of verbal or sequencing subtests (Reinisch & Sanders, 1992). All of these subtests show small to negligible gender differences, and the results for the performance subtests are likely to have been spurious, particularly in light of the small sample.

Females with Turner Syndrome show some specific cognitive deficits, although they perform normally on measures of vocabulary and general intelligence (Garron, 1977). The best-documented deficit is in spatial abilities, although other abilities, including numerical ability, memory or attention, and verbal fluency, are also impaired (Ross & Zinn, 1999; Rovet, 1990; Temple & Carney, 1996; Waber, 1979). Males typically excel on some of the tests that show impairment, whereas females typically excel on others, and still others appear to be gender neutral. One study found that the impairments in females with Turner Syndrome were larger on tasks that show gender differences favoring either males or females than on gender neutral tasks (Collaer, Geffner, Kaufman, Buckingham, & Hines, 2002). The particularly marked impairments

on gendered tasks were interpreted to suggest that the cognitive deficits relate in part to gonadal hormonal deficiency. Impairment on tasks at which females excel may also support a role for ovarian hormones in feminization of some cognitive characteristics (Collaer et al., 2002). These findings of greater deficits on tasks at which males or females excel have not yet been replicated, however.

For men with IHH, reduced performance has been described on a variety of spatial tasks, including measures of mental rotations, spatial perception, and spatial visualization (Buchsbaum & Henkin, 1980; Cappa et al., 1988; Hier & Crowley, 1982). The first two categories of spatial tasks show appreciable gender differences favoring males, but the third does not. Men with IHH do not appear to show impairment on measures of vocabulary (Cappa et al., 1988; Hier & Crowley, 1982), but one study also reported that they showed reduced performance on a measure of verbal fluency (Cappa et al., 1988), a type of task at which females typically excel. Another study found that men who became hypogonadal after puberty showed no deficit in performance on spatial tasks, whereas those who had been hypogonadal from earlier in life did show this deficit (Hier & Crowley, 1982). This study also reported that treatment with testosterone in adulthood did not reverse the deficit in spatial performance. Because men with IHH appear to have normal concentrations of androgens before birth, but are deficient thereafter, these findings suggest that the early postnatal surge in testosterone that is seen in male infants might contribute to gendered aspects of spatial cognition. Evidence that boys and men with CAH show reduced spatial abilities, as well as reduced androgen concentrations shortly after birth, also supports this conclusion (Hines, Fane, et al., 2003).

Numerous studies have related variation in hormones after puberty to gendered patterns of cognition, but these studies also have not produced consistent outcomes. Although some reports suggested that hormonal changes across the menstrual cycle related to cognitive performance in predicted ways, for example, with women performing better on spatial tasks when estrogen was low (Hampson, 1990), and that treatment of XY individuals with estrogen as part of transitioning to live as women reduced spatial performance and increased verbal performance (Van Goozen, Cohen-Kettenis, Gooren, Frijda, & Van De Poll, 1995), these findings have not been replicated consistently (see, e.g., Epting & Overman, 1998; Gordon & Lee, 1993; Pomerleau, Teuscher, Goeters, & Pomerlau, 1994, for examples of failures to replicate menstrual cycle effects, and Miles, Green, & Hines, 2006; Wisniewski,

Prendevill, & Dobs, 2005, for failures to replicate the effects of estrogen treatment). Also, treatment of healthy men with testosterone in adulthood does not alter gendered cognition in expected ways. Instead, two studies have found that testosterone treatment has an effect opposite that predicted—improved verbal fluency, with no effect on spatial tasks (Alexander et al., 1998; O'Connor, Archer, Hair, & Wu, 2001). Similar treatment of hypogonadal men is also without effect on spatial abilities (Alexander et al., 1998; Hier & Crowley, 1982; O'Connor et al., 2001), as is testosterone treatment of boys experiencing delayed puberty (Liben et al., 2002).

Cognition has also been studied in individuals with CAIS. Ten patients with CAIS showed a deficit relative to their unaffected relatives on Block Design and other performance subtests of the Wechsler Scales (Imperato-McGinley, Pichardo, Gautier, Voyer, & Bryden, 1991). Because the Wechsler subtests show small to negligible gender differences, it is not clear that the deficit was related to the lack of androgen receptors. The small sample also limits confidence in the finding.

As discussed earlier, girls and boys tend to prefer different toys and activities, and these gender differences in the way children play could contribute to their development of different cognitive strengths. Activities that girls tend to engage in may promote verbal communication, for example, whereas those that boys tend to engage in may promote spatial abilities (Maccoby, 1966; Sherman, 1967). In support of this latter suggestion, girls who engage in boys' activities either spontaneously, or because of an experimental manipulation, have been found to show better spatial performance than those who do not (Sprafkin, Serbin, Denier, & Connor, 1983). In addition to these individual findings, meta-analytic results suggest that engagement in activities that males typically engage in is associated with better performance on spatial tasks (Baenninger & Newcombe, 1989).

Training also improves performance on spatial tasks, a finding that has been confirmed by meta-analysis (Baenninger & Newcombe, 1989). Training improves performance in both sexes, and does not always eliminate the gender difference in performance, although it has been suggested that it would do so if training continued to maximum performance (Terlecki & Newcombe, 2005). Computer and videogame usage are also associated with mental rotation performance, and play with videogames as part of an experiment protocol improves mental rotations performance (Feng, Spence, & Pratt, 2007; Terlecki & Newcombe, 2005). This effect can generalize to other

spatial tasks (Terlecki & Newcombe, 2005), and can eliminate the gender difference in mental rotations performance (Feng et al., 2007).

Cross-cultural evidence also suggests that social or cultural factors influence gender differences in cognitive performance. For instance, differences between the average child in two different cultures can be many times as large as the differences between girls and boys within a given culture. Looking at mathematics performance, for example, results from an international assessment in 2011 showed that students in Singapore performed the best, and that girls in Singapore performed somewhat better than boys, whereas boys in the United States performed somewhat better than girls (Mullis, Martin, Foy, & Arora, 2012). Gender differences were far smaller than cultural differences in performance. On the Numbers section of the test, girls and boys in Singapore scored 83 and 69 points higher than girls and boys in the United States. In contrast, in the United States, boys scored 10 points higher than girls. Other sections of the test, such as Geometric Shapes and Measures, showed cultural and gender differences similar in size to those seen on the Numbers section.

Similar findings have emerged from international testing on science performance (M. O. Martin, Mullis, & Foy, 2008). Here, again, the differences between cultures are far larger than the differences between boys and girls. Cross-nationally, girls outperformed boys. Singapore again scored the highest, and boys and girls in Singapore scored 46 and 51 points higher than boys and girls in the United States. The gender difference in performance in the United States was 12 points.

These cross-cultural differences do not appear to reflect genetic differences. The survey of science performance looked at some individual states in the United States, and found large differences in performance, despite similar genetic backgrounds. Students in Massachusetts were found to score like those in Singapore, and better than other students in the United States as a whole. Children in Massachusetts also showed a gender difference in performance favoring boys, whereas no gender difference was seen in Singapore. Taken together, these findings suggest that the educational environment in Massachusetts fosters high performance, but also introduces a male advantage, whereas in Singapore, high performance is fostered, with no difference between girls and boys.

There is also other evidence that the different patterns of mathematics performance in different countries are not the result of genetic differences. This evidence comes from studies of mathematics and reading performance in

15-year-old students from 40 countries. Overall, results showed a 10.5-point advantage on mathematics for boys, and a 32.7 point advantage for girls on reading (Guiso, Monte, Sapienza, & Zingales, 2008). More importantly, scores on a measure of gender inequality in individual countries positively predicted the size of the male advantage in mathematics performance, both for the sample as a whole and for the upper 1% of the distribution, so that countries that were less gender egalitarian showed bigger differences between males and females in math performance. These data suggest again that cultural factors contribute to the gender differences in this area. In addition, the size of the female advantage on reading related negatively to gender inequality, so that more gender egalitarian countries showed larger differences favoring females in reading. This study also compared subgroups of countries with high genetic similarity, and found the same pattern of results within these genetically similar countries, suggesting that the results cannot be explained by genetic differences between people from different countries.

Family factors and children's own expectations also play a role in the acquisition of gendered patterns of cognitive performance. In the United States, girls and their parents expect them to perform less well than boys on mathematics and such expectations relate to different performance (Eccles, 1994; Eccles & Jacobs, 1986, 1992; Eccles, Jacobs, & Harold, 1990). One specific way in which expectations can influence performance involves a process called stereotype threat. Stereotype threat can operate when negative stereotypes about a group's performance are activated. For example, as noted above, there is a stereotype in the United States that women are not as good at mathematics as men are. When this stereotype is activated, it is thought to have psychological consequences, such as increased anxiety, that impair performance. Stereotypes are generally known, but they can be made more salient by reminding people of them. If research participants are reminded of the stereotype that males perform better on certain tasks than females, females perform worse on the tasks than if they are told that males and females perform equally well (Cadinu, Maass, Rosabianca, & Kiesner, 2005; Good, Aronson, & Harder, 2008; Spencer, Steele, & Quinn, 1999). Stereotype threat can also be activated more subtly, for instance by having a woman take a mathematics test in a room with many men (Inzlicht & Ben-Zeev, 2000). The negative effects of stereotype threat are not limited to mathematics performance. Similar impairment has been seen in women's performance on other tasks that

are thought to favor men, including spatial tasks, such as mental rotations (Moe, 2009; Moe & Pazzaglia, 2006).

Stereotype threat is thought to act by limiting the resources available to perform tasks, by inducing stress and activating anxiety, and by leading to performance monitoring and attempts to suppress negative thought processes (Schmader, Johns, & Forbes, 2008). There is evidence suggesting that the effects of stereotype threat can be mitigated by training focused on emphasizing the ability to improve performance, or by training that helps individuals to see performance difficulties as caused by situational factors, such as moving to a new school or being assigned more difficult material, rather than by personal factors (Good, Aronson, & Inzlicht, 2003).

In summary, hormones, either during early life or after puberty, have been assumed to play an important role in the development of gendered cognitive performance. The evidence supporting this conclusion is not strong, however. In contrast, there is consistent evidence that training and videogame usage can improve the performance of females on spatial tasks at which males typically excel. In addition, stereotype threat appears to play a role in reducing the performance of females on these tasks and on measures of mathematical ability. There are also large cross-cultural differences in mathematics and science performance, and differences between the sexes are not consistent across nations. Nations where females perform more like males, or even better than males, on these types of tasks appear to be those that are characterized by more gender equality. The male advantage in mathematics correlates negatively with gender equality, and the female advantage in writing correlates positively with gender equality. However, there has been relatively little research on most aspects of cognitive performance at which females excel, such as verbal fluency, perceptual speed and writing. There has also been little research examining how the different factors that contribute to gendered aspects of cognition might work together or interact.

Psychiatric Diagnoses

Much research has attempted to discover the developmental origins of psychiatric conditions that differ by sex, but relatively little research has focused on the causes that might differ for males and females. In terms of the sex chromosomes, early hormone environment, social reinforcement, and cognitive developmental processes that are the framework of research on gendered development, the early hormone environment, particularly

concentration of androgens before birth, has received the most attention.

For instance, it has been suggested that prenatal exposure to the androgen testosterone contributes to the male propensity to be diagnosed with classic autism or other conditions on the autistic spectrum (Baron-Cohen, 2002). Initial studies provided some support for a contribution of early testosterone exposure to characteristics related to autism. Baron-Cohen's team reported that testosterone measured in amniotic fluid related positively to characteristics associated with autism, such as reduced empathy (Chapman et al., 2006; Knickmeyer et al., 2006). Also, girls and women exposed to high levels of androgen prenatally, because of CAH, have been found to show elevated scores on a questionnaire measure of characteristics related to autistic spectrum conditions (ASC) (Knickmeyer et al., 2006). None of the girls with CAH had scores sufficiently high to meet the criteria for diagnosis with an ASC, however. One study has looked directly for a link between testosterone measured in amniotic fluid and the likelihood of being diagnosed with classic autism or other ASC (Baron-Cohen et al., 2014). This study used information from a Danish Historic Birth Cohort, which stored amniotic fluid samples from individuals who could be linked to the Danish Psychiatric Central Register and so determine who later received an ASC diagnosis. Results suggested no difference in amniotic testosterone concentrations between 217 control boys and 128 boys diagnosed with classic autism or other ASC. The researchers measured several additional hormones in the amniotic fluid samples, including progesterone, 17alpha-hydroxy-progesterone, androstenedione, and cortisol, and they reported that a latent variable identified by a principal component analysis (which they labeled a steroidogenic factor) significantly predicted an ASC diagnosis. This factor could not be described as androgenic, however. This single significant relationship had not been predicted and so could be spurious. Regardless, the results did not support the idea that amniotic fluid testosterone concentrations contribute to the development of autism or other ASC. Other researchers have suggested that ASC and other developmental disorders that are more common in boys than in girls relate to genes encoded on the X and Y chromosomes (Reinius & Jazin, 2009; Skuse, 2006), although research to date is again inconclusive. There is no evidence that girls and boys are socialized in different ways that might lead boys to be more susceptible to ASC or other developmental disorders. Also, although ASC has been linked to altered gender identity development in the

form of increased gender dysphoria, this appears to apply to males and females equally and so is unlikely to explain the disparate sex ratio in ASC diagnosis.

As with autism, more males than females are diagnosed with obsessive compulsive disorder (OCD) and Tourette syndrome, and these disorders have also been suggested to relate to early testosterone exposure. Some support for this suggestion has come from evidence that individuals with these disorders are more masculine than other individuals in regard to other characteristics, such as childhood play interests, that have been related to prenatal testosterone exposure (Alexander & Peterson, 2004). There are no studies examining more direct links between early testosterone exposure and later diagnosis with OCD or Tourette syndrome, however. The possibility that these disorders relate to social or cognitive developmental processes that differ for males and females also has not been explored.

Just as testosterone has been suggested to contribute to disorders, such as autism, OCD, and Tourette syndrome, that are diagnosed more frequently in males than in females, testosterone has been suggested to protect against eating disorders, because these show the opposite gender pattern, being diagnosed more frequently in females than in males. One research team reported that female twins with male co-twins scored lower than those with female co-twins on a measure of disordered eating (Culbert, Breedlove, Burt, & Klump, 2008). This result was interpreted to suggest that females with male co-twins were exposed to some of their testosterone during fetal development and that this testosterone provided protection against disordered eating. The finding was not replicated, however, in a second twin study, using a different measure of disordered eating (Raevuori et al., 2008). Other research on the causes of the gender difference in eating disorders and other disorders that differ by gender have suggested that gender differences in emotion regulation may contribute (Nolen-Hoeksema, 2012). For instance, women tend to ruminate more than men do and this has been linked to greater depression and anxiety in women than in men. These findings do not elucidate the direction of possible causation, however, and they raise additional questions, such as why women ruminate more than men do. Again, as for other gender-linked disorders, links to social or cognitive processes involved in other aspects of gendered development have not been explored extensively.

The presence of substantial gender differences in many psychiatric diagnoses has been noted and highlighted as a possible clue to understanding the causes of these disorders (Rutter et al., 2003). There has been little systematic

research, however, applying understanding of the factors that produce gendered behavior more generally to guide research on the causes of disorders that differ by gender. What little research there is has focused largely on the sex chromosomes and on concentrations of testosterone during prenatal development. To date, this research has produced little convincing evidence to support contributions from either source. The main focus of the studies of contributions from early testosterone exposure, however, has been on testosterone measured in a single clinical sample of amniotic fluid, taken at an uncontrolled time of day, and this single measure may not provide a sufficiently sensitive measure of early androgen exposure (Constantinescu & Hines, 2012). There is also surprisingly little research looking at other types of factors known to influence the development of gendered behavior more generally, such as gendered patterns of social reinforcement or gendered cognitive frameworks. Thus, understanding of the factors that influence gender development more generally has yet to be utilized as effectively as it might be in exploring the causes of gender differences in psychiatric diagnoses.

THE GENDERED BRAIN

Understanding of the brain and its relationship to behavior has been an area of intensive recent research activity, and researchers interested in gender development have tried to identify aspects of brain structure and function that differ between males and females. One basis for this interest is the understanding that behavior requires the brain, so linking aspects of brain structure and function to gendered behavior could help identify neural regions that regulate gendered behaviors. Not too long ago, group differences in the brain, such as those between men and women, were also thought to suggest inborn, irreversible differences. The ways in which the brain changes both structurally and functionally in response to experience are now better understood, however, and the brain is now known not only to form new synapses, and grow and retract dendrites in adulthood, but also to produce new neurons. Thus, brain differences are no longer correctly interpreted to indicate inborn determination. Experience has to change the brain, otherwise we would not learn, and there is ample evidence of changes in brain structure as a consequence of a variety of experiences. It is useful to keep this concept of the changing brain in mind as you read about the gendered brain.

The most consistently replicated brain difference between men and women is that in overall brain size. The

male brain is about 11%–13% larger on average than the female brain (Luders et al., 2005; Pakkenberg & Voight, 1964). Although the sex difference in brain size was originally observed using brain tissue obtained at autopsy, it has also been found in studies using noninvasive approaches to visualize the brain. A 2014 meta-analysis of studies using noninvasive measures found that total brain volume was 11% greater in males than in females (Ruigrok et al., 2014), similar to the original findings based on autopsy material. This meta-analysis also noted that the great majority of studies of gender differences in brain structure have focused on adults, Ages 18 to 45 years, and so little is known about developmental trajectories. The size of the difference in the average adult male versus female brain also is similar in magnitude to the sex difference in adult body size, which is about 12%–15% (Peters, 1991). The implications of the gender difference in brain size are not known, although the larger brain could simply be one manifestation of the larger male body. Perhaps surprisingly, however, the correlation between brain size and height does not appear to be large ($r = .20$ in men and $r = .12$ in women) (Pakkenberg & Voight, 1964).

Subregions of the brain, like the entire brain, tend to be larger in males than in females, and the gender difference in overall brain size complicates the study of gender differences in its subcomponents (Luders et al., 2005). Some researchers have attempted to compensate for the larger male brain by dividing the size of subregions by total brain size, but this procedure tends to make most, if not all, subregions larger in the female brain—but perhaps only because they have been divided by total brain size.

More sophisticated approaches to adjusting for brain size, however, also suggest that numerous regions of the cerebral cortex are larger in the female than in the male brain, and that the female brain shows greater complexity and greater cortical thickness than the male brain (Luders et al., 2004, 2006). These differences cannot be explained simply by the larger male than female brain, however, because differences remain when male and female brains of equal size are compared (Luders, Gaser, Narr, & Toga, 2009). This study of male and female brains matched for size also evaluated very large male brains and very small female brains, and found no differences within either sex based on brain size. It also found no differences between the sexes in the proportion of gray matter, white matter, or cerebrospinal fluid. The comparisons of the male and female brains suggested three primary clusters of increased gray matter in the female brain. These were located in the left superior frontal gyrus, in the left superior

temporal gyrus, and in the right and left caudate, extending into adjacent areas of the basal ganglia and into the left orbitofrontal regions. Prior studies, using autopsy material and imaging of the living brain with other methods of adjusting for the larger male brain, have also found some areas of the brain that support language, including the superior temporal cortex and the dorsolateral prefrontal cortex, to be larger in female than in male brains (Harasty, Double, Halliday, Kril, & McRitchie, 1997; Schlaepfer et al., 1995). There is no evidence that any subregions of the brain are larger in males than in females when brains matched in size are compared (Luders et al., 2009). The relevance of areas of greater gray matter in the female than the male brain to behavior are largely unknown. As noted before, some brain areas that are larger in females than in males are involved in language processing and so the differences in these areas could potentially relate to the female advantage on tasks such as verbal fluency or reading. This possibility has not yet been explored, however.

Much research has also focused on the corpus callosum, the major fiber tract connecting the two cerebral hemispheres. A report on brains obtained at autopsy suggested that the posterior fifth of the callosum, as viewed in mid-sagittal section, was larger and more bulbous in female than in male brains (de Lacoste-Utamsing & Holloway, 1982). In addition, the maximal width of the splenium, the area of the splenium and total callosal area were all larger in females than in males, although these measurements were analyzed relative to brain size, which is, as discussed above, a problematic procedure. The same researchers replicated these results in a second sample of adult brains (Holloway & de Lacoste, 1986), and reported greater splenial width relative to brain size in female than in male fetuses (de Lacoste, Holloway, & Woodward, 1986). Subsequent narrative and meta-analytic reviews appeared to refute the existence of these gender differences (Bishop & Wahlsten, 1997; Byne & Parsons, 1993), but many studies included in these reviews used different methodology from that used in the original reports. For instance, some defined the margins of the splenium differently, or measured sections of the callosum without accounting for individual differences in curvature. Many studies also used clinical images, which were not necessarily designed to produce precise midline images. Because the fibers of the callosum fan out extensively after crossing the midline, such images could contain substantial error variability, reducing the power to detect differences. Some studies using procedures similar to those used in the original reports of gender

differences in the corpus callosum have also found gender differences, although these are smaller than they originally appeared to be. In addition, as noted above, the adjustments used to compensate for the larger male brain could have caused the apparent gender-related differences in the callosum. One study used template deformation morphometry (TDM) in an attempt to address this issue. TDM registers each subject to a template, avoiding the use of overall brain size to adjust for the difference in the overall size of the male and female brain, while still scaling volumes for overall size. This study found the splenium to be larger in females than in males (Dubb, Gur, Avants, & Gee, 2003).

The genu, or most anterior portion, of the corpus callosum also appears to show a gender difference, but in the opposite direction to that reported in the splenium. One study defined the genu as the most anterior fourth of the corpus callosum, as viewed in mid-sagittal section, and found that it was larger in men than in women (Reinartz, Coffman, Smoker, & Godersky, 1988). A second study focused on a smaller area of the anterior callosum, calling this the genu, and again found the genu to be larger in male than in female brains (Witelson, 1989). A third study, using TDM, found a similar gender difference in the genu (Dubb et al., 2003).

A third subregion of the corpus callosum, the isthmus, defined as the posterior third of the callosum minus the posterior fifth, both viewed in mid-sagittal section, has also been reported to vary by gender (Witelson, 1985, 1989), but for this gender difference hand preferences are important. The isthmus is smaller in people who use their right hand consistently across a range of motor tasks than in those who do not. Also, among these consistent right-handers, the isthmus is larger in females than in males, but among those who do not use their right hand consistently for motor tasks, there is no gender difference. These results, like those reported for the splenium, were debated and appeared not to be supported by other studies (Kertesz, Polk, Howell, & Black, 1987), but again, the methodology adopted in the failures to replicate was often different to that used in the original reports. Most notably, some studies used different procedures to define handedness groups, including defining groups based solely on the hand used for writing.

Corpus callosum anatomy has also been related to gendered cognitive functioning. Among women, the surface area of the posterior callosum, particularly the splenium, as viewed mid-sagittally, has been reported to correlate positively with verbal fluency, which is typically higher in women than in men (Hines, Chiu, McAdams, Bentler, & Lipcamon, 1992). This finding suggests a positive relationship between female-typical cognitive performance

and female-typical callosal structure. More recent studies, using improved technology, suggest that the corpus callosum is thicker in women than in men (Luders, Narr, Zaidel, Thompson, & Toga, 2006), and that its size, particularly in posterior regions, relates positively to general intelligence, controlling for overall brain volume (Luders et al., 2007).

Differences in the corpus callosum of males and females have also been studied in rodents, and in rodents rearing conditions appear to influence callosal anatomy (Juraska, 1991; Juraska & Kopcik, 1988). For instance, among rats reared after weaning in complex environments, involving group housing and new objects introduced into the cage daily, females develop more myelinated axons in the posterior callosum than males do. In contrast, among rats reared after weaning in isolation, involving no cagemates and no objects beyond those required to provide food and water, there is no gender difference. Similar differences in rearing conditions have been found to influence dendritic growth in several regions of the cerebral cortex, and these rearing differences can produce, enhance, reduce or reverse neuroanatomical differences between the sexes (Juraska, 1991). Thus, in rats, gendered brain structure can be altered by rearing conditions after weaning.

As noted above, neural gender differences have sometimes been assumed to have been in place since birth, and so to reflect inborn influences on gender-related development. In regard to the cerebral cortex, in particular, this assumption is unsafe. Many types of experiential factors appear to influence cortical anatomy. For instance, taxi drivers in London, who must memorize the routes between every possible London location, have larger hippocampi than other people, and the length of time that they have been driving a taxi positively predicts hippocampal size (Maguire et al., 2000). Similar differences are not seen among London bus drivers (Maguire, Woollett, & Spiers, 2006) who differ from taxi drivers in that they need to learn only a single route. Similarly, people who meditate have greater hippocampal and frontal gray matter volumes than people who do not (Luders, Toga, Lepore, & Gaser, 2009). The brain can also be changed by experimental manipulations of experience. People who are taught to juggle show a transient change in a neural region associated with complex visual motion (Draganski et al., 2004).

Subcortical regions of the brain that have been found to show gender differences in other species, such as the SDN-POA, have not been visualized in the living human brain. Three studies of brains obtained at autopsy, however, have reported a gender difference, similar to that in the rodent SDN-POA, in an apparently comparable region of

the human brain, called the third interstitial nucleus of the anterior hypothalamus (INAH-3). This region is larger in men than in women (Allen, Hines, Shryne, & Gorski, 1989; Byne et al., 2000; LeVay, 1991). Two studies have also found the SDN-POA to be smaller in homosexual than in heterosexual men, and similar in size to heterosexual women (Byne et al., 2001; LeVay, 1991). Another subcortical region, the central region of the bed nucleus of the stria terminalis (BSTc) has also been reported to differ by sex and gender identity, being larger in men than in women, and reduced in size in transwomen (natal men who have changed to live as women) (Zhou, Hofman, Gooren, & Swaab, 1995).

As noted above, some researchers study gender differences in the brain because they assume that any differences in brain structure are inborn and irreversible, although this assumption is incorrect. Similarly, correlations between gendered brain structures and gendered behavior do not necessarily mean that the brain regions are responsible for the behavioral outcomes. For instance, a third factor, such as early hormones or experiences, could cause both outcomes without there being a causal relationship between the two outcomes. The existence of these neural differences also does not mean that any related behavioral differences are inborn. As noted above, experience can influence cortical anatomy. Although less is known about possible experiential influences on the structure of subcortical neural regions, such as INAH-3 or BSTc, the possibility of similar effects cannot be ruled out. Surprisingly, the gender difference in the brain region that has been found to differ in transwomen is not present in children, although most transwomen report having felt gender dysphoric from childhood, suggesting that the neural difference appeared after the gender dysphoria, and so could not have caused the dysphoria.

In addition to investigating structural differences in the human brain, researchers have compared the function of male and female brains, using techniques such as functional MRI and positron emission tomography (PET). In general, it appears that male and female brains function similarly (Frost et al., 1999; Mansour, Haier, & Buchsbaum, 1996), including when they are performing tasks, such as mental rotation, on which one sex or the other excels (Halari et al., 2005). Although some differences in brain function have been reported, their significance is largely unknown, and results of these functional studies have been highly inconsistent.

Identifying functional differences in the brains of men and women is more complicated than it might appear. Many

methodological factors can influence the results obtained. These include, for example, the age of the individuals studied, their hand preferences, whether they are resting or conducting a task, the specific task that they are conducting, its difficulty level, their skill or prior experience with the task, the way responses are made, the specific imaging approach used, the procedures used to quantify neural functioning, and the statistical approach to analyzing the data. A 2013 review concluded that almost no two studies among the hundreds that have been conducted on human brain function used the same methodology (Button et al., 2013). It may, therefore, be unsurprising that there are as yet no consistent findings of gender differences in neural functioning that have been reliably related to gender differences in behavior.

In addition, there is some evidence that males and females may use different neural mechanisms to produce the same behavior. For example, a study assessing neural function using PET found that, among men, scores on the SAT Math correlated with activation in the temporal lobes, but that, among women matched to the men for mathematics performance, there was no correlation between performance and activation in this region or any other neural region (Haier & Benbow, 1995). Similarly, men and women have been reported to show different patterns of asymmetry of brain activation when performing similarly on a language task (Shaywitz et al., 1995). Performance on measures of intelligence have also been reported to correlate with the volume of different neural structures in men and women, with performance relating to frontal gray and white matter volumes in women, but to parietal regions in men (Haier, Jung, Yeo, Head, & Alkire, 2005). These are just a few examples of the numerous studies of this nature (for a review, see Halpern et al., 2007). It is important to note that these gender-related differences in neural activation or correlations of behavior with neural structure are typically reported for men and women showing similar behavioral performance, so they cannot explain behavioral differences between the sexes. It has even been suggested that differences between male and female brains help the sexes to function similarly (G. J. De Vries, 2004). From this perspective, some sex differences in the brain allow males and females to behave similarly, despite differing physiologically, e.g., in levels of circulating hormones.

In summary, several gender differences have been reported in the structure of the human brain, although the great majority have not been independently replicated. Exceptions are the larger male than female brain and the

larger INAH-3 in men than in women. The existence of these differences does not elucidate their origins. Any behavioral difference, regardless of the factors that produced it, will be reflected in brain structure or function. Thus, such differences, even if causally related to gendered behavior, could result from numerous types of influences or their interactions. Similarly, although correlations between some gender-related brain differences and some gender-related behavioral differences have been reported, neural plasticity and the inability of correlation to prove causation argue against interpreting these relationships as indicative of inborn influences. These studies of gender differences in the brain could help elucidate the neural mechanisms involved in generating gendered behavior, but the gender differences could result from inborn factors, or from life experiences, or, most probably, from interactions between different types of influences.

TOWARD AN INTEGRATED UNDERSTANDING OF GENDERED DEVELOPMENT

The genome, the early hormone environment, postnatal socialization by parents, peers, and others, self-socialization, and perhaps hormones at or after puberty all contribute to the development of gendered behavior. The specific combination of factors, and their weighting, appears to differ for different aspects of gendered behavior, however, at least in the cultural contexts where they have been studied to date. For instance, sexual orientation and gender identity appear to be less influenced by early androgen exposure than are gender-typed childhood toy preferences. In addition, gender differences in mathematics performance appear to be powerfully influenced by the social and cultural environment, and by expectations, with perhaps little or no role for androgen exposure, either early in life or after puberty. Genes on the Y chromosome, and other sex-determining genes, provide the foundation for all of these types of influences. They determine whether the gonads become testes or ovaries, which then produce differing concentrations of androgens that can influence the brain and behavior. In addition, gonadal steroids influence physical sexual differentiation, producing male or female phenotypes that then influence social responses to individuals based on their apparent gender. Children also develop an understanding that they are male or female and that males and females differ in their behavior, and they come to value adopting behaviors that conform to these differences.

Gender development involves systems interacting over time. The genetic, hormonal, social, cultural and cognitive developmental influences described above could provide components of such a system, but we have little information as to how these components work together. As outlined above, the available information suggests that differential treatment of children based on their gender begins as soon as that gender is known, with parents often selecting different names, clothes and room décor even before the child's birth. The newborn then enters a gendered environment, and is treated from the moment of birth somewhat differently, again depending on whether the child is a girl or a boy. This different treatment for girls and boys comes not just from parents but from many other people. Parents often dress children to signal their gender, for example, putting bows on the bald heads of daughters, thus facilitating this differential treatment by others. Eventually, children themselves signal their gender to others and value conforming to expectations of their behavior based on their gender.

In addition, children enter the world with propensities to develop somewhat different gender-related interests, based in part on their exposure to testosterone and perhaps other hormones prenatally. These different interests also influence parental behavior, because parents tend to encourage the activities that interest their children. These can be gender atypical activities, particularly for daughters. Children's individual interests also shape other aspects of their environments. Children with strong gender-typical (or atypical) interests are likely to gravitate toward other children with similar interests, thus pushing themselves further in the direction of strongly gender-typical (or atypical) behavior. The strength of children's gender identity also plays a role in their acquisition of gendered behavior. Children who are more strongly identified with their gender appear to do more self-socializing of gendered behavior. Gender identity is in turn influenced by exposure to androgens prenatally, and androgen could play a role in gendered development through the amplifying mechanism of gender identity.

QUESTIONS FOR FUTURE RESEARCH

Although some of the elements of the interactive systems involved in gendered development have been identified, still others may remain unknown. For instance, in mice, genes on the sex chromosomes appear to affect aggressive behavior and parental behavior, independent of gonadal steroids. Are there similar sex chromosomal influences

on human behavior? In addition, although much research has investigated social and cognitive influences on the development of children's gendered play, similar information about possible social or cognitive influences on other gendered behaviors, such as sexual orientation or gender identity, or the risk of receiving a psychiatric diagnosis that differs by gender, is less abundant. Also, normal variability in the early hormone environment has been related to subsequent individual variability in gendered play behavior in typically developing girls and boys. Similar influences of normal variability in hormones have not been investigated in regard to many other aspects of gendered behavior, including aggression, sexual orientation and gender identity, however. One challenge in conducting such studies has been finding a reliable method for assessing early hormonal exposure. Finger ratios that show a small sex difference have been used in many studies, but they appear to be unreliable reflections of the early hormone environment, even in large samples. Similarly, studies relating testosterone measured in amniotic fluid or umbilical cord blood to later cognitive outcomes have produced inconsistent results, perhaps because these sources of hormone measures have been available only on a single occasion, uncontrolled for time of day. Findings relating the area under the curve for testosterone measured repeatedly during early postnatal development to subsequent behavior (Lamminmaki et al., 2012) could provide a methodology for such studies, however. Testosterone can be measured in the saliva or urine of infants and can be obtained repeatedly at specified times of day, providing potentially stable estimates of early exposure, which could then be related to subsequent behavior. This methodology could enable dynamic systems approaches to hormone environment interactions during early development as well, since hormones, child behavior and parental behavior could be measured repeatedly during the first months of postnatal life—a period of great neurobehavioral plasticity.

One appealing aspect of a developmental systems perspective is that it can obviate the misleading nature versus nurture debate. The focus of developmental systems research is often on periods of change. The elements of the system at this time of change are examined and an attempt is made to discover how these elements combine to produce change at that time. The approach also can produce information that is directly relevant to intervention. For instance, such an approach to understanding the combinations of factors that influence girls to drop out of scientific or mathematical endeavors in adolescence could produce strategies for avoiding this drop out. Based on data suggesting that

gendered toy preferences emerge when children are Ages 12 to 24 months, this also would be an interesting period to study to understand the developmental systems involved in their emergence. Similarly, Ages 10 to 13 years might be of particular interest for studying persistence and desistance in individuals with gender dysphoria, and early to middle adolescence might be particularly relevant to studying systems involved in the greater incidence of depression in girls than in boys.

In general, identification of how the elements of interactive systems governing different aspects of gendered development work together would be a useful focus for future research. Such studies are challenging for many reasons, not least because boys and girls typically differ on several dimensions simultaneously. For instance, boys experience relatively high concentrations of testosterone during early development and then are socialized as boys, whereas girls experience relatively low concentrations of testosterone during early development, and then are socialized as girls. Individuals exposed to atypical hormone environments, such as girls with CAH, provide one approach to disentangling these factors, and studies of these girls have provided valuable information. However, more work of this kind would be useful. Other situations where one element of the system is altered, such as gender-typical socialization, would also be of value. Brain imaging has the potential to identify the neural systems related to gendered behavior, but, to date, has produced limited reliable information, partly because inconsistent approaches have been used across studies. It might be informative to explore possible changes in neural systems in response to alterations in the interactive systems involved in gendering. For instance, does playing videogames alter neural regions related to visuospatial abilities? Also, less effort has been devoted to understanding the feminine behavioral phenotype than the masculine behavioral phenotype. For example, more is known about the factors influencing sexual orientation in males than in females, and more is known about the origins of cognitive abilities at which males excel, such as mental rotations ability, than cognitive abilities at which females excel, such as verbal fluency or reading. The study of the feminine behavioral phenotype should be another fruitful area for future research.

CHAPTER 21

The Development of Sexuality

LISA M. DIAMOND, SUSAN B. BONNER, and JANNA DICKENSON

THEORETICAL FRAMEWORK	889
CHILDHOOD SEXUALITY	890
Sexual Arousal and Desire	891
Sexual Activity	892
THE PUBERTAL TRANSITION	893
Variability in the Timing of Gonadarche	893
Adolescent Sexual Desire	894
Gender Differences	894
Socialization and Sexual Scripts	895
ADOLESCENT SEXUAL BEHAVIOR	895
Adolescent Masturbation	895
Partnered Sexual Activity	896
Coitus	897
Timing of Coitus	898
Quality of Intercourse Experiences	900
Reducing Risks for Pregnancy and STIs	901
PARENTAL INFLUENCES	902
SEXUAL COERCION	904
NEW CHALLENGES: SEXUALITY IN THE INTERNET AGE	905
Access to Sexually Explicit Images	905
Electronic Communication	907

Historically, developmental science has adopted a relatively limited perspective on child and adolescent sexuality, perhaps best reflected by the fact that this edition of the *Handbook on Child Psychology* represents the first to include a stand-alone chapter on child and adolescent sexuality. The longstanding reluctance to systematically address issues of childhood sexuality represents the wider cultural view that child and adolescent sexual expression brings risks and dangers, and that optimal psychological development requires delaying sexual activity as long as possible, ideally until marriage. This view denies that sexual motivation, desire, behavior, and expression represent normative features of child and adolescent development that have the potential to foster and enhance the happiness, psychological development, and well-being of youth.

SEXUAL-MINORITY YOUTH	908
Defining the Population	909
Nonexclusive Patterns of Attraction	910
Same-Sex Attractions Versus Same-Sex Orientations	912
Change Over Time	913
Mental Health of Sexual-Minority Youth	914
Gender-Nonconforming Youth	915
Transgender Youth	917
Exposure to Stigmatization	918
FUTURE DIRECTIONS	919
Attention to Early Stages of Sexual Development	919
More Integrative Biosocial Models	920
Greater Use of Mixed Models	921
Integration of Dyadic Approaches	922
CONCLUSION: MOVING TOWARD MODELS OF POSITIVE SEXUAL DEVELOPMENT	923
REFERENCES	924

An increasing number of researchers have challenged negatively oriented perspectives on sexual risk, arguing for more sensitive, in-depth, multimethod investigations into positive meanings and experiences of child and adolescent sexuality that will allow practitioners to identify and encourage healthy sexual-developmental trajectories. Our review reflects a balanced approach: Although we devote appropriate attention to the risks associated with early sexual behavior, such as pregnancy, sexually transmitted infections (STIs), and sexual coercion, we also highlight the normative and healthy features of child and adolescent sexuality.

Our primary focus in this chapter is on child and adolescent sexual feelings and behaviors, including developmental changes in sexual desire and motivation, participation in

partnered and unpartnered sexual behavior, prevention of pregnancy and sexually transmitted infections, and sexual coercion. We also review the unique experiences of young people with same-sex attractions and behavior, as well as with atypical gender expression (i.e., *transgender* youth). This discussion is consolidated in a single section at the end of the chapter, rather than woven throughout the chapter, to reflect the fact that the vast majority of empirical research on adolescent sexuality has been based on exclusively heterosexual samples (or at least, those presumed to be heterosexual). Hence, by dividing the chapter in this way, we hope to remind readers that the findings of research on heterosexual youth may not generalize to youths with same-sex attractions and behaviors, or to transgender youths.

THEORETICAL FRAMEWORK

This review is theoretically grounded in “cascade” models of human development, in which early traits and experiences continuously feed forward to shape individuals’ changing skills, capacities, and propensities over time. Most notably, we draw on Bronfenbrenner’s person-process-context model of human development (1986), which emphasizes the dynamic processes through which individual-level characteristics (such as attachment style, temperament, etc.) interact with contextual factors (such as family environment, socioeconomic status, etc.) to shape developmental outcomes. Importantly, we do *not* interpret this to mean that cultural and contextual factors simply tweak processes that have already been fundamentally determined by biological factors, but that certain environmental contexts are determinative themselves, altering the expression of genetically based traits and leading to lasting changes in developmental trajectories (see Lickliter and Honeycutt, Chapter 5, this *Handbook*, Volume 1).

Based on these theoretical frameworks, this review is guided by three implicit premises about sexual development. First, *the individual’s developmental status shapes his or her sexual feelings, motives, and experiences*. Through childhood, adolescence, emerging adulthood, middle adulthood, and later life, the individual’s changing developmental status (including endocrinological, physical, cognitive, and socioemotional factors) influences his or her sexual urges, motives, thoughts, fantasies, goals, behaviors, and relationships and also the meanings attached to these phenomena. Hence, the very same sexual experience (for example, masturbation) may have

different antecedents and implications when pursued by a 5-, 21-, or 50-year-old, and the meaning of any such phenomenon cannot be fully understood without attention to its total developmental context. Second, *sexual feelings, experiences, and relationships shape social and psychological development*. As children become aware of sexual feelings and begin to explore sexual behavior (both partnered and solitary), they are increasingly tasked with challenges related to self-regulation and impulse control, and must also begin the complex process of navigating their own urges, impulses, and desires with their local culture’s developmentally specific expectations. Sexual feelings and experiences also prompt individuals to consider and question their conceptions (and their local culture’s conceptions) of gender and gender differences. Hence, childhood and adolescent sexual experiences are both outcomes and drivers of development across the lifespan, promoting continued growth by eliciting a changing repertoire of developmentally specific tasks and abilities. As individuals repeatedly strive to understand and meet their own sexual needs and those of different partners, they become increasingly adept at balancing a complex interplay of motives, fears, goals, and skills. As a result, each successive sexual experience is influenced by the individual’s current cumulative developmental history and also feeds forward to shape future development across multiple domains of psychological functioning.

The third premise follows directly from the first two: Because sexuality represents both the “output” of prior development and the “input” for forthcoming development, it exerts *cumulative, context-specific, and dynamic* influences on mental and physical functioning over the life span (see also Overton and Molenaar’s model of relational developmental systems in Chapter 1, this *Handbook*, Volume 1). In essence, this amounts to a cascade model of sexual development, in which the individual’s total trajectory of sexual feelings, experiences, and relationships exerts a lasting press on his or her ongoing psychosocial development (although, of course, some experiences and some periods of life will prove more influential than others). In the ensuing review, we will repeatedly reconsider whether certain types of sexual experiences—both positive and negative—have notably different implications depending on where they occur within an individual’s total sexual-developmental trajectory, and the processes through which these trajectories change and stabilize over time.

Given that our theoretical approach emphasizes the individual’s total sexual-developmental history, we begin as “early” in development as possible, with a review of

children's sexual feelings and behaviors (a topic that remains woefully understudied due to longstanding cultural taboos, as we discuss). We then discuss the biological and social factors that come into play during the pubertal transition and their immediate and long-range impact on the changing sexual experiences and expectations of male and female adolescents. With regard to activity, we take care to discuss and distinguish among three different forms of sexual activity—masturbation, penile-vaginal intercourse, and partnered activities *other than* penile-vaginal intercourse—in order to emphasize the fact that *all* of a young person's sexual activities are developmentally relevant, despite the fact that penile-vaginal intercourse has received the lion's share of cultural and scientific attention. We highlight what is known about the developmental onset of different behaviors, children's and adolescents' subjective assessments of the *quality* of their sexual experiences, risks regarding pregnancy and sexually transmitted infections, and sexual coercion.

We also discuss what is currently known about parental influences on their children's sexual development, their exposure to sexual risks and rewards, and we highlight some of the new sexual-developmental challenges posed by the Internet age, including adolescents' access to sexually explicit images and their use of the Internet to meet potential partners. The discussion then turns to same-sex sexuality and gender expression, providing a comprehensive review of what is known about the long-term development of young people with same-sex attractions, same-sex behavior, lesbian/gay/bisexual sexual identities, or atypical gender presentations. We focus on the etiology of these phenomena and the special challenges that they pose for youth and their families.

Although we devote a separate section at the end of the chapter outlining directions for future research, we have highlighted productive and provocative future research directions throughout the chapter, embedded within specific topic areas, hoping to provide a roadmap to the next generation of scientific research on this critical—but still understudied—area of human development. It also bears emphasizing that we have chosen to address ethnic and cultural differences in sexual expression throughout the chapter, rather than treating ethnic and cultural variation as a distinct topic in and of itself. This is done in order to explicitly avoid casting white sexuality as normative and ethnic-minority sexuality as “other”; this has been the unfortunate practice of much previous sexuality research, particularly in light of the fact that ethnic minorities in many industrialized Western countries show greater

sexual risks than Whites, including earlier age of onset of penile-vaginal intercourse, greater number of partners, higher rates of adolescent pregnancy, and so forth (see Agocha, Asencio, & Decena, 2014). Extensive research indicates that these differences are mediated by the social disenfranchisement, social stress, socioeconomic burdens, and family practices encountered by ethnic minorities (see Caputo, 2009). In other respects, ethnic minorities and Whites undergo fundamentally similar processes of sexual development with similar timetables and underlying mechanisms. Hence, in discussing relevant ethnic, cultural, and even socioeconomic variations in child and adolescent sexuality, our guiding assumption is that basic sexual-developmental processes characterize all adolescents, but that the exquisite sensitivity of these processes to ongoing and cascading environmental inputs gives rise to substantial social and cultural variation in the developmental trajectories of young people. Hence, no single group can be considered to show either “normal” or “atypical” sexual development: All sexual development is context-specific and takes shape to meet the adaptive challenges that are unique to the individual's local conditions.

CHILDHOOD SEXUALITY

Manifestations of childhood sexuality can be seen as early as the first few months of life. Childhood sexuality is defined using the framework put forth by de Graaf and Rademakers (2011), which incorporates a range of different phenomena including displaying or touching one's own genitals, looking at or touching the genitals of another, and the variety of feelings and psychological experiences that both motivate and result from these experiences. Observational data collected from parents and caretakers have consistently documented sexual interest and behavior in children as young as 2 years of age (reviewed in depth by de Graaf & Rademakers, 2011), yet the collective base of knowledge on these experiences, their normative developmental time course, and their phenomenology (from the child's perspective) is woefully limited, given that cultural taboos have made it difficult for researchers to systematically study these experiences (Lamb, 2013). In fact, the vast majority of published papers on childhood experiences of sexuality focus on the sexual *abuse* of children, rather than children's own volitional sexual activity (de Graaf & Rademakers, 2011). The lack of attention to normative features of childhood sexuality not only hampers our basic understanding of life-span sexual development,

but also hinders our understanding of how exactly sexual abuse alters the sexual-developmental trajectories of youth. In the glaring absence of basic knowledge regarding normative childhood sexual expression, many parents and clinicians treat *any* overt sexual feelings or behaviors during childhood as markers that the child might have been abused (Bancroft, 2003). This is problematic not only for its inaccuracy, but because it contributes to a general social climate—readily interpretable by children themselves—that their sexual thoughts and feelings are “bad” and should be hidden or suppressed.

Although parents and clinicians often seek to distinguish between “normal/harmless” and “unusual/dangerous” sexual behaviors, the empirical grounding for such a distinction is lacking. de Graaf and Rademakers (2011) point out that “unusual” sexual behaviors may not be harmful at all, whereas “normal” behaviors that are undertaken in a context of fear and shame may have notable negative repercussions. In order to appropriately discern the implications of different types of childhood sexual experiences, we need to understand children’s own emotions, cognitions, and interpretations regarding these experiences. However, this requires a level of detailed questioning that has historically been viewed as harmful by parents and institutional review boards. Hence, although the collection of basic, foundational, descriptive data about childhood sexuality—especially the earliest years of childhood—remains a key priority for future research (as it has been for the past 30 years), it is likely to remain out of reach for cultural and logistical reasons.

Sexual Arousal and Desire

It is impossible to reliably discern when children begin to experience feelings that adults would classify as sexual desire, given obstacles in language, terminology, and communicative competence. Sexual desire is typically defined as “a wish, need, or drive to seek out sexual objects or to engage in sexual activities” (Regan, 1998, p. 346), and hence it is a fundamentally subjective experience that often diverges from physiological arousal. Accordingly, studies of sexual desire and arousal in adults typically rely on self-report, and these reports show remarkably diverse interpretations and phenomenologies (e.g., Diamond, 2008b). The same is likely true of children. Freud (1905/1962), of course, famously theorized that children’s sexual drives remain “latent” until puberty, but there is no empirical evidence to this effect (Lamb, 2002; Okami, Weisner, & Olmstead, 2002). Herdt and

McClintock (2000) argued that a key developmental transition for children’s sexual desires occurs between 6 and 10, when the adrenal glands reach maturation (denoted adrenarche), and begin to produce adrenal androgens such as DHEA, DHEAS, and androestione. DHEAS is thought to be the marker of adrenarche and gradually rises from mid-childhood to early adulthood, stimulating the growth of human pubic hair, axillary hair, as well as sweat and sebaceous glands. Developmental increases in DHEAS are thought to also trigger increases in erotic interest and attractions, and have been posited as an explanation for the fact that many adults recall their first memorable sexual attractions to peers as occurring around Age 10.

Within each developmental period, there is likely to be considerable diversity in experiences of sexual desire and arousal. In other words, sexual desire is not a uniform, unchanging experience, but one that takes different forms in different environments and at different stages. In particular, it is important to distinguish between an *interest* in sexual objects and a drive to *seek* sexual objects. This distinction has received much more attention in research on nonhuman primates than on humans (reviewed in Wallen, 1995). In the primate literature, the urge to seek and initiate sexual activity has been denoted *proceptivity*, whereas the capacity to become interested in sex upon encountering erotic stimuli has been denoted *receptivity* or *arousability*. Within-person and between-person variability in proceptive sexual desire has been shown to be tightly linked to corresponding variability in levels of gonadal hormones (specifically, testosterone in men and both testosterone and estrogen in women), whereas this is not the case for variability in arousability (reviewed in Diamond, 2006).

This difference may help to explain the distinction between childhood and adolescent sexual arousal and desire. Prior to puberty, children are clearly arousable, but do not show the intense sexual motivation and preoccupation with seeking sexual release that is partially attributable to pubertal surges in gonadal hormones (Udry & Billy, 1987). Social and cultural factors likely build upon these differences. Sexual arousal, desire, and behavior during the adolescent years receive widespread discussion by parents, educators, physicians, and the mainstream media, effectively “priming” youth to attend to increases in their sexual thoughts and urges. In contrast, childhood sexuality receives little explicit discussion, especially in front of children themselves, and hence some children may not even interpret their feelings or thoughts as sexual in nature.

The complex interplay between the cultural and biological determinants of maturational differences in sexual desire deserves substantive future study, and remains an important direction for future research (despite the ever-present cultural obstacles to such research). As argued by McClintock and Herdt (1996), sexual desire does not simply switch on at puberty, but instead undergoes gradual development over the course of childhood and adolescence, reflecting a progressive interbraiding of biological, social, and psychological transitions experienced within changing social contexts. Yet this general model leaves many details unspecified. For example, what are the contextual factors (ranging from family discussions of sexuality, media images, peer sex play) that influence children's abilities to reliably identify certain feelings and sensations as "sexual"? Do these influences change after the adrenarchal and pubertal transitions? How does the child's sexual phenomenology change as the "mix" of biosocial determinants changes? One intriguing (but untested) possibility is that prepubertal desires are akin to hormone-independent arousability, whereas postpubertal desires are akin to hormonally mediated (and more motivationally intense) proceptivity. Testing such possibilities, and investigating interindividual *variation* in maturationally specific sexual phenomenology, would not only contribute to the basic developmental science of childhood sexuality, but would also help us to understand how experiences of abuse, trauma, and neglect experienced at different ages have specific implications for the child's developing sexual self.

Sexual Activity

Perhaps the most reliable evidence of children's sexual interest and capacity for sexual pleasure is their participation in masturbation. Childhood self-stimulation is relatively common, with retrospective and observational studies suggesting that between 40% and 60% of children exhibit this behavior (Bancroft, 2003). Masturbatory behavior has been observed in children as young as 2 years old (Martinson, 1994) and genital touching has been observed in infants as young as 2 months, accompanied by signs of enjoyment such as flushing, sweating, and quick breathing (Leung & Robson, 1993). Importantly, we know little about children's motivations for self-stimulation (i.e., pleasure, relaxation, escape, curiosity, sexual release, etc.). Boys often discover self-stimulation accidentally, whereas girls are more likely to discover it through peers (Janssen, 2007). Little is known regarding children's interpretation of masturbation, and it is likely that parents' attitudes are

particularly influential in this regard: Small children may not perceive an inherent difference between scratching an itch and stimulating their genitals until their parents scold them for the latter and not the former. Gagnon (1985) interviewed 1,500 parents of prepubertal children, and found that most parents were aware of their children's masturbation, although less than half wanted their children to have positive attitudes about it, and these rates were even lower among highly religious parents. Peer disapproval of masturbation is also highly pervasive in many different cultures. For example, one study of Greek youth found that among the worst insults was to be accused by peers of masturbation (Papadopoulos, Stamboulides, & Triantafillou, 2000).

Like the research on children's masturbation, research on children's sexual activity with other children is largely based on parental observation and on retrospective reports collected from adults. Hence, these data reflect sexual activity that is observed, remembered, and reported to researchers, and not necessarily all of the activity that actually occurs. As with masturbation, these activities provide indirect evidence of children's sexual interest and capacity for sexual enjoyment, and are fairly widespread (although specific prevalence estimates vary widely across studies using different methodologies and assessing different behaviors). The most common sexual behaviors reported by and observed among children as young as 6 years of age include hugging and kissing other children or relatives, showing body parts to other children or viewing/touching other children's body parts (including genitals), masturbating with friends, making verbal comments to other children about sex, and playing role-play or fantasy games that incorporate these activities (Lamb, 2002; Pluhar, 2007; Thigpen, 2009). Studies have found no links between children's participation in wanted, consensual sexual activities and their future psychosocial adjustment (Okami, Olmstead, & Abramson, 1997), but it is important to note that adults retrospectively report widely different emotional responses to their childhood sexual experiences, and the nature of the specific activity pursued is a poor predictor of the individual's affective reaction to that experience (Lamb, 2002). Hence, as summarized by Lamb, adult categories of "trivial" versus "serious" sexual acts may be irrelevant for understanding how children respond emotionally to such acts, and the degree to which they experience them as positive and enjoyable. This issue touches on the larger question of how exactly children and adolescents define the construct of "sex," and how their definitions contrast with those used by adults. Lamb's interview research (2002)

suggests that whereas adults tend to define “mature” forms of sexual activity as those involving greater genital involvement, children define “mature” forms of sexual activity as those involving greater sexual arousal (as opposed to simple curiosity or play).

We will revisit the question of diversity in conceptions of “real” or “adult” forms of sexual experience in the context of adolescent sexual behavior, but we want to close this section by emphasizing, yet again, the importance of studying *children’s* sexual phenomenology, including their subjective experiences and interpretations of sexual activities. As with understanding the basic developmental maturation of sexual desire, we need a more comprehensive understanding of the factors that influence the changing motives for, and interpretations of, young people’s partnered and unpartnered sexual activities. Such knowledge can assist parents and clinicians in differentiating between typical and atypical trajectories of childhood sexual development, in identifying children with early developing sexual problems, and in reassuring parents and teachers about the benign nature of childhood sex play so that they do not introduce stigmatizing penalties for developmentally normative behavior.

THE PUBERTAL TRANSITION

Puberty has been historically treated as a milestone event in sexual development. Although the previous section demonstrates that prepubertal children clearly experience sexual feelings and engage in sexual exploration, the hormonal changes associated with gonadarche and adrenarche and the social and interpersonal changes that accompany early adolescence introduce new intensity into the sexual impulses and explorations of youth. Puberty consists of a complex cascade of neuroendocrine changes that promote development of the reproductive system and the transition to adulthood, including changes in height, weight, muscle mass, and fat distribution. In economically developed societies, this process begins around 10 for girls and 12 for boys and appears to be triggered in part by the achievement of critical body weight, weight-to-height ratio, and body fat ratio (Kasa-Vubu, Ye, Borer, Rosenthal, & Meckmongkol, 2006). Chemical and neural signals stimulate the hypothalamus to produce a signaling molecule, kisspeptin, which then stimulates secretion of GnRH (gonatropin-releasing hormone) from the hypothalamus. This leads to the release of LH and FSH from the pituitary gland, stimulating the production of gonadal hormones. In both boys and girls,

increased androgen levels are responsible for growth of pubic and axillary hair, and (in boys) muscular development and the deepening of the voice. Increased estrogen levels in both sexes produce increases in bone density, and in girls estrogen stimulates growth of the endometrium and breasts, widening of the pelvis, thickening of the mucosal surface of the vagina, and the onset of menarche.

Although researchers typically use menarche (i.e., the first menstrual period) as a marker of pubertal status, menarche is one of the last events in the overall sequence of girls’ puberty. Our culture has historically attached considerable significance to this event as the critical transition from “girl to woman,” despite the fact that a girl’s first year of menstrual cycles are typically anovulatory (Apter, 1980). The male equivalent of menarche is the first ejaculation (spermarche), which is marked by testicular growth and changes in texture of scrotal skin. In addition to the physical changes of puberty, there are notable social changes, especially given that pubertal changes in physical appearance tend to elicit changes in treatment from peers and family members, including increased rules and expectations from family, increased standing and expectations of maturity among same-sex peers, and increased sexual teasing, solicitation, and harassment from other-sex peers (McMaster, Connolly, Pepler, & Craig, 2002).

Variability in the Timing of Gonadarche

The average age of gonadarche for both girls and boys has been declining steadily in most developed countries since the mid-1800s, a phenomenon that Tanner (1978) called the “secular trend.” This trend (which is notably stronger for girls than for boys) is likely due to improved living conditions and nutrition, as the combination of extreme stress and malnutrition have been associated with pubertal delay (Dixon-Mueller, 2008). Extensive attention has been paid to psychosocial predictors of pubertal timing in contemporary society, and researchers have found that earlier puberty is associated with high levels of chronic family stress, experiences of maternal conflict in early childhood, and more internalizing problems in late childhood (Chisholm, Quinlivan, Petersen, & Coal, 2005; Kim & Smith, 1998). One particularly reliable predictor of early menarche among girls is paternal absence (reviewed in Ellis, 2004). Explanations for this effect center on evolutionary “life history” models. These models conceptualize girls’ pubertal timing as the endpoint of an evolved developmental strategy which *lengthens* the duration of childhood dependency if a girl has a high-quality

rearing environment with involved, engaged parents, but *shortens* childhood dependency if the rearing environment is neglectful or conflictual. According to Ellis (2004), the links between pubertal timing and contextual-psychosocial factors should be stronger for girls than boys because of the high energy demands of pregnancy and nursing. These demands create a starker trade-off for girls than boys between allocating resources to one's own physical growth and allocating resources to one's offspring.

The life-history perspective implies that variation in pubertal timing should be linked to variation in *subsequent* psychological and/or sexual development, and this view is supported by numerous studies. Early reproductive maturation predicts early dating, early participation in sexual behavior, more advanced sexual behavior, and (in girls) greater risk of pregnancy (Ellis, 2004; Mendle & Ferrero, 2012), although some of these associations are moderated by socioeconomic status and ethnicity (Cavanagh, 2004). Earlier pubertal maturation has also been linked to greater delinquency and rule breaking behaviors, and this association appears to reflect complex gene-environment interactions (Harden & Mendle, 2012). Specifically, data on twin pairs in the National Longitudinal Study of Adolescent Health indicate that early menarche, which is genetically influenced, renders girls more susceptible to nonshared environmental influences (i.e., those that differ between twins) on later delinquent behavior. Other studies have documented that individual differences in the basic levels of stress sensitivity of youth moderate links between maturation and later delinquency. For example, one study found that among later maturers, those with higher cortisol reactivity engaged in more rule-breaking behavior, whereas among early maturers, those with *lower* cortisol reactivity engaged in more rule-breaking behavior (Susman et al., 2010). These findings support the emerging view of "differential vulnerability," which postulates that risk and protective factors such as family environment and pubertal timing have different implications for later adjustment among children with different types and levels of stress sensitivity (Belsky & Pluess, 2009; Ellis & Boyce, 2008). Taken together, these findings indicate that links between pubertal timing and later development are moderated by a wide range of preexisting individual differences *and* social-environmental factors.

Adolescent Sexual Desire

It is commonly thought that sex drive is particularly potent during the adolescent years, due to the dramatic changes in hormone levels coupled with the increased cultural

emphasis on the emergent sexuality of youth. Although there is no definitive evidence that adolescents experience more intense sexual urges than either children or adults, some lines of brain research support this possibility. Adolescence is a key developmental period for the prefrontal cortex, which is critically involved in behavioral and emotional regulation, planning, and inhibitory processes. Moreover, adolescents appear to have a stronger subcortical responses and a weaker prefrontal (or regulatory) response to emotional stimuli. This "subcortical-PFC imbalance" (Somerville, Jones, & Casey, 2010) is thought to contribute to some of the emotional and behavioral changes associated with puberty. Hence, the combination of rapidly increasing gonadal hormone levels and subcortical sensitivity and underdeveloped inhibitory neural processes may render sexual urges particularly potent for adolescents.

Gender Differences

Gender differences in sex drive have long been a topic of research on adult sexuality (reviewed in Baumeister, Catanese, & Vohs, 2001), but little research has attempted to identify the specific role of puberty in their expression, and the relative (and interacting) roles of social and biological components of pubertal maturation (with some notable exceptions, such as Udry, 1988). Specifically, although research has long documented that adolescent and adult men report experiencing more frequent, intense, and preoccupying sexual desires than adolescent and adult women, the manner in which biological and cultural factors interact to shape this difference has been difficult to pin down. On the biological side, researchers have argued that the large postpubertal differences between boys and girls in circulating androgen levels helps to explain the fact that women tend to report less frequent and less intense sexual thoughts and feelings than do men. For example, Knoth, Boyd, and Singer (1988) found that male adolescents typically recall having experienced sexual arousal prior to Age 13, whereas girls report more variable timing. Many girls in their study recalled that their first experience of sexual arousal occurred several years *after* puberty, suggesting that adolescent girls' desire may depend more strongly on post-gonadarche changes in estrogen levels.

This possibility is consistent with research demonstrating the important role played by estrogen in female sexual motivation (Wallen, 2001), and also suggests the importance of attending to periodicity in girls' desires. Extensive evidence indicates that women's sexual desires, autoerotic activity, and motivation to initiate sexual activity

change as a function of fluctuating estrogen levels over the course of the menstrual cycle, peaking around the time of ovulation (reviewed in Diamond, 2006). We do not know, however, why some women appear to show more cyclic fluctuation in sexual motivation than others, and when such cyclicity develops. For example, one possibility is that it emerges as soon as women begin ovulating; another possibility is that it develops gradually, and may not fully emerge until young women have had a certain number of ovulatory cycles. Another unanswered question concerns pubertal changes in the basic female sexual arousal cycle. Although historical models of sexual desire have tended to view it as an innate, automatic, drive-like force that influences (but is not influenced by) sexual activity, research by Basson (2001) suggests that female sexual arousal is a more circular, responsive system, such that sexual activity sometimes provides a trigger for the experience of sexual arousal (rather than vice versa). Future research should investigate whether the female sexual arousal cycle has its own estrogen-dependent developmental trajectory. In other words, might girls and boys show similar arousal processes prior to puberty, but then diverge after the hormonal changes of puberty? Answering such questions would help to elucidate the potential biological basis of gender differences in sexuality, a topic of longstanding interest and debate.

Socialization and Sexual Scripts

By the time children reach puberty they have already encountered pervasive cultural messages suggesting that boys want sex more than girls do, and that a girl's role in the sexual marketplace is to be the "sexual gatekeeper," fending off boys' sexual overtures in order to guard themselves against pregnancy, STIs, and the appearance of being "loose" or "slutty." This view, of course, denies the realities of girls' own powerful sexual desires and their roles as sexual initiators. Fine (1988) criticized this cultural framework over 25 years ago in a seminal review of sex education discourses, noting that such discourses disempowered girls by casting them in a fundamentally receptive position and denying them the opportunity to explore and take responsibility for their own pleasure and desire. The result is that girls discount their own bodily experiences of sexual desire and dismiss their own motives for sexual contact (Tolman, 2002). For example, one study found that less than half of female teenagers reported that they could always detect when they were sexually aroused, compared to nearly *all* male teenagers (Knott et al., 1988). The cultural factors encouraging girls to discount and

dismiss their own capacity for sexual arousal continue to generate vociferous debate among youth advocates and developmental psychologists about the best way to encourage girls' sexual agency in a cultural climate that commercializes and commodifies their bodies and behaviors (APA Task Force on the Sexualization of Girls, 2010; Lerum & Dworkin, 2011).

Accordingly, one of the most important directions for future research on adolescent sexuality, and particularly girls' sexuality, involves the development of interventions and educational approaches that seek to reduce girls' sexual commodification and exploitation *without* inadvertently discouraging girls from expressing and embracing their own sexuality. Heated Internet debates in 2013 about sexually explicit performances by the former child star Miley Cyrus exemplify the difficulty of striking this balance. Cyrus first gained television fame as a young girl, and literally underwent sexual maturation in the public eye. At the age of 18, her use of near-nude costumes and sexually suggestive gestures and dance moves in her music performances generated widespread debate and criticism, with some commentators claiming that her early fame had left her with bad judgment, loose morals, and poor taste, others portraying her as the victim of mainstream sexual commodification, and still others championing her for showing that women could actively claim and act out their own sexual desires and fantasies. Many commentators were parents who wondered about the impact of Cyrus' developmental transformation on her young fans: What message about female sexuality was she sending? In truth, we know surprisingly little about how adolescent girls interpret the public shaming *and* public celebration of female sexuality, and whether there are certain messaging strategies that might prove effective in helping girls to navigate conflicting cultural messages as they chart their own healthy developmental trajectories. What is needed, instead of speculative complaints about various cultural "impacts" on adolescents, is rigorous research capable of documenting how the type, degree, context, and timing of adolescents' consumption of conflicting media messages about sexuality influences their developing sexual self-concepts.

ADOLESCENT SEXUAL BEHAVIOR

Adolescent Masturbation

Masturbation is the most common form of adolescent sexual behavior, and this activity tends to increase after gonadarche, particularly among boys (Herbenick et al.,

2010). Not only do boys generally engage in more masturbation than girls, but boys' rates of masturbation are more strongly associated with their pubertal status than is the case for girls (Bancroft, Herbenick, & Reynolds, 2003). Gender differences in masturbation appear to be sensitive to social and cultural factors: Bancroft et al. (2003) noted that social changes facilitating girls' sexual awareness and sexual self-expression have produced increases in girls' masturbation. Supporting this view, research by Shulman and Horne (2003) found that adult women reporting masturbation had higher levels of sexual self-awareness, greater expressiveness in their intimate relationships, and more resistance to sexual double-standards. Such findings suggest that as social restrictions on female sexuality continue to erode, adolescent girls will be more likely to masturbate and more willing to report doing so. This is consistent with the findings of Peterson and Muehlenhard (2007), who found smaller gender differences in masturbation within societies characterized by greater gender equality. Hence, the fact that researchers consistently find higher rates of masturbation among adolescent boys than adolescent girls appears to be more strongly driven by cultural factors (including cultural pressures on girls to underreport their masturbatory behavior) than by biologically based differences in girls' versus boys' desires for or enjoyment of sexual release.

Gender differences in masturbation are interesting not simply for what they tell us about basic differences between female and male sexuality, but also because they may have important health implications (Hogarth & Ingham, 2009). A small but growing body of research indicates that masturbation facilitates healthy sexual identity development and more satisfying partnered relationships by enhancing awareness of sexual needs and providing young people with satisfying alternatives to riskier sexual activities (Kaestle & Allen, 2011). Yet positive and health-enhancing views of masturbation may be relatively rare among contemporary adolescents, many of whom report guilt and shame regarding masturbation (Laumann, Gagnon, Michael, & Michaels, 1994). An important topic for future research concerns the potential effectiveness of sexual health interventions encouraging youth to replace partnered activities with masturbation in order to provide them with an outlet for sexual release that does not place them at risk for pregnancy and STIs. Currently, it is not clear whether—and for whom—such interventions might be effective, given that survey data indicate that adolescents who masturbate have higher rates of partnered sexual activities (Robbins et al., 2011). To be effective, it is likely

that public health approaches would have to make a specific case to youth about *replacing* partnered sexual activity with masturbation, rather than simply supplementing partnered activity with masturbation. This, of course, might be interpreted by many parents and educators as inappropriately "encouraging" masturbation among youth who have never done so. At the present time, we simply do not know whether such concerns are valid—nor do we know whether such interventions would be effective enough to warrant challenging social opposition. Hence, researchers should rigorously test the possibility of a "pro-masturbation" sexual health intervention, one that communicates to youth that they are entitled to sexual release, but tries to guide them toward solitary versus partnered activities for the time being. Decisions about the development and dissemination of such approaches should be based on solid empirical data on their risks and benefits, particularly for subgroups of youth at different stages of development and with different familial and cultural backgrounds.

Partnered Sexual Activity

The majority of youth report having participated in non-coital partnered activities such as mutual masturbation and oral-genital contact prior to Age 16, usually with partners of the same age (Bauserman & Davis, 1996). The question of whether adolescents tend to progress through noncoital activities in a particular order has been addressed by several national studies (Halpern, Joyner, Udry, & Suchindran, 2000; O'Sullivan, Mantsun, Harris, & Brooks-Gunn, 2007), and the results suggest that the most common sequence begins with mutual nongenital touching (such as fondling breasts) and then progresses to genital touching (first over and then under clothes), direct manual stimulation of the genitals, oral-genital contact, and penile-vaginal intercourse. Anal stimulation is relatively rare among adolescents, with participation rates around 10% (Lindberg, Jones, & Santelli, 2008), but becomes substantially more common in young adulthood, with one study finding that 30% of young adults had at least one experience with this activity (Leichliter, Chandra, Liddon, Fenton, & Aral, 2007). Hence, whereas most noncoital sexual activities tend to precede penile-vaginal intercourse developmentally, anal stimulation proves the exception, with most adolescents forgoing this activity until after they are older and more experienced.

Oral-genital stimulation appears to be increasingly widespread, although prevalence estimates range from less than 10% of youth to more than half (Chandra,

Mosher, Copen, & Sionean, 2011; Herbenick et al., 2010). Oral-genital contact tends to occur at the same age as first intercourse, but there is considerable variation in whether it is pursued before or after first intercourse (Chandra et al., 2011), given that some young people view it as more intimate and “advanced” than penile-vaginal intercourse whereas others view it as a precursor or substitute for intercourse (Cornell & Halpern-Felsher, 2006). Because adolescents tend to perceive oral-genital contact as a “safer” sexual activity than penile-vaginal intercourse, they are less likely to use protection against STIs (Prinstein, Meade, & Cohen, 2003). Furthermore, studies have found that although parent-child communication about the risks of intercourse predicts adolescents’ intercourse behavior, it does not predict their oral sex behavior; rather, young people’s oral sex behavior is more strongly influenced by whether they think their friends condone and participate in oral sex (Bersamin, Walker, Fisher, & Grube, 2006). In light of such findings, and in light of the increasing rates of oral sex among adolescents, a critically important direction for future research involves identifying the distinct motives, attitudes, myths, and concerns that youth bring to oral sex versus intercourse, the interpersonal contexts and social settings in which this behavior occurs, and the factors that facilitate or hinder the ability and willingness of youth to use protection against STIs. Such work will likely require an in-depth, narrative focus, such as that employed by Burns, Futch, and Tolman (2011) in their analyses of adolescent girls’ narratives of first fellatio experiences. Surprisingly, the authors found that half of their 98 interviewees invoked an “achievement discourse” when discussing their experiences and concerns with performing fellatio, expressing concerns over “doing it right,” obeying partner instructions, being evaluated positively, and simply “getting it done”—some girls explicitly likened the act to “homework.” Identifying and understanding such psychological contexts is critical for the development of educational interventions that can address young people’s questions, concerns, and motives for oral sex and facilitate their sexual decision-making. More substantive attention to gender differences is also critical. Contrary to the case of penile-vaginal intercourse, in which each act involves both genders, boys tend to receive more oral stimulation of their genitals than they provide to girls genitals (Chandra et al., 2011; Herbenick et al., 2010). This pattern is not surprising, given that it reflects longstanding power differentials between adolescent boys and girls that typically give boys more control over the selection of sexual activities. Yet given the increased rates of oral-genital contact,

research should specifically investigate whether gender imbalances in oral-genital contact within a couple have the effect of entrenching sexual scripts that cast girls in the role of “givers” but not “receivers” of sexual pleasure.

Coitus

The most widely researched form of sexual activity among adolescents is coitus, or penile-vaginal intercourse, reflecting the significant social and health implications of this behavior. Not only does coitus introduce risks for pregnancy and STIs, but it also serves as the cultural marker of “mature” sexuality. Perhaps the most important historical change regarding adolescent sexuality over the past 50 years is the increasing prevalence of premarital coitus, in both Western and non-Western countries (Centers for Disease Control, 2002; Dehne & Riedner, 2005). Cross-national data compiled by the World Health Organization indicate that most youth have engaged in coitus by the age of 20, although ages of first debut vary widely within each country, ranging from 12 to 24 (Dehne & Riedner, 2005). One of the persistent obstacles in tracking the timing of sexual debut concerns ambiguity among adolescents—both within and across cultures—regarding the specific acts that definitively “count” as sex. In a study by Peterson and Muehlenhard (2007), over one-third of respondents thought that they had engaged in sex if they had engaged in oral sex or mutual masturbation. Other young people claim that they have *not* had sex even if they have engaged in penile-vaginal penetration, as long as there was no thrusting and no ejaculation (a practice sometimes called “floating”). For youth living in restrictive cultural environments, adopting alternative definitions of sex allows them to retain their status as virgins and to maintain that they have not violated family, community, or religious guidelines forbidding premarital sex. Longitudinal studies have found that adherence to such guidelines motivates some youth to retract previous reports of virginity loss (Rosenbaum, 2006). Not only do such reversals create difficulties for researchers attempting to develop accurate models of adolescent sexual behavior, but they also pose difficulties for advocates attempting to educate adolescents about the risks of sexual activity. Youth who convince themselves and their peers that certain activities do not “count” as sex may have little motivation to use condoms or birth control. Perhaps for this reason, studies have found that adolescents taking a virginity pledge have STI rates that are just as high as youth who do not take such a pledge (Bruckner & Bearman, 2005).

The experience of orgasm also plays a role in young people's definitions of sex, depending on the relational context and on "who does what to whom." Some heterosexual college students believe that a man who penetrates a woman anally has only "had sex" if he experiences orgasm, whereas *vaginal* penetration is usually considered sex even if the man does not have an orgasm (Bogart, Cecil, Wagstaff, Pinkerton, & Abramson, 2000). Of course, vaginal penetration is always considered to be sex for the *woman*, regardless of whether she experiences orgasm, testifying to the historical inattention to women's experiences of sexual desire and satisfaction. As for oral sex, heterosexuals generally think that you "had sex" if you received oral sex, especially if you had an orgasm, but not if you were the one to *perform* oral sex (Sanders & Reinisch, 1999). These findings clearly indicate that adolescent sexual activity is not simply a sequence of physical acts, but a sequence of acts imbued with *personal and social meaning*. Accordingly, an important and vastly understudied direction for the next generation of research on adolescent sexuality involves assessing the multiple factors that inform the personal and social meaning that youth attach to penile-vaginal intercourse *and* a range of other sexual activities. Studies of adults reliably demonstrate that individuals with different social backgrounds, sexual orientations, and relationship histories place different value and importance on certain sexual acts, and these determinations do not always correspond to the perceived enjoyability or social acceptability of such acts. Currently, little is known about how young people at the beginning of their sexual-developmental trajectories move progressively from pre-event *expectations and motives* to their subjective experiences *during* sexual interaction to their postevent *interpretations, emotions, and cognitions*, all of which feed forward to direct future behavior. In line with our cascade model of sexual development, we believe that the value and meaning youth attach to different sexual experiences should be treated as critical developmental phenomena themselves, and investigators should develop and test hypotheses about specific developmental trajectories for certain sexual behaviors and certain types of relationships (for example, casual versus committed relationships). Such knowledge will not help us to identify, at an early age, youth who might be at risk for STIs, pregnancy, and sexual coercion, but may also help us to understand why some youth enter young adulthood with a strong sense of sexual pleasure and empowerment, whereas others enter young adulthood with a sense of sexual shame, anxiety, or disappointment. This knowledge may be particularly

critical for the treatment of adult sexual dysfunction, given that sexual dysfunction is known to be strongly influenced by a complex interplay among psychological, biological, and social/cultural factors (Laumann, Paik, & Rosen, 1999). By carefully attending to the progressive unfolding of children and adolescents' sexual cognitions and experiences, and to the ongoing revisions and elaborations in their desires, motives, and roles, we will be better able to model sexual function and dysfunction in adulthood as outcomes of lifespan developmental processes.

Timing of Coitus

Significant attention has been devoted to understanding factors predicting the timing of adolescents' sexual "debut" and the implications of early versus late timing. Contemporarily, the average age of sexual debut in the United States is approximately 16–17 (Cavazos-Rehg et al., 2009; Santelli, Lindberg, Finer, & Singh, 2007) and therefore young people whose first intercourse occurs after the age of 18 are generally considered "late" whereas those whose first intercourse occurs at the age of 15 or younger are considered "early." There are notable ethnic differences in the timing of sexual debut, with African Americans and Latino/a Americans showing earlier ages of debut and Asian Americans showing later ages (Cavazos-Rehg et al., 2009). Importantly, the designation of sexual debut after the age of 18 as "late" is a statistical category, rather than an ideological one. Many parents and educators would argue that there is no such thing as "waiting too long" to have coitus, and that adolescents should ideally forgo intercourse altogether until marriage. This approach is generally unsuccessful, given that 90% of youth under the age of 27 report having engaged in premarital coitus (Halpern, Waller, Spriggs, & Hallfors, 2006). Yet it bears noting that there have been declines in the rates of coitus among never-married youth in the United States (Centers for Disease Control, 2002), as well as notable declines in rates of adolescent pregnancy (Santelli et al., 2007). Even with these recent declines, U.S. rates of adolescent pregnancy and childbearing remain substantially higher than rates in other countries. For example, in 2009 the rate of teenage (Age 15–19) childbearing in the United States was 38 births per 1,000 girls, compared to 25 in the United Kingdom, 14 in Canada, 10 in France, and 5 in Japan (Kearney & Levine, 2012).

Studies have consistently found that youth whose first coitus takes place at earlier ages tend to show a variety of additional sexual risk factors and adjustment problems,

including lower rates of condom and contraceptive use, greater numbers of sexual partners, poorer grades, lower educational attainment, greater substance use, and greater delinquency (Haydon, Herring, Prinstein, & Halpern, 2012; Parkes, Wight, Henderson, & West, 2010). Yet early sexual debut does not appear to "cause" these outcomes: Rather, youth with early sexual debut appear to possess a range of characteristics that channel them into early sex *and* a host of other risky behaviors. For example, those with earlier pubertal maturation tend to show earlier sexual debut (Cavanagh, 2004), which may reflect the fact that they experience stronger hormonally mediated motivation to pursue sexual activity than their "on-time" peers, and that they tend to look more physically mature, increasing their desirability to older partners. Other studies have found that adolescents with earlier sexual debut tend to have higher levels of unconventionality, lower endorsement of prosocial norms, and that they come from families with lower incomes, less rule-setting, lower parental engagement and supervision, and lower parent-child relationship quality (Boislard & Poulin, 2011; Cavazos-Rehg et al., 2010; House, Mueller, Reininger, Brown, & Markham, 2010; Price & Hyde, 2009). One seminal study (Bingham & Crockett, 1996) followed a group of adolescents from a single school district in a rural community from 9th through 12th grade and found that the correlation between early sexual debut and later psychosocial problems was completely mediated by psychosocial problems *prior* to sexual debut. Such findings indicate that encouraging young people to delay sexual debut would not necessarily improve their adjustment outcomes or inoculate them against future risks. Rather, early sexual debut appears to be part of a trajectory of psychosocial risk that is set in motion long before pubertal maturation.

The longitudinal, biosocial research of Udry and colleagues (Udry, 1988; Udry, Talbert, & Morris, 1986) has focused on disentangling the relative impact of hormonal and social factors on girls' and boys' coital timing. Udry's work has used data on maturational changes in hormone levels in concert with detailed assessments of social-attitudinal factors, such as friends' participation in sexual activity, peer popularity, grades, sexual permissiveness, future orientation, parents' education, and locus of control. The results have revealed notably gender-specific patterns. Specifically, maturational changes in free testosterone levels were directly related to initiation of coitus for White males, to the exclusion of all social variables save for popularity among other-sex friends. Importantly, the pattern of results was the opposite among White girls.

Hormonal changes had no direct effect on girls' first coitus (although they significantly predicted girls' sexual thoughts and fantasies), and instead *every* social variable emerged as a significant and unique predictor of first intercourse. A different pattern of results was observed for African American girls. The single strongest predictor of sexual behavior was whether a girl *looked* physically mature to peers.

A number of additional studies (reviewed in Halpern, 2003) across different cultures and cohorts have yielded similar findings regarding the greater sensitivity of young women than men to social and environmental influences on participation in intercourse. In interpreting this pattern, Udry et al. (1986) have emphasized the fact that adolescent boys face a uniformly positive environment regarding their sexual behavior: Although parents may discourage teenage boys from participating in sexual activity, these boys receive consistent messages from their peers and from the media suggesting that sexual activity makes them desirable and mature. Hence, it makes sense that once their hormonally mediated sexual motivation increases, their behavior will follow suit. Yet adolescent girls face inconstant, highly differentiated environments that send an array of conflicting and confusing messages about the desirability and costs of sexual behavior. Some girls' social contexts portray adolescent female sexual behavior in the same positive light as adolescent boys' behavior, whereas other girls may occupy more restrictive social environments which portray sexually active girls as "loose" and not worthy of respect. Hence, given this diversity in attitudes and contexts, it should not be surprising that social and environmental factors prove stronger predictors of girls' behavior than their hormonally mediated sexual urges.

One important question for future research is whether associations between the timing of sexual debut and later psychosocial development vary according to the type of sexual activity pursued (i.e., oral sex versus coitus) and its interpersonal context (i.e., casual experimentation versus romantic involvement). Historically, most young people pursued their first sexual experiences within romantic relationships, but growing numbers of contemporary youth also pursue sexual activity during "hookups" (casual, one-time-only sexual interactions) or in "friends with benefits" arrangements (periodic sexual behavior among friends, with no expectations of romantic involvement) (Grello, Welsh, & Harper, 2006). Participation in sexual activity outside the context of established romantic relationships is sometimes associated with sexual and

psychological health risks, such as greater alcohol and drug use and greater numbers of sexual partners (reviewed in Manning, Longmore, & Giordano, 2005), but not in all circumstances, and not for all youths. The developmental status of young people, their motives and expectations, and the specific features of different relational contexts must be considered in order to discern the developmental significance of different types of sexual arrangements.

Quality of Intercourse Experiences

Another key factor that might moderate links between the timing of sexual debut and subsequent sexual trajectories is the subjective quality of young people's early experiences. If a 15-year-old girl finds her initial vaginal intercourse experiences to be enjoyable, exciting, and emotionally intimate, she is more likely to repeat this behavior and to maintain the relationship in which they occurred. These choices may influence her subsequent sexual and interpersonal development by increasing her likelihood of socializing with sexually experienced peers, her popularity, her time demands, and so forth. If, instead, she finds her initial vaginal intercourse experiences to be unsatisfying, embarrassing, awkward, and even regrettable, she may be less likely to repeat this behavior, and may find herself gravitating toward activities and peer groups that reduce opportunities for this behavior. These choices, too, will reshape her developmental trajectory in crucial ways. Hence, understanding the subjective quality of the initial sexual experiences of young people is important for accurately discerning the role of early sexual experiences in directing subsequent psychosexual development.

Relatively few studies have focused on the subjective quality of the sexual experiences of young people, and these studies reveal a diversity of correlates. One large longitudinal study of Scottish and English adolescents between 13 and 16 years of age found that the majority appraised their first sexual experience and their most recent sexual experience positively, but girls were more likely than boys to report lack of enjoyment during their most recent intercourse. Also, girls were more likely than boys to report that they experienced pressure during their first intercourse experience. In general, sexual experiences characterized by less control and more pressure are evaluated more negatively (Wight et al., 2008). The interpersonal context is also significant: Both boys and girls report more happiness, enjoyment, and satisfaction with their most recent sexual experiences, and less guilt and shame, when those experiences take place with steady and

significant partners (Wight et al., 2008). One consistent pattern is that girls generally evaluate the quality of their first sexual experience more poorly than do boys (Higgins, Trussell, Moore, & Davidson, 2010). This is likely due to multiple factors, including the low skill and sensitivity of their young partners, lack of knowledge about what to expect, lack of control over the timing and dynamics of the experience, women's lower likelihood of orgasm during penile-vaginal intercourse, and the greater shame and risk attached to sexual activity for women than for men (Higgins et al., 2010).

One important topic for future study concerns how young people's judgments of the subjective quality of their sexual experiences are influenced by the motives and expectations that they brought into the interaction, and how their motives and expectations are subsequently *changed* as a result of high-quality and low-quality experiences, in a cascading pattern over time. Previous research has found that crafting meaningful understandings of both positive and negative life experiences helps individuals to cope with and learn from stressors and challenges, particularly if individuals use their experiences to derive insights that can guide their future choices and self-knowledge (McLean & Pasupathi, 2007). Hence, youth who craft meaningful insights from stressful or disappointing sexual experiences, and who make an effort to determine what to do in the future to reduce the likelihood of such experiences, may actually show enhanced development relative to youth who avoid sexual activity altogether. Such processes may help to account for the mixed patterns of association that have been detected between sexual experience and adolescent well-being, with some studies showing greater happiness and self-esteem among more sexually experienced girls (Horne & Zimmer-Gembeck, 2005) and others showing the opposite (Cairano, Bonino, Kliewer, Miceli, & Jackson, 2006). The quality of young people's sexual experiences may prove to be the key unmeasured variable: Notably, one study found that girls who reported more satisfying sexual experiences had more positive, approach-oriented sexual self-concepts (Impett & Tolman, 2006). Another area for future research concerns the degree to which youth use their own histories of satisfaction with sexual activities to make conscious decisions about which activities they choose to pursue in the future. For example, girls with higher levels of assertiveness report having more cunnilingus partners over their entire sexual history as well as during the past 3 months, and report that both they and their partners enjoyed this activity. Hence, one possibility is that assertive, confident girls who find penile-vaginal intercourse disappointing

will make an effort to pursue the sexual acts that they *do* enjoy, and to seek out partners interested in pleasing them. Overall, a greater understanding of how young people subjectively evaluate and interpret their sexual experiences over the course of adolescence is important for understanding the larger role of sexuality as both a cause and an effect of multiple social developmental processes.

Reducing Risks for Pregnancy and STIs

According to the World Health Organization, the highest rates of STI infection occur among youth between the ages of 15 and 24, and adolescents face particular risks for HIV, chlamydia, and gonorrhea (Centers for Disease Control, 2002; Dehne & Riedner, 2005). Each year, nearly 750,000 teen girls aged 15–19 become pregnant, and the vast majority of these pregnancies are unplanned (Alan Guttmacher Institute, 2006). Notably, the United States has a disproportionately high rate of adolescent pregnancy in comparison to other Western industrialized nations, despite the fact that U.S. teens engage in coitus at approximately the same rates and ages as do youth in other Western industrialized countries (Teitler, 2002). Low rates of condom and contraceptive use are likely responsible: Studies of American adolescents have found that approximately one fourth of women and one third of men reported not having used any contraception during the first time they had intercourse (Kahn, Huang, Rosenthal, Tissot, & Burk, 2005) and approximately 20%–30% of adolescents reported not doing so the most recent time that they had intercourse (Santelli, Lowry, Brener, & Robin, 2000). Rates of condom and contraceptive use show wide cross-national variability. Across 15 different international surveys, the World Health Organization found that rates of condom use among adolescents varied from 5% in Tanzania to 33% in Singapore to 62% in Zambia, although across all cultures the most common pattern of condom use among adolescents was *never* (Dehne & Riedner, 2005). In all cultures studied, youth with better education are more likely to report condom use, but even they report problems with correct usage, social stigma, and availability (Dehne & Riedner, 2005).

Cultural taboos against premarital sex often stand in the way of efforts to increase access to condoms and contraception among adolescents, despite consistent evidence that increasing access can increase contraceptive use and reduce rates of pregnancy and STIs among youth (Blake et al., 2003; S. Ryan, Franzetta, & Manlove, 2007). In many countries, mandated parental notification provides

a significant disincentive for youth to seek and use contraceptives, but these youth continue to have sex and to face health risks: One national survey of family planning clinics asked adolescents how they would respond if clinics began requiring parental consent for contraception. Only 7% reported that they would stop having sex (Jones, Purcell, Singh, & Finer, 2005). The level of knowledge of young people about the mechanisms through which contraceptives work also contributes to their use, or lack thereof (S. Ryan et al., 2007). Young people who do not understand how exactly the birth control pill works are not able to judge the risks associated with skipping one or more pills. In light of the fact that adolescence is a period of significant maturation in cognitive and reasoning skills, future-oriented thinking, and the evaluation of hypothetical probabilities (Lehalle, 2006), young people may be poorly suited to make reasonable judgments about the specific risks and benefits of consistent condom use and contraception. Studies reveal that adolescents tend to focus on the *benefits* of forgoing condoms and contraception (such as immediate pleasure and feelings of physical and emotional connection to the partner) rather than the risks (Parsons, Halkitis, Bimbi, & Borkowski, 2000).

Adolescents' sensitivity to rejection and to social evaluation also plays a role in condom and contraceptive use. Some young people forgo condoms and contraception for fear of offending the partner, because they believe that they know the partner's history well enough to trust him/her, because they do not know how to bring it up, or because they are concerned about their reputation (Dehne & Riedner, 2005; O'Sullivan, Udell, Montrose, Antoniello, & Hoffman, 2010). Although one might expect that negotiation of condom and contraceptive use might be easier and more successful in committed romantic relationships, this is not necessarily the case. In fact, many adolescent couples *stop* using condoms once they view their current relationship as committed and monogamous (Matson, Adler, Millstein, Tschan, & Ellen, 2011). Power differentials within couples also play a role. One study found that 20% of young women believed that they did not have enough control within their sexual interactions to make their own decisions about contraceptive use, especially in cases where they wanted to use condoms and their partner did not (Rickert, Sanghvi, & Wiemann, 2002). Similar dynamics have been observed across the globe, with young women uniformly disempowered in the context of negotiated condom and contraceptive use (Dehne & Riedner, 2005). Ambivalence about pregnancy also provides a disincentive to contraceptive use and a strong predictor of unplanned

pregnancy (Sipsma, Ickovics, Lewis, Ethier, & Kershaw, 2011). Studies have found that adolescent girls with low socioeconomic status, low levels of education, high levels of generalized stress, and who live away from their natural parents are disproportionately likely to report that they sometimes want to have a baby (Cowley & Farley, 2001). In interpreting such patterns, some researchers have argued that youth with limited social and economic opportunities may seek early childbearing as an adaptive coping response which offers them meaning and purpose (Stevens-Simon & Lowy, 1995).

In light of the persistent difficulties with motivating youth to reliably use condoms and contraception, some youth advocates have argued that the best strategy for reducing sexual health risks is to promote 100% abstinence among adolescents. In the past decade, numerous “abstinence only” programs have been developed and implemented across the United States, as well as programs encouraging adolescents to take “virginity pledges” until marriage. Several comprehensive reviews of the effectiveness of these programs have been conducted. One such effort summarized the results of 13 scientifically rigorous trials involving over 16,000 youth (Underhill, Montgomery, & Operario, 2007) and found no evidence for significant effects on adolescents’ age of sexual initiation, their rates of participation in unprotected vaginal sex, their number of sexual partners, or their condom and contraceptive use. Similar null effects have been found in other studies (Kohler, Manhart, & Lafferty, 2008), and even when positive effects of these programs have been found, the effects rapidly disappear at follow-up assessments (Jemmott III, Jemmott, & Fong, 1998). In contrast, programs offering comprehensive sexual education have been found to be associated with reduced risks of pregnancy and STIs (Kohler et al., 2008). In light of these findings, many experts in the field have argued that abstinence-only programs and policies are not only ineffective, but unethical, as they withhold critically needed information from adolescents and undermine comprehensive sexual education efforts (Santelli, Ott, Lyon, Rogers, & Summers, 2006).

“Virginity pledges” also appear to be ineffective. One study found that 5 years after taking a virginity pledge, pledgers and non-pledgers showed no differences regarding age of sexual debut, participation in premarital sexual behavior, and number of sexual partners, but pledgers had lower rates of contraceptive and condom use (Rosenbaum, 2006). This is echoed by the findings of a study of Add Health respondents, which used urine samples to compare rates of human papilloma virus,

chlamydia, gonorrhea, and trichomoniasis among youth who did or did not take a virginity pledge: The results revealed that virginity pledgers had infection rates equal to nonpledgers (Bruckner & Bearman, 2005). The authors speculated that virginity pledgers might be at particular risk for condom nonuse at sexual debut, consistent with the findings of Rosenbaum (2006), and that they might also be less likely to be tested, diagnosed, and treated for sexually transmitted diseases. The willingness of virginity pledgers to deny or ignore the realities of their own health risks is exemplified by the fact that in Rosenbaum’s study, 82% of the virginity pledgers denied having taken the pledge to begin with.

These findings do not suggest that abstinence is a completely unworkable strategy, only that its implementation in the form of sex education, and its displacement of comprehensive information about condoms and contraception, appears ineffective. Notably, one longitudinal study tracking adolescent girls over a 4-year period found that the strongest predictor of girls’ abstinence was their own personal attitude about abstinence, even after controlling for peer norms about sexual behavior and family attitudes toward sexual behavior (Akers et al., 2011). Hence, it appears that the most effective strategies for encouraging the use of condoms and contraceptives for young people are those that seek to foster motives to avoid pregnancy and STIs, while providing youth with accurate information about—and confidential access to—condoms and contraception. Long-term, repeated messaging over time is also important, given that adolescents tend to show declining rates of condom use as they become more sexually experienced (Tanner, Hensel, & Fortenberry, 2010). The most successful interventions comprehensively integrate sexual health information and access across multiple dimensions of young people’s social lives, including youth development programs, clinical services, and school contexts (Kirby, Crosby, Santelli, & DiClemente, 2009).

PARENTAL INFLUENCES

The influence of parental practices on their children’s sexual attitudes and behaviors has been a longstanding topic of research. De Graaf, Vanwesenbeeck, Woertman, and Meeus (2011) comprehensively reviewed this literature, focusing on three of the most widely investigated parental characteristics—support, control, and monitoring. They synthesized the evidence linking these factors to the timing of sexual debut, the use of protection against

pregnancy and STIs, and psychological attitudes and enjoyment regarding sexuality. They found consistent evidence that high parental support (which in some studies was operationalized as high warmth, affection, and familial cohesion) predicts later onset of sexual intercourse (especially among particularly young adolescents), greater use of protection from pregnancy and STIs, more positive feelings about sexuality, and greater competence within sexual interactions (for example, efficacy in discussing condoms and contraception and efficacy in refusing unwanted sexual activity). Parental control (operationalized as clear, fair, and consistent rule-setting) also shows consistent associations with delayed sexual activity and use of protection against pregnancy and STIs. Associations with young people's psychological experiences regarding sexuality, however, appear sensitive to instances of overcontrol (i.e., cases in which parental discipline is perceived as arbitrarily harsh and authoritarian), and youth with overcontrolling parents show greater feelings of guilt regarding sexuality, poorer competence in sexual communication, and more involvement in unwanted sexual activity. Lastly, parental knowledge shows the most consistent patterns of association, such that adolescents whose parents have accurate knowledge of their whereabouts and activities (through consistent monitoring) show later sexual debut, greater use of protection from pregnancy and STIs, and more satisfaction, confidence, and assertiveness regarding their sexual activities.

Yet in summarizing these results, de Graaf et al. pointedly remark that although it is typical to interpret such findings as indicating that parental practices "lead" to certain patterns of adolescent sexual behavior, this conclusion is overly simplistic. It is a truism that parenting practices influence child outcomes, but the mechanisms through which specific parenting dimensions shape specific adolescent sexual outcomes remain largely untested. Some mechanisms are easier to intuit than others: It is relatively straightforward to posit that high parental monitoring makes it more difficult for adolescents to engage in early sexual behavior, but why does parental warmth show the same pattern of association, and why is parental warmth positively associated with young people's competence within sexual interactions? De Graaf et al. (2011) suggest the possibility that youth raised by warm and supportive parents may be more psychologically adjusted in general, rendering them better able to make sound sexual choices, deal responsibly with sexual risks, and effectively communicate their needs during sexual negotiations. Yet as they note, there is little *direct* evidence for such mechanisms,

given that most research linking parenting practices to adolescent sexual outcomes has devoted more attention to documenting such associations than to systematically explaining them.

In particular, de Graaf and colleagues note the underattention to reciprocal effects. The casual arrow is typically presumed to operate in one direction only—from parents to children—despite evidence for reciprocal influences (Ream, 2006). Although parental attitudes and behaviors certainly influence their children, parents are also influenced by their children, and often tailor their parenting practices (both consciously and unconsciously) in response to their child's emerging and evolving strengths, weaknesses, and traits. Hence, as de Graaf and colleagues point out, the fact that unsupportive parents have children who engage in early sexual behavior might reflect the fact that parents whose children begin to experiment with sexuality at an early age may begin to distance themselves from these children, showing both subtle and overt signs of rejection and disapproval. Similarly, parents may begin monitoring their children less consistently, and seeking less information about their activities and whereabouts, once they realize that their children are involved in activities they do not condone and do not know how to control. Little research has attempted to uncover the nature of such potential reciprocal effects, and the manner in which parental behavior and adolescent sexuality unfold in a dynamic dialectic over time. Yet such information is critical not only for informing potential family-based interventions designed to foster healthy adolescent sexual development, but for developing a fundamental understanding of the diverse "drivers" of adolescent socio-sexual development.

The quality of parents' communication with their children has also received extensive study, and results suggest that, although the quality of parent-child communication appears to influence the behavior of youth, in some cases it has unintended consequences. Parents who overemphasize the negative consequences of sexual activity may end up discouraging their children from talking to them about sex at all. Notably, culture and ethnicity appear to moderate these effects. O'Sullivan, Meyer-Bahlburg, and Watkins (2001) conducted focus groups with African American and Latina American mothers and daughters and found that African American mothers placed a high priority on preventing pregnancy and STIs, and therefore used their conversations with their daughters to seek information about their daughter's activities. Latina American mothers, however, were more likely to discourage *all* sexual activity whatsoever, which had the effect of discouraging their

daughters from frank discussion of sexual matters, and inadvertently sending them to peers to seek information on sexual health. One notable finding from the study by O'Sullivan and colleagues is the role played by adolescents in effectively “shutting down” their parents’ efforts to communicate openly about sex. A persistent issue raised by the mothers in this study was the antagonism they faced from their daughters when they initiated discussions of sexual matters. Girls reported actively withholding information from their mothers, in direct resistance to their perception that their mothers were overly negative and controlling, and that their parents only wanted them to disclose sexual activities for the purpose of restricting them. Such findings suggest that research on parent-child communication about sex needs an increased focus on the interpersonal dynamics of these conversations, and how they unfold in families with different cultural and religious backgrounds, different histories of warmth and discipline, and different communicative skills and habits. Such research is important for providing families with tailored information on how best they can achieve communicative practices with their children that are successful and beneficial for *both* the parents and children, and which set up lines of communication that children will make use of throughout their adolescent years.

SEXUAL COERCION

Around the globe, many children and adolescents have been victims of coerced sexual activity at the hands of relatives, strangers, acquaintances, and intimate partners (Basile, Chen, Black, & Saltzman, 2007; Dehne & Riedner, 2005). A random representative phone survey of nearly 10,000 American adults found that 10.6% of women reported at least one incidence of forced sex during their lifetime, and the most common age range for such experiences (comprising 35% of accounts) is between 12 and 17 (Basile et al., 2007). Adolescent girls are substantially more likely than boys to report experiences of sexual coercion, but it is not known whether some of this difference is attributable to underreporting by boys (Wekerle & Wolfe, 1999). Existing statistics also likely underrepresent experiences that fall short of conventional social definitions of *force*. Researchers have increasingly come to view sexual assault as part of a broader continuum of coercive attempts to gain sexual access to an unwilling partner, which includes physical force on the high end, but pleading, bullying, manipulation, and the provision

of drugs or alcohol on the low end (O’Sullivan, 2005). Psychological forms of coercion are particularly common in established romantic relationships, whereas forcible rape is more commonly committed by acquaintances (Testa & Livingston, 2000). From a developmental perspective, it bears noting that many individuals describe their *very first* sexual experiences as being unwanted. In their representative study of adults, Laumann et al. (1994) found that 25% of women and 8% of men described their first intercourse experience as unwanted, but not coerced.

Adolescent sexual coercion is associated with a range of negative outcomes, including greater hopelessness, sadness, and risk behaviors such as alcohol or drug use (Coker et al., 2000; Howard, Wang, & Yan, 2007). Among girls, forced sex is also associated with more romantic involvement, greater overall exposure to violence, emotional distress, earlier initiation of coitus, multiple sexual partners, and nonuse of contraceptives and protection against STIs (Howard et al., 2007). The psychological consequences of participation in unwanted or mildly coercive sex are less severe than for forcible sexual assault, but they nonetheless pose significant risks to well-being, especially when the coercion is chronic; these risks include psychological distress and trauma, guilt and shame, low relationship satisfaction, and problems with sexual functioning (Testa, VanZile-Tamsen, Livingston, & Koss, 2004). The prevalence of sexual coercion in established relationships appears to be attributable to the fact that established couples tend to presume an implicit contract ensuring mutual sexual availability (Basile, 2002). Hence, many men—and their female partners—view sexual pressure or persuasion as acceptable activities, and do not even consider them coercive (O’Sullivan, 2005). Adolescents may be particularly vulnerable to these distorted perceptions, given their lack of experience in romantic relationships and their lack of familiarity with “normal” standards governing sexual access. As a result, adolescent girls may acquiesce to a male partner’s implicit or explicit pressure, with little open resistance, for the sake of preserving the relationship or because they feel it is their duty (Basile, 2002; Vannier & O’Sullivan, 2010).

Greater attention to the personal, interpersonal, and contextual factors that foster unwanted sexual activity, and the long-range implications of this activity for the socioemotional development of young people, is one of the most important directions for future research on adolescent sexuality. The longstanding (and well-justified) focus on the starker cases of sexual violence may have inappropriately blinded us to the types of ambiguous sexual situations

that potentially serve as precursors for later abuse. One of the most important questions for future research concerns whether coercive sexual dynamics are best conceived as relationship phenomena or individual phenomena. Although researchers commonly conceptualize sexual violence as a trait of individuals (such that these individuals will pursue coercion within all of their relationships), it is possible that “lower levels” of coercion, such as pleading, manipulation, and guilt-induction, are better understood as properties of *relationships* rather than individuals, born of the interpersonal dynamics created when certain personalities, carrying forward their own unique expectations regarding relationship roles and obligations, come together under charged and interpersonally demanding circumstances. In understanding such dynamics and their implications for later development, researchers must also take care to investigate sexual coercion *not* simply as the “cause” of future negative outcomes, but as the outgrowth of complex, longstanding patterns of psychosocial vulnerability which may stretch back to early childhood, often involving violence in the family of origin (H. A. Sears & Byers, 2010).

NEW CHALLENGES: SEXUALITY IN THE INTERNET AGE

Access to Sexually Explicit Images

Parents and educators have long considered the positive and negative implications of media exposure for child and adolescent development (Anderson & Kirkorian, Chapter 22, this *Handbook*, Volume 2), but these concerns have increased in recent years due to adolescents’ increasing use of digital media (Calvert, Chapter 10, this *Handbook*, Volume 4). The Internet is now the dominant source of adolescents’ exposure to sexual information and images (Roberts, Henriksen, & Foehr, 2009). One representative survey found that 95% of adolescents have access to the Internet, either through computers or mobile phones (Pew Research Center, 2013) and are therefore able to seek out sexually explicit materials with a far greater degree of ease and confidentiality than past generations. Undoubtedly, unlimited access to sexually explicit material on the Internet constitutes one of the most significant historical changes in the social context of child and adolescent sexuality. Although children and adolescents have always been curious about—and have made efforts to procure—sexually explicit materials such as

books, magazines, and films, their access to these materials was once quite limited. Contemporarily, adolescents with access to a computer can instantly view *every single pornographic image imaginable*, including live-streaming videos of real-time sexual activity and images of sexual violence and abuse, with a click of the mouse. Even the mouse may soon be out of date in this context, as studies show that adolescents increasingly use smartphones as a primary means for accessing the Internet, especially adolescents from lower income households who might not have a home computer with Internet access. Historically, Internet access and usage has been lower among ethnic-minority adolescents and those in lower income households, but this gap in usage has been closing due to adolescents’ increasing access to and use of smartphones. A study conducted by the Pew Center (Pew Research Center, 2013) found that 78% of American teens currently have a cellphone, and approximately half of those phones are smartphones. In all, 93% of teens have access to the Internet through a computer in their home, but approximately 25% of teenagers say that they primarily access the Internet through their phone (compared to only 15% of adults). Notably, ethnic-minority youth and those from lower income families are more likely to use smartphones to access the Internet. Hence, although there continues to be a “digital divide” with regard to home Internet use, Internet access through smartphones has substantially closed this divide among contemporary American youth. Internet use is also on a sharp rise around the globe, at far faster rates than those observed in North America. Whereas North American Internet use has increased approximately 150% since 2000, European Internet use has increased nearly 400% since 2000, to a rate of 63% in 2012. In Latin America and the Caribbean, Internet use has increased 1,300% since 2000, to a 2012 rate of 43%. The most dramatic increases are in Africa (3,600% increase since 2000, to a 2012 rate of 15.6%) and the Middle East (2,700% increase since 2000, to a 2012 rate of 40%). It also bears noting that although North America boasts the highest within-population rates of Internet use, North Americans account for only 11% of Internet users worldwide. In contrast, 45% of Internet users are Asian and 22% are European (Internet World Stats, 2012). The increasing use of the Internet worldwide makes it increasingly important to understand how Internet use influences—and is influenced by—young people’s concurrent sexual development.

Importantly, the factors that render some individuals disproportionately likely to seek sexually explicit material on the Internet appear to be the same for adolescents

and adults: Peter and Valkenburg (2011b) found greater rates of usage among males, those with high levels of sensation-seeking, and sexual minorities. Hence, when considering the “effects” of Internet use, it is important to remember that there are powerful selection effects at work, making it difficult to determine whether Internet use “pushes” the sexual interests and cognitions of youth in a certain direction, or whether young people with certain patterns of sexual thought and behavior disproportionately seek out Internet materials that reflect and condone those patterns. The question is an important one, given that studies have found higher rates of sexually risky behavior (specifically, multiple lifetime sexual partners, more than one sexual partner in the past 3 months, and substance use during sexual encounters) among youth who have been exposed to sexually explicit websites (Braun-Courville & Rojas, 2009). Yet other studies have failed to find consistent associations between risky behaviors and the use of sexually explicit Internet materials among youth (Luder et al., 2011), and hence it is likely that the degree of association between Internet use and young people’s sexual attitudes and behaviors varies for different subgroups of youth with different temperamental characteristics and different cultural and family contexts. One (untested) possibility is that access to sexually explicit materials on the Internet poses the greatest risk for youth with psychosocial deficits (for example, low impulse control and low social competence) who are raised in families characterized by low supervision and low openness regarding sexuality. These young people might have particularly strong motivations to seek sexual information privately on the Internet, given their inability to seek accurate information from their parents. Their low background knowledge of sexuality, combined with the lack of a strong peer group to provide a “reality check” on the information that they discover, potentially renders them highly susceptible to influence. A key direction for future research is to identify youth and situations that are associated with particularly negative risks regarding Internet use and to understand the mechanisms underlying these links.

It is not yet clear whether the use of Internet materials by young people shows fundamentally different patterns of association with psychosocial outcomes than their use of other media. For example, Ybarra and Mitchell (2005) found that adolescents who intentionally sought out pornographic materials were significantly more likely to report delinquent behavior and substance use in the past year, regardless of whether the materials were “online” or “offline,” but those who sought online materials reported

twice as many depressive symptoms and lower emotional bonding with their parents than did youth who sought offline materials. Rather than reflecting the fact that exposure to Internet materials “makes” young people more depressed and impairs their social functioning, this may reflect the fact that those who have these characteristics find it easier and more comfortable to obtain explicit materials through the privacy and anonymity of the Internet. An unanswered question is whether there are cascading effects of Internet use that unfold over longer stretches of time: For example, if lonely and depressed youth are more likely to satisfy their sexual curiosity through Internet use than through playing explicit video games with large groups of friends, the amount of solitary time that they spend viewing these materials might exacerbate their feelings of loneliness and isolation, which might then encourage additional Internet use. Such cascading effects are difficult to capture, given that they require repeated, detailed assessments of adolescents’ feelings, motives, and cognitions before, during, and after multiple sessions of Internet use, but collecting such data is critically important for understanding the *developmental* impact of Internet use, especially for youth of different ages. One possibility is that these cascading influences are likely to be stronger among children than among adolescents. In order for parents and schools to develop appropriate policies about Internet use and to develop effective interventions for youth with problematic patterns of use, such process-oriented, developmental data are indispensable.

Cascading effects might also be evident in the context of young people’s use of the Internet to meet sexual partners. The risks of online sexual solicitation of children and adolescents have raised considerable concern, despite the fact that rates of unwanted sexual solicitation of youth have declined since the early days of the Internet (Mitchell, Wolak, & Finkelhor, 2007). Adolescents continue to face greater risks for online solicitations than adults, but adolescents appear to share adults’ perceptions of these solicitations as risky, and those who report being solicited online do not show higher levels of sexual risk behaviors (Baumgartner, Valkenburg, & Peter, 2010b). Additionally, short-term prospective research suggests that risky online sexual behaviors (searching online for someone with whom to talk about sex, searching online for sexual partners, sending photos or videos to someone online, and sending personal contact information to acquaintances who are known exclusively online) do not appear to change young people’s norms and attitudes about acceptable sexual behavior. Young people’s perceptions

of their friends' involvement in these behaviors and their perceptions of their own vulnerability longitudinally predicted their future participation in these behaviors, but the reverse causal pathway (from behaviors to perceptions) was not found (Baumgartner, Valkenburg, & Peter, 2010a). This suggests that young people's Internet experiences—even when these experiences are highly risky—do not appear to distort their preexisting sexual perceptions and attitudes. Of course, however, a 6-month follow-up assessment may not be long enough to capture longer-term shifts in the attitudes, perceptions, and self-concepts of young people that might accompany long-term Internet use, and that might be linked to actual experiences of pleasure and danger in online interactions. As with Internet use more generally, research must attend to feedback loops between adolescents' pre-existing attitudes and dispositions and their Internet experiences over time in order to accurately understand the risks associated with online social interactions.

It also bears noting that not all adolescent Internet use is intentional. One study found that over two-thirds of youth who reported having viewed sexually explicit materials on the Internet described this exposure as "unwanted" (Wolak, Mitchell, & Finkelhor, 2007). Unwanted exposure rates were higher among girls, young people who reported histories of interpersonal victimization (offline), young people who reported sexual harassment or solicitation online, and those with higher depressive symptoms. Unwanted exposure might prove particularly harmful when the images viewed include violence, degradation, and domination, commonly directed against women. Some researchers have investigated whether the viewing of stereotypic images of women appears to increase adolescents' belief in these stereotypes (e.g., that women say "no" to sex when they actually mean "yes," a phenomenon known as "token resistance"). One study found that adolescents who supported traditional gender roles were more likely to believe that women engaged in token resistance, but there was no association between use of sexually explicit websites and belief in token resistance (Peter & Valkenburg, 2011a). Among adults, however, there was a significant association between use of sexually explicit websites and the belief that women engage in token resistance. One possibility is that self-selection effects may be stronger for adults than adolescents in this regard (i.e., adults who already believe in women's token resistance may be more likely than adolescents to seek sexual images on the Internet that confirm this perception); another possibility is that links between Internet use and perceptions of women

may be "dose-dependent," such that these links strengthen and cascade over time. Given growing debate over the developmental impact of both Internet and mainstream media portrayals of women, and particularly the "sexualization" of ever-younger girls (APA Task Force on the Sexualization of Girls, 2010; Lerum & Dworkin, 2011), prospective study of the influence of Internet use on both boys' and girls' perceptions of gender roles in the context of sexuality warrants continued scrutiny.

Electronic Communication

Researchers have been increasingly concerned with the implications of online communication for sexual health. Despite concerns about sexual solicitation, noted earlier, online communication may actually provide a unique opportunity to facilitate adolescents' sexual knowledge and comfort, especially because the anonymity provided by online communication allows adolescents to address sensitive sexual issues that they might have trouble addressing directly with peers and parents (Valkenburg & Peter, 2011). For example, adolescents often seek advice about sexual health online (Suzuki & Calzo, 2004) and engage in discussions of emotional and moral issues about sexuality (Subrahmanyam, Greenfield, & Tynes, 2004). Additionally, online communication presents new opportunities for youth questioning their sexual orientation, who use the Internet to meet lesbian, gay, and bisexual peers and to discuss issues of openness and disclosure (DeHaan, Kuper, Magee, Bigelow, & Mustanski, 2012; Jamil, Harper, & Fernandez, 2009). Yet the long-term benefits and outcomes of such communications are largely unknown. One study examined adolescents' display of sexual references on their Internet profile pages, and found that 24% of young people's profiles contained references to personal sexual preferences, disclosures of sexual experiences, or sexual photographs (Moreno, Parks, Zimmerman, Brito, & Christakis, 2009). Girls tended to display sexual content more frequently than boys, and youth with same-sex attractions made more references to sexual behaviors than heterosexual youth. In contrast, those who displayed religious, sports or hobby involvement were less likely to make sexual references. Another study compared sexual risk behavior among college freshman who displayed sexual references on Facebook and those who did not. They found that youth who made sexual references on Facebook reported greater intentions to have intercourse, but these youth did not have greater rates of sexual behavior, greater numbers of sexual partners, or lower

rates of condom use (Moreno, Brockman, Wasserheit, & Christakis, 2012). Hence, as with exposure to sexually explicit media, young people's own preexisting intentions and motives may influence their Internet use more than the reverse.

Considerable concerns have been raised about the sending and receiving of sexually explicit photos through text messaging, commonly called *sexting*. One study found that approximately 20% of youth report having sexted a sexually explicit photo, and more than 30% reported having been the recipient of a sexually explicit photo (Strassberg, McKinnon, Sustaíta, & Rullo, 2013). Far fewer young people report disseminating sexually explicit photos than report having received such photos, indicating that a relatively small number of youth may be responsible for sexually explicit images of peers that go viral, becoming widely disseminated across large networks of peers (largely due to the ease with which sexually explicit images and messages can be sent and forwarded to multiple recipients at once). In general, boys appear more likely than girls to receive explicit pictures, and older adolescents are more likely to engage in sexting than are younger adolescents (Strassberg et al., 2013).

Motivations to engage in sexting appear to vary across adolescents. A national study of 10- to 17-year-old youth (Mitchell, Finkelhor, Jones, & Wolak, 2012) found that most of the individuals who had appeared in explicit photographs that were disseminated via text messaging had created the pictures themselves. When they were asked about their motivations, common responses included "I was dating a boy. He wanted a picture, so I sent him one," "I was curious as to what my body would look like to other people," and "We were just messaging around and being guys." Responses associated with receiving a sexually explicit image included "Someone set me a picture of my boyfriend and another girl, and he is no longer my boyfriend" and "A boy had four pictures of naked girls—he was showing everybody in the classroom." Moreover, the researchers found that 28% of the youth who had appeared in photographs and 25% of the youth who had received photographs felt upset, embarrassed, or afraid. Additionally, most young people who had received sexually explicit photos claimed that they did not forward these photos to others.

The long-term implications of sexting are not clear: As with the other risky behaviors discussed, it is not clear whether sexting influences the sexual behavior of young people or whether those who are predisposed to certain patterns of behavior are more likely to engage in sexting.

One study examined sexting in 35 U.S. high schools (Dake, Price, Maziarz, & Ward, 2012) and found that adolescents who reported sexting also reported higher rates of oral sex, anal sex, and intercourse, more numerous sexual partners, and less condom use. Yet another national sample of young adults aged 18–24 found no relations between sexting and sexual risk behavior (Gordon-Messer, Bauermeister, Grodzinski, & Zimmerman, 2013). Again, we need prospective research examining how sexting influences *and* is influenced by young people's sexual attitudes and behaviors. Such research becomes increasingly important given that adolescents' growing use of cellphones and smartphones makes sexting increasingly accessible. Another critical area for future research is the long-term effect of the shame and embarrassment young people may feel after their sexually explicit photos are publicly disseminated, and the impact of "cyber bullying," in which young adults use online communication (such as text messaging or social networking) to spread sexually related information about their peers. Youth are increasingly undergoing their most significant sexual-developmental milestones (first kiss, first girlfriend or boyfriend, first breakup, first sexual intercourse) *in public*, documenting their experiences in a permanent digital record, and opening themselves up for enduring comment and critique. Such behavior is not surprising, given that adolescence is known to be a time of self-centeredness, but the widespread dissemination and permanence of young people's digital sexual archives is historically unprecedented, and we know little about how the current cohort of youth will view these archives, and the degree of their exposure to peers, as they progress through adulthood. Long-term prospective studies of this phenomenon are a critical topic for future study.

SEXUAL-MINORITY YOUTH

Attention to the experiences of *sexual-minority* youth (i.e., those with same-sex attractions and/or behaviors) has increased dramatically over the past 30 years. Between 1980 and 1990, fewer than 150 articles were published in peer-reviewed psychological journals on the topic of sexual orientation and same-sex sexuality among children and adolescents. Between 1990 and 2000, the number of publications on this topic doubled, and since 2000 it has more than doubled again, reflecting greater awareness of and interest in this topic from psychologists as well as society more generally. Furthermore, the tone of social scientific research on sexual-minority children and

adolescents has changed markedly, especially since the removal of homosexuality from the *DSM*'s list of mental disorders in 1973. Prior to this point (and stretching back to the 19th century), same-sex sexual behavior or interest among *both* adults and children was treated as an indicator of pathology, maladjustment, or developmental dysfunction. Yet contemporarily, the most common question asked regarding sexual-minority youth is no longer "what went wrong?" but "what are their needs and experiences?" It is now widely recognized that a substantial number of adolescents deviate from conventional norms positing exclusive and uniform heterosexuality, and that although they are not intrinsically "disordered," they nonetheless face distinct developmental challenges. Scholars have therefore turned significant attention to the factors that predict both positive and negative psychosocial development across the lifespan.

Below we review this emerging body of research. Importantly, our review includes *sexual-minority* youth (i.e., those with same-sex attractions, fantasies, or behaviors) as well as *gender variant* youth (i.e., those whose appearance, behavior, interests, or identity violate traditional norms for masculinity or femininity). The latter group also includes *transgender* youth, who adopt a gender identity that does not conform to their biological sex. Although sexual-minority and gender-variant youth are often conflated with one another (for example, gender-nonconforming children are frequently suspected of being gay), they represent distinct populations. We discuss both of these populations in this chapter because of what they have in common: a set of complex psychosocial challenges deriving from the fact that their very existence challenges many of our culture's most deeply held beliefs about "normal" sexual and gender development. It would be impossible in a single chapter to comprehensively review everything that is currently known about sexual-minority and gender-variant adolescents, and hence we focus on aspects of their experiences that are most relevant from a sexual-developmental perspective. We specifically highlight the diversity of sexual-minority populations, especially regarding the prevalence of nonexclusive rather than exclusive same-sex attractions and the diversity of young people's identity labels and self-concepts. We also discuss the mental health implications of young people's exposure to stigma and social marginalization.

Defining the Population

Most empirical research on sexual-minority and gender-variant youth speaks of "lesbian and gay" or "lesbian/

gay/bisexual" or "lesbian/gay/bisexual/transgender" youth, but these terms can be misleading and usually underrepresent the population of interest. Numerous large, representative surveys conducted in a variety of countries have found that the majority of individuals with same-sex attractions do *not* openly identify as lesbian, gay, or bisexual, but instead maintain a heterosexual identity label despite their same-sex attractions and/or behaviors (Chandra et al., 2011; Hayes et al., 2012; Savin-Williams, Joyner, & Rieger, 2012; Wichstrom & Hegna, 2003). Each of these studies has also found that the majority of individuals with same-sex attractions actually experience attractions to *both* sexes and not exclusively to the same sex. Perhaps most intriguing (and most problematic, from the perspective of research aiming to establish the population prevalence of same-sex sexuality), the majority of individuals with same-sex attractions do not report tidy correspondences among sexual desires, romantic feelings, sexual behaviors, sexual relationships, and sexual identity, but instead report mild to moderate discrepancies among these domains (i.e., desires that are never acted upon; same-sex sexual liaisons in the absence of lesbian-gay-bisexual identification, etc.). Hence, knowing about one specific dimension of a young person's same-sex sexuality (for example, frequent sexual fantasies about same-sex partners) cannot provide reliable information about other dimensions (such as romantic feelings or relationships, self-identification, sexual behavior, etc.).

This is why researchers increasingly focus on documenting different manifestations of same-sex sexuality during childhood, adolescence, and adulthood rather than attempting to identify reliable predictors of same-sex sexual orientations. The construct of sexual orientation denotes a multifaceted sexual predisposition for the same sex, the other sex, or both sexes, encompassing sexual attractions, fantasies, affectional feelings, and behavior. Despite common assumptions to the contrary, there is little evidence that adolescent experiences of same-sex attraction or behavior provide reliable predictors of enduring same-sex predispositions. Some youth with same-sex attractions and behaviors have generally heterosexual predispositions, whereas some with exclusively heterosexual attractions and behavior will end up discovering in adulthood that they have a same-sex predisposition. Hence, in most cases there is simply too little information on which to make claims about adolescents' sexual orientation; statements about adolescent same-sex sexuality, however, are more empirically valid because they can be directly assessed (through self-report) without requiring presumptions about

the respondents' enduring sexual orientation. Although some might argue that the only forms of same-sex sexuality that warrant significant research attention during the adolescent years are those that signal the emergence of a young person's same-sex orientation (as opposed to those that may prove transient or experimental) we would argue to the contrary. Same-sex attractions and behaviors are increasingly common phenomena among contemporary youth, and they warrant just as much attention (with regard to prevalence, motives, developmental course, and long-term implications) as do behaviors such as oral and anal sex (which, like same-sex behavior, may be pursued more frequently during adolescence than during adulthood). By using the broad umbrella term "same-sex sexuality" instead of sexual orientation, we convey our focus on *all* forms of same-sex sexuality during childhood and adolescence, regardless of whether the participants eventually identify as lesbian, gay, or bisexual.

How common are such behaviors? The National Longitudinal Study of Adolescent Health found that 13% of American girls and 6% of American boys reported same-sex attractions, same-sex relationships, or nonheterosexual identities (Savin-Williams, 2005). The National Survey of Family Growth, with a representative national sample of nearly 14,000 American individuals, found that 5.2% of male teenagers and 12.5% of female teenagers reported same-sex sexual contact (Chandra et al., 2011). Importantly, longitudinal research indicates that same-sex behavior in adolescence is not necessarily a precursor to a sexual-minority identity. Savin-Williams and Ream (2007) found that, among the adolescents in the National Longitudinal Study of Adolescent Health who reported same-sex behavior at Wave 1 (at a mean age of 16), very few (1 in 5 females and 1 in 25 males) described themselves as "homosexual," "mostly homosexual," or "bisexual" by Wave 3 (at a mean age of 22), and the overall percentage of youth adopting one of these descriptors was low (2.4% of males and 3.8% of females). Similarly, in the National Survey of Family Growth, 2.8% of 18- to 19-year-old males and 7.7% of 18- to 19-year-old females identified as gay, lesbian, or bisexual (Chandra et al., 2011). These findings concord with other research conducted with large samples of adolescents, indicating that the vast majority of youth reporting same-sex attractions or same-sex behavior present themselves as heterosexual (Chandra et al., 2011; Garofalo, Wolf, Wissow, Woods, & Goodman, 1999).

These findings have important implications for interpreting the findings of previous research on sexual-minority

youth. The majority of extant published research on the developmental and clinical issues facing sexual-minority youth is based on relatively narrow samples of youth who openly identify as lesbian/gay/bisexual (often recruited from social service organizations that serve these populations). Although these studies have provided critically important insights into the unique needs of this population, they underrepresent youth who are less open or less certain about their sexual and/or gender identity, and who may therefore be facing altogether different social-developmental concerns. Also, researchers have argued that samples of lesbian/gay/bisexual youth recruited from social service organizations might actually over-represent the most troubled youth, given that these agencies tend to draw youth who *need* their services (Savin-Williams & Ream, 2003). Studies have also tended to underrepresent bisexual, ethnic-minority, rural, and working-class youth, hampering the generalizability of research findings.

Nonexclusive Patterns of Attraction

The underrepresentation of individuals with bisexual (or "nonexclusive") attractions is particularly problematic, given the increasing body of research indicating that such individuals represent the *vast majority* of those with same-sex attractions. For example, in Wave 4 of the National Longitudinal Study of Adolescent Health (during which participants were in early adulthood), 6.4% of men and nearly 20% of women reported same-sex attractions, and of these individuals, 95% of the girls and 74% of the boys reported attractions to *both* the same sex and the other sex. Similar results have been found in adults (Chandra et al., 2011) as well as internationally: A random sample of British adults found that 5.2% of men and 6% women reported a nonheterosexual orientation, and of these individuals, 90% of the women and 80% of the men reported attractions to both sexes. In a large cohort study of New Zealanders, 5.6% of men and 15.9% of women reported some degree of same-sex attraction, and of these individuals, 95% of the women and 79% of the men reported attractions to both sexes (Dickson, Roode, Cameron, & Paul, 2013). Hence, directly contrary to the conventional wisdom that individuals with exclusive same-sex attractions represent the prototypical "type" of sexual-minority individual, and that those with bisexual patterns of attraction are infrequent exceptions, the opposite is true: Individuals with nonexclusive patterns of attraction are indisputably the "norm," and those with exclusive same-sex attractions are the exception. This is critically

important information to convey to young people who have begun to question their experiences of same-sex attraction and who may believe that their nonexclusive attractions make them “strange” or “different.”

The specific distribution of attractions to same-sex versus other-sex partners also warrants attention: In every large-scale representative study that has been conducted, the single largest group of individuals with same-sex attractions—typically accounting for between 50% to 80% of individuals with same-sex attractions—are those who describe themselves as predominantly, but not exclusively, heterosexual (Chandra et al., 2011; Laumann et al., 1994). We might think of such individuals as “Kinsey 1s” or “mostly straight” (following Thompson & Morgan, 2008). On the Kinsey scale, zero represents exclusive heterosexuality and 6 represents exclusive same-sex sexuality. Hence, individuals who consider themselves “Kinsey 1s” perceive themselves as having enough same-sex attractions to rule out a completely heterosexual identity, but not enough same-sex attractions to warrant bisexual or lesbian/gay identifications. What is particularly interesting about the high prevalence of these individuals from study to study is that they have historically been treated with the *most* skepticism and denigration from scientists and laypeople alike, and hence we know little about the long-term course of their sexual development. Over the long term, it appears that many such youth eventually adopt a heterosexual identity, despite continuing to acknowledge a propensity for periodic same-sex attractions (Ott, Corliss, Wypij, Rosario, & Austin, 2011). Importantly, such long-term change is not unique to this group: Substantial longitudinal variability has been observed among *all* youth with same-sex attractions, whether they are closer to a Kinsey 1 or a Kinsey 6 (Dickson et al., 2013; Savin-Williams & Ream, 2007).

Studies employing in-depth qualitative interviews suggest that youth with “mostly heterosexual” patterns of attraction often resist adopting a bisexual or gay identity label because they have internalized cultural messages telling them that their same-sex attractions are not exclusive enough to “count” as nonheterosexual. The dominant cultural model of sexual orientation continues to posit two and only two categories of sexual orientation—exclusive homosexuality and exclusive heterosexuality—neither of which represents their experiences. Even the “bisexual” label seems a poor fit, given that many individuals assume (albeit incorrectly) that bisexuality must entail roughly equal degrees of attraction to both men and women. Furthermore, bisexuality continues to be widely dismissed

in the culture at large as a “false” or “transitional” identity (reviewed in Diamond, 2008a). Accordingly, individuals with “mostly straight” patterns of attraction generally find that none of the available identity labels represents their experiences, and many conclude as a result that their same-sex attractions may represent a transient aberration, perhaps attributable to confusion or curiosity, rather than an important component of their overall sexual disposition.

Such experiences are substantially more likely to occur among women than among men, considering that substantially more women than men describe their attractions as “mostly opposite-sex.” In Chandra et al.’s study (2011), for example, fully 12% of American women described their attractions as “mostly other-sex,” whereas 5.1% endorsed “both sexes,” “only same-sex,” or “mostly same-sex.” Among men, this difference was not as stark (3.7% endorsing “mostly other-sex” compared to 3.4% endorsing the other categories). Similar gender differences have emerged from other studies. Fergusson, Horwood, Ridder, and Beautrais (2005) found in a large New Zealand birth cohort that 12% of women but only 4%–5% of men described their attractions as predominantly other-sex and described their identity as “mostly heterosexual.” In a random, representative survey of American adolescents, nearly 11% of young women described themselves as “mostly heterosexual but somewhat attracted to people of the same sex,” whereas only about 4% of male adolescents endorsed this description (Udry & Chantala, 2006). In Laumann et al.’s 1994 study, women with “mostly heterosexual” attractions accounted for 62% of all women reporting any same-sex attractions, whereas men with mostly heterosexual attractions accounted for 40% of those with any same-sex attractions. In the Adolescent Health data reported by Savin-Williams, Joyner, and Rieger (2012), “mostly heterosexual” individuals accounted for 80% of women but 55% of men with same-sex attractions. In a sample of nearly 2,000 Montreal high school students, over 9% described their sexual identity as either “unsure” or “heterosexual with same-sex attraction,” and 69% of these students were female.

These data indicate that parents, educators, clinicians, and advocates seeking to provide support and affirmation for young people with same-sex attractions should understand that this population may be larger and more “hidden” than previously thought. Contrary to stereotypes portraying sexual-minority youth as gender-atypical “loners” showing little or no interest in heterosexual peers, the average sexual-minority youth experiences heterosexual attractions, participates in heterosexual relationships, and

identifies as heterosexual, making them difficult to identify. Yet the fact that these young people might appear so “typical” on the surface does not mean that they do not need support and—in some cases—intervention. Studies indicate that young people and adults with bisexual patterns of attraction actually have *greater* risk for adjustment problems than young people and adults with exclusively same-sex attractions (reviewed in Diamond, Butterworth, & Savin-Williams, 2010). The reasons for this enhanced risk are not clear, but one likely possibility is the increased stigma that such individuals face from *both* heterosexual and sexual-minority communities, with each social network potentially questioning and delegitimizing the individual’s personal identity and journey.

Same-Sex AtTRACTIONS Versus Same-Sex Orientations

A common question posed about youth with same-sex attractions and/or behavior is whether these phenomena represent a transient phase or whether they signal an underlying same-sex orientation. Currently, there is no way to answer this question because there is no scientific consensus on the exact constellation of experiences that definitively qualify an individual as lesbian, gay, or bisexual. Sexual orientation is typically considered multidimensional, incorporating sexual attractions, romantic feelings, sexual behavior, and sexual fantasies, and studies have reliably documented notable discrepancies across these domains among both adolescents and adults. Studies have revealed no definitive strategies for differentiating between young people whose same-sex interests and activities will persist into adulthood and those whose interests and activities will not. For example, longitudinal research on adolescent and young adult sexual-minority women has found that factors such as age of first same-sex attractions, age at first sexual questioning, and age of first same-sex contact failed to distinguish women who ended up, by their mid-30s, maintaining lesbian-bisexual versus heterosexual identities (Diamond, 2008a).

A significant body of research conducted in the late 1980s and early 1990s attempted to chart the normative process through which same-sex orientations emerged in adolescence by asking youth and adults to recollect the process by which they first came to be aware of their same-sex attractions and first began to question their sexual orientations. Although the stated aim of this research was to identify uniform “milestones” of sexual-minority development, it has become clear over the years that such milestones show far too much variability to yield

any definitive developmental models. Some youth report becoming aware of their same-sex attractions as early as 9 or 10 years of age (which notably corresponds to the surge of adrenal androgens that typically accompanies the prepubertal maturation of the adrenal gland, as argued by Herdt & McClintock, 2007), whereas other young people do not report any awareness of same-sex attractions until late adolescence or early adulthood. Some youth question their sexuality after pleasurable experimenting with same-sex sexual behavior, whereas others complete the entire process of sexual questioning and sexual-minority identification without ever having acted on their same-sex attractions (Dubé & Savin-Williams, 1999; Rosario, Schrimshaw, & Hunter, 2008). Hence, researchers have largely jettisoned the aim of charting the normative timescale across which same-sex orientations unfold, in favor of documenting the diversity of young people’s sexual-developmental trajectories and understanding both the antecedents and implications of different trajectories (Savin-Williams, 2011).

Given that most research on the process of sexual questioning is conducted by collecting self-report data from openly-identified LGBT adolescents, little is known about the prevalence and implications of childhood experiences of sexual questioning, and the degree to which they reliably indicate an emergent same-sex orientation. One notable study, however (Carver, Egan, & Perry, 2004), directly tackled this understudied topic. As they noted, the increasing availability of media images and information regarding same-sex sexuality makes it increasingly likely that children—regardless of whether they have actually experienced same-sex attractions—will actively question their own interest in same-sex sexuality. Some of these children will eventually adopt a sexual-minority identity, whereas others will not, and the study by Carver, Egan, and Perry sought to understand whether there were any reliable psychosocial predictors of the questioning process. In essence, their approach treated sexual questioning not simply as a uniform precursor to same-sex sexuality, but an important social-cognitive developmental experience in and of itself, which might bear its own unique and important relationship to the child’s overall psychosocial developmental context. This approach is particularly valuable for situating sexual-developmental processes within a larger body of parallel developmental processes that may have little to do with sexuality per se, but which a child’s emerging sexual feelings may serve to highlight or “trigger.” For example, sexually questioning children, like sexually questioning adolescents, tend to report feeling

“different” from their peers, but these feelings may have little to do with their sexuality. In some cases the specific reasons for these feelings cannot be identified, and in other cases they have more to do with gender atypicality than with sexual desires (Carver et al., 2004).

One question that warrants future attention is whether the very nature of the questioning process is developmentally distinct. Adolescent sexual questioning typically involves straightforward reflections on same-sex and other-sex attractions and (in some cases) sexual behaviors, and consideration of whether these experiences signal gay, lesbian, or bisexual sexual orientations. In childhood, however, experiences of sexual desire and attraction are typically less intense, more ambiguous, and have highly diverse triggers that prove unreliable signposts of stable predispositions. Accordingly, Carver, Egan, and Perry (2004) elected not to ask their 9- to 13-year-old respondents direct questions about same-sex attractions, and instead they asked respondents how confident they were that they would feel heterosexual attractions and have heterosexual relationships in the future. Hence, “sexual questioning” in this context was operationalized as low confidence and security in one’s heterosexual identity. They assessed sexual questioning at both the beginning and the end of the school year, and found that initial levels of sexual questioning predicted declines in social competence from fall to spring. Yet, importantly, there was no evidence that adjustment problems at the beginning of the year (specifically, low self-worth, low social competence, and low acceptance by both same-sex and other-sex peers) prompted increases in sexual questioning over the course of the year. Hence, sexual questioning did not simply serve as an indicator of broader underlying maladjustment.

This study also found no evidence that sexual questioning stemmed from initial gender nonconformity, since youth with high or increasing levels of gender nonconformity did not show increases in sexual questioning over time. Rather, children who initially reported questioning their heterosexuality showed increases in self-perceived gender nonconformity over time. Importantly, there are multiple potential explanations for such an association. Although some scholars have posited that same-sex sexuality and gender nonconformity may share a common causal pathway (reviewed in Bailey, Dunne, & Martin, 2000), such that gender nonconformity might simply be a late-appearing “symptom” of same-sex sexuality, it is also possible that children who begin to question their sexual orientation might intentionally explore gender-atypical appearance and behavior as part of their questioning

process. Given widespread cultural and media messages portraying nonheterosexual individuals as gender atypical, youth who question their sexuality may assume that they are *supposed* to be gender atypical, and that the best way to meet other nonheterosexual youth is to display their nonconformity.

Change Over Time

It is commonly thought (by laypeople as well as social scientists) that sexuality and sexual orientation are fundamentally stable traits that express themselves in a fairly uniform manner over the lifespan. Yet in actuality, most sexual minorities recall having undergone notable shifts in their patterns of sexual attractions, behaviors, and/or identities over time (Kinnish, Strassberg, & Turner, 2005; Weinberg, Williams, & Pryor, 1994). Of course, retrospective reports of change have obvious shortcomings, and much more reliable data on the phenomenon of change have come from a number of prospective studies (Diamond, 2008a; Dickson, Paul, & Herbison, 2003; Ott et al., 2011). All of these studies have documented notable changes over time, especially among women. For example, Savin-Williams et al. (2012) examined stability of self-reported same-sex attractions in Waves 4 and 5 of Add Health, and found an increase in the percentage of respondents who reported same-sex attractions, especially among women. In Wave 4, 86% of the women and 94% of the men described their attractions as exclusively heterosexual, but by Wave 5, 6% of these women and 1% of these men switched out of this category and reported same-sex attractions. Dickson et al. (2003) sampled a cohort of approximately 1,000 New Zealanders born in the early 1970s. Of participants who reported any same-sex attractions at Age 21, 35% of men and 55% of women underwent a major shift in their attractions by Age 26 (the three categories they could endorse were “occasional attraction to the same sex,” “major attraction to the same sex,” and “only attracted to the opposite sex”). Additionally, of the individuals who described themselves as “only attracted to the opposite sex” at 21, 12% of the women but only 2% of the men shifted to one of the same-sex attraction categories by Age 26. Similar patterns (greater change in women than among men) have been found in every other large-scale prospective study of same-sex sexuality that has been published, on samples ranging from adolescence to early adulthood (Mock & Eibach, 2012; Ott et al., 2011; Savin-Williams et al., 2012; Savin-Williams & Ream, 2007).

Other widely replicated patterns include the propensity for individuals with nonexclusive patterns of attraction to show more change than those with exclusive patterns of attraction (Diamond, 2008b; Mock & Eibach, 2012; Ott et al., 2011; Savin-Williams et al., 2012), and for more individuals to move *toward* nonexclusivity than away from it over time. Hence, contrary to the notion that bisexual attractions are transitional states, and that most individuals' attractions become narrower and more specialized over time, the data suggest the opposite: Over the course of adolescence and adulthood, individuals tend to show broader rather than narrower patterns of attraction, even if their sexual behaviors and relationships remain stable and limited. This is particularly true for women. All of the prospective studies summarized earlier found that women were more likely than men to shift toward greater nonexclusivity. In the study by Dickson et al. (2003), men were equally likely to transition to the "occasional same-sex attraction" category as they were to transition to the "only opposite-sex" or "major same-sex" attraction category. Women, in sharp contrast, were twice as likely to transition to the "occasional same-sex category" as to the "only opposite-sex" or "major same-sex" attraction categories. Although this study did not differentiate between exclusive and nonexclusive forms of "major" same-sex attractions, it supported the notion that women's changes are more likely to involve movement toward nonexclusivity than toward exclusivity.

Similar findings were reported by Ott et al. (2011), who examined changes in a large prospective cohort study of over 13,000 young people. They found that, between the ages of 13 and 23, the percentage of women adopting nonexclusive identity labels (bisexual or mostly-heterosexual) increased by nearly 10%, representing more than a threefold increase (from 4.6% to 14.4%), whereas the percentage adopting "mostly or completely homosexual" identities increased by a single percentage point (from 0% to 1%). In contrast, among men there was an 11-fold increase in the percentage of men identifying as mostly/completely homosexual, from .3% to 3.5%, but only a twofold increase in the percentage identifying as bisexual or mostly heterosexual (from 2.8% to 5.9%). Again, the pattern is clear: Men start out with more exclusive patterns of same-sex sexuality than do women, and over time they tend to become more exclusive. Women start out with more nonexclusive patterns of same-sex sexuality, and over time they tend to become even more nonexclusive. The fact that these findings have been consistently replicated in numerous large-scale studies using different

sampling frames and assessing men and women at different ages is particularly striking. Some have argued that they point to a greater capacity for "fluidity" and "plasticity" in women's desires (Diamond, 2008b), but there is little research directly comparing men's and women's capacities for "fluid" sexual desires at different stages of the lifespan. Hence, the size of the potential gender difference in sexual fluidity, and the manifestations of sexual fluidity during childhood and early adolescence, remains an important topic for future research.

Given that experiences of change directly contradict conventional models of sexual orientation, young people experiencing changes in their attractions and/or behaviors are likely to wonder what these changes mean, and whether they signal underlying maladjustment. As with bisexual patterns of attraction, young people need to know that changes in their sexual feelings are perfectly normal, and that their current constellation of feelings and behaviors does not necessarily reflect their future feelings and behaviors. Such information is critically important given that young people with same-sex attractions already tend to feel different and deviant, and hence may be particularly sensitive to aspects of their experiences that appear to diverge from widespread norms. Simply reassuring young people that their "crazy," "mixed up," "unstable" feelings are common may be one of the most important forms of support that adults can provide such youth.

Mental Health of Sexual-Minority Youth

Do young people with same-sex attractions, behaviors, or identities show greater mental health problems than their heterosexual counterparts? The answer is *perhaps*—it depends on which populations are being sampled. Numerous studies have found that sexual-minority youth, lumped together as a unitary unit, often report heightened feelings of stress, loneliness, anxiety, and depression, and heightened use of drugs and alcohol, and that stigmatization and victimization—more broadly known as *minority stress*—play critical roles in these problems (Horn & Nucci, 2006; Mallon, 2001; Rosario, Schrimshaw, & Hunter, 2006; Russell & Consolacion, 2003). Minority stress represents the unique strain experienced as a result of occupying a socially marginalized category (Meyer, 2003). The fundamental tenet underlying the conceptualization of minority stress is that individuals learn about themselves and develop their self-concepts partly on the basis of how they are treated and perceived by others. Hence, chronic negative evaluations, at the level of both

concrete interpersonal interactions and broad-based cultural norms, have detrimental effects on sexual minorities' self-evaluations and, accordingly, their mental well being. Given that adolescence is a period during which young people show heightened concerns about how they are viewed and treated by others, and during which their self-concepts undergo rapid and frequent revision, experiences of sexual-minority stress may be particularly acute (see Marks, Ejesi, McCullough, and García Coll, Chapter 9, this *Handbook*, this volume, for a discussion of similar processes among ethnic-minority youth). Yet, importantly, stigma, discrimination, and minority stress are *not* uniform experiences. Not only do sexual-minority adolescents face vastly different exposure to minority stress, depending on their individual family backgrounds, social class, geographic environments, etc., but they are also equipped with vastly different coping resources, due to personality characteristics, familial and school resources, and institutional protections from harassment and discrimination. This variability helps to explain why some studies have *not* found significantly greater mental health problems among sexual-minority individuals than among their heterosexual counterparts. Because different studies capture different subgroups of sexual-minority youth, with different psychosocial risk factors, different degrees of exposure to prejudice and discrimination, different sets of family issues, and different coping mechanisms, such variability in the findings is to be expected. Furthermore, social attitudes toward same-sex sexuality have been gradually changing over the years, reducing some sexual-minority individuals' exposure to minority stress. Hence, while some sexual-minority youth continue to face unrelenting stigma in their local communities as a result of their same-sex sexuality, others are able to live lives that are relatively free of harassment, shame, and denigration, and may enjoy full support, validation, and acceptance from friends, family members, and coworkers. In this respect, sexual-minority youth in Europe and North America appear to be better off than sexual-minority youth in countries where there is substantially less acceptance and visibility of same-sex sexuality, and where there are often fewer social support resources for sexual-minority adolescents and adults (Chan, 2010; J. T. Sears, 2005a, 2005b).

Yet one point bears emphasis: Among the diverse forms of stigmatization that sexual-minority youth may experience, the single most pernicious is familial rejection. One influential study of a diverse sample of sexual-minority youth aged 21 to 25 (C. Ryan, Huebner, Diaz, & Sanchez, 2009) found that family rejection was reliably rated to

poorer physical and mental health outcomes, including an eightfold increase in the risk of suicide attempts, a 6-fold increase in the risk of depression, and more than a threefold increase in the risk of substance use and unprotected sexual intercourse. Notably, boys were more likely to report familial rejection than girls, and Latino American male youth reported the highest rates of family rejection overall, suggesting that cultural variations in notions of gender and sexuality must be taken into account when considering young people's differential exposure to minority stress. Yet perhaps even more striking, this study found that increased risks for mental and physical health problems and suicide attempts were also found for youth reporting familial disapproval rather than outright rejection: They measured reports by youth of their families' negative reactions to their sexuality, and found a linear relationship between the negativity of families' responses and children's health outcomes. This is a particularly important finding given that many youth report that although they have disclosed their sexuality to their parents, their parents refuse to discuss it openly, and often make their disapproval known in numerous subtle ways (D'Augelli, Grossman, & Starks, 2005). Clearly, sexual-minority youth appear to be highly sensitive to their family's responses to their sexuality, and even mildly negative responses have potentially negative implications for young people's adjustment and development. Future research is clearly needed on the long-term processes through which families—and particularly parents—gradually progress from initial disapproval of a family member's same-sex sexuality to increasing acceptance.

Gender-Nonconforming Youth

Much of the stigmatization that sexual-minority youth face from their immediate peers as well as the culture at large is inextricably tied in with an explicit or implicit condemnation of gender nonconformity (reviewed in Toomey, Ryan, Diaz, Card, & Russell, 2010). Adolescence is a developmental period during which gender norms take on increased salience and significance, and a young person's peers can be unforgiving enforcers of gender-appropriate behavior. In this scenario, gender nonconformity and same-sex sexuality come to be conceptualized as proxies for one another. A girl who appears too "mannish" is taunted as a lesbian, and a gay boy is considered "not a real man." Gender-nonconforming adolescents often face the same stigmatization and condemnation that are typically heaped upon openly identified lesbian/gay/bisexual

adolescents, regardless of whether they experience same-sex attractions. Similarly, young people with same-sex attractions who also happen to be gender-nonconforming are disproportionately likely to be suspected of homosexuality and hence targeted for harassment and victimization (Grossman, D'Augelli, Howell, & Hubbard, 2005). Thus, it becomes critically important to take account of the range of gender-linked traits and behaviors comprising a young person's personal and externally perceived gender identity in order to make sense of his or her particular psychosocial developmental trajectory.

With this in mind, certain clarifications are in order. Gender identity refers to an individual's internalized psychological experience of being male or female, whereas gender nonconformity refers to the degree to which an individual's appearance, behavior, interests, and subjective self-concept deviate from conventional norms for masculinity/femininity. This distinction is critically important, because although research has found that some lesbian/gay/bisexual individuals are more gender-nonconforming than heterosexuals on certain traits, this does not typically extend to their core sense of internalized maleness or femaleness (Lippa, 2000). Thus, although it has long been common to view gay men and lesbians as "reversed" in their gender identity because they possess "reversed" sexual desires, this is not generally the case. Furthermore, research has found notable diversity regarding the sexual orientations of transsexual individuals (i.e., individuals whose gender identities are discordant with their biological sex). For example, there are biological males with female gender identities who are sexually attracted to women, biological males with female gender identities who are sexually attracted to men, and so on (Cole, Denny, Eyler, & Samons, 2000; Devor, 1993).

Research on gender-nonconforming youth lags far behind research on sexual-minority youth, and thus many basic questions such as "how many adolescents are gender-nonconforming" remain unanswered. One large-scale study of 6- to 10-year-old children (Sandberg, Meyer Bahlburg, Ehrhardt, & Yager, 1993) found that approximately 23% of boys and 39% of girls showed 10 or more different gender nonconforming behaviors. It is difficult to make inferences about the prevalence of adolescent gender nonconformity from these data, however, because there is evidence that, as children grow older and begin to perceive the social implications of gender nonconformity, they consciously modify their own behavior, sometimes becoming extremely gender-stereotyped in order to avoid and compensate for

prior stigmatization (Hunter, 1993). At the same time, some young people who were relatively gender-typical in childhood may go through a gender-nonconforming phase during adolescence as they work through changes in their internalized sense of masculinity/femininity brought about by the biological and social transitions of sexual maturation (Bancroft, 1990).

One of the most salient factors differentiating adolescents' experiences of gender nonconformity is gender itself. Mild forms of gender nonconformity are more common among women, less stigmatized, less likely to be treated as an indicator of psychiatric disturbance, and less strongly perceived to be associated with same-sex sexual orientation (Kosciw, Greytak, & Diaz, 2009; Zucker & Bradley, 1995). For example, young "tomboys" are often extremely popular with both peers and teachers, and their behavior does not typically trigger extreme parental concern unless it persists in marked form well into adolescence (reviewed in McGann, 1999). In contrast, "sissies" face more outright condemnation and social rejection, and their behavior is more likely to be considered potentially pathological by parents, teachers, and physicians (Zucker & Bradley, 1995).

In addition to the obvious issues of stigmatization, social ostracization, and harassment, it is important to consider the internal psychological sequelae of gender nonconformity during the adolescent years, particularly the concerns of young people about the nature of their sexual identity. As noted above, as a result of cultural associations between gender nonconformity and homosexuality, gender-nonconforming youth are not only frequently suspected of being lesbian/gay/bisexual, but often wonder themselves whether this is the case, even in the absence of same-sex attractions, reflecting the fact that there is more cultural space for a notion of gender-typical sexual minorities than for gender-nonconforming heterosexuals (Hunter, 1993). In other words, although people may no longer unilaterally presume that all gay men are hyperfeminine, it is still commonly presumed that any man who is hyperfeminine is likely to be gay. Thus, in addition to confronting the same risks for stigmatization, isolation, and harassment that are confronted by sexual-minority youth, gender-nonconforming youth also face the problem of having their sexual identity defined for them, often before they have even had a chance to reflect upon it themselves.

On this point, it bears noting that the association between gender nonconformity and sexual orientation is not altogether fallacious. Sexual-minority adolescents and adults

recall significantly more gender-nonconforming ideation and/or behavior in childhood than do heterosexuals, as well as reporting significantly more contemporaneous gender nonconformity (Lippa, 2000). The perennial question, of course, is why. One possibility (consistent with most folk wisdom on the issue) is that gender nonconformity and same-sex sexual orientation have a common biological etiology, whereas another possibility is that the widespread cultural conflation of these two phenomena creates a socially induced self-fulfilling prophecy, such that sexual-minority individuals end up recalling and adopting the very gender-nonconforming behaviors that everybody expects them to recall and adopt (see Bailey, 1996). Both possibilities may be operative. The most important point is not to *assume* direct correspondence between a young person's gender nonconformity and his or her sexual identity.

Transgender Youth

Whereas gender-nonconforming youth deviate from gender norms and stereotypes while maintaining a clear-cut sense of their personal identity as male or female, transgender youth are those whose gender-related *identification* does not conform to conventional standards presuming a coherent, singular, and unambiguous self-concept as male or female. Historically, most research on transgender individuals focused exclusively on *transsexuals*, who typically reported feeling that there was a fundamental mismatch between their psychological sense of gender and their biological sex, and who sought to resolve this misalignment through a combination of physical transformation (via clothes, makeup, demeanor, hormones, or surgery) and formal changes in legal status (Henton, 2006; Lawrence, 2007). Yet although transsexualism might be the most widely known form of transgender experience (among both psychologists and laypeople alike), it is certainly not the only one. In fact, the word and concept *transgender* came into use specifically because many individuals with more complex and ambiguous experiences of gender identity felt that they were poorly described by models of transsexualism.

In fact, one of the most important developments over the past several decades of research on gender identity expression has been the increasing appreciation of the diversity of the transgender population (Ekins & King, 1999; Gagné, Tewksbury, & McGaughey, 1997; Halberstam, 2005; Roen, 2002). Contrary to the widespread assumption that most

transgender individuals are distressed by, and hence seek to resolve and eliminate, discrepancies or ambiguities in their psychological experience and physical expression of gender, research has revealed that many transgender children, adolescents, and adults *embrace* their fluid, shifting, and ambiguous gender identifications, and do not seek unambiguous identification as male or female. For example, Gagné et al. (1997) charted multiple forms of gender identity in their diverse sample of transgender participants. Although some sought a complete and clear-cut switch from one gender category to the other, others maintained various mixtures of male and female attributes, sometimes aided by the selective use of surgery and hormones and sometimes not. The diversity of contemporary transgender experience is reflected by the wide array of identity terms adopted by transgender youth and adults, including gender blender, gender bender, gender outlaw, gender queer, drag king/queen, trans, transgender(ist), and queer (Ekins & King, 1999).

In embracing the complexity and fluidity of their gender identities, transgender youth pose an inherent challenge to traditional assumptions that the normative and healthy endpoint of transgender identity development must involve the adoption of a stable, integrated, unambiguous identification as 100% male or 100% female (Diamond, Pardo, & Butterworth, 2011). After all, as early as 1987, the *Diagnostic and Statistical Manual of Mental Disorders (DSM-III-R*; American Psychiatric Association, 1987) recognized a lack of coherent identity as a risk factor for poor mental health outcomes (Poston, 1990). Yet there have been important conceptual and theoretical advances to researchers' understanding of gender and transgender identity development. For example, Denny, Leli, and Drescher's model (Denny, 2004) deemphasized the rigid gender binary that characterized conventional models of gender identity development, and instead presumed the existence of parallel gender continuums inclusive of male and female dimensions. Despite these changes, psychologists tend to express ambivalence about whether it is healthy for young people to embrace permanently liminal, flexible senses of gender, instead of moving progressively toward the goal of consistently identifying as male or female (reviewed in Mallon & DeCrescenzo, 2009). Yet there is no empirical data directly speaking to this question. In contrast to the extensive body of research on conventional gender identity development (Ruble et al., 2007), little research has focused on the basic developmental processes of transgender identity development in nonclinical populations (Gagné et al., 1997), or has

explored normative and resilient outcomes in this population. This is clearly an important topic for future research.

Exposure to Stigmatization

One finding regarding the mental health of transgender adolescents is unambiguously clear: Social stigmatization, including physical victimization, poses the preeminent threat to the mental and physical health of transgender youth. These findings concord with the *minority stress* model of sexual-minority health (Meyer, 2003), which specifies that sexual minorities' acute exposure to environmental stressors such as verbal or physical abuse, institutional discrimination, interpersonal harassment, and general social marginalization confers cumulative psychological stress. This stress, in turn, negatively affects both mental and physical well-being. Transgender and gender-variant individuals are subjected to widespread psychological and physical abuse (Feinberg, 2006). A recurring survey conducted by the National Coalition of Anti-Violence Programs (NCAVP) of bias-motivated violence against gender and sexual minorities has found that hate crimes against gender-nonconforming adolescents and adults accounted for one-fifth of all documented murders (National Coalition of Anti-Violence Programs, 1999, 2007). A survey of 515 trans-identified people (392 male-to-female, 123 female-to-male; Clements-Nolle, Marx, & Katz, 2006), reported that 28% of the respondents had been in an alcohol or drug treatment program, 62% had experienced gender discrimination, 83% had experienced gender-related, verbal discrimination, 59% had experienced sexual assault (rape), and 32% had reported attempted suicide. Among the sample's youth (<25 years of age), nearly half had attempted suicide as a result of gender-based victimization.

Transgender and gender-variant adolescents are particularly vulnerable to environmental stressors. Such youth routinely face verbal and physical harassment at the hands of peers (Sausa, 2005), sometimes several times a day, leaving them feeling fundamentally unsafe at school. Even youth who escape victimization in school must contend with heightened psychosocial stress in their daily lives. In addition to the normative stressors associated with adolescent social and psychological development, gender nonconforming adolescents often struggle with an inability to articulate to others *why* they feel different, and hence frequently report feeling isolated, depressed, hopeless, or utterly invisible to friends and family (Swann & Herbert, 1999). To cope with feelings of shame and isolation,

transgender and gender-variant youth may display a range of externalizing problems, including running away from home, dropping out of school, abusing substances, or self-harm (Sausa, 2005).

In the context of these risks and stressors, what conclusions might we draw about different trajectories of transgender identity development? One likely possibility is that during the adolescent years, it may be difficult—or impossible—to tell whether a particular young person is “headed” for one trajectory or another. Although some adolescents may self-identify as transsexual at fairly early ages, expressing clear desires to permanently change their gender, it is important to remember that such youth may perceive that this is the *only* outcome of gender questioning. The possibility of adopting a more fluid, liminal sense of gender may never have occurred to many youth; in addition, they are unlikely to have any visible models of such forms of gender fluidity. Hence, their ability to craft a meaningful autobiographical narrative that contains—and makes sense of—their conflicting and changing experiences of masculinity and femininity is impaired. Given this limitation, the healthiest identity trajectory for transgender adolescents may be one that makes no presumptions about desirable outcomes, and sets no timetables for resolution, but instead remains open to multiple possibilities over potentially long periods of time. Young people need time, support, information, and autonomy as they grapple with their own sense of gendered selfhood and seek a comfortable and personally authentic constellation of female-typed, male-typed, and gender-neutral traits. *Changes* in this constellation—at the level of cognition as well as appearance, and occurring during adolescence as well as adulthood—may be part and parcel of the identity development process.

One thing, however, is abundantly clear: Neither transgender youth nor adults can embark on this process without a basic sense of safety. As long as transgender individuals are forced to navigate their school and family worlds with an ever-present, debilitating fear of stigmatization, ostracization, humiliation, and physical violence, they cannot be expected to achieve a healthy sense of self-determination, whether such self-determination involves switching their gender identity or making peace with a lasting sense of gender fluidity. Supportive adults can play a key role in facilitating resilience and positive development (Mallon & DeCrescenzo, 2006; C. Ryan et al., 2009). Decades of research on resilience, conducted with mainstream as well as at-risk populations, has shown that adults can strengthen youth by teaching them how to respond positively to

adversity (Luthar, Crossman, & Small, Chapter 7, this *Handbook*, this volume). With respect to transgender youth in particular, adults may require special education and awareness. For example, learning the preferred names and pronoun usage of transgender youth is critical to gaining their trust and supporting their own developmental pathways. Similarly, ensuring and maintaining confidentiality is critical for demonstrating to transgender youth that their safety will not be compromised, given the risks that these youth typically face for discrimination and violence. Finally, research on resilience suggests that young people flourish when they know that adults believe and nurture their capacity to succeed, and hence it is important to encourage transgender and gender nonconforming youth to be visible and proud leaders and role models for others just like them. It bears noting that most of what we know about the developmental needs of transgender and gender-nonconforming youth comes from research conducted in North America. Although similar processes for fostering resilience and healthy development likely operate across cultures, much more research is needed on the culturally specific needs of young people with diverse gender identities and presentations.

FUTURE DIRECTIONS

In reviewing the historic record on approaches and attitudes regarding adolescent sexuality, Maccoby (1998) concluded that the legendary sexual revolution of the 1960s and 1970s involved a realization by youth that they have a right to sexual pleasure and fulfillment, and a right to resist restrictive social standards regarding “good” versus “bad” sexual behaviors and pursue their own standards. Yet despite these dramatic changes, contemporary society continues to hold ambivalent and fearful views of adolescent sexuality, and these views have hampered our understanding of the best ways to promote the sexual well being of young people (Lerner, Lerner, Bowers, & Geldhof, Chapter 16, this *Handbook*, Volume 1). In short, it is difficult to foster positive sexual-developmental trajectories among adolescents if we have no idea (and no empirical evidence) about what such trajectories look like. Clearly, one of the consequences of our culture’s historical emphasis on negative aspects of adolescent sexuality is that researchers have spent comparatively little time developing coherent, evidence-based models of healthy, positive sexuality that involve more than the simple absence of negative outcomes. Given the long-standing tendency

for researchers to conceptualize adolescent sexuality as a constellation of discrete and dangerous behaviors and experiences, insufficient attention has been paid to the total psychological and physical experience of erotic and affectional desires, cognitions, and behaviors of young people. The next section outlines some of the most important and pressing areas for future research that can help scientists, educators, advocates, and parents to identify and foster positive sexual-developmental trajectories from childhood to adulthood.

Attention to Early Stages of Sexual Development

Perhaps the most pressing area for future research concerns the sexual feelings, cognitions, and experiences of young children, including the processes by which they consciously question and consider *both* same-sex and other-sex feelings and experiences. As noted above, the logistical obstacles to such research are daunting: Our culture generally frowns on direct assessments of children’s sexual thought and feelings, and assessments of *same-sex* thoughts and feelings are even more taboo, prompting fears that they might “nudge” children in a same-sex direction. Yet a decade after Carver et al.’s groundbreaking study of children’s sexual questioning (discussed earlier) was published in *Developmental Psychology* (Carver et al., 2004), the key questions that they identified as critical “next steps” remain unanswered. Specifically, we still do not know the basic factors that lead children to begin questioning their sexuality; the degree to which (or situations under which) childhood questioning predicts adolescent or adult same-sex sexuality; whether sexual questioning has different causes or consequences when undertaken by heterosexual versus sexual-minority youth; the mental health risks and benefits associated with questioning; and how best adults can support and assist children undergoing sexual questioning.

Of the publications that have cited Carver et al.’s paper since its publication, nearly all focus on childhood gender atypicality, rather than sexual questioning, and the studies that specifically address sexual questioning focus on adolescents and young adults. Hence, there remains an enormous blind spot in our understanding of the phenomenology, antecedents, and implications of *childhood* experiences of sexual questioning, despite considerable evidence (from the retrospective reports of adults) that sexual questioning often begins in childhood. Importantly, this blind spot hampers our understanding of the development of *heterosexual* orientations just as much as it hampers

our understanding of the development of gay, lesbian, or bisexual orientations. Longitudinal studies indicate that adolescents often express as much ambivalence and uncertainty regarding their *other-sex* attractions as their same-sex attractions (Diamond, 2008b; Savin-Williams & Ream, 2007). Basic questions about the process and time course by which children begin to link their erotic impulses to a stable set of gender-linked attributes, and the subsequent process of linking those impulses to the phenomenon of emotional attachment (i.e., romantic love) have never been systematically addressed. We know that children experience relatively amorphous sexual impulses in their early years, and that their emotional ties are divided between friends (which are usually same-sex) and family (which include both same-sex and other-sex members). We know that, by the end of adolescence, their most intense and involving emotional bonds are typically formed with sexual partners, typically opposite-sex partners, and that their sexual feelings typically center on the opposite sex partners as well (with the exception of approximately 10% of the population who experience consistent sexual attractions for both sexes, and a much smaller percentage who experience all of their attractions for the same sex). But how do children get from Time 1 to Time 2? What are the intermediate, childhood stages of sexual development that are specifically relevant to sexual orientation? Retrospective accounts by adults provide some information, but this information is always filtered through adult knowledge, language, and experience. Understanding the development of both heterosexual and nonheterosexual orientations *from the child's unique phenomenological point of view*, and having accurate scientific data on the long-term developmental implications of this process, would provide parents, clinicians, and educators with the information that they need to provide appropriate support and scaffolding for all youth undergoing the normative transitions of sexual development.

More Integrative Biosocial Models

Historically, biological research on adolescence focused predominantly on developmental changes in gonadal hormones. Yet contemporary scientists studying the biological changes of childhood and adolescence focus on a much broader range of processes, including changes in brain structure and functioning, epigenetic processes, and stress-regulatory systems (in this *Handbook*, see de Haan, Chapter 18, Volume 1; Gunnar, Doorn, & Esposito, Chapter 4, this volume; Lickliter and Honeycutt, Chapter 5,

Volume 1; Marshall, Chapter 7, Volume 1; Stiles, Brown, Haist, & Jernigan, Chapter 2, Volume 2). Too little of this groundbreaking work has been applied to the study of sexual development and expression, perhaps reflecting the degree to which developmental scientists have tended to treat sexuality as a “special topic” rather than a fundamental, integrative component of normative child and adolescent experience.

Among the most promising topics for future study is the role of adolescent brain development for adolescent sexual development. There is now an extensive body of neurobiological research on sexuality (most commonly using functional magnetic resonance imaging, or fMRI, but also PET, or positron emission tomography, and less often EEG, or electroencephalography). One of the most important and provocative topics of inquiry in this domain concerns the degree of overlap between brain regions involved in adolescent experiences of romantic love and attachment and brain regions involved in sexual arousal (reviewed in Diamond & Dickenson, 2012). Findings from research on adults currently suggest that romantic love and sexual arousal are neither neurobiologically independent nor wholly overlapping. The specific pattern of brain regions that show activation for love versus desire suggest that differences between the subjective experiences of “targeted” arousal (i.e., sexual arousal in response to a specific love object) versus generalized arousal might be neurobiologically mediated. If so, then developmental changes in the brain structures involved in sexual desire may correspond to developmental changes in young people’s subjective experiences of sexual desire. Investigating this question can make tremendous contributions to the basic developmental science of sexuality, and can elucidate the degree to which other aspects of neural development (for example, maturation in structures related to decision-making, future-oriented thinking, self-regulation) interact with the brain regions involved in sexuality to shape trajectories of sexual behavior and other behaviors in young adults. Hence, the next major “wave” of research on adolescent sexual development may involve the integration of traditional hormonal and self-report assessments with neuroimaging.

Integration of research on adolescent sexuality with research on adolescent stress-response systems offers another important area of study. A growing body of research has investigated whether individual differences in autonomic nervous system (ANS) and hypothalamic-pituitary-adrenocortical (HPA) reactivity to stress predispose children to be differentially sensitive to environmental

challenges. Most of this research has adopted a diathesis-stress or “dual-risk” perspective, positing that negative rearing environments have disproportionately negative effects on children with exaggerated ANS and HPA responses to stress (reviewed by Boyce & Ellis, 2005). Yet, as noted earlier, recent work adopting a “differential susceptibility” perspective (Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011) has demonstrated that, for some outcomes and some contexts, heightened stress reactivity not only increases children’s sensitivity to the risks of negative environments, but *also* increases their sensitivity to the benefits of positive environments. The potential evolutionary basis for differential sensitivity has been laid out in the adaptive calibration model of stress responsivity (Del Giudice, Ellis, & Shirtcliff, 2011), which posits that, during the first year of life (and also potentially during certain transitional “windows” of development, such as puberty), humans’ stress-response systems encode and filter information about the degree of advantage and adversity in the immediate environment, in order to “calibrate” relevant stress response systems toward greater or lesser vigilance in the service of overall adaptation. According to this model, children born within adverse environments will develop highly reactive stress-response systems that allow them to quickly detect and respond to potential threats. Yet this heightened reactivity *also* renders young people more “open” to positive environmental influences. Hence, the heightened sensitivity of infants born into adversity offers both risks and benefits as these children progress through adolescence and adulthood, rendering them more sensitive to environmental deficits and strengths.

Thus far, research testing the differential vulnerability model has focused on conventional adjustment outcomes such as mental health and social competence (for example, Diamond, Fagundes, & Cribbet, 2012). Yet it is likely that individual differences in stress-response systems also shape young people’s susceptibility to positive and negative influences on their sexual development and expression. Normative developmental increases in sexual desire and behavior, with their attendant emotional and self-regulatory challenges and opportunities, place heightened demands on stress-regulatory systems that are still “under construction” on a neurobiological level (Dahl & Spear, 2004), potentially increasing some young people’s susceptibility to the repercussions of positive and negative emotional experiences. Hence, greater assessment of individual differences in the physiological stress reactivity of young people,

in concert with detailed assessment of their early rearing environments and their current environmental contexts, can reveal long-range patterns of adaptation and adversity that help to explain how different youth may undergo similar sexual experiences in adolescence, and yet show markedly different adjustment outcomes. In particular, research investigating the mechanisms underlying positive and negative family and peer influences on adolescent sexuality (reviewed above) should systematically consider *which* young people (i.e., those with certain reactivity profiles) are most susceptible to such influences, and how this information can be integrated into attempts to develop health-promoting interventions.

Greater Use of Mixed Models

Although the vast majority of previous research on adolescent sexuality has relied on quantitative self-report assessment, a key direction for future research involves the application of more diverse methodologies, particularly mixed qualitative/quantitative modeling (Tolan & Deutsch, Chapter 19, this *Handbook*, Volume 1). Although researchers have collected increasingly detailed and reliable data on adolescent sexual behavior around the globe, we lack sufficient information on the motives, needs, expectations, and interpretations of young people as they move through successive sexual experiences from childhood to adulthood. A 15-year-old working-class girl in Ireland might report the same number of weekly intercourse experiences as a 15-year-old middle class boy in South Africa, but the underlying *reasons* for their behavior might differ markedly, as will their developmental implications. Detailed data on the sexual experiences of young people should ideally be integrated with assessments of the degree to which young people *intentionally* sought certain types of sexual experiences and relationships. Additionally, we lack information on how they interpret sexual experiences after they are over, and how they understand the reasons why one experience might be more satisfying or stressful than another. The processes through which young people make sense of their unfolding sexual thoughts and feelings—both privately and in interaction with peers and family members—may vary markedly as a function of age, gender, social class, religion, and ethnic background, and yet we understand little about such processes and their potential impact on future adjustment.

Hence, future research should complement the collection of quantitative data on the sexual experiences of young people with *qualitative interview data* assessing their

motives and expectations regarding different types of experiences and their interpretations and evaluations of those experiences after they have occurred. The work of Tolman provides an important model for this approach, with its longstanding emphasis on using qualitative interviews to investigate young people's subjective interpretations of their sexual/romantic experiences and to understand the specific implications of these subjective interpretations for mental and sexual health (Tolman, 2002, 2006). The most important direction for future research involves greater *integration* of qualitative, phenomenological data with conventional quantitative measures of adolescent sexual behavior and functioning, and the application of this mixed modeling approach to longitudinal studies. Such studies have the potential to reveal how the motives, expectations, and interpretations of young people regarding their sexual experiences relate reciprocally to the unfolding of their sexual-developmental trajectories over time. Bidirectional patterns of association between behavior and meaning-making are likely, in concert with cascade models of cumulative adversity and advantage (Ryff, Singer, & Seltzer, 2002). Specifically, the motives, expectations, and interpretations of young people are expected to shape their decisions, intensions, and actions in subsequent relationships, and the quality of these subsequent relationships will necessarily feed forward to shape future motives, decisions, intensions, and actions. Hence, by integrating longitudinal quantitative data on the sexual/romantic trajectories of young people with longitudinal interview data, researchers will be able to investigate how and why young people transition from one type of sexual relationship to another over the course of adolescence, how and why their desires may change, and whether their interpretations of specific experiences predict the future direction of their trajectories.

This information will be particularly useful for understanding cases in which the sexual-developmental trajectories of youth "change course," as when they experience unexpectedly positive or negative sexual experiences. Deriving beneficial insights from otherwise negative experiences appears to be particularly important for psychosocial adaptation (for example McLean, Breen, & Fournier, 2010). In the case of sexuality, young people who craft meaningful insights from sexual experiences that prove stressful, disappointing, or traumatic might be best equipped to achieve higher-quality sexual relationships in the future. Hence, understanding these processes can directly contribute to the future development of health-promoting interventions aimed at fostering the abilities of young people to form and benefit from

healthy sexual relationships during the adolescent years and beyond.

Integration of Dyadic Approaches

Ideally, application of the mixed modeling approach recommended above should incorporate the perspective of adolescents *and their current sexual partners*. Historically, studies of child and adolescent sexuality have treated the individual as the unit of analysis, even though partnered sexual interactions are inherently dyadic phenomena. Thus, in attempting to predict an adolescent's pattern of sexual activity from his or her biology, personality, motives, environment, or personal history, we are effectively assuming (incorrectly) that *partners* are blank slates without biological predispositions, personalities, motives, environments, or personal histories of their own. Dyadic approaches have been increasingly applied to studies of adolescent peer and romantic relationships (Furman & Rose, Chapter 22, this *Handbook*, this volume), and warrant similar integration into studies of sexuality. The lack of simultaneous data collected from *both* members of adolescent sexual dyads may represent the single most important "missing link" in the study of child and adolescent sexual development. The reasons for this missing link are numerous: To the extent that it is challenging to convince young people to reveal personal, potentially sensitive information about their sexuality to researchers, it is doubly challenging to convince young people to invite their sexual partners to do the same, especially when these sexual partners are "hookups" or "friends with benefits" instead of established boyfriends or girlfriends. Normative adolescent concerns about social evaluation make it unlikely that young people would feel comfortable participating in a study in which they and their partner reported on their feelings and experiences *with each other*, and these concerns are likely more pronounced among sexual-minority youth. Youth in longer-term relationships may prove less susceptible to such concerns, and may present the most promising possibilities for dyadic research. Ideally, future research should investigate the push-and-pull between each partner's motives, expectations, personalities, priorities, and fears, from the initial decision to pursue sexual activity to the negotiation of condom and contraceptive use to the moment-by-moment unfolding of different acts to "post-coital" interactions. Of course, the well-known problem of statistical nonindependence between reports of partners in a dyad has historically made it difficult to conduct valid and interpretable dyadic analyses, but there are now well-validated techniques for analyzing dyadic and other

forms of nested data, such as structural equation modeling and multilevel random coefficient modeling (sometimes called hierarchical linear modeling). Such techniques make it possible, for example, to test hypotheses about the degree to which each adolescent's personal characteristics contribute to characteristics of the sexual dyad (e.g., latency to begin sexual activity within a particular relationship).

Even in cases of seemingly "individual" phenomena such as sexual desire, fantasy, and masturbation, researchers should attend to young people's cognitions and motives regarding dyadic sexual contact. Van Anders (2012) has found that the hormonal underpinnings of dyadic desire (i.e., desire for sexual activity and release *with another person*) differs significantly from the hormonal underpinnings of solitary desire (i.e., desire for sexual release without a partner). Although most research fails to even acknowledge this distinction, van Anders' work has shown that in adults, the distinction has important biobehavioral implications. Specifically, she found that women's testosterone levels were positively linked to their solitary desires, and that masturbation frequency moderated this link. Yet testosterone levels were negatively correlated with dyadic desires in women, once concurrent levels of cortisol and self-reported stress were controlled for. These provocative findings suggest that even before adolescents begin acting on their desires with other individuals, the very *idea* of dyadic sexual activity may engender different neuroendocrinological processes, and may have altogether different social and behavioral moderators than desires for solitary sexual release. Investigating these distinctions among adolescents, and charting their developmental time course, provides a provocative and potentially groundbreaking direction for future research on sexual development. For example, one possibility is that the very distinction between solitary and dyadic desire may only become meaningful after the pubertal transition, due to the changing levels of gonadal hormones. Another area for future study concerns youths' own interpretations of solitary versus dyadic desires, and the factors that render some youth better able to discern whether they simply want sexual release (which can be easily accomplished with masturbation) or whether they want sexual *partners*.

CONCLUSION: MOVING TOWARD MODELS OF POSITIVE SEXUAL DEVELOPMENT

The researchers whose work we reviewed in this chapter adopt diverse perspectives on positive, healthy sexual development during childhood and adolescence, but we

think that most would hew to the interpretation offered by the World Health Organization (2004), which convened a meeting on sexual health in 2002 to clarify such definitions. According to WHO, sexuality "is a central aspect of being human" that incorporates eroticism, intimacy, pleasure, reproduction, and one's own gender identity. Manifestations of sexuality include not only sexual behaviors, but wishes, desires, fantasies, attitudes, roles, and relationships. WHO also views sexuality as inherently multidimensional, integrating biological, cultural, social, economic, psychological, ethical, and spiritual factors. "Positive" or "healthy" sexuality, then, requires that individuals have adequate freedom and knowledge to pursue safe and satisfying sexuality. In the compelling words of WHO, "Sexual health is a state of physical, emotional, mental and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe sexual experiences, free of coercion, discrimination and violence" (2004, p. 3).

Importantly, positive sexual development cannot simply be switched on at sexual maturation. Rather, positive sexual-developmental trajectories have their origins much earlier, in pathways of positive interpersonal and psychosocial development that become established in childhood. The transitions of sexual maturation weave together different strands of psychological, physical, and social development in powerful and potentially transformative ways. Unless those individual strands already contain the foundations for healthy self-concepts, feelings of agency, and social competence, it is unlikely that young people can suddenly repair prior deficits and craft new and healthy sexual pathways to adulthood. Thus, advocacy for positive *lifespan* sexual development must begin with an expanded research focus on positive *child and adolescent* sexual development.

Such an approach does not entail that we deemphasize sexual risks, but that we place them in context. As reviewed by Baumgartner et al. (2010a), risk behaviors can be defined as *any* behaviors with the potential for negative consequences. According to this perspective, *all* sexual behavior is risk behavior, given that all sexual behaviors (even those between married, consenting adults) involve the potential for sexually transmitted infections, embarrassment, and exploitation of vulnerability, misunderstanding, and disappointment. Hence, from a developmental perspective, the right question is not "how do we eliminate risk from adolescent sexuality," but "what sexual risks are appropriate and reasonable

at different stages of development, and what types of factors (including personality traits, relationship factors, family background, and sociocultural context) augment or ameliorate these risks?" Approaching sexual development from this perspective opens up the possibility for broader conversations about risk/benefit balances in all dimensions of life, most notably intimate relationships. Murray, Derrick, Leder, and Holmes (2008) have argued that processes of risk regulation play a fundamental role in close relationships, given that individuals cannot experience the benefits and rewards of interpersonal closeness and intimacy without taking the risk of making themselves vulnerable to their partner and thereby exposing themselves to the potential for pain, rejection, shame, and betrayal. Similar dynamics are at play with sexual intimacy, and we need more systematic research on how children and adolescents gradually begin to understand the risk/benefit trade-offs in their own sexual expression at different stages of development.

The importance of developmental change cannot be overemphasized: One of the weaknesses of previous research on adolescent sexuality is the implicit presumption that child and adolescent sexuality simply represents an "underdeveloped" version of adult sexuality, and that growth and maturity can be charted by simply measuring young people's desires, attitudes, beliefs, and behaviors against those of adults. Although there are certainly many aspects of child and adolescent sexuality that fit this overall model (for example, developmental increases in the ability of young people to control their sexual impulses and make conscious decisions about their expression), there are other aspects of child and adolescent sexuality (for example, the content of adolescent fantasies, the nature of childhood sex play) that may best be treated on their own terms, as "fully mature" forms of sexual expression *for certain developmental stages*. Hence, instead of encouraging adolescents to "grow out" of their interest in pornography, their frequent masturbation, or their urge to publicly disseminate sexual information about themselves to their peers, we might instead devote greater attention to understanding the factors that render certain sexual feelings and behaviors normal, healthy, adaptive, and appropriate during certain developmental periods, even if these practices might appear, from an adult perspective, to be unconventional, immature, confusing, or disturbing. Furthermore, we must devote greater attention to the full range of young people's sexual experiences, including their romantic and sexual fantasies and beliefs, rather than focusing exclusively on sexual behavior. As stated by de Graaf et al. (2011) in their

review of research on predictors of first sexual intercourse, "sexual experience *per se* is not a very good measure of sexual health" (p. 28).

We maintain that a developmentally sensitive, positively valenced approach is best suited for developing accurate, unbiased, evidence-based models of sexual development that contain the information needed by parents, educators, and clinicians to foster child and adolescent well-being. The earlier in development that parents, teachers, and clinicians convey positive, self-enhancing messages about sexuality to children, the more likely that children will develop positive developmental trajectories that are enhanced by frequent and open dialogue with their parents. Carpenter (2001, p. 128) noted that "sexuality constitutes a central feature of identity: individuals are to a great degree defined by themselves and others, both socially and morally, in terms of their sexuality." For this reason, attempts to foster optimal child and adolescent development cannot afford to *ignore* issues of sexuality and their lifelong interconnectedness with other dimensions of well-being.

INTRODUCTION

In this chapter, we discuss the current state of the literature on children and adolescents' dyadic peer relationships.

Preparation of this paper was supported by Grant 50106 from the National Institute of Child Health and Human Development (W. Furman, Principal Investigator).

We focus primarily on children's and adolescents' romantic relationships and same-sex friendships because of their particular significance to development. However, we also discuss other dyadic peer relationships, such as other-sex friendships and antipathies. We discuss the links between dyadic peer relationships and the broader peer group, but a more comprehensive review of peer group interactions can be found in Rubin, Bukowski, and Bowker (Chapter 5, this

Handbook, Volume 4). Our aim is not to provide a comprehensive review of the topic—an impossible task given the breadth of the literature—but to describe recent important findings in the field and identify promising directions for future research. Accordingly, we focus on research that has appeared in 2005 or later. Further information on friendships and romantic relationships can be obtained from other reviews (e.g., Brown & Larson, 2009; Collins, Welsh, & Furman, 2009; Connolly & McIsaac, 2009; Rubin, Bukowski, & Laursen, 2009; Rubin, Bukowski, & Parker, 2006).

We propose a unified relational perspective for conceptualizing all dyadic peer relationships. This perspective has four key features. First, friendships and romantic relationships need to be studied as relationships. By relationships we mean an ongoing set of interactions between two people. They are dyadic phenomena with a history. That is, they are influenced by each person's characteristics, the interaction of their characteristics, and the pattern of their interactions over time. Each person affects the other person's behavior within an occurrence of interaction, and each occurrence affects subsequent occurrences. Such relationships acquire meaning, which is reflected in the participants' cognitions, emotions, and behavior and in subsequent relationships.

Second, children's and adolescents' friendships, romantic relationships, and other dyadic peer relationships share common features. They have been studied as separate phenomena and typically by different investigators. Yet, they are all peer relationships. Many adolescents consider their romantic partner to be friends; many romantic partners were once friends, and, less commonly, some friends were once romantic partners. Friendships, romantic relationships, and other dyadic peer relationships differ in some respects, but both similarities and differences must be identified to understand which processes are specific to one type of peer relationship and which are common to different types of peer relationships or perhaps all close relationships.

If we are to fully understand any particular type of peer relationship, we need to simultaneously consider all of these relationships. We believe that many of the same issues, problems, and insights that have emerged in studies of one relationship apply to the others. Some topics have received considerable attention with regard to one relationship, but could profit from additional attention in the study of other relationships. Thus, one goal of our chapter is to help research on one relationship learn from the research on other relationships. In effect, we hope to promote the integration of the different relationship fields.

Third, any particular relationship is embedded in a network of dyadic relationships. For example, any particular friendship is embedded within a network of other relationships, including other friendships, romantic relationships, and relationships with family members. We review literature on the associations between dyadic peer relationships and family relationships as well as between friendships and romantic relationships.

Finally, our unified perspective not only emphasizes the importance of networks of close dyadic relationships, but also other contextual influences as well. These include the broader peer group, media, and culture. Dyadic peer relationships cannot be understood without consideration of the contexts in which they occur.

With regard to context, an important limitation of the current literature is that the work primarily has been conducted in North America and secondarily in Europe. Thus, we are not able to generalize to other countries. Moreover, many studies in North America and Europe try to obtain samples that are representative in terms of ethnicity, race, or social class. However, these studies often do not examine differences among the ethnic/race or social class subgroups within the sample. Therefore, the conclusions apply to the culture overall but not necessarily to each of the ethnic, racial, or SES subcultures within the sample.

The friendship and romantic relationship literatures also are limited by their primary focus on one type of relationship. Friendship research focuses on same-sex friendships, and the romantic literature focuses on heterosexual romantic relationships. Sometimes other-sex friendships and same-sex romantic relationships are included in studies of friendships or romantic relationships, but these studies usually do not examine differences between same- and other-sex relationships. Therefore, their conclusions apply to friendships or romantic relationships overall but not necessarily to specific subtypes of friendships and romantic relationships.

Using this unified relational perspective, the current chapter reviews research on dyadic peer relationships. In each section, we first review promising new research on friendships and then discuss promising new research on romantic relationships. Next, we compare and contrast the literatures on the two types of relationships with the idea that work on each type of relationship could profit from the work on the other.

Our unified relational perspective also is reflected in the topics we review. We recognize the importance of relationship history by beginning with a discussion of the development of dyadic relationships in childhood and

adolescence. We review research from early childhood through late adolescence. Research on early adulthood is generally considered beyond the scope of the review. The chapter then reviews characteristics of individuals and their partners that influence their relationships. This includes a section on gender and a section on other self and partner characteristics. These sections are followed by discussions of the contexts in which dyadic peer relations are embedded, including family relationships, broader peer group dynamics, media, and cultural contexts. The links between dyadic peer relationships and adjustment are also considered. In each section, future directions are proposed in terms of the specific topic considered. Then, in a separate section, we consider broader future directions in regards to the study of dyadic peer relationships. This includes identifying definitional, conceptual, methodological, analytical issues and understudied topics. We conclude by discussing the merits of a unified relational perspective.

RELATIONSHIP DIMENSIONS

An understanding of relationships requires a multifaceted framework. In this chapter, we primarily examine the following facets: (a) presence and number of relationships, (b) relationship features, including relationship qualities, cognitions and emotions, (c) characteristics of the self and partner, and (d) the history of the relationship.

The presence of a relationship and number of relationships simply refers to whether one has a particular kind of relationship, and, if so, the number of such relationships. In the romantic relationship field, investigators have sometimes examined whether one has a current romantic relationship or not, and sometimes whether one has had such a relationship during some recent period. In the friendship literature, the number of friends one has is often considered.

Relationship features include the quality and content of relationships, relationship cognitions, and emotions. In regards to quality and content, most close personal relationships can be characterized along four dimensions: (1) positive relationship qualities, such as affiliation, warmth, closeness, support, disclosure, and affection; (2) negative relationship qualities, which include conflict and antagonism; (3) relative status/power; and (4) relationship comparisons (i.e., comparisons of the relationship with other relationships, which may be reflected in features such as jealousy, rivalry, or desires for exclusiveness).

Most research has focused on positive and negative features, and less is known about power/status or relationship comparisons. Relationship cognitions and emotions refer to the thoughts and feelings someone has about him/herself in the relationship, about the partner, and about the relationship. We include not only feelings towards one another, but also expectations or representations of oneself in the relationship, of the partner, and of the relationship.

The characteristics of the person and the partner refer to the personal attributes that each person brings to the relationship and their attributes during the course of the relationship. Not only is it important to consider the characteristics of the person and the partner but also the interplay between the two individuals' characteristics.

The final dimension is the history of the relationship over time. Relationships change over time, and the current status of the relationship cannot be fully understood without knowing the history. Individuals develop an affective bond to each other, and have the prospect of future interactions, which are features that distinguish such interactions from those with whom one does not have an ongoing relationship. Despite the importance of history to understanding relationships, this dimension has received little attention, as will be evident in our review.

Finally, it is important to recognize that multiple perspectives exist regarding any particular relationship. An individual has one perspective, the partner has another, and an outsider, such as a social scientist, has a third perspective. There is no such thing as *a* relationship. There are *multiple* relationships. The person has one relationship, the partner has a different one, and outsiders witness another. Even if we had methodologically perfect measures of the different perspectives, they would not converge completely because they ultimately assess different relationships. The key point is that different perspectives provide different information about the relationship due to meaningful differences in perspectives.

Although we have described number, features, person and partner characteristics, and history as separate facets, it is important to examine their interrelations. Similarly, it is important to study how different interactions within particular relationships affect one another in order to understand how relationships function as a whole. In other words, our theories and methods need to take into account the idea that relationships are self-organizing systems. A relationship-centered approach is needed to complement the variable-centered approach that is usually taken.

DEVELOPMENT

In this section we discuss: (a) how the characteristics of relationships change with age and (b) how a particular relationship may change over time in terms of its initiation, growth, and dissolution. We refer to the former as developmental changes in relationships and the latter as within-relationship development.

Friendships: Developmental Changes

Theories of developmental change in friendships highlight the importance of proximity and play in early childhood, helping and shared activities in middle childhood, and intimacy and self-disclosure in adolescence. These developmental differences are generally confirmed by empirical studies (see Rubin, Bukowski, et al., 2006). Recent extensions include: (a) additional evidence of the salience of friendships in early childhood, (b) longitudinal (versus cross-sectional) work on developmental changes in middle childhood and adolescence, and (c) greater attention to the idea that different friendship types may develop as opposed to one universal friendship trajectory.

Recent work suggests that dyadic friendships in early childhood have more in common with friendships of older youth than originally thought. For example, although proximity and play typically have been emphasized in young children's friendships, even early childhood friendships can be differentiated from other peer relationships on the basis of qualities typically assessed later in development, including intimacy, support and conflict (Sebanc, Kearns, Hernandez, & Galvin, 2007). Moreover, among preschoolers, kindergarteners, and first graders, friendship dyads high on positive features are more likely to be stable across the school year.

Research indicates developmental trends in friendship qualities. Although many cross-sectional studies indicate developmental changes in friendship features (see Rubin, Bukowski, et al., 2006), fewer longitudinal studies exist that address these changes. According to recent longitudinal research with samples of Latino/a American, Asian American, and African American youth and Dutch youth, friendship support increases from middle to late adolescence, stabilizing in early adulthood (De Goede, Branje, & Meeus, 2009; Way & Greene, 2006). Negative interactions, including conflict, decrease with age throughout adolescence and stabilize in early adulthood. In addition,

adolescents report more adaptive responses to anger than school-aged children (von Salisch & Vogelgesang, 2005). Specifically, adolescents are less likely than children to report that they would confront, harm, or ignore a friend when angry. Adolescents are more likely than children to report that they would try to explain themselves, reconcile, and, interestingly, use humor to diffuse the situation.

The research previously described adopted a variable-centered approach and is complemented by person-centered studies that highlight different kinds of friendships. For example, three friendship types can be identified on the basis of middle childhood and early adolescents' characteristics in the broader peer group—the socially withdrawn type, the prosocial type, and the antisocial type (Güroğlu, van Lieshout, Haselager, & Scholte, 2007). Friendships consisting of antisocial youth are more common in adolescence than middle childhood, perhaps suggesting greater acceptance of antisocial behavior in adolescence. Socially withdrawn friendships are relatively common among girls in both middle childhood and adolescence. However, for boys, socially withdrawn friendships are rare in middle childhood and more common in adolescence. Prosocial friendships are more common among girls than boys in both middle childhood and adolescence.

Friendships: Within-Relationship Development

How friendships are initiated, maintained, and dissolved has received less attention. Little research exists on how a friendship is initiated. However, the results of one study of preschoolers highlight the social dynamics of friendship formation in early childhood (Schaefer, Light, Fabes, Hanish, & Martin, 2010). Children tend to reciprocate social ties, playing with children who initiate play with them. Over the course of the year, they also tend to form closed triads; that is, one child playing with two other children increases the likelihood that those two children will become friends.

The motivations of children and adolescents for forming friendships have been studied as well. Motivations include intrinsic motivation, or wanting to make friends because it is enjoyable, and extrinsic motivation, or wanting to make friends because they think that adults desire them to have friends (Ojanen, Sijtsema, Hawley, & Little, 2010; Richard & Schneider, 2005). Preadolescents and early adolescents with greater intrinsic motivation form higher-quality friendships (Ojanen et al., 2010) and are less

lonely (Richard & Schneider, 2005). Surprisingly, extrinsic motivation is not related to friendship quality or loneliness.

The maintenance of friendships also has received some attention (see Poulin & Chan, 2010). Same-sex and same-race/ethnic friendships of school-aged children are more stable than cross-sex or cross-ethnic/race friendships (Lee, Howes, & Chamberlain, 2007). Best friendships of early adolescents are more stable than other friendships, and friends who interact both in and out of school have more stable friendships than those who interact in only one context (Chan & Poulin, 2007). Similarity between adolescent friends is important for friendship stability (Hafen, Laursen, Burk, Kerr, & Stattin, 2011). Friends who are more similar in terms of delinquent behavior, frequency of intoxication, achievement motivation, and self-esteem are more likely to maintain their friendship over a year. Moreover, the degree to which the youth are similar to one another before they become friends also predicts greater stability. Less research focuses on how friends' interactions with one another influences the longevity of the relationship.

Romantic Relationships: Developmental Changes

Although some school-aged children may have interests in romantic relationships (Carlson & Rose, 2007), romantic experiences and relationships typically begin in adolescence or early adulthood, depending on the culture. Earlier investigators have delineated the typical developmental course of such experiences in Western societies (see Collins & van Dulmen, 2006; Furman & Winkles, 2012; Seiffge-Krenke & Shulman, 2012). In middle childhood, most friendships are with same-sex peers in Western societies. Early adolescents interested in the other sex engage in affiliative activities in a group context (e.g., go to dances and parties). Subsequently, they begin to go out on "dates" with others, often as part of a group. Finally, they form dyadic romantic relationships, which become more intimate and supportive as they grow older.

More recent work has extended the literature in several directions. Romantic fantasies and infatuations have been examined. Such fantasies are very common in adolescence, occurring more often than either romantic relationships or other-sex friendships (Bowker, Spencer, Thomas, & Gyoerkoe, 2012; Tuval-Mashiach, Walsh, Harel, & Shulman, 2008). They may be even more common earlier, as the relative proportion of unreciprocated (versus reciprocated) romantic relationships decreases from childhood to middle adolescence (Carlson & Rose, 2007).

Past findings based on cross-sectional research have been strengthened by new longitudinal findings. Early and middle adolescents tend to follow a sequence of steps of having: (1) no relationship, (2) one casual relationship, (3) multiple casual relationships, and finally (4) a steady relationship. However, skips in steps are common as is movement back toward a step that typically occurs earlier (Meier & Allen, 2009). Feelings of passionate love, emotional rewards, instrumental support, and dating confidence increase through adolescence and early adulthood. Efforts to influence the partner and actual influence increase with age as well (Giordano, Manning, Longmore, & Flanigan, 2012).

In addition, in Western cultures, romantic cognitions and experiences in adolescence are predictive of subsequent ones. Adolescent attachment styles regarding friendship and romantic relationships are moderately stable over two years; stability is higher when they are in the same best friendship or romantic relationship (Doyle, Lawford, & Markiewicz, 2009). A youth in the United States who is involved in a steady relationship of long duration in adolescence is more likely to be married at 25 than one who is casually dating or not dating; a youth who is not dating is less likely to be cohabiting in early adulthood and have had fewer relationships (Meier & Allen, 2009). Having fewer romantic partners and higher-quality romantic relationships in middle adolescence is predictive of higher-quality romantic relationships in early adulthood (Madsen & Collins, 2011). Thus, these early experiences in romantic relationships may have an enduring effect on the timing and nature of committed relationships in adulthood.

Research on same-sex romantic relationships is also beginning to appear, but findings are still quite tentative (see Russell, Watson, & Muraco, 2012). In North America and Europe, adolescents who are attracted to the same-sex are more likely to have same-sex relationships than in past times. Such relationships are often less public because of concerns of being stigmatized. In fact, relationships with other-sex partners are common among youth attracted to same-sex partners as they serve as a way to explore their sexual identity or conceal their same-sex attraction. In regards to development, the emergence of same-sex relationships may be linked more strongly to the development of sexual identity than age per se. Moreover, the developmental paths may differ for male and female adolescents. Male same-sex relationships may be more likely to develop from sexual encounters, whereas female same-sex relationships may be more likely to develop from friendships and may be closer and more intimate.

Recent work also has begun to recognize the heterogeneity of romantic experiences. Although romantic experiences and relationships change substantially over the course of development, a single normative pattern does not exist. Both within and across cultures, youth vary in terms of when they develop romantic interests, begin to date, and establish romantic relationships. For instance, having a mature physical appearance predicts earlier initiation of romantic relationships in middle adolescence (Zimmer-Gembeck, Siebenbruner, & Collins, 2004). Similarly, the degree of romantic involvement and the sequence of experiences vary across youth. For example, greater satisfaction with physical appearance and friends' greater romantic involvement are related to both greater casual and serious dating in middle adolescence (Furman & Winkles, 2010). Finally, not all individuals end up in committed relationships, nor is that necessarily desired.

Consistent with these ideas, two investigative teams independently identified two dimensions of romantic involvement that seem quite similar (Dhariwal, Connolly, Paciello, & Caprara, 2009; Furman & Winkles, 2010), although the former team studied young adults in Italy and the latter team studied middle adolescents in the United States. The first is casual or exploratory. Those who are high on this dimension have multiple relationships, on and off relationships, breakups, and a high diversity of activities. The second is serious or consolidated. Those high on this dimension have long, more serious relationships in which a high proportion of time they are in love and engage in frequent sexual activity. Interestingly, the casual (exploratory) and serious (consolidated) dimensions are only minimally correlated with each other, underscoring the potential diversity of experiences.

Cluster analyses also yield different types of romantic relationships in adolescence: (a) serious relationships with sex, which are relationships with a high degree of participation in many activities, including sexual intercourse, (b) serious relationships without sex, which are relationships in which there is almost as high a range of different activities, but sexual intercourse has not occurred, (c) group-oriented relationships, which emerge out of friendship groups and typically entail going out together in a group, (d) physically oriented relationships, which primarily entail sexual activity, and (e) low involvement relationships, which involve little interaction and are relatively rare (Crissey, 2005).

Characteristics of middle adolescent dyads also fall into different types: (a) commensurate relationships, in which both members are high in affiliation and romantic feelings

and preoccupation; (b) affiliative relationships, in which both members are high in affiliation and low in romantic feelings and preoccupation; (c) romantic relationships, in which both members are high on romantic feelings and preoccupation and average or low on affiliation; (d) nonlove relationships, in which both members are low in affiliation and romantic feelings and preoccupation; (e) female-oriented relationships, in which females are average in affiliation and romantic feelings and preoccupation, whereas males are low on both; (f) male-oriented relationships, which is the reverse of female-oriented relationships (Seiffge-Krenke & Burk, 2013). The presence of such types underscores the heterogeneity of romantic relationships.

Romantic Relationships: Within-Relationship Development

Relatively little is known about the developmental course of a romantic relationship, but preliminary information is available. When asked what they find desirable in potential partners, adolescents place most emphasis on positive personality characteristics, such as reliability, honesty, and kindness; the relative importance of different characteristics is quite similar for males and females, although males rate attractiveness as relatively more important (Ha, Overbeek, & Engels, 2010). Like adults, early adolescents are attracted to others who are similar to them (Simon, Aikins, & Prinstein, 2008).

In general, social events, such as spending time with a partner in a group or alone or meeting a partner's parents, occur earlier than romantic events, such as declarations of being a couple or being in love. Genital sexual activity tends to occur after these events (O'Sullivan, Cheng, Harris, & Brooks-Gunn, 2007). However, how consistent the sequence of events is across adolescents and what is predictive of different sequences are not known.

Little is known too about what factors lead to changes in romantic qualities over time. Certainly, studies have examined associations among different features of relationships, but evidence regarding the causal links among features is less apparent as few studies examine the same relationship over time. Higher levels of caring and enmeshment, however, predict subsequently engaging in sexual intercourse (Giordano, Manning, & Longmore, 2010).

Some descriptive information exists on the dissolution of middle adolescents' relationships. Such relationships most commonly end because of unfulfilled intimacy or

affiliative needs in middle adolescence (Connolly & McIsaac, 2009). Also cross-ethnic/racial relationships in adolescence are less stable (Wang, Kao, & Joyner, 2006). Otherwise, little is known about dissolution.

Future Directions

The literatures on the development of friendships and romantic relationships share some similarities with respect to what has been learned and remains to be learned. How features of these relationships change with age in childhood and adolescence in Western cultures is relatively well documented. Long-term longitudinal studies have significantly advanced our knowledge of the developmental course of both relationships through adolescence, but work describing the developmental course into adulthood is needed (Furman & Winkles, 2012). Investigators have also described how romantic relationships emerge within peer networks (see Furman & Collins, 2009), but aside from the initial emergence of romantic relationships, we know little about how developmental changes in romantic relationships, same- and other-sex friendships, and the general peer group are interrelated. More generally, we do not know much about the developmental processes underlying the age changes in relationships. Such an understanding will require a comprehensive examination of developmental tasks. For example, the establishment of a long-term commitment may involve coordinating career paths and life plans with those of a romantic partner (Shulman & Connolly, 2013). Three important steps toward a unified relational perspective will be: (1) identifying interrelations in developmental changes in different dyadic peer relationships, (2) identifying developmental processes underlying such changes, and (3) considering the broader life context in which relationships occur.

Given developmental changes in the features of friendships and romantic relationships, it also is likely that developmental changes in the causes and consequences of these relationships exist. For instance, a child who is not interested in intimate disclosure may not be disadvantaged in forming friendships in childhood but may have difficulties as an adolescent. Likewise, variables that are linked to romantic relationships in adolescence may differ from those that are linked in adulthood. For example, parent-child relationship processes are less strongly related to romantic relationship quality in middle adolescence than early adulthood (Madsen & Collins, 2011). Similarly, greater romantic involvement is associated with poorer adjustment in adolescence, but better adjustment in early adulthood (Furman & Collibee, in press).

The literatures on both friendships and romantic relationships reflect increasing awareness of the heterogeneity in these relationships. The traditional normative model not only fails to capture the experiences of those who deviate from its parameters, but also does not do justice to those who follow the more common paths. Efforts to identify different dimensions or types have made progress; further work is needed on the developmental course of the different dimensions or types and on the underlying developmental processes and consequences associated with these dimensions or types.

On a related note, some longitudinal studies have assessed relationship features at multiple times. For some individuals these relationships are the same ones at different time points, but for others, they are different. Often these are not differentiated in the analyses, yet it seems likely that consistency within and across relationships differs.

Much more information also is needed on the initiation, development, and termination of specific friendships and romantic relationships. We know little about the actual events or interactions that increase the likelihood of children and adolescents moving from being acquaintances to friends. Similarly, little is known about the processes that lead to the initiation of romantic relationships. Moreover, although we know that a notable proportion of friendships dissolve during any given year, we know little about the process of termination. Some friends may simply grow apart, whereas other friendships may be severed more abruptly by an argument or betrayal. Additionally, some dissolutions are likely mutual, and others may be one-sided. When the termination is one-sided, some friends may have an interaction in which they specifically dissolve the relationship, whereas others may send more subtle signals. Research also is needed regarding the termination of romantic relationships, although some initial work has been done (Connolly & McIsaac, 2009). Friendship researchers could use that work as a preliminary guide for learning more about how and why friendships dissolve. For both friendships and romantic relationships, more work is needed regarding whether and when the nature of the dissolution affects children's and adolescents' well-being and their expectations regarding future relationships.

We not only have limited understanding of the changes in the course of a relationship, but our assessments of a relationship are surprisingly static in nature. To assess within-relationship development, investigators have either seen what features are associated with length or degree of commitment, or compared features at two time points. Little attention has been paid to the processes that lead to change and development within a relationship.

Conceptualizations of the nature of change are essential for selecting the appropriate analytic technique for assessing either within-relationship development or developmental changes (Young, Furman, & Laursen, 2011).

Most work on within-relationship changes focuses on actor or partner characteristics; some of these characteristics are relatively stable in nature; thus, they may not be promising candidates for explaining why relationships develop over time. We need to consider how relationship events, relationship features, or the history of a relationship affect its development. We need to consider what processes may lead to change in a relationship and what characteristics are simply reflections of the current state of a relationship. Finally, we need to consider how within-relationship development changes with age.

Notably, studying the development of relationships is challenging in that relationships may start at any time and many are short-lived, making it unlikely that repeated assessments of the relationship will occur in a typical longitudinal study. More intensive data collection techniques will be required to capture such changes and their implications for development.

Finally, one striking omission is the absence of literature on the development of romantic relationships in non-Western cultures. The emergence of romantic relationships often does not occur until adulthood in other cultures. Some initial forms of romantic relationships in Western cultures, such as casual or group dating, may simply not exist. In cultures where marriages are arranged, a series of romantic relationships may not occur. Moreover, the within-relationship development of arranged and nonarranged relationships may take different forms. For example, feelings of love may emerge after marriage in arranged relationships. A global perspective is needed to better understand which features of relationship development are universal and which are culture specific.

GENDER

Considerable work has examined gender differences in same-sex friendships (Rose & Rudolph, 2006). This section reviews promising new directions on such differences. We also review the limited work on gender differences in adolescent romantic relationships.

Friendships

Females' friendships involve greater disclosure, support, and closeness than males' friendships. Engaging in joint

activities plays a more central role in males' friendships. Recent extensions include examining gender-typical versus atypical styles, more extreme forms of sex-typed behavior, and social cognitions.

Having a gender-atypical style may be linked with poor adjustment. Early adolescent females are more likely than males to have preoccupied friendship styles in that they monitor friendships closely and feel distress at separations; early adolescent males are more likely than females to have avoidant styles in that they downplay the importance of friends, deny distress at separation, and act distant when they have problems (Menon, 2011). Adolescent males with preoccupied styles and females with avoidant styles are at risk for low self-esteem, low perceived social competence and elevated depression. Although female-typed styles confer risk for males, some male-typed styles may confer risk for males as well. Adolescent males who focus on activities with friends, avoid talking to friends, and fight to gain respect are at risk for depression, low self-esteem, and poor friendship quality (Gupta et al., 2013). Work is needed to identify friendship styles that are adaptive for males.

Gender-linked behaviors at extreme and moderate levels also have been considered. For example, among middle adolescents, females who "compete to win" have fewer and lower-quality friendships, but "competing to win" is unrelated to friendship characteristics for males; simply "competing to excel" is unrelated to the characteristics of both males' and females' friendships (Hibbard & Buhrmester, 2010). Similarly, hypercompetitiveness (i.e., competing to demonstrate superiority and experiencing distress at losing) is positively related to companionship for early adolescent Canadian males but negatively related for females (Schneider, Woodburn, del Toro, & Udarvi, 2005). Gender differences in moderate levels of competitiveness are less striking. Thus, gender differences may be more apparent at extreme levels of a characteristic. Although these gender differences exist in North America, hypercompetitiveness is not linked with positive friendship outcomes for early adolescent males or females in Latin America (Schneider et al., 2005). Perhaps competition is less accepted in collective cultures, which underscores the role of culture in determining gender differences.

Research on co-rumination considers an exaggerated form of another gender-typed behavior, talking about problems. Co-ruminating friends rehash problems, speculate about problems, and dwell on negative feelings (Rose, 2002). Adolescent females co-ruminate with friends more than males (e.g., Hankin, Stone, & Wright, 2010; Stone, Hankin, Gibb, & Abela, 2011). Co-ruminating adolescent friends are close and have high-quality relationships but

are also at risk for internalizing symptoms (e.g., Hankin et al., 2010; Rose, Carlson, & Waller, 2007; Stone, Hankin, Gibb, & Abela, 2011). Moreover, co-rumination may be linked with positive friendship adjustment more strongly for males and with internalizing symptoms more strongly for females (Rose, 2002; Rose et al., 2007). If so, co-rumination may not only be more common for females but also carry fewer benefits and greater costs for females.

Recent work on social cognitions also provides insight into gender differences in friendships. For example, when early adolescents have problems, females take the friends' perspective more than do males, which may account for females' greater positive friendship quality (Smith & Rose, 2011). However, females' greater perspective taking also may contribute to greater empathetic distress, wherein they experience the friends' distress as their own. Females are also more likely than males to have positive expectations for the outcomes of talking about problems (Rose et al., 2012), including expecting to feel cared for and understood. Males are more likely than females to expect that talking about problems will make them feel like they are wasting time. These gender differences may account for females' greater disclosure to friends. Interestingly, despite females' positive social cognitions in response to friends' problems, females react especially negatively to minor friendship transgressions (MacEvoy & Asher, 2012). In this context, females are more likely than males to feel devalued and controlled and to judge the violations as severe.

Romantic Relationships

Although many investigators have examined gender differences in marriages and other romantic relationships of adults, almost no work has been done on gender differences in adolescent romantic relationships. The results of one large longitudinal study suggest that females have greater dating confidence than males throughout adolescence and early adulthood (Giordano et al., 2012). Early adolescent males and females have similar levels of communication awkwardness, but females show greater decreases in the adolescent and early adulthood years. Females find romantic relationships more emotionally rewarding. In early adolescence, females provide less instrumental support to their partners than do males, but by early adulthood they provide at least as much as males. Females report making more attempts to influence the other and having more actual influence and decision making power. Aside from this study, gender has primarily been used as a control variable in studies, which means we do not yet have a

good picture of the role of gender in adolescent romantic relationships.

Future Directions

The role of gender has received considerably more attention in the study of friendships than romantic relationships. More work is needed on romantic relationships, especially as the existing findings regarding power and confidence are unexpected based on gender stereotypes. Furthermore, mean level comparisons cannot provide a complete picture of the role of gender. Work is needed examining how patterns of associations with romantic experiences differ as a function of gender. The promise of such work is illustrated by research showing that the link between co-rumination and friendships differs by gender (e.g., Rose, 2002).

Additional work on friendships is also needed. Research identifying gender differences in social cognitions in friendships suggest these may be underlying processes that explain gender differences in behavior. Investigators could also examine males' and females' perceptions of competitive behaviors in friendships. Whether females who engage in extreme competitive behavior are aware of their behavior and understand that their behavior may carry costs for their friendships is not known. Whether perceptions of these behaviors depend on the gender of the perceiver is also of interest. Males may be more accepting of extreme forms of competitive behavior in their friendships with both males and females. Alternatively, friends of both genders may be more accepting of extreme competitive behaviors when displayed by male friends than female friends.

Other individual differences, such as gender-role traditionality and schemas, may also contribute to gender-typed behavior in peer relationships. The degree of socialization pressure from parents and peers also likely varies and may contribute to gender-typed behavior in these relationships.

Comparisons of gender differences in same-sex and other-sex friendships and romantic relationships would contribute to a unified relational perspective. When interacting with other-sex peers, males and females may adopt interactional styles at least somewhat typical of the other sex in order to facilitate cross-sex interaction. If they adopt more gender-neutral styles in other-sex relationships than same-sex relationships, it would be interesting to know whether this is strategic or whether having a cross-sex partner simply pulls for these changes. If youth adopt more gender-neutral styles in both same- and other-sex romantic relationships than in same- and other-sex friendships, this would suggest differences in the nature of romantic

relationships and friendships (rather than differences driven by gender).

The role of culture and historical time also needs greater attention. The friendship literature has produced interesting findings indicating that gender differences may be enlarged in some cultures and minimized in others. Gender differences in adolescents' romantic relationships are almost certainly more pronounced in traditional cultures than in Western cultures. Moreover, as traditional cultures become more influenced by Western cultures, females' and males' behaviors in romantic relationships may become more similar.

THE ROLE OF THE SELF AND PARTNER

The characteristics of the person and the partner each play major roles in determining whether a relationship will occur and what the features of the relationship are. Early work typically gathered data from one person, and thus focused on the role of the self. Recent work has examined the role of the partner, and the interplay of the two individuals' characteristics.

The Self and Friendships

Investigators have considered how the behaviors of individuals affect their friendships. Those who are verbally and physically aggressive toward their peers have difficulties in friendships (Rubin, Bukowski, et al., 2006). Recent research indicates that relationally aggressive early adolescents have friendships that are high in both negative and positive qualities (Banny, Heilbron, Ames, & Prinstein, 2011). Friends who talk in relationally aggressive ways about peers increase in both positive friendship quality and conflict over 6 months. Perhaps friends experience increased intimacy and solidarity as a result of aggressing together against a shared victim.

Although socially withdrawn children have difficulties in the larger peer group, they may find dyadic contexts less intimidating and fare better in friendships. In middle childhood, a shy/withdrawn child is just as likely as other children to have a stable reciprocal friendship (Rubin, Wojslawowicz, Rose-Krasnor, Booth-LaForce, & Burgess, 2006). However, the friendships are of lower quality and likely to be with other shy/withdrawn and victimized children. The friendship difficulties of shy/withdrawn children may emerge in part because their reasoning about what

makes a friendship close and lasting is less advanced than that of other children (Fredstrom et al., 2012). Nonetheless, not all solitary children have friendship difficulties. In middle childhood, anxious/solitary children, who want to play with others but are too shy or afraid, have fewer, less stable friendships than other children (Ladd, Kochenderfer-Ladd, Eggum, Kochel, & McConnell, 2011). In contrast, unsociable children, who prefer to play alone, have just as many friends and friendships that are just as stable as those of other children.

Other work focuses more directly on specific friendship competencies, such as knowing how to help a friend. In two studies, youth ranging in age from middle childhood to middle adolescence were presented with vignettes in which a friend has a stressful encounter with peers (e.g., being teased or picked on). Results showed that those who endorse avoidant or hostile strategies in response to these vignettes have fewer friends and lower-quality friendships concurrently (Rose & Asher, 2004) and over time (Glick & Rose, 2011). Moreover, having more friends predicts decreases in avoidant and hostile strategies, and high-quality friendships predict increases in emotionally engaged strategies, such as giving support (Glick & Rose, 2011). Thus, not only do social competencies affect friendships, but friendships provide a context for the development of social competencies.

The Partner and Friendships

With regard to partner effects, adolescent females with friends who engage in excessive reassurance seeking experience the relationship as lower in positive friendship quality one year later (Prinstein, Borelli, Cheah, Simon, & Aikins, 2005). Similarly, adolescents with friends who consistently turn the focus of conversations toward themselves experience the relationship as low in positive qualities (Schwartz-Mette & Rose, 2009). Excessive reassurance seeking and conversational self-focus are both common among youth with depressive symptoms. These findings are consistent with interpersonal theories of depression suggesting that depressed friends engage in aversive behaviors, leading others to withdraw from these relationships.

Another way in which partner effects are considered is by examining selection and socialization effects. Such studies examine whether select friends with similar characteristics and friends socialize each other so that they become more similar over time. Most studies, however, focus on selection and socialization effects on adjustment, which is covered in a subsequent section.

The Self and Romantic Relationships

The literature on actor effects in romantic relationships is not very systematic. Demographic characteristics, such as gender, ethnicity, race, or social class are commonly included, but primarily as control variables. Certainly, investigators have examined different characteristics, such as personality characteristics or attachment styles, but usually only a couple of studies have been conducted examining each particular characteristic. Moreover, these few studies typically examined different aspects of romantic relationships. A few characteristics have, however, received more attention.

An adolescent who is physically mature and attractive is more likely to have a romantic relationship, whereas body weight is inversely related to having one (McCarthy & Casey, 2008). For each point on the Body Mass Index scale, the probability of an adolescent female having a romantic relationship decreases by 6% (Halpern, King, Oslak, & Udry, 2005). A female in a romantic relationship in which sexual intercourse has not occurred is more likely to be dieting than one not in a relationship or in a relationship in which intercourse has occurred. Perhaps she believes her attractiveness is more important in retaining a boyfriend when they have not had intercourse. Alternatively, sexual activity may make her feel more confident about her attractiveness, or a sexually active female may enter a relationship with more confidence about her appearance.

Like research on social withdrawal in friendships, research on romantic relationships has examined shyness and dating anxiety. Shy early adolescents are less likely to have initiated dating, whereas those who derive pleasure from novel, intense activities are more likely to date (Ivanova, Mills, & Veenstra, 2011). Dating anxiety in middle adolescence is related to the quality of best friendships, whether they have or have had a romantic relationship, and the quality of romantic relationships (La Greca & Mackey, 2007).

The Partner and Romantic Relationships

One of the earliest partner effects to receive attention in regards to romantic relationships was the age of the partner. Early adolescents with older partners are at risk for multiple problems. Recent work sheds light on why they are at risk. Links between pubertal maturity and risk behaviors are mediated by having a romantic partner, particularly an older one (Halpern, Kaestle, & Halfors, 2007). In addition, the association between having an older partner

and engaging in sexual intercourse as an early adolescent can be explained by exposure to peer norms favoring sex and being in situations conducive to sexual behavior, such as parties without adults (Marín, Kirby, Hudes, Coyle, & Gómez, 2006). An adolescent female who has an older partner is prone to become depressed, which may stem from an increase in substance use (Haydon & Halpern, 2010). This line of work nicely illustrates a movement from simply identifying a phenomenon (the risk of an older partner) to identifying underlying processes.

Actor and partner effects can be simultaneously examined by using actor-partner interdependence models. For example, middle adolescents' working models of romantic relationships affect their own behaviors in the relationship (actor effects) and their partners' behavior toward them (partner effects; Furman & Simon, 2006). Specifically, adolescents with secure working models display positive communication skills, whereas adolescents with dismissing working models display poorer skills. Adolescents with preoccupied working models engage in more conflictual behavior and tend to display more negative affect. Adolescents with dismissing models display less positive affect. Such actor effects are more common, but partner effects are also present. For example, adolescents with more secure working models have partners who display positive communication skills.

Other research also shows that actor effects are more common, but that partner effects occur too. For example, a middle adolescent female's own behavior during conflict, but not the partner's behavior, predicts her expression of autonomy; however, both the male's own and the partner's behavior predicts his expression of autonomy (McIsaac, Connolly, McKenney, Pepler, & Craig, 2008). Similarly, both genders' affiliative experiences are linked with better conflict resolution skills, and females with more frequent affiliative experiences have partners with better conflict negotiation behavior in middle adolescence (Seiffge-Krenke & Burk, 2013). In related research, middle and late adolescents who are self-silencing by not expressing feelings and thoughts have poor communication skills, such as giving in during conflicts with partners. They also have partners who are frustrated and uncomfortable (Harper & Welsh, 2007). Other work on partner characteristics involves adjustment and is covered in a subsequent section.

Future Directions

More work on actor effects has been done on friendships than romantic relationships. Peer relations research has

long focused on social competence. Although past work focused primarily on how generally well-liked children or adolescents are, recent work indicates that social competence also influences dyadic friendships. Parallel work is needed on romantic relationships. Some social skills may be required for both friendships and romantic relationships, but others may be unique to friendships or romantic relationships. Studies simultaneously examining actor (or partner) effects in both friendships and romantic relationships would provide valuable information about the consistency and nature of such effects and contribute to a unified relational perspective.

Many characteristics of individuals have received little attention. Particularly needed are studies of interpersonal characteristics that may affect the interchanges in relationships, such as empathic understanding (Haugen, Welsh, & McNulty, 2008) or dating goals (Kelly, Zimmer-Gembeck, & Boislard, 2012).

In addition, most studies of partner effects have focused on the effects on the current relationship. Some work reviewed in a later section also indicates partners' influences on global outcomes, like adjustment. However, less is known about whether partners' influences carry over to subsequent relationships. Work is needed to address the degree to which social skills and interactional styles learned from one partner in one relationship carry over to the next. In addition, existing work on the interfacing of self and partner characteristics has primarily focused on selection and socialization effects on adjustment. As yet, we know little about how the interfacing of the two individuals' characteristics affects their pattern of interaction or relationship.

Finally, most of the work, especially with partner effects, is cross-sectional. For nearly all of the studies considered, it would be reasonable to think that the relationship affects the person instead of, or in addition to, the person affecting the relationship.

FAMILY PROCESSES

The associations between many different family processes and peer relationships have been studied. These processes include parents' marriage, parent-child relationships, attachment, parenting styles, and sibling relationships. We focus on several particularly promising lines of research.

Friendships

Recent research builds on previous studies through the use of longitudinal designs and the consideration of processes

that may explain associations between family relationships and friendships. Secure attachment to parents is associated with positive experiences with friends in childhood (e.g., McElwain, Booth-LaForce, Lansford, Wu, & Dyer, 2008; McElwain, Booth-LaForce, & Wu, 2011) and adolescence (e.g., Doyle et al., 2009; Y.-L. Liu, 2008). The relationship between parents is also important. Parents with a more positive marriage when their child is 1 month old have a more securely attached child, and this predicts friendship quality in fourth grade (Lucas-Thompson & Clarke-Stewart, 2007).

Factors that may help explain the association between parent-child attachment and later friendships are of interest. For example, infants' secure attachment predicts their mothers talking with them about cognitions at 24 months, which predicts greater positive friendship quality at 54 months (McElwain et al., 2011). Young children with secure attachments also demonstrate greater peer competence in middle childhood, which predicts more secure friendships in adolescence (Simpson, Collins, Tran, & Haydon, 2007).

Other aspects of the parent-child relationship have received recent attention as well. Preschoolers with parents who respond supportively to their negative emotions show more coordinated play with friends (McElwain, Halberstadt, & Vollung, 2007); parental sensitivity in the first 3 years of life predicts positive interactions with friends in the early school years (McElwain et al., 2008). Mediators have been considered too. Parental sensitivity at 36 months predicts affective mutuality in the mother-child relationship and children's language ability at 54 months and peer competence in first grade, which predicts positive friendship quality in the third grade (McElwain et al., 2008). Importantly, this work incorporates linguistic variables, which have received little attention in the relationship literature.

Work with older youth corroborates studies of young children, indicating that the parent-child relationships influences youths' characteristics in ways that affect friendships. For example, parental psychological control during late childhood predicts poor emotional security in early adolescence, which in turn predicts lower friendship competence in middle adolescence (Cook, Buehler, & Fletcher, 2012).

Although work is generally motivated by the idea that parents influence their children's friendships, these friendships also may influence parent-child relationships. For example, throughout adolescence, parent-child relationship qualities predict changes in the qualities of friendships

(De Goede, Branje, Delsing, & Meeus, 2009). However, the magnitude of the effect of parent support on youths' friendships decreases with age. Moreover, support and power in friendships predict changes in those qualities in the parent-child relationships, and the effect of negative friendship interactions on negative parent-child interactions becomes stronger with age. In other research (Van Doorn, Branje, van der Valk, De Goede, & Meeus, 2011), conflict resolution styles with parents predict friendship conflict resolution styles throughout adolescence. By middle adolescence, friendship conflict resolution styles also predict conflict resolution styles with parents. Together, these findings suggest that the influence of parents on friendships may be strongest in early adolescence, but that, by later adolescence, parents and friends may be similarly influential.

Finally, although family systems theorists have long argued for considering multiple relationships within the family, research on family relationships and friendships has focused almost exclusively on parent-child relationships. However, sibling relationships also share an important connection with friendships. For example, children who interact positively with a friend before a sibling is born have more positive interactions with the sibling in childhood and even into adolescence (Kramer & Kowal, 2005).

Romantic Relationships

Several longitudinal studies of young children have now been going on long enough to examine links between early family relationships and romantic relationships in adolescence and adulthood. Parent-child relationships as early as the toddler years are linked with romantic experiences in adolescence and young adulthood. Those who are more secure with respect to proximity seeking in infancy have less anxious romantic relationship styles. Although maternal sensitivity in infancy is not predictive of late adolescent anxious or avoidant romantic attachment styles, increases in maternal sensitivity over early and middle childhood are associated with less avoidant and anxious styles (Fraley, Roisman, Booth-LaForce, Owen, & Holland, 2013). Higher average levels of maternal sensitivity in early and middle childhood are also related to higher-quality romantic relationships in middle adolescence (Roisman, Booth-LaForce, Cauffman, Spieker, & The NICHD Early Child Care Research Network, 2009). Interestingly, however, higher maternal sensitivity is related to lower romantic involvement in middle adolescence. This suggests that marked romantic involvement in adolescence may be premature (also see Furman &

Collibee, in press). In addition, other research indicates that higher quality parenting at two years of age predicts the security of romantic representations, positive perceptions of the relationships, and observed quality of romantic relationships in early adulthood; attachment security at 1 year was less consistently predictive (Haydon, Collins, Salvatore, Simpson, & Roisman, 2012). Moreover, adults' working models of their parents and their working models of romantic partners are both uniquely linked to positive perceptions of their romantic relationship quality and the observed quality of romantic relationships. These findings suggest that representations of romantic relationships and experiences in romantic relationships are not only influenced by each other, but also by early parent-child relationships.

Family processes in adolescence are also related to later romantic relationship experiences. For example, the quality of middle adolescents' family relationships predicts discord, conflict tactics, and connectedness in young adults' romantic relationships (Crockett & Randall, 2006). Marital hostility during middle adolescence, as well as hostility in friendships, is predictive of hostility in romantic relationships in late adolescence (Stocker & Richmond, 2007).

Investigators have also attempted to identify intermediary processes that may explain the associations between family relationships and romantic relationships. Some studies have predicted later romantic experiences using regression analyses in which the predictor variables are entered in chronological order; for example, early childhood experiences first, then middle childhood experiences, and finally adolescent ones. This sequence tests whether more proximal variables contribute over and above variables representing earlier experiences. For example, child abuse and witnessing intimate partner violence in early childhood predicts dating violence in early adulthood; boundary violations and negative interactions in parent-early adolescent relationships are also predictive even controlling for early childhood experiences; finally, friendship quality in middle adolescence is predictive of dating violence even controlling for both early childhood and early adolescent experiences (Linder & Collins, 2005). Similarly, early supportive care predicts early adulthood romantic relationship quality, and early adolescent parent-child interactions are predictive as well, even after controlling for early supportive care and peer competence in middle school. Similarly, after controlling for these earlier experiences, adolescent romantic quality positively predicts early adulthood romantic quality, and the number of recent romantic partners in middle adolescence negatively predicts early adulthood romantic

quality (Madsen & Collins, 2011). Although these studies indicate that more proximal variables contribute after accounting for the effects of the variables assessed earlier, whether the effects of earlier variables are mediated through the more proximal variables, or whether the earlier variable have direct effects on the outcomes, is not known.

Some studies also have considered how early experiences predict relationship experiences in middle childhood or adolescence, and how those experiences then predict later romantic experiences. As mentioned, secure attachment in infancy is related to childhood peer competence, which predicts adolescent friendship security, which then predicts the emotional tone and observed relationship quality of romantic relationships in early adulthood (Simpson et al., 2007). Similarly, poor quality parent-child relationships in early to middle childhood predict conflict with parents in adolescence, which predicts poor romantic relationship quality in early adulthood (Overbeek, Stattin, Vermast, Ha, & Engels, 2007). Such findings underscore the importance of identifying intermediary or proximal processes that occur in childhood or adolescence; at the same time, the findings indicate that these processes may have roots in early childhood. In both of these studies, however, the early childhood processes did not directly affect romantic relationship quality in adulthood, suggesting that the distal links described in the prior paragraph may be mediated through more proximal relationship processes.

Finally, other studies have considered mediating and moderating processes other than specific relationship characteristics. For example, parents' emotion dysregulation predicts their adolescent sons' emotion dysregulation, which predicts the sons' romantic relationships in early adulthood (H. K. Kim, Pears, Capaldi, & Owens, 2009). Additionally, processes that may underlie the link between interparental conflict and romantic relationships are of interest. Potential mediators of this link include adolescents' emotional reactivity in friendships (Cook, Buehler, & Blair, 2013), difficulties in social information processing (Fite et al., 2008), and appraisals of interparental conflict (Simon & Furman, 2010).

Future Directions

Synergy exists between studies of the influence of parent-child relationships on friendships and romantic relationships. Many of the same positive aspects of parent-child relationships are associated with positive experiences in later friendships and romantic relationships. However, the links between early family experiences and

adolescent friendships are better established than the links between early family experiences and adult friendships. For romantic relationships, evidence is stronger for links between early family experiences with adult romantic relationships than with adolescent romantic relationships. Research on the links with adult friendships and adolescent romantic relationships would allow for comparing and contrasting family predictors of friendships and romantic relationships and foster integration of the work on the two relationships, contributing to a unified perspective.

Research reviewed above also suggests that early experiences with parents predict friendship experiences, which predict romantic relationship outcomes. More such studies are needed to determine whether the impact of early parent-child relationships on later romantic relationships is direct or mediated by experiences with friends. Moreover, with few exceptions (e.g., Stocker & Richmond, 2007), family variables are assessed at earlier ages than friendship variables in studies predicting romantic relationships. As a consequence, it is difficult to determine whether differences in the predictive power of family and friendships stem from the type of relationship considered or the time that the relationship was assessed. Early relationships could be more influential if they serve as prototypes for subsequent relationships; however, more recent relationships could be more influential as they may be more similar to later relationships or because less time has passed. Finally, more research is needed to examine the direction of effects. As noted, relatively little is known about how peer relationships affect family processes.

More research is needed regarding how parent-child relationships, friendships, and romantic relationships coexist in later adolescence and early adulthood when they need to be simultaneously managed. One study considered two time points in adolescence and two time points in early adulthood (Meeus, Branje, van der Valk, & de Weid, 2007). Those who shifted from indicating that their most important peer was a friend to indicating that their most important peer was a romantic partner showed increases in commitment to the romantic partner and decreases in emotional problems. A stronger commitment to a romantic partner in early adulthood, but not in adolescence, was also associated with fewer emotional problems (see Furman & Collibee, in press, for a similar association). Moreover, stronger parental support in early adulthood was associated with greater commitment to a romantic partner. These findings suggest that romantic relationships become more psychologically meaningful than friendships in late adolescence and early adulthood and suggest that links

between relationships with parents and romantic partners become stronger when the romantic relationships become more committed. Additional research is needed to understand how youth healthy romantic relationships, while maintaining healthy relationships with parents and friends.

Other aspects of family relationships also need to be considered. Although social scientists increasingly have examined multiple facets of parenting in the same study, more work is needed. Particularly promising may be studies integrating family structure and family process. Socioeconomic and structural characteristics of the family may set the context for different processes to occur. For example, many middle- or upper-class parents may approach childrearing in terms of “concerted cultivation” in which they attempt to promote children’s skills and talents through organized activities; many working-class parents may approach childrearing as the “accomplishment of natural growth” in which they provide children with the conditions to grow, but leave leisure activities for the children themselves (Lareau, 2011). The time and nature of experiences with extended family and peers may also differ, and such a difference may moderate links between family processes and dyadic peer relationships. Finally, family structure is not static and may change repeatedly over time; the number of transitions in family structure in childhood and adolescence predicts having a current romantic relationship and the number of subsequent romantic relationships (Cavanagh, Crissey, & Raley, 2008). Conceptualizations and studies of the family need to take into account the dynamic processes involved.

Also, most research on links with family processes has considered involvement in friendships or romantic relationships or the characteristics of the relationships. Less research has considered the characteristics of the friends or romantic partners. However, parents likely affect the types of friends and romantic partners youth choose. Moreover, the degree to which parents approve of friends and romantic partners likely influences the parent-child relationship.

In addition, although most children have siblings, few studies have examined associations between sibling relationships and friendships, and even less is known about the associations between sibling relationships and romantic relationships. Studies should explore the idea that having other-sex siblings may increase the comfort and social competence of heterosexual youth with other-sex peers.

Finally, research to date does not represent the wide array of family types. As with other topics, virtually all of the research has been conducted in North American and

European cultures. Although work is increasing on racial and ethnic minority families in these cultures, we know little about how variations within and across families of different backgrounds are associated with children and adolescents’ experiences with friends and romantic partners. Moreover, the families that have been studied tend to be traditional ones. Little is known about immigrant families or families with GLBT parents. Such work would enhance our understanding of the links between children and adolescents’ family experiences and their experiences with friends and romantic partners.

PEER PROCESSES

In this section, links are considered among friendships, romantic relationships, and peer group processes. Associations between experiences in friendships and romantic relationships are considered first. Associations between broader peer group experiences and friendships are discussed next, followed by a discussion of associations between broader peer group experiences and romantic relationships.

Friendships and Romantic Relationships

Considerable work indicates that having higher-quality friendships is associated with having higher-quality romantic relationships (see Connolly & McIsaac, 2009; Furman & Collins, 2009). Recent research has focused on more complex associations, including mediation, moderation, trajectories of growth, and within-subject associations. In the previous section on family processes, we discussed how friendships may mediate the links between family processes and romantic relationships. With regard to moderation, having deviant peer friends is associated with higher rates of dating violence perpetration in early adolescence, but this effect is particularly strong when parents support aggressive solutions to conflict (S. Miller, Gorman-Smith, Sullivan, Orpinas, & Simon, 2009).

Virtually all research has only examined predictor variables at one time point, but growth curves have been examined in one instance (Fraley, Roisman, Booth-LaForce et al., 2013). Higher levels of positive friendship quality in middle childhood and increases in positive friendship qualities from middle childhood to middle adolescence were predictive of less avoidant romantic attachment styles in late adolescence.

Another new direction involves examining both between- and within-person effects. Between-person associations refer to instances where differences between people on one variable are associated with differences on another variable. For example, adolescents who typically have friends who engage in dating violence engage in more dating violence throughout adolescence; those who typically have high-quality friendships, and females who typically have friends with prosocial beliefs engage in less dating violence throughout adolescence (Foshee et al., 2013). Within-person associations refer to instances where variations within a person over time on one variable are associated with variations within a person over time on another variable. For instance, adolescents engage in more dating violence than usual when they are higher in social status than usual; levels of dating violence are lower than usual at times when they have more friends with prosocial beliefs than they typically do (Foshee et al., 2013). Thus, studies of within-person effects can provide information about *when* activities occur (versus who is likely to engage in them). Such studies are central to many psychological theories, because social scientists, especially developmentally oriented ones, are often interested in changes within a person in addition to differences between people. Knowing both who and when are essential to understanding developmental processes.

Friendships and Peer Groups

The characteristics of friendships are also associated with processes in broader peer group, such as peer group acceptance, perceived popularity, and victimization. In terms of peer acceptance, children and adolescents with friends and high-quality friendships are well-accepted by peers (see Rubin, Bukoski, et al., 2006). Recent work indicates that school-aged children with friends are better accepted than children without friends, even when the friends have undesirable characteristics, such as aggressive tendencies (Palmen, Vermande, Deković, & van Aken, 2011).

In regards to perceived popularity, having perceived popular friends increases individuals' own perceived popularity in childhood (Logis, Rodkin, Gest, & Ahn, 2013) and adolescence (Dijkstra, Cillessen, Lindenberg, & Veenstra, 2010). However, early adolescents who are liked by peers perceived to be popular, but are not friends with them, are better accepted than those with a friend perceived to be popular (Dijkstra et al., 2010). Prospective research also indicates that children (Logis et al., 2013) and adolescents

(Dijkstra, Cillessen, & Borch, 2013) become more similar to friends in perceived popularity over time.

Recent work has also addressed links between friendship and victimization. Earlier work indicated that children and adolescents with friends are less victimized and that having friends buffers them from the negative effects of victimization (see Rubin, Bukoski, et al., 2006). Recent studies further consider the timing and directionality of these associations. Having poorer-quality friendships predicts later victimization in middle childhood and early adolescence (Kendrick, Jutengren, & Stattin, 2012; Malcolm, Jensen-Campbell, Rex-Lear, & Waldrip, 2006). Children who are chronically friendless or who lose friends across a school year during middle childhood also experience increases in victimization, whereas children who have stable friendships or who gain friends do not experience increased victimization (Wojslawowicz Bowker, Rubin, Burgess, Booth-LaForce, & Rose-Krasnor, 2006).

Other recent work has considered whether associations between friendships and victimization are bidirectional. Previous research was largely motivated by the idea that having few friends leaves children and adolescents vulnerable to victimization (Rubin, Bukoski, et al., 2006). However, the stress of victimization could deplete the social and emotional resources youth bring to friendships, and peers may be concerned that friendships with victimized youth will lead themselves to be victimized. In fact, during middle childhood and early adolescence, victimized individuals are less likely to form new friendships, and the friendships of victimized girls are less stable (Ellis & Zarbatany, 2007). Other research, though, found that victimization is not associated with decreases in friendship quality in middle childhood and early adolescence (Malcolm et al., 2006; Kendrick et al., 2012). More research is needed to determine whether victimization leads to friendship problems.

Last, whether findings for older youth apply to young children has been considered (Hanish, Ryan, Martin, & Fabes, 2005). Even kindergarteners with reciprocal friends are less victimized than their friendless peers. However, reciprocal friends do not protect preschoolers from victimization. Instead, preschoolers who engage in more social play and are in classrooms with higher levels of overall aggression are likely to be victimized. These findings suggest that preschoolers may aggress somewhat indiscriminately toward peers who happen to be nearby, whereas older aggressors may be more strategic and avoid children with friendship alliances.

Romantic Relationships and Peer Groups

Early research on peer group processes and romantic relationships primarily focused on who was more likely to establish romantic relationships. This work indicated that those who interact more with the other-sex, have more other-sex friends, or are popular are more likely to subsequently develop romantic relationships (see Connolly & McIsaac, 2008; Furman & Collins, 2009). More recently, it has become clear that multiple pathways lead to having romantic relationships (S. Miller, Lansford, et al., 2009). For example, popular youth (i.e., those who are well-accepted) and controversial youth (i.e., those who receive high numbers of liked-most and liked-least nominations from peers) are both more likely to have romantic partners in early adolescence than neglected youth (i.e., those who receive few liked-most and few liked-least nominations). Given the ubiquity of friendships and romantic relationships in our lives, it seems quite likely that numerous pathways exist. As statistical techniques continue to become better able to identify multiple pathways, more pathways are likely to be identified.

Much of the recent focus on links between the peer group and romantic relationships has been with regards to dating violence. Associating with adolescent peers who engage in dating violence or other forms of aggression predicts engaging in dating violence oneself (see Capaldi, Knoble, Shortt, & Kim, 2012). Importantly, whether youth aggress in the peer group is related to their tendency to aggress against a dating partner. For example, in one study (Foshee et al., 2011), 40% of the early and middle adolescent females and 19% of the males who were aggressive toward their peers were aggressive toward a dating partner. In contrast, among youth who were not aggressive toward peers, only 10% of females and 4% of males were aggressive toward a dating partner. Such work suggests that a significant number of youth are at risk for multiple forms of violence, and prevention programs focusing on multiple forms of aggression may be more efficient.

Future Directions

Some similarities exist between work on friendships and romantic relationships in regards to connections with the larger peer group. Those who are well-accepted or perceived as popular fare well in regards to both friendships and romantic relationships. The friendship literature has also considered links between friendship features and victimization by peers, and the romantic relationship

literature has considered links between dating violence and connections with deviant peer groups. Future work would benefit from integrating these literatures. Longitudinal work could test whether youth who are victimized peers are likely to be victims of dating violence. Whether supportive friendships can protect youth from dating violence similar to how friendships protect youth from victimization is also unknown.

Additionally, most research on the links between friendships and romantic relationships has considered characteristics of the relationships. Less is known about the similarities or differences in the characteristics of friends or romantic partners. Adolescent friends and romantic partners are similar in delinquency, attractiveness, popularity, and depression (Lonardo, Giordano, Longmore, & Manning, 2009; Simon et al., 2008), but what is less understood is why this is the case. It may simply reflect similarities in an adolescent's selection of peers, or be the results of the adolescent's socialization of both, or the friend and partner socializing each other. Understanding the interplay of the dynamics in friendships and romantic relationships will be key for developing a unified relational perspective.

In addition, future research should examine the processes through which friends may influence romantic relationships. Conceptual papers exist on how friends may influence romantic relationships (e.g., Brown, 1999). For example, friends may approve or disapprove of potential partners, introduce peers to potential dating partners, facilitate or disrupt relationships, provide advice about relationship issues, or keep an eye on a partner's behavior. Similarly, partners may engage in comparable behaviors regarding friends. These processes might be considered analogous to parental monitoring and are in need of empirical attention.

MEDIA

In this section, we consider how use of media by children and adolescents is linked with their experiences in friendships and romantic relationships. This is an important topic given the sheer amount of time youth devote to media use and the advances in technology that allow youth to use digital media (e.g., texting) to communicate with friends and romantic partners.

Friendships

Adolescents are much more likely to communicate online with real-life friends than with people whom they know

only over the Internet (Reich, Subrahmanyam, & Espinoza, 2012; Smahal, Brown, & Blinka, 2012). Moreover, Internet communication is associated with higher friendship quality for early and middle adolescents who communicate primarily with face-to-face friends versus with those known only online (Valkenburg & Peter, 2007). Adolescents who instant message also show increases in positive relationship quality in face-to-face friendships and romantic relationships (Blais, Craig, Pepler, & Connolly, 2008; Valkenburg & Peter, 2009a). The effect for friendships is accounted for by online self-disclosure (Valkenburg & Peter, 2009a), that is, preadolescents and adolescents who instant-message more and disclose more about personal feelings in their messages, which predicts later positive friendship quality. In contrast, using the Internet for chat rooms, games, and general entertainment predicts decreases in some positive friendship and romantic relationship qualities (Blais et al., 2008). In summary, interacting online with preexisting friends can strengthen relationships, but online activities that do not involve communicating with friends may detract from friendships.

Two hypotheses address who benefits from communicating online with friends (see Valkenburg & Peter, 2009b). According to the rich-get-richer hypothesis, socially competent youth are most likely to seek out online communication as one more platform for enhancing friendships. In contrast, the social compensation hypothesis suggests that less socially competent youth feel more comfortable communicating online because there is no face-to-face contact and more time to compose responses. Support exists for both hypotheses. Consistent with the rich-get-richer hypothesis, socially anxious early and middle adolescents may be less likely to communicate online than those who are not socially anxious (Valkenburg & Peter, 2007). However, consistent with the social compensation hypothesis, socially anxious adolescents feel more comfortable talking about more topics and more sensitive topics online than face to face (Valkenburg & Peter, 2007). Moreover, the negative impact of middle adolescent males' social anxiety on friendship quality is not significant for friends who interact on the computer together (Desjarlais & Willoughby, 2010).

Less research has considered whether positive friendship adjustment may contribute to greater online communication. However, those who interact positively with friends in early adolescence are especially likely to have a social networking webpage in early adulthood and to have a large number of friends on their webpage (Mikami, Szwed, Allen, Evans, & Hare, 2010). In contrast, relationships with

parents that are problematic also may increase Internet use (Willoughby, 2008). Compared to other youth, early adolescents whose mothers fail to support their autonomy and relatedness are more likely to have formed a friendship with someone they met online during early adulthood (Szwe, Mikami, & Allen, 2011). Perhaps youth who experience poorer parenting are less likely to develop the skills necessary for success in face-to-face friendship interactions.

Romantic Relationships

The depiction of sex in the media has received significant attention for some time. However, that literature has not focused on sexual behavior in romantic relationships per se. In fact, only half of the individuals depicted having sexual intercourse on television have an established relationship (Kunkel, Eyal, Finnerty, Biely, & Donnerstein, 2005). Instead, the focus of research has been on the high frequency of sexual content overall and the limited consideration of sexual risk and responsibilities. Work has been done regarding how adolescents' media diet of sex is linked to sexual attitudes and behavior in general, casual sexual behavior, or sexual risk taking, but little has been done on the links to sexual attitudes and behavior in romantic relationships per se. Indeed, relatively little consideration has been given to the depiction of romantic relationships in the media.

Content analyses reveal that a heterosexual script is commonly portrayed in adolescents' favorite primetime network television programs (J. L. Kim et al., 2007). Males are depicted as preoccupied by females' bodies and consumed by sexual thoughts, desires, and experiences. Males are portrayed as initiating sexual activities, whereas females set sexual limits and are judged by their sexual conduct. Males use active and powerful strategies to win females' affection; females use passive, alluring strategies. Males are seen as wanting and needing independence, whereas females are depicted as wanting and needing relationships, boyfriends, or husbands. Males are portrayed as preferring sexual fulfillment over emotional commitment and as homophobic. Such descriptions may affect whom adolescents are attracted to romantically and how they interact in romantic relationships. Consistent with this idea, watching romantic television programs is associated with having more traditional gender role attitudes about romantic relationships; watching nonromantic programs is associated with middle adolescent youth having less traditional attitudes; watching soap operas is associated with earlier age of starting to date and having a larger number of partners (Rivadeneyra & Lebo, 2008).

Little work has focused on the new media and romantic relationships. Qualitative descriptions suggest that digital media may influence adolescents' romantic relationships (Ito et al., 2010). Social network sites may increase opportunities for meeting potential romantic partners. Such opportunities may be particularly important for GLBT youth. Long-distance relationships may be easier to develop or maintain. Whether near or far apart physically, adolescents can be in frequent, if not continuous, contact with romantic partners, which may lead to expectations of being available and responsive at almost any moment. At the same time, text messages and social networking provide individuals opportunities to compose messages before communicating. Moreover, adolescents may find it easier to meet others or have romantic relationships about which their parents have little knowledge. Of course, some parents may oversee or access their adolescent's social network sites or text messages. Certainly, communications are commonly accessible by partners or friends, intentionally or unintentionally. Romantic partners may find it easier to know of each other's activities, especially given the ease of sharing videos and pictures. A suspicious or jealous partner may have easier means of checking on a partner's behavior; this may not only provide opportunities for determining instances of infidelity or troubling behavior but also may lead to misperceptions of a partner's intentions. The restricted channels of communication in digital media may lead to misperceptions of what is said or perhaps greater opportunities for deliberate ambiguity. Finally, relationships can be ended quite indirectly. At the same time, a former lover may find it relatively easy to keep track of or even stalk an ex-partner.

Byproducts of the new media have raised concerns. A 2010 survey of adolescents in the United States showed that in the past year 2.5% of preadolescent and adolescents "sexed," or sent a nude or nearly nude image via electronic media; 7% received one (Mitchell, Finkelhor, Jones, & Wolak, 2012). Ten percent of early and middle adolescents in the United States reported being victims of cyber dating abuse (Zweig, Dank, Yahner, & Lachman, 2013). The most common form is using a social networking account without permission. Receiving texts/e-mails soliciting unwanted sexual acts, being pressured to send sexually explicit photographs, receiving threatening text messages, or receiving intimidating numbers of text messages/e-mails also occur. Importantly, victims of cyber dating abuse are more likely to also have experienced physical, sexual, or psychological dating abuse; perpetrators are more likely to report perpetrating other forms of abuse.

Future Directions

The literatures on media use on friendships and romantic relationships are strikingly different. Substantially different questions have been addressed in the two fields, which illustrates the importance of a unified relational perspective. Some similarities between media use in friendships and romantic relationships are likely, but what are they and what are the differences? For example, does Internet use affect socially anxious adolescents' romantic relationships differently from their friendships? Coordinated work in the two fields may lead to a better understanding of the role of media in each relationship.

In addition, more work is needed on multiple types of media use and face-to-face interactions. Because adolescents typically use multiple forms of media and face-to-face contact to communicate with friends, separating out the influences of each will be challenging. Variation in the relative use of particular media forms could be considered, but this variation is likely conflated with the characteristics of the individual, partner, and relationship stage.

Although the frequency of media use is important, the content of use, motives for use, and the degree of identification with the media figure also warrant more consideration (see Ward & Friedman, 2006 for an example). Cohort effects are also likely to be striking; indeed, the changes in new media are so rapid that the size of a cohort is becoming increasingly smaller, as youth close in age may use media in substantially different ways.

Several topics have received little attention. Many adult relationship researchers have been interested in how online dating affects romantic relationships. Some online dating sites specifically cater to adolescents, but we are unaware of any work on their effects on adolescents' relationships. In addition, virtually all of the research described in this section has been conducted in technologically advanced cultures; the role of media in other cultures remains to be studied. Finally, just like the technology, research on digital media is rapidly developing. The speed of the research and the technology provide extra challenges for researchers, yet exciting opportunities for much growth in our knowledge in the upcoming years.

CULTURE

Cultural context affects friendships and romantic relationships. By culture we mean both countries or societies and subcultures within countries or societies. Such subcultures would include different ethnicities and social classes.

Most of the research we reviewed was conducted in North America and secondarily in Europe. Investigators have used Asian and other understudied cultures to examine issues that have been studied in North America or Europe; however, the rationale has often been that few studies have been conducted in that culture, and little information about the culture is reported in the study. Virtually all of these investigators are remiss as well in discussing how their country's culture may affect their results; similarly, studies of European Americans rarely consider how their subculture affects their results. For studies to shed light on culture, cultural processes need to be explicitly considered. In a minority of studies, investigators have discussed how the cultural context may influence the results. In most of these instances, however, the cultural processes are not measured. Consequently, we know relatively little about cultural context. Instead of describing the limited and disparate literature on cultural context and friendships and romantic relationships, we present examples of work that illustrate its potential for insights into friendships and romantic relationships.

Countries and Societies

One promising strategy has been to conduct studies comparing friends or romantic relationships across more than one country. For example, compared to a child in the United States, an Indonesian child is more likely to disengage from friendship conflicts, such as by avoiding the other child or changing the conversation or activity (French, Pidada, Denoma, McDonald, & Lawton, 2005). A child in the United States is more likely to negotiate or compromise. Notably, in Indonesia only, disengagement is associated with being well-accepted, suggesting that disengagement is not only more common among Indonesian children but more adaptive as well. Interpersonal relationships are highly valued in Indonesia, and avoiding overt conflict is seen as one way to maintain positive relationships.

In regards to romantic relationships, a middle adolescent in Canada is more likely to have had a romantic relationship and had more relationships than an adolescent in China (Li, Connolly, Jiang, Pepler, & Craig, 2010). Canadian adolescents' romantic relationships are also perceived to involve more trust and companionship than the romantic relationships of Chinese adolescents. Canadian females perceive their romantic relationships as more intimate than do Chinese females. Finally, friendship qualities are more strongly related to romantic experiences in Canada than in China. Canadian adolescents may have romantic partnerships that

are more intimate due to the relative emphasis on nonfamilial (versus familial) relationships in Canada versus China. The salience of nonfamilial relationships in Canada may also help to explain the greater interconnectedness between friendships and romantic experiences.

As another example, rates of dating aggression in middle adolescence are similar in Canada and Italy, but the links with other relationship characteristics differ (Connolly et al., 2010). In Canada, dating aggression is related to romantic conflict. In Italy, dating aggression is also related to romantic conflict but to a lesser extent. In Italy, imbalances in power are also associated with dating aggression, perhaps because gender roles are more traditional in Italy. Importantly, these studies also provide some insight into possible commonalities across cultures (e.g. rates of dating aggression).

To date, most studies have compared two countries, but some multi-country studies exist. For example, friendship conceptions were assessed among youth ranging from middle childhood to middle adolescence in former East Germany, Iceland, China, and Russia (Gummerum & Keller, 2008). The results showed that youth from Iceland and East Germany have less mature friendship conceptions than Chinese and Russian youth. Iceland and East German are more individualistic than China and Russia, and individualist countries may foster less sophisticated relationship cognitions.

Seiffge-Krenke et al. (2010) examined reports of romantic stress in early and middle adolescence in 17 countries grouped into seven regions. The results showed that adolescents in Middle and Southern Europe report greater romantic stress than do adolescents in Northern and Eastern Europe, South Africa, South America, and the Middle East. Stress may be higher in these European regions as the development of a romantic relationship plays an important role in the process of separating from the family and leaving home in those cultures. Stress may be lower in other regions because family rules regarding romantic relationships are clearer or stricter, making opportunities for choices regarding romantic experiences more limited. Finally, the differences may arise because adolescents in South America and the Middle East are more concerned about other stressors, such as identity concerns.

Multi-country studies have particular promise, as they allow multiple comparisons among countries, which may shed light on cultural processes that affect friendships and romantic experiences. Although such cross-cultural comparisons present some challenging methodological and conceptual issues regarding equivalence of measures,

samples, and constructs, we believe that such work can provide intriguing insights into the nature of dyadic relationships, as cultures vary markedly on a number of important dimensions.

Another promising direction is to directly measure the processes believed to explain cultural differences. For example, a process-oriented approach could involve considering youth of a single ethnicity who differ in the degree to which they are socialized in Westernized contexts. One study compared late adolescent Indian youth in homeland single-sex colleges, Indian youth in coeducational colleges in India, and Indian youth whose parents had immigrated to Canada (Dhariwal & Connolly, 2013). The results show that all desire romantic experiences. Those attending college in Canada, however, engage in more romantic activities than youth in other contexts. They also have more autonomy in selecting partners than those in coeducational schools in India, who have more autonomy than those in single-sex schools. The three groups also differ in the amount of Western and social media they consumed, their number of other-sex friends, friends having permissive expectations, and the intimacy of their conversations with friends. Importantly, when differences in the media and friendships are taken into account, differences in romantic activities and autonomy no longer exist. Exposure to Western media and intimate conversations with friends may induce acculturation, which may explain the greater romantic involvement of youth in these contexts. This study was one of the first to attempt to deconstruct culture and to identify processes, such as the influence of friendships and media, which might be responsible for cultural differences in romantic experiences.

Race, Ethnicity, and Social Class

Cultural context also plays a role within particular countries or societies. Subcultural differences exist as a function of race/ethnicity, social class, or neighborhood. Most past work was done with European American middle-class samples. Most studies today try to obtain more representative samples in terms of ethnicity or race, although this seems to be less true for social class. However, even studies that are representative of race, ethnicity, or social class often do not examine subgroups within the sample (see Crissey, 2005; Giordano, Manning, & Longmore, 2005, for exceptions). More typically, race, ethnicity, or social class is included, but only overall mean differences are reported. Thus, generalizations can be made about the population overall, but not about particular ethnic/racial groups or social classes.

There are at least two notable challenges when conducting and interpreting research on racial/ethnic differences. One is that race/ethnicity is often confounded with SES or neighborhood. Another is that research on race/ethnicity differences often describes mean-level differences but does not adopt a process-oriented approach. A few studies attempt to address process by considering whether the ethnic group differences exist in the links between variables such as those among different relationships. For example, ethnic minority Dutch adolescents (primarily of Turkish or Moroccan origins) who have more committed romantic relationships have poorer-quality relationships with parents (Ha, Overbeek, de Greef, Scholte, & Engels, 2010). This association is not found for native Dutch adolescents. The association may emerge for ethnic Dutch adolescents because ethnic Dutch parents place more limits on romantic relationships, and a very committed relationship may be problematic from their perspective.

An even more effective strategy is to assess the cultural processes that may affect friendships or romantic relationships in different ethnic/racial groups or social classes. Studies directly assessing such processes are uncommon, but noteworthy exceptions exist. One approach is to examine cultural models, or themes that members of a cultural group use to describe relationships. The more a theme is discussed, the more relationships are thought to be organized around that theme. Cultural models have been examined through qualitative interviews of Mexican American and African American middle adolescents (Milbrath, Olson, & Eyre, 2009). Five cultural model factors have been identified: (1) Hispanic cultural mores, such as *familismo, respeto, marianismo, and machismo*; (2) conceptions of care, which include directives about appropriate male behavior and idealized models of romance and courtship; (3) expectations in serious romantic exchanges, including expectations regarding sexual exclusiveness and knowing what the other wants; (4) ways of having multiple partners and strategies for managing a partners' fidelity; and (5) gaming, which involves verbal persuasion and social manipulation. Mexican Americans talked more about cultural mores and romantic care, whereas African Americans talked more about serious exchanges and gaming, suggesting that relationships in the two racial/ethnic groups are organized around different dimensions. This research did not examine the degree to which individuals from different ethnic backgrounds adhered to or disagreed with these cultural themes, but future work could examine these individual differences and test whether they account for racial/ethnic differences in romantic relationships.

Another approach involves examining individual differences in the degree to which children or adolescents within a single ethnic group adopt values that are especially salient for that group. For example, Mexican American adolescents who adopt *familistic* values that emphasize interpersonal harmony in the family also tend to adopt solution-oriented conflict resolution styles with friends, which involve discussion and working together to solve problems, as opposed to nonconfrontational strategies or controlling strategies (Thayer, Updegraff, & Delgado, 2008).

Cross-Race/Ethnic Relationships

Homophily is a driving force in the selection of dyadic peer relationships. Friendships tend to be between same-race/ethnic peers from early childhood through adolescence (Rubin, Bukowski, et al., 2006). Most adolescent romantic relationships are between same-race/ethnic individuals; for example, one set of estimates revealed that over 90% of African American and European American relationships are same-race/ethnic relationships, and over 60% of Hispanic and Asian American relationships are (Wang et al., 2006).

Research is mixed regarding differences in the quality and stability of same-race/ethnic and cross-race/ethnic friendships (McGill, Way, & Hughes, 2012; Schneider, Dixon, & Udarvari, 2007). However, factors that increase the likelihood of cross-race/ethnic friendships have been identified. Asian American and Latina/o American middle adolescents whose families have lived in the United States for longer and are more fluent in English are more likely to have cross-race/ethnic friends (Hamm, Brown, & Heck, 2005). African American adolescents with relatively stronger academic orientations and European American adolescents with relatively weaker academic orientations are more likely to have cross-race/ethnic friends. Social cognitions also play a role in the formation of cross-race/ethnic friendships. During middle childhood, children with more positive perceptions of different racial/ethnic groups are more likely to have cross-race/ethnic friendships (Feddes, Noack, & Rutland, 2009).

Other work considers the idea that cross-race/ethnic friendships introduce children and adolescents to new peer groups and increase their social perspective taking and social skills. Cross-sectional studies during middle childhood suggest that children with cross-race/ethnic friends are especially well-liked, leaders, and inclusive of others (Kawabata & Crick, 2008; Lease & Blake, 2005). In middle childhood, children with more cross-race/ethnic

friends also experience decreases in relational and physical victimization and increases in perceived support from friends across the school year (Kawabata & Crick, 2011). Interestingly, the effects for physical victimization and peer support hold only for classrooms that are especially diverse. Additional longitudinal work is needed to test whether socially competent children and adolescents are especially likely to form cross-race/ethnic friendships.

Having cross-race/ethnic friends during early adolescence is also associated with more positive attitudes about peers of other races/ethnicities (Knifsend & Juvonen, 2013). However, the benefits may differ for majority and minority children and adolescents. For example, for the majority German children, having more Turkish friends predicts more positive attitudes about Turkish children across the school year. The same effect does not emerge, though, for minority Turkish children (Feddes et al., 2009). The out-group attitudes of Turkish children may be based on broader experiences in society and not as malleable to the influence of specific friends. Similarly, although having cross-race/ethnic friends contributes to feeling safe at school among preadolescents (Graham, Munniksma, & Juvonen, 2013), these effects also may vary by majority/minority status. Having cross-race/ethnic friends is related to feeling safe at school for preadolescent and early adolescent Latina/o Americans when they are in the majority at the school (Munniksma & Juvonen, 2012), but not for European American adolescents when they are in the minority.

Interestingly, in multiracial/ethnic settings, having more same-race/ethnic friends may have mixed effects. Having more same-ethnic friends is linked with having a positive ethnic identity, including feeling good about one's ethnic group (Graham et al., 2013). However, having more same-ethnic friends is also associated with more stressful perceptions of cross-race/ethnic relations. Specifically, during middle childhood, African American children who have more African American friends are especially likely to report that African American children will be discriminated against (Rowley, Burchinal, Roberts, & Zeisel, 2008). The authors speculated that African American children who affiliate with same-race/ethnic peers may be discriminated against more often or may be socialized within their friendship networks to expect discrimination.

Less work has considered cross-race/ethnic romantic relationships. However, adolescents in cross-race/ethnic relationships are less likely to talk to their mothers or other people about these relationships (Wang et al., 2006). They are also less likely to meet their partners' parents.

These findings suggest that society and parents are less approving of such relationships, or at the very least adolescents think they are. Such cultural factors may lead to instability in cross-race/ethnic romantic relationships and greater homogamy in romantic relationships.

Finally, efforts have been made to identify processes underlying social class and neighborhood effects. Work on romantic relationships has considered the idea that relationships in the context of low-income neighborhoods may be more culturally heterogeneous. That is, more variation may exist in the lifestyles of residents of low-income neighborhoods than in higher-income neighborhoods (Harding, 2007). Consequently, children and adolescents may be exposed to heterogeneous models of relationships in these neighborhoods. Indeed, low-income neighborhoods have greater heterogeneity in attitudes about getting pregnant and the ideal sequence of events in romantic relationships, such as declarations of love, meeting parents, sex, pregnancy, or marriage. Such heterogeneity is associated with less consistency between adolescents' attitudes about pregnancy or romantic events and their actual behavior, even taking into account average neighborhood income levels.

Future Directions

One of the key propositions of our unified relational perspective is that dyadic peer relationships are embedded in a cultural context. The existing research provides clear evidence of such contextual effects, but more work is needed, especially research that disentangles processes underlying cultural differences (e.g., Dhariwal & Connolly, 2013). Research on such processes is important as too many cultures exist to compare them all, and focusing on processes will promote the integration of research in different cultures and contribute to a unified relational perspective.

Only a few friendship studies have examined developmental processes that reflect cultural variables, such as acculturation, experiences of racism, or ethnic identity. To the best of our knowledge, these variables have not been explored in regards to romantic relationships. More attention also needs to be paid to specific contexts in which these relationships occur, such as the school or neighborhood. The racial/ethnic make-up of the school context influences peer-group dynamics and the prevalence of cross-racial/ethnic friendships (see Graham, Taylor, & Ho, 2009). However, almost nothing is known about how the diversity of the school context affects romantic relationships. The degree of diversity in the school context likely affects not only the prevalence of cross-racial/ethnic

romantic relationships but also the degree to which they are accepted. Classmates' perceptions of cross-racial/ethnic romantic relationships, in turn, may influence who chooses to engage in these relationships and how they influence youths' adjustment.

Existing work on dyadic peer relationships in the United States has focused on African Americans, Asian Americans, and Latina/o Americans. Less is known about Native Americans, multiracial youth, or immigrant youth.

In addition, although work has focused on different ethnic/racial groups, religious differences are also important. One study considered Muslim and Christian Indonesian early adolescents (Eisenberg et. al., 2009). Like research on cross-race/ethnic friendships, this work suggests some benefits for youth with cross-religion friendships. Given that racial/ethnicity and religious subcultures are often confounded in countries and societies, work is needed to disentangle the influence of each on close peer relationships.

Historical contexts have also been understudied. Historians have written about changes in relationships, particularly romantic relationships. Today greater opportunities exist for social scientists to examine such changes. Not only are there a number of large-scale surveys that are periodically conducted, but investigators have more opportunities to gather data that corresponds to previously collected data. Taking into account historical changes may be especially important when considering differences across cultures. Globalization may be influencing the degree and nature of differences across different countries. Increased globalization likely provides new opportunities but also new challenges as the values of Western cultures often clash with other cultures. Similarly, immigrants must reconcile differences in the values, behaviors, and traditions of their old and new countries in their relationships.

Examining historical changes may be especially important when considering associations between behavioral traits and adjustment in relationships. Traits such as sociability, shyness/inhibition, behavioral control, and aggression are valued differently and associated differently with peer group status across different countries (see X. Chen & French, 2008). Associations of these traits with friendships and romantic relationships may also differ across countries. Notably, though, the nature of these cultural differences has changed over the past two decades (J. Liu, Chen, Li, & French, 2012). Earlier findings indicated that shyness was associated with lower peer status in the United States but not in China. However, urban China has experienced marked economic and cultural changes, and current findings indicate that shyness now is related to

lower peer status in China. Such studies of historical change provide new opportunities for examining how changes in cultures may be linked to interpersonal relationships.

ADJUSTMENT

In this section, we consider associations between children's and adolescents' friendships and romantic relationships and their psychological adjustment. We focus on internalizing and externalizing symptoms as that work illustrates the directions the field has taken.

Friendships

Friendship Involvement. The importance of friendships for adjustment is well-accepted (see Rubin, Bukoski, et al., 2006). Friendless children and adolescents are at greater risk for internalizing than externalizing problems (recent examples include Engle, McEwan, & Laski, 2011; Pedersen, Vitaro, Barker, & Borge, 2007; Waldrip, Malcolm, & Jensen-Campbell, 2008). Having friends also mitigates the impact of other risks. Rejection sensitivity is related to social anxiety most strongly for friendless early adolescents (Bowker, Thomas, Norman, & Spencer, 2011); during middle childhood, social isolation is related to later internalizing and externalizing symptoms most strongly for friendless children (Laursen, Bukowski, Anuola, & Nurmi, 2007). *Developmental cascades* are also present during middle childhood such that children who are excluded by peers experience exponentially increasing depressive symptoms, especially if they are friendless (Bukowski, Laursen, & Hoza, 2010).

Friendship Features. Not all friendships are similarly protective as friendship quality is also related to adjustment. Friendship quality is associated with emotional adjustment most strongly when early adolescents experience stressors, such as victimization (Woods, Done, & Kalsi, 2009). Supportive friendships also mitigate the impact of other risks, such as the effect of rejection sensitivity on emotional problems during middle adolescence (McDonald, Bowker, Rubin, Laursen, & Duchene, 2010). However, prospective effects of friendship quality on later emotional problems sometimes fail to emerge. Prospective associations may only be present under specific circumstances (e.g., for poorly accepted preadolescents and early adolescents; Waldrip et al., 2008; or preadolescents and early adolescents who engage in aversive behaviors; Prinstein et al., 2005).

Friendship qualities may also not be related consistently to emotional adjustment due to variation in the emotional adjustment of youth with high-quality friendships. Although high-quality friendships may protect some youth from internalizing problems, those ranging in age from middle childhood to middle adolescence who have high-quality friendships and co-ruminate may exacerbate their symptoms (Rose et al., 2007). Co-rumination is also linked with clinical levels of depression in middle childhood and adolescence (Stone et al., 2011; Stone, Urlass, & Gibb, 2010).

Alternatively, the other direction of effect may be stronger, such that emotional problems are more predictive of problematic friendship quality. That is, children's and adolescents' depressive symptoms may predict changes in friendship quality more consistently than friendship quality predicts changes in depressive symptoms (Oppenheimer & Hankin, 2011; Prinstein et al., 2005; Rose et al., 2011).

Findings are mixed regarding the relation between friendship quality and externalizing symptoms. Cross-sectional associations exist between poor-quality friendships and externalizing problems in early childhood (Engle et al., 2011) and middle childhood/early adolescence (Waldrip et al., 2008). However, friendship quality is not a consistent predictor of changes in externalizing symptoms (Engle et al., 2011). Like internalizing symptoms, friendship quality may be related to externalizing symptoms for only some youth, such as middle adolescents with particular attachment styles (McElhaney, Immele, Smith, & Allen, 2006) or children and early and middle adolescents who experience particular parenting styles (Yu & Gamble, 2010).

Friends' Characteristics. In recent years, interest in friends' influence has increased (Brechwald & Prinstein, 2011; Dishion & Pihler, 2009). Similarity between friends can occur because those who are similar become friends (selection), because friends become more similar over time (socialization), or because those who are dissimilar cease to be friends (deselection). All are important processes in friendships.

In terms of internalizing problems, selection effects are present such that adolescents who are similar in depressive symptoms are likely to become friends (Giletta et al., 2012; Kiuru, Burk, Laursen, Nurmi, & Salmela-Aro, 2012; van Zalk, Kerr, Branje, Stattin, & Meeus, 2010; for an exception see Giletta et al., 2011). Moreover, deselection effects also exist such that friends who are less similar in depressive symptoms are more likely to terminate their friendships.

Parallel selection effects are present for externalizing behaviors. Adolescents choose friends who are similar to themselves in aggression (Dijkstra, Berger, & Lindenberg, 2011; Sijtsema et al., 2010) and substance use (de la Haye, Green, Kennedy, Pollard, & Tucker, 2013; DeLay, Laursen, Kiuru, Salmela-Aro, & Nurmi, 2013; Giletta et al., 2012; Popp, Laursen, Kerr, Stattin, & Burk, 2008).

Investigators also find socialization effects with friends becoming more similar to one another over time. In terms of internalizing symptoms, this process is often referred to as contagion. Some studies indicate depression contagion within one specific friendship for each person (Giletta et al., 2011; Prinstein, 2007; Stevens & Prinstein, 2005). Social network analyses allow contagion effects to be tested simultaneously for all dyads within social groups, while controlling for selection effects. This approach indicates that adolescents become increasingly similar in depressive symptoms to peers with whom they spend time, suggesting that contagion effects are present within broad networks of affiliated peers (Kiuru et al., 2012; van Zalk et al., 2010). It is reasonable to suspect that contagion effects are stronger in closer relationships, but the evidence is mixed (Conway, Rancourt, Adelman, Burk, & Prinstein, 2011; Giletta et al., 2011; Giletta et al., 2012; Prinstein, 2007).

Recent research also highlights processes that may account for the contagion of internalizing symptoms. Having depressed peers predicts increases in middle adolescents' anticipation of failure, which predicts increases in depression (van Zalk et al., 2010). Having depressed friends also predicts co-rumination, which predicts increases in early and middle adolescents' depression (Schwartz-Mette & Rose, 2012).

A long line of research indicates that having friends who engage in deviant or delinquent behavior or use substances increases youths' own deviant/delinquent behavior and substance use (for recent examples, see Giletta et al., 2012; Piehler, Véronneau, & Dishion, 2012; Selfhout, Branje, & Meeus, 2008; Vitaro, Brendgen, & Wanner, 2005). These effects are typically found for adolescents, but even kindergarteners who have friends with externalizing symptoms develop more school conduct problems (Snyder et al., 2005).

Recent extensions also include considering context, friend, and relationship characteristics that exacerbate the risks of having deviant friends. Regarding contexts, socialization effects for risk attitudes, such as liking to smoke, skip school, and damage property, are especially strong for early adolescents who are in classrooms in which the

perceived popular youth hold these attitudes (Rambaran, Dijkstra, & Stark, 2013).

Parental engagement may also reduce risk. Children and early and middle adolescents with high-quality friendships exhibit less delinquency when parental monitoring is high but more delinquency when parent monitoring is low (Yu & Gamble, 2010). Likewise, early adolescents whose friends drink are more likely to start drinking if they spend unsupervised time together (Light, Greenan, Rusby, Nies, & Snijders, 2013). However, parents' forbidding particular friendships increases contact with deviant peers and delinquent behavior among early and middle adolescents (Keijsers et al., 2012). More work is needed to pinpoint the most protective forms of parent involvement because effectiveness may depend on the type of involvement, developmental stage, and the youths' initial levels of deviant behavior (Tilton-Weaver, Burk, Kerr, & Stattin, 2013).

In terms of adolescent friends' characteristics, the older friend is more influential than the younger friend (Popp et al., 2008) and the better-accepted friend is more influential than the less-accepted friend (Laursen, Hafen, Kerr, & Stattin, 2012). Evidence is mixed regarding whether deviant friends pose greater risks for adolescents in reciprocal (as opposed to nonreciprocal) friendships or higher- (versus lower-) quality friendships (Giletta et al., 2012; Selfhout et al., 2008). However, research on conversational processes suggests that deviant friends pose greater risks in well-functioning friendships (Dishion & Piehler, 2009). Deviancy training, in which friends respond positively (e.g., laugh) to rule-breaking talk, predicts escalating externalizing behavior in later childhood and adolescence and has even been observed in kindergarten (Snyder et al., 2008; Snyder et al., 2005). Friends in middle adolescence are at the greatest risk when the deviant talk is characterized by responsiveness, reciprocity, and cooperation (Piehler & Dishion, 2007).

Romantic Relationships

Romantic Involvement. Current or past romantic involvement is associated with depressive symptoms in adolescence, particularly for early adolescents and females (see Davila, 2008). Similarly, romantic involvement is linked to externalizing symptoms and substance use (Furman & Collibee, in press). Most research has been done in North America, but similar results have been found in China (Z. Chen et al., 2009).

Several explanatory models have been proposed (Davila, 2008): (a) a normative trajectory model—early or

precocious romantic experiences places one at greater risk for depression or other adjustment problems than adhering to developmentally appropriate norms; (b) an attention impairment model—romantic involvement takes time or attention away from other important areas of life, causing difficulties which lead to depression; (c) a stress and coping model—romantic experiences are inherently stressful, which place adolescents, especially those with poor coping skills, at risk for depression; and (d) an individual differences model—certain personality or interpersonal characteristics affect romantic experiences, leading to depression.

The normative trajectory model needs some revision because romantic experiences are linked with depression in adolescence even when they occur at an age that is typical or normative (see Davila, 2008). The alternative developmental task model proposes that romantic involvement is an *emerging* developmental task in adolescence, such that precocious involvement could undermine development (Roisman et al., 2009). Romantic involvement eventually becomes a *salient* developmental task in adulthood, and, as it does, such involvement should be linked to concurrent and subsequent adaptation. Consistent with this idea, having a romantic relationship is associated with poorer adjustment in adolescence but better adjustment in early adulthood (Furman & Collibee, *in press*).

The other three models have received support in studies examining moderators and mediators (see Davila, 2008). For example, co-rumination with friends predicts increases in depressive symptoms for early adolescent females with more romantic experiences and decreases for females with fewer romantic experiences (Starr & Davila, 2009). If romantic experiences are stressful, co-ruminating about them may be depressogenic; on the other hand, if females are not co-ruminating about romantic experiences, the experiences may be less stressful and not depressogenic. The findings also are consistent with an individual differences explanation in that females who co-ruminate are more likely to have more romantic experiences and be more depressed.

Romantic Relationship Features. Not all adolescents who are romantically involved are equally at risk. An important direction for research has been to identify the characteristics of romantic relationships that are linked to such problems. Middle adolescents with romantic relationships characterized by fewer supportive and more negative interactions are more likely to have adjustment problems (Collibee & Furman, 2013; La Greca & Harrison, 2005).

In contrast, an adolescent who reports being in love with a partner is less likely to engage in delinquent behavior (McCarthy & Casey, 2008).

Investigators have also begun to examine developmental changes in the patterns of associations between relationship characteristics and adjustment. The links between positive characteristics (e.g., support, commitment, & relationship security) and adjustment are sometimes stronger in early adulthood than in adolescence (Collibee & Furman, 2014; Meeus et al., 2007; van Dulmen, Goncy, Haydon, & Collins, 2008). Such findings are consistent with the idea that romantic relationships become increasingly important with age, and indeed are salient developmental task in early adulthood.

Romantic Partner Characteristics. Characteristics of romantic partners are also influential. In terms of substance use, the more adolescents are exposed to smoking by a close romantic partner, the more likely they are to initiate smoking and the less likely they are to stop smoking. Conversely, the more time they spend in a close romantic relationship with a nonsmoker, the more likely adolescents are to stop smoking (Kennedy, Tucker, Pollard, Go, & Green, 2011). Romantic partner substance use also predicts adolescents' subsequent substance use a year later and 6 years later (Gudino-Miller, Lewis, Tong, Tu, & Aalsma, 2012); such findings are noteworthy because most of the relationships had dissolved before a year had passed. At the same time, it is unclear if these effects on smoking and other substance use reflect selection or socialization.

Investigators have demonstrated that adolescent romantic partners are similar in adjustment, most typically in terms of externalizing behavior (e.g., Lonardo et al., 2009). However, most studies are cross-sectional and cannot address whether the similarities stem from selection or socialization effects. In a noteworthy exception, Simon et al. (2008) assessed early adolescent and romantic partner adjustment prior to and after the initiation of the relationship. Prior to their relationship, pairs were similar in depressive symptoms, indicating selection effects. An overall effect of socialization was not found, but some adolescents were socialized. Those who dated less depressed partners became less depressed; those who dated more depressed partners did not change. Moreover, only those who were high in depression showed change when paired with a partner low in depression; those who were low in depression did not change, regardless of the partner's level of depression.

Such findings are noteworthy for several reasons. The study was one of the few to examine whether some partners

are more influential than others and if some adolescents are more open to influence than others. It also illustrates the potential for healthy influences by romantic partners. This is particularly noteworthy because these romantic relationships only lasted three months on average. Finally, the observed associations were evident even after taking into account the socializing effects of friends, illustrating the unique influences of different types of dyadic peer relationships (see also Lonardo et al., 2009).

Interestingly, not only friends and romantic partners but also friends of romantic partners may be influential (Kreager & Haynie, 2011). Early and middle adolescents' prior drinking and their partners' prior drinking 18 months earlier are predictive of drinking. Notably, the adolescents' and partners' prior drinking are not very related to each other, suggesting that the partner effects are socialization effects, not selection. Friends' drinking is predictive, but not once the adolescents' prior drinking is taken into account; suggesting that the adolescents select friends with similar drinking habits. Most important, partners' friends' prior drinking is more predictive of adolescents' drinking than partners' drinking is. These associations hold after taking into account adolescents' prior drinking, suggesting that this is not a selection effect. Instead, romantic partners may serve as a bridge or liaison, connecting adolescents to new peers who promote changes in drinking behaviors and allow such behaviors to spread across peer networks.

Dating Violence

Although considerable research has examined associations between romantic experiences and internalizing or externalizing problems, one aspect of many romantic relationships is recognized as a serious problem in itself—dating or intimate partner violence. Until this century, virtually no research examined psychological, physical, or sexual dating violence in adolescence, but now the topic may be the most extensively studied topic in the field of adolescent dating and romantic relationships.

Recently, the Partner Abuse State of Knowledge Project systematically reviewed the literature on adolescent and adult intimate partner violence. Several conclusions were drawn. First, approximately half of intimate partner violence is bidirectional (Langhinrichsen-Rohling, Misra, Selwyn, & Rohling, 2012). Such findings led to an increased recognition of the importance of a dyadic perspective for understanding dating violence (O'Leary & Slep, 2012). Second, physical and psychological violence have detrimental effects not only on psychological

well-being, but also on physical health and health behavior, particularly for females (Lawrence, Orengo-Aguayo, Langer, & Brock, 2012). Third, risk factors for dating violence include minority group status, acculturation stress and other types of stress, violence between parents, experience of child abuse, antisocial behavior, and substance use problems (Capaldi et al., 2012). Family conflicts are also a risk factor, whereas parental monitoring, involvement, and support are protective. Similarly, associating with aggressive peers is a risk factor, whereas higher friendship quality is protective. Hostility toward women, relationship beliefs justifying violence, and relationship conflict are important proximal predictors.

As the number of risk factors increases, the likelihood of perpetrating violence in multiple romantic relationships in middle adolescence increases (Williams, Connolly, Pepler, Craig, & LaPorte, 2008). Moreover, different pathways exist for the recurrence of dating aggression in multiple relationships. Delinquency, aggression, and associating with aggressive peers predict recurrence for those who are accepting of dating aggression. These factors are not predictive for those who are not accepting of dating aggression. Instead, being previously involved in a conflictual and hostile relationship predicts recurrences. Perhaps the conflictual style or a sensitivity to rejection in the prior relationship is brought forward to the new relationship.

As the list of risk factors suggests, dating violence is linked with other forms of violence. At the same time, only some of those who are aggressive toward peers aggress toward a dating partner. Early and middle adolescents who are aggressive toward a dating partner as well as peers are high in depression, substance use, and family conflict and have more peer models and peer approval of deviant behavior (Foshee et al., 2011). These findings provide valuable information about factors that lead to aggression toward a dating partner in particular, and not just aggression toward nonromantic peers. Further work on identifying factors that lead specifically to dating violence is needed. Also work has begun on mediators, or developmental processes underlying dating violence. For example, feelings of stigmatization after sexual abuse are predictive of anger five years later, which predicts adolescent dating violence (Feiring, Simon, Cleland, & Barrett, 2013). Further work on underlying processes is needed. Particularly needed are studies of protective factors.

Developmental changes also may occur in risk factors. For example, heavy alcohol use increases the likelihood of dating violence by any early adolescent, but in late adolescence heavy alcohol use particularly increases the

likelihood of dating violence for those who are embedded in violent family or peer contexts (Reyes, Foshee, Bauer, & Ennett, 2012). More generally, adolescent intimate partner violence is likely to differ in nature from that which occurs in adult committed relationships. Far fewer adolescents are constrained by being married or cohabiting, having children, or relying financially on their partners. Thus, it may be easier to leave a relationship, although the desire to have a relationship may keep some adolescents in violent relationships. Adolescents also may be less socially skilled or experienced than adults; accordingly, they may have less established ideas about what appropriate behavior is for themselves or their partner. Thus, the risk factors, processes underlying the violence, and outcomes may differ, but we know relatively little about such differences.

Early interventions for intimate partner violence were relatively unsuccessful. Recently, more effective programs have been developed; changes have occurred in knowledge and attitudes, and, in some instances, violent behavior (see O'Leary & Slep, 2012; Whitaker, Murphy, Eckhardt, Hodges, & Cowart, 2013). In fact Safe Dates and the 4th R are listed in SAMHSA's National Registry for Evidence-Based Programs and Practices (<http://nrepp.samhsa.gov>). Innovative approaches have also emerged, including a family-based prevention program (Foshee et al., 2012), a program to make school buildings a safe place where sexual victimization does not occur (Taylor, Stein, Mumford, & Woods, 2013), and a program in which coaches encourage athletes to intervene when they witness dating violence-related behaviors (E. Miller et al., 2013). These and other promising programs differ from earlier ones in three important respects. First, they focus on preventing intimate partner violence, rather than treating it. Second, most target young adults and especially adolescents, the time when aggression is most likely to first occur. Finally, they recognize that intimate partner violence is most commonly mutual and thus a dyadic phenomenon; in fact, it may prove most effective to focus on both individuals' behavior, even when violence is unidirectional and solely the responsibility of one person.

Future Directions

Both similarities and differences exist in how the friendship and romantic relationship literatures have considered associations with adjustment. Both have examined the influence of having a friend or a romantic partner. Of course, the implications are different in that having friendships is a developmentally appropriate task throughout childhood

and adolescence, whereas the optimal level of involvement in romantic relationships for youth of particular ages is not clear and almost certainly varies across cultures. Both literatures reveal benefits of having high-quality relationships. Both have examined the influence of the relationship on adjustment more often than the reverse. Neither field has examined the links between the history of a relationship and adjustment. The trajectories of a relationship's features over time may be important predictors of adjustment. For example, increases in conflict may predict adjustment problems.

The romantic relationship literature indicates that ties between quality and adjustment increase with age, but we know less about developmental changes in the links for friendship. There may be developmental stages during which friendship difficulties are especially likely to forecast later relationship and adjustment problems. Specific aspects of friendships also may influence adjustment differently at different developmental stages.

The friendship literature has begun to highlight ways in which better-functioning relationships actually confer risk. Perhaps ironically, through connected and cohesive conversations, friendships can confer risk for internalizing problems through co-rumination and exacerbate risks of deviant talk on externalizing problems. Having more experience with romantic relationships is associated with both risky behaviors and psychosocial competence (Furman, Low, & Ho, 2009). Future research should consider whether there are additional hidden risks of high-quality romantic relationships as well.

Future studies are also needed to shed light on influence processes in regards to positive behaviors. One study showed that adolescents with friends who engage in prosocial behavior toward peers begin to engage in more prosocial behavior themselves (Barry & Wentzel, 2006). Additional work could examine socialization of other positive behaviors, such as volunteering in the community.

Little is known about the long-term links between dyadic peer relationships and adjustment. Dating in early adolescence is predictive of depression, but these effects dissipate over time (Natsuaki, Biel, & Ge, 2009). Similarly, conflict and poorer problem solving in romantic relationships in middle adolescence are not predictive of the long-term course of depression, but depression in middle adolescence is predictive of romantic relationship quality over the course of the next five years (Vuyeva & Furman, 2011). Aside from this work, little is known.

Violence and abuse have also been investigated in romantic relationships but not in friendships. Some children

and adolescents are victimized in friendships; whether these interactions rise to the level of violence or abuse experienced in some romantic relationships is not known. Violence may be less common in friendships than romantic relationships, but some youth might stay in very damaging friendships.

Another important direction is to identify mechanisms that underlie selection and socialization effects. For example, do individuals actively seek out similar peers for relationships or are they simply likely to meet one another because they find themselves in similar contexts? Do people change their behavior because of the partner's disapproval and the risk to the relationship? Do changes occur because of the effect on one's daily life? In regards to romantic relationships, do changes occur because of thoughts about what being in a more committed relationship entails about one's own identity?

Additionally, most work has examined how friendships or how romantic relationships are linked to adjustment, but do not consider both relationships simultaneously (see Lonardo et al., 2009; Simon et al., 2008, for recent exceptions). Supportive relationships of one kind may buffer the impact of problems in the other. Additive or interactive effects of the different relationships on adjustment may also occur. A unified relational perspective is essential to understand the interplay among the developmental trajectories of friendships, romantic experiences, and psychological adjustment.

Finally, few empirically supported programs for promoting healthy friendships or romantic relationships exist other than those that have aimed to prevent dating violence. Friendship skills are sometimes taught as part of programs to enhance peer acceptance, but no program has focused on friendships *per se*. Aside from the dating violence programs, those related to romantic relationships have focused on marital education more broadly. In fact, often the education programs are part of a broader curriculum, which may be offered as family and consumer science classes, character education programs, abstinence education programs or community-based initiatives (Karney, Beckett, Collins, & Shaw, 2007). Relatively few evaluations of the education programs exist, and most of these are quasi-experimental designs. A review of these programs characterized the results regarding their effectiveness as "at most suggestive" (Karney et al., 2007). One of the few randomized control trials of a relationship education curriculum found changes in middle adolescents' attitudes and knowledge but not behavior a year later (Kerpelman, Pittman, Adler-Baeder, Eryigit, & Paulk, 2009). Additional

evaluations and new programs are needed to determine how to promote healthy dyadic relationships.

OTHER DYADIC PEER RELATIONSHIPS

Other-Sex Friendships

The vast majority of children's and adolescents' friends are same-sex friends (Mehta & Strough, 2009). However, the proportion of other-sex friends increases with age in adolescence, especially for females (Poulin & Pedersen, 2007). Interestingly, females tend to have more other-sex friends in their out-of-school friendship networks than males do. Females' other-sex friends also tend to be older than males' other-sex friends.

Similarities and differences occur in same- and other-sex friendships. Children and adolescents see same- and other-sex friendships as similar in terms of companionship (Hand & Furman, 2009; McDougall & Hymel, 2007). However, they perceive same-sex friendships as more intimate and see themselves as more similar to or compatible with same-sex friends. Interestingly, they comment positively on other-sex friends' personalities more than those of same-sex friends'. Other-sex friends also provide opportunities to learn about other-sex peers. Compared to same-sex friendships, adolescents are more concerned about ambiguity in other-sex friendships (e.g., if one friend develops romantic feelings) and that others will misunderstand the relationship (Hand & Furman, 2009).

Notably, females may be disadvantaged in other-sex friendships (Rose, 2007). Females may alter their interpersonal styles more than males to match other-sex friends (McDougall & Hymel, 2007). Females report greater common activities in other-sex friendships than in same-sex friendships, perhaps because of the focus on common activities in males' same-sex friendships. In contrast, males do not report greater intimacy in other-sex friendships than same-sex friendships, despite females' focus on intimacy in same-sex friendships. Moreover, adolescent males seek and receive more help from other-sex friends than do females (Poulin & Pedersen, 2007; Sears, Graham, & Campbell, 2009). These studies may not be generalizable to all cultures, however. Chinese middle adolescent females report greater help and security in their other-sex friendships than do males (Cheung & McBride-Chang, 2011).

Males are more likely than females to perceive heterosocial benefits of other-sex friendships. They are also more likely than females to perceive other-sex friendships

as venues for meeting other-sex peers and to see physical attraction in other-sex friendships as a benefit of the relationships (Hand & Furman, 2009). In fact, other-sex friendships may serve as models for developing skills for romantic relationships. Middle adolescents with more other-sex friends have lower dating anxiety (La Greca & Mackey, 2007), and those with higher-quality other-sex friendships are especially likely to be in romantic relationships (Cheung & McBride-Chang, 2011).

Having other-sex friends also may be particularly risky for females' adjustment. Early adolescent females with more other-sex friends are more likely to use alcohol at age 18 (Poulin, Denault, & Pedersen, 2011); females in middle adolescence with more other-sex friends are especially likely to be smoking 1 year later (Mrug, Borch, & Cillessen, 2011). Females who increase their proportion of other-sex friends through early and middle adolescence experience increases in their alcohol and drug use (Poulin et al., 2011). These effects are not significant for males. In fact, middle adolescent males with other-sex friends are less likely than other males to be smoking 1 year later (Mrug et al., 2011). Similar findings emerge for antisocial behaviors (Arndorfer & Stormshak, 2008; Haynie, Steffensmeier, & Bell, 2007). The greater risk for adolescent females may occur in part because females' other-sex friends tend to be older, out-of-school friends (Poulin & Pederson, 2007). These friends are more likely than females' agemates to be experimenting with alcohol and drugs. In addition, because males are more likely than females to engage in antisocial or violent behavior, males may elicit these behaviors in the females.

Antipathies

Antipathies are relationships in which two individuals dislike each other. Children and adolescents with antipathies are less well liked by peers, more victimized, and have more externalizing and internalizing problems than those without antipathies (Card, 2010). The two individuals in early adolescent antipathies tend to be dissimilar in terms of perceived popularity (Berger & Dijkstra, 2013) and behavior (Güroğlu, Haselager, van Lieshout, & Scholte, 2009). Many antipathies involve one person who is antisocial and another who is withdrawn. The withdrawn one may be especially at risk for maltreatment. An early adolescent is especially likely to be victimized within an antipathy if the other youth is physically strong and aggressive and is not victimized by others (Card & Hodges, 2007). Moreover, being the more aggressive youth within an antipathy

increases risk for behavioral problems. During middle to late childhood, a child with an antipathy becomes more aggressive over time if the person who she or he dislikes is generally not aggressive, but not if the disliked one is aggressive (Erath, Petit, Dodge, & Bates, 2009). Disliking, and perhaps aggressing against, a nonaggressive peer may be more reinforcing than sharing mutual dislike with a peer who responds with aggression. This finding illustrates the importance of a relational perspective. It is important not only to examine the characteristics of the individuals, but also to consider the combination of characteristics of individuals within a dyad.

Future Directions

More work is needed on these understudied relationships. For example, more information is needed on factors that contribute to the development of other-sex friendships. Children and adolescents with interpersonal styles more characteristic of the other sex may be especially likely to have other-sex friends. However, the interplay between the partners is also likely to be important. Cross-sex dyads with similar interpersonal styles may be likely to become friends. Implications for adjustment also need to be better understood. Having other-sex friends carries risks, especially for females. However, positive experiences in other-sex friendships should foster skills needed for high-quality romantic relationships. These lines of research need to be integrated to identify how children and adolescents can reap the benefits of other-sex friendships while minimizing the risks.

A better understanding of antipathies is also needed. We need to know how antipathies develop, the nature of interactions between antipathies, and whether antipathies are ever resolved amicably. According to retrospective reports, many antipathies were formerly friends and mutual dislike developed through perceived friendship transgressions (Card, 2010; Casper & Card, 2010). Longitudinal work is needed to track the development, dyadic nature, and implications of these relationships.

Some other types of relationships have received virtually no attention. Although work on same-sex romantic relationships in adulthood has increased, little is known about such relationships in adolescence (see Diamond & Lucas, 2004, for an exception). Similarly, both the scientific field and media have focused on "friends with benefits," which young adults' characterize as relationships with ongoing sexual exchanges, often between friends (Furman & Shaffer, 2011). This work has focused on college students,

and we know virtually nothing about such relationships in adolescence, even their prevalence. Finally, although most adolescents and young adults' interactions on the Internet are with friends with whom they also interact face-to-face (Reich et al., 2012; Smahal et al., 2012), some friendships may only entail online communication; we know little about such "virtual friendships."

Although the distinctions among different types of relationships have much merit, it is important to recognize that boundaries among categories can be unclear. Someone may be uncertain whether a relationship is a romantic relationship or a friend-with-benefits relationship; certainly, two members of a dyad may disagree about the status of the relationship. Moreover, an individual may consider a relationship to fall into two categories—for example, a friendship and a romantic relationship. Overlaps between friends and biological relatives, such as cousins or siblings, may be particularly likely in non-Western cultures. In some instances, it may be valuable to focus not on friendships or romantic relationships *per se*, but to study the relationships youth consider most important (Kerr, Stattin, & Kiessner, 2007).

Further research on these understudied relationships will contribute to a unified relational perspective. As we learn more about the different types of dyadic peer relationships, we will acquire a better understanding of what features and developmental processes are specific to particular relationships and which are shared by different ones.

ISSUES FOR FUTURE RESEARCH

Definitional Issues

Many studies have simply considered the influence of peers without specifying the nature of their relationships with different peers. Yet peers are a heterogeneous group; some are close friends, some friends, some acquaintances, and some antipathies. Making differentiations among these different relationships and studying their unique contributions to development is critical for building our understanding of what is specific to friendships and what reflects effects of the general peer group.

In addition, in studies of friendship, an adolescent may list a romantic partner as a friend unless the investigator explicitly said not to do so. As a consequence, some studies of friendships may actually be studies of both friendships and romantic relationships. One could argue that romantic relationships are friendships and should be included; however, the point is that investigators should make clear to participants what kind of relationship they are studying.

Theoretical and Conceptual Issues

Although some work has been based on Eriksonian or Sullivanian theory, most research on dyadic peer relationships in childhood and adolescence has not been guided strongly by theory. Theories such as attachment theory, behavioral systems theory, evolutionary theory, the investment model, and social exchange theory have guided work on close relationships in adulthood, and seem just as applicable to children's and adolescents' relationships. More theoretically guided work would help us accumulate a more systematic body of knowledge. Mini-theories or theoretical explanations of particular phenomena are also valuable. Davila (2008) presented four possible explanations for why adolescent romantic involvement is linked to depression. Subsequent work has tested such explanations, leading to faster progress on the topic (see "Adjustment" section).

Also, much of the literature focuses only on one aspect of relationships, such as a conflict style. Focused in-depth studies of particular phenomena are essential but need to be complemented by studies that examine multiple facets of relationships, multiple predictors, or multiple consequences of relationships. If not, our understanding of relationships will be fragmented. Moreover, research simultaneously examining involvement, relationship quality, partner characteristics, and relationship history is needed. Failing to take into account all of the dimensions can lead to incorrect inferences about associations with particular dimensions.

In addition to simultaneously examining multiple variables, key variables need to be identified and isolated. In one study, for example, 13 different variables were all correlated with perpetrating dating violence, but when all were entered in the same logistic regression, only four remained as unique predictors (Banyard, Cross, & Modecki, 2006). This does not mean that the other nine variables are unimportant; whether a variable uniquely contributes is highly dependent on the other variables under consideration. However, this example illustrates the challenge of identifying key relations in complex networks of variables.

Structural equation modeling may help identify the common, potentially core, components that underlie our variables and underlie the links among constructs. For example, Kogan et al. (2013) measured three aspects of parenting in middle childhood (warmth, monitoring, & inductive reasoning) and three aspects of relationship quality in early adulthood (satisfaction, lack of verbal conflict, & absence of violence). All nine correlations between the three manifest parenting variables and the three manifest relationship

quality variables were below .22. Yet the path between a latent parenting variable and a latent relationship quality variable exceeded .50. In effect, SEM allowed measurement error to be controlled and identified underlying constructs that were linked.

Another factor that contributes to a piecemeal understanding is that separate fields of study have emerged around specific topics of interest. For example, the literature on dating violence is quite separate from that on normative aspects of romantic relationships. Similarly, sexual behavior and romantic relationships developed as separate fields, although some recent progress has been made toward integrating them. Most literature on all dyadic peer relationships has focused on specific age periods, limiting our understanding of developmental changes in the nature and function of different relationships. Literature spanning the transition from adolescence to adulthood is particularly limited (see Furman & Winkles, 2012). Indeed, the child/adolescent and adult literatures on relationships historically have had little contact with each other. This bifurcation is problematic as the literature on adults' relationships, especially their romantic ones, is quite extensive, and different from that on children's and adolescents' relationships. Fortunately, several long-standing longitudinal studies now span the transition, and developmental scientists are increasingly interested in emerging or early adults' relationships. Finally, psychology, sociology, and other disciplines are also rather isolated from one another, although the emergence of the field of relationship science has promoted interdisciplinary contact.

Methodological Issues

The increasing availability of large scale, long-standing longitudinal data sets has greatly advanced the field. At the same time, they pose methodological challenges. In our review, we repeatedly noticed differences in the specific variables examined in studies using the same data sets. For example, one paper may report results on one relationship variable, whereas another reports on a different, yet seemingly similar, variable. It is often unclear why different variables were used. The practice raises questions about the robustness of the findings. The inclusion of indices that are similar from paper to paper would strengthen the inferences that can be drawn from the study.

Data collection points in most longitudinal studies also tend to be far (e.g. a year or more) apart. This approach provides invaluable information about the development and long-term consequences of relationships, but wide-spread

time points may not be ideal for studies of mediation or process because the durations over which many variables have their strongest impact are much shorter. Short-term longitudinal studies with many points of data collection may be required to assess processes of change in friendships or romantic relationships. This work is particularly important in our field because many relationships do not even last for a year. Few such studies currently exist, but more may shortly appear as investigators begin to use smart phones and other electronic means for collecting such data.

Analytic Issues

Our analytic toolbox is much greater than a decade ago. Of particular relevance are advances in techniques for studying dyads (see Card, Selig & Little, 2008; Kenny, Kashy, & Cook, 2006). As can be seen in this paper, studies using techniques such as the Actor Partner Interdependence Model or Sienna are increasing in number. Few investigators, however, have taken advantage of sequential analyses or time series data to identify patterns of interaction in dyads. State space grids that analyze event sequences need to be explored more (Hollenstein, 2007).

Contemporary analytic tools, such as growth curve analyses or analyses of between- and within-person effects, allow for examination of the developmental course of particular relationships, a topic that has been neglected. Such techniques can also be used to examine how trajectories of predictors are associated with relationships and how trajectories of relationships are associated with outcomes (e.g., Fraley, Roisman, & Haltigan, 2013; Vuyeva & Furman, 2011).

In addition, recently developed statistical models permit the identification of trait and state elements of behavior. Specifically, trait-state-occasion and trait-state-error models allow one to determine how much a characteristic is stable over time (i.e., a trait) and how much varies from occasion to occasion (Cole, Martin, & Steiger, 2005). Moreover, what variables are predictive of the trait and occasion components of behavior can be examined to determine how stable characteristics of individuals contribute to patterns of interaction. For example, approximately 50% of the variation in late adolescent and young adults' negative behavior toward a friend or romantic partner can be attributed to a trait component, whereas the remaining proportion is occasion specific (Hatton et al., 2008). Moreover, the trait component is predicted by a mother's earlier negative behavior toward the adolescent and the adolescent's self-evaluation, negative emotionality, and

security of romantic representations; none of these factors predicted the occasion-specific variance. The difference in the predictors of the trait and occasion components illustrates the challenges of determining what underlies particular interactions in relationships.

More work testing mediation is also needed. We have made great progress identifying variables that are associated with different facets of dyadic peer relationships, but we know less about why they are related. This chapter includes a number of examples of such process-oriented work that illustrates its potential. Process work should prove particularly valuable for dyadic phenomena, such as mutual dating violence, where each person may play a role.

Existing studies of mediation have made progress in that more studies incorporate three time points rather than one. However, virtually all of these studies have assessed the predictor at time one, the mediator at time two, and the outcome at time three, which is not as strong as designs in which all three variables are assessed at all three times (Cole & Maxwell, 2003). Without such an assessment, it is difficult to determine if the mediator is actually involved in the process or simply covaries with the variables that are responsible. Indeed, few studies have examined multiple potential mediators, leaving it unclear clear whether the studied mediators are key processes or are simply associated with key processes. Moreover, the nature of the associations between predictors and outcome variables is often not clear. That is, if the variables treated as predictors at time one had been assessed at time three, they might have been predicted by the variables treated as outcomes if those variables had been assessed at time one. As noted, most studies examining family variables have examined how family processes predict subsequent friendships or romantic relationships and have not examined how friendships or romantic relationships predict family processes. Similarly, most studies examine how friendships predict romantic relationships, whereas only a few examples of the reverse exist.

Whether early experiences with friends or romantic partners have enduring effects on competence is also of interest. An early experience could anchor a child's developmental trajectory and directly influence later behavior by processes such as cognitive representations that are consolidated early in development. Alternatively, seemingly long-term effects may be indirect; that is, an experience may affect competence at an early age, which affects subsequent competence. Moreover, seemingly long-term effects could stem from consistencies in experiences over

time. Statistical techniques now exist for differentiating such models (Fraley, Roisman, & Haltigan, 2013).

Understudied Topics

Genetic Factors

Recent work suggests that the examination of genetic factors has promise (see Brendgen, 2012). A few studies have examined gene-environment correlations, or the degree to which different dimensions of friendships are associated with the genetic make-up of individuals. Genetic factors appear to be weakly related (van Lier et al., 2007) or unrelated (Brendgen et al., 2008) to young children's tendency to have aggressive friends. However, genetic factors contribute to young children's tendency to have socially reticent friends (Guimond et al., 2013), and older children and adolescents choose friends based on their own genetic makeup (see Brendgen & Boivin, 2009).

A few investigators have also examined gene by environment interactions, or whether experiences with friends exacerbate or mitigate genetic risks. For example, children with a genetic predisposition toward depression are less likely to be depressed if they have friends (Brendgen et al., 2013). Children with a genetic predisposition toward physical aggression are especially aggressive if they have aggressive friends (Brendgen et al., 2008; Van Lier et al., 2007). We know of only one study that has used molecular genetic techniques to study adolescent peer relationships (Fraley, Roisman, Booth-LaForce, et al., 2013); that study found little evidence for genetic antecedents of late adolescent romantic attachment styles. Clearly, more work is needed on genetic factors. Such work also would provide information about nonshared environments as discrepancies between monozygotic twins may stem from nonshared environmental influences.

Psychophysiological and Neurological Processes

Research on psychophysiological, neurological, and other biological processes has exploded in the past decade; however, only a few studies have considered such processes in children or adolescents' friendships or romantic relationships. This work primarily focuses on the neuroendocrine and autonomic nervous systems (see Murray-Close, 2012). Notably, friendship experiences can mitigate physiological stress responses. A child's physiological response to stress as reflected in cortisol levels is mitigated when a best friend is present (Adams, Santo, & Bukowski, 2011). In addition, children who are rejected by classmates have a flattened diurnal cortisol rhythm, suggesting

hypothalamic–pituitary–adrenocortical (HPA) axis dysregulation. Importantly, this flattened diurnal rhythm is most pronounced for children with few or low-quality friends (Peters, Riksen, Walraven, Cillessen, & de Weerth, 2011). Thus, work on psychophysiological processes in regards to dyadic peer relationships is in its infancy. Moreover, although marked advances have been made in neuropsychology, we are unaware of research that examined neurological processes and the dyadic peer relationships of children or adolescents.

Adolescent Parents

Studies of adolescent romantic relationships have focused on youth who are not residing with their partners, yet a significant minority of adolescents cohabit with their partners, often raising children together. Little research exists on the relationships between adolescent parents, yet such relationships may prove to be key to the couples' and their children's adjustment (see Moore, Florsheim, & Butner, 2007).

THE MERITS OF A UNIFIED RELATIONAL PERSPECTIVE

In this chapter, we have argued for a unified relational perspective. Our thesis has several key points. First, friendships and romantic relationships need to be studied as relationships. They are dyadic phenomena with a history; they are influenced by each person's characteristics, the interaction of their characteristics, and the pattern of their interactions over time. Each person affects the other person's behavior within an occurrence of interaction, and each occurrence affects subsequent occurrences. To date, work has focused primarily on individual's characteristics and, to a lesser degree, partner's characteristics. We have learned much from this work yet without more work on the partner, the interfacing of the person and the partner's characteristics, and especially the temporal history of their interactions, we will have an incomplete picture of the relationship and its impact. Indeed, the fact that relationships develop over time underscores the importance of studying interpersonal processes in the dyad, a seriously understudied topic.

Second, our unified relational perspective emphasizes that close peer relationships share some common features. The specific nature of the similarities (and differences) needs to be delineated further as only few studies have compared interactions in friendships and romantic

relationships (Furman & Shomaker, 2008). Moreover, although we described links between friendships and romantic relationships, the literatures on the two relationships are not that connected. We reviewed the literature on the two types of relationships in parallel to encourage greater cross-fertilization. As seen in our review, the two fields often focused on different issues, yet many topics examined in relation to one type of relationship could be studied in regards to the other type of relationship. Certainly, some facets of friendships and romantic relationships are not the same, and differences in research topics are expected. However, we can profit from greater coordination in the theory, method, and research topics in the two fields.

Third, our unified relational perspective emphasizes the importance of multiple contextual factors. A key factor is that any relationship is embedded in a network of dyadic relationships. Different relationships affect one another, and we should consider the set of relationships simultaneously.

One reason for examining networks of relationships is that the characteristics of different relationships often covary. For example, levels of support in middle adolescents' relationships with friends, romantic partners, and mothers are moderately related (Laursen, Furman, & Mooney, 2006). In fact, the three common configurations of relationship networks in middle adolescence in a U.S. sample are those in which levels of support are high in relationships with friends, romantic partners, and mothers, low in all three, or low in relationships with friends and mothers, and no romantic relationship. These similarities in different relationships underscore the importance of a unified relational perspective.

Most studies have included one type of relationship as a predictor or one type as an outcome; few have included multiple relationships assessed at the same age (see Lonardo et al., 2009; Stocker & Richmond, 2007, for exceptions). Including multiple relationships as concurrent predictors in the same study, even the same analysis, can help identify what links are common across relationships and what links are specific to one type of relationship. Evidence of convergence and divergence may lead to a better understanding of the nature of the relationships. Moreover, one type of relationship often moderates the effect of another type of relationship (e.g., S. Miller, Gorman-Smith, et al., 2009). On a related point, the examination of behavior in multiple types of relationships can also provide a better understanding of both the behavior itself and its significance. For example, sexual intercourse

with special romantic partners is not related to delinquency, but intercourse with nonromantic partners or with both romantic partners and nonromantic partners is linked to increases in delinquency (McCarthy & Casey, 2008). An understanding of sexual activity will require that we take the relational context into account.

The fact that an adolescent often does not have a current romantic partner underscores the importance of a network perspective. When an adolescent is not in a relationship, the functions fulfilled by that relationship are either unfulfilled or fulfilled by another relationship. By examining when another relationship substitutes for a romantic relationship and when it does not, we can identify processes common to different relationships and those particular to romantic relationships. We also can learn about the impact of romantic relationships by comparing characteristics of social networks when a romantic relationship exists and when one does not.

Moreover, little research has examined associations in multiple types of relationships simultaneously; thus little is known about whether, *within an individual*, differences among different types of relationships are associated with other differences in relationship cognitions, behaviors, or outcomes. One study of middle adolescents examined associations between patterns of interactions and relationship representations with mothers, friends, and romantic partners (Furman, Stephenson, & Rhoades, 2013). The results revealed that the more positive interactions there are in one relationship relative to the individual's own average level of positive interactions across relationships, the less avoidant the representations are for that type of relationship. Associations between representations of one relationship and interactions in another relationship do occur but are attenuated when representations of the same type of relationship are controlled for. Attachment theory has emphasized cross-relationship links, but it is important to consider how cognitive representations and experiences within a particular type of relationship affect each other as well.

Finally, our unified perspective not only emphasizes the importance of the system of close relationships but also of contextual factors, such as the peer group, media, culture, and historical time. Dyadic peer relationships cannot be understood without incorporating the contexts in which they occur; conversely, these contexts need to take close dyadic relationships into account to understand how they influence individuals and development. In effect they are part of a multilevel system that is constantly evolving as the different parts influence one another.

In sum, dyadic relationships are both part of a system of relationships and are embedded in multiple levels of context, all of which influence one another. As a consequence, they are key to our development, well-being, and health. Indeed, a recent meta-analysis revealed that they have as big an impact on mortality as well-known risk factors, such as smoking, obesity, and substance use (Holt-Lunstad, Smith, & Layton, 2010). Stated simply, relationships are powerful and should be central in our work as social scientists.

Children's Religiousness, Spirituality, and Well-Being	990

INTRODUCTION

Religion and spirituality have long been integral in the human experience. Fittingly, some of psychology's early giants wrestled with the religious and spiritual impulse, such as James' (1902/1982) deep exploration of religious and spiritual experience and Freud's (1927/1961) dismissal of religion as a universal neurosis. The field's early turn to objectivist, positivist science and the rise of behaviorism contributed to a neglect of religiosity and spirituality in empirical psychology. This neglect has occurred in

developmental science as well. But times have changed, as reflected dramatically by the first-ever inclusion in 2006 of a chapter on religion and spirituality in the *Handbook of Child Psychology*. (In contrast, the 1998 edition had a mere handful of references to religious or spiritual topics.) The 2006 chapter, "Religious and Spiritual Development Throughout the Life Span," by Oser, Scarlett, and Bucher, emphasized a theoretical life-span approach, appropriate for its position in *Volume 1: Theoretical Models of Human Development*. In light of burgeoning research on these

topics, this chapter is situated in the more research-focused *Volume 3: Socioemotional Processes*.

Our chapter reviews current knowledge on child and adolescent religiousness and spirituality and presents a vision for the future. We examine theoretical frameworks but focus on the recent explosion of findings on religion and spirituality in childhood and adolescence. As such, we first describe religious and spiritual development as unique domains of human development and explore how young people develop in both. Second, we discuss how religion and spirituality may serve as developmental systems or contexts that contribute distinctively to child and adolescent development.

We first discuss the field's recent growth and describe the demographic landscape of religion and spirituality in the lives of children and adolescents, in the United States in particular. We present data indicating that religion and spirituality are important aspects of the everyday lives of millions of young people in our world. We then move to the challenge of defining our terms—religious and spiritual development. Next, we examine major theoretical perspectives that are particularly helpful for understanding religious and spiritual development. We then devote most of the chapter to religion and spirituality in childhood and adolescence. We attempt to elucidate what religious and spiritual development entails and how religion and spirituality may matter in the lives of youth. Finally, we offer suggestions for a more integrative science of religious and spiritual development as well as map future directions for the field.

For several reasons we discuss children and adolescents separately. First, there is an ever-growing number of scholars and practitioners particularly interested in adolescence. Thus, developmental scientists have become increasingly age segregated, if you will, with the strong establishment of the Society for Research in Adolescence and many adolescence journals. Second, the designs and samples of studies are almost always age-segregated themselves; in fact, a distinct shortcoming of the field is the dearth of longitudinal or even cross-sectional studies spanning childhood and adolescence. Third, the foci of religion and spirituality research are different for the two age periods. Research on children is dominated by a cognitive-developmental orientation that examines how children *think* about religious topics (e.g., God) and a socialization orientation that focuses on the family and parent-child dynamics. In contrast, little work on adolescents examines their religious cognition, and the socialization approach is considerably broader, incorporating peers, ethnic issues, and other factors. Finally, in

contrast to the growing but still small amount of work on children's well-being in relation to religion and spirituality, extensive research on adolescents is concerned with religion and spirituality in association with psychosocial issues such as identity, thriving, risk, and resilience. Thus, when developmental scientists talk about children's and adolescents' religion and spirituality, they are often talking about different things.

At the outset, we want to note a couple of limitations of our chapter. The study of religious and spiritual development in children and adolescents has not, until recently, been anywhere close to a mainstream concern of scholars. Thus, in many ways the field is in its nascent stages. Consequently, the existing literature is limited in its scope. For instance, existing research is dominated by U.S. samples as well as Western assumptions regarding the self and human development. Given the unusually high rates of religiousness in the United States (Lippman & McIntosh, 2010) and the history of the field of psychology of religion within the American Psychological Association, it may not be surprising that the extant research comes largely from the United States, on American samples; hence our literature reflects this. That said, we do review studies from outside the United States as well as examine literature that focuses on many particular ethnic groups in the United States. In addition, the vast majority of research has focused on how religion and spirituality are associated with variables that are standard psychological outcomes (e.g., mental health, academic performance, substance use). Consequently, our review here says relatively little about how religion and spirituality may be linked in children and adolescents to more extreme negative outcomes, such as intergroup hostility, violence, or terrorism. We hope that future research may illuminate whether childhood and adolescent socialization experiences influence the odds for youths' involvement in such violent and antisocial acts, but for now the psychological literature is rather quiet on these matters within the age range that is the scope of our chapter.

DEMOGRAPHICS OF ADOLESCENT RELIGIOUSNESS AND SPIRITUALITY

Across cultures and continents, many adolescents endorse strong religious beliefs (Lippman & McIntosh, 2010). One apparent trend is a de-emphasis on traditional religious values as countries became more developed, and another theme is the "clear imprint" of some countries' influential

religious traditions leading to higher rates of religiosity among youth.

Benson, Scales, Syvertsen, and Roehlkepartain (2012) conducted a “global portrait” of youth spirituality among 6,725 youth ages 12–25 spanning eight countries across five continents. Participants were invited through in-country research partner organizations to complete primarily web-based questionnaires. Although sampling was not random, efforts were made to represent a range of socioeconomic and educational backgrounds. The results suggested that spirituality and religion are relevant to many of the world’s youth. According to Benson, Scales, et al., 77% of youth indicated some type of religious affiliation, with Christianity the largest (49%), followed by Hinduism (15%), Islam (9%), Buddhism (2%), and “other religion” (2%). Approximately 18% of respondents indicated that they did not ascribe to any religious affiliation. Most participants indicated that the following aspects of spirituality were important life goals: following God or a higher power (61%), feeling close to God or a higher power (65%), and praying, meditating, and studying sacred texts (69%).

Major overviews of the literature demonstrate that religion and spirituality are prominent in children’s and adolescents’ psychological development (Pargament, Mahoney, Exline, Jones, & Shafranske, 2013; Roehlkepartain, King, Wagener, & Benson, 2006). The most representative study of religion in American youth documented that the vast majority of adolescents (84%) affiliate with one particular religious group (Smith & Denton, 2005). In terms of specific religious identifications, NSYR data show that most U.S. youth self-identify as Christian (75%) with 52% identifying as Protestant and 23% Catholic. In addition, 2.5% self-identify as Mormon, 1.5% as Jewish, 0.5% as Muslim, and another 1%–2% with other religions. Approximately 3% of adolescents self-identify with two different religions, likely due to the increase in interreligious marriages in U.S. society. The 16% minority of NSYR adolescents who did not report any religious identification were labeled *nonreligious*. Among these, most self-identified as “just not religious” (10%), “atheist” (1.5%), or “agnostic” (1.5%). The remaining 3% of “nonreligious youth” seemed uncertain, suggesting some adolescents may have “unexplored” religious identities. Some teenagers who did not identify with a religion were raised in a household where religion was present. Interview data suggested that intellectual skepticism and disbelief were the main reasons for lack of religious transmission in these homes.

Although “nonreligious” youth are a minority, this segment of youth is growing. According to ChildTrends

(2013) Monitoring the Future Data, during the 1990s the percentage of youth reporting that religion was very important in their lives fluctuated slightly, though in general it increased among all grades studied. But between 2000 and 2010, the share of youth who report such a role for religion decreased significantly, from 37% to 29% among 14-year-olds, 32% to 25% among 16-year-olds, and 32% to 27% among 18-year-olds. Thus, as in the adult population (Pew Forum, 2012), the numbers of religiously unaffiliated adolescents are increasing.

Perhaps the most studied variables indexing religiousness beyond religious self-identification is individuals’ self-rated importance of religion and frequency of attendance of religious services. These measures are often combined and globally referred to as religiosity or religiousness. (Combining these different kinds of variables may be problematic, as some index identity or beliefs and some index religious behavior, though the different measures are usually highly correlated.) Smith and Denton (2005) reported that about half of U.S. adolescents (Ages 13–17 years) indicate a strong and positive orientation to religion and faith in their lives and the other half have little or no regard for them. Recent analysis suggests that just more than a quarter of U.S. adolescents report that religion is “very important” to them (ChildTrends, 2013). ChildTrends noted that, despite a rise in youth who report attending a service once a week from 1991 to 2002, religious attendance decreased significantly between 2002 and 2010 for 14-, 16-, and 18-year-olds, dropping from 44% to 39%, 42% to 33%, and 35% to 30%, respectively.

Sex differences in adolescent religiousness and spirituality are consistently reported. ChildTrends (2013) reported a higher proportion of females responding that religion is very important in their lives. Specifically, in 2010, this gender gap increased slightly with age, from four percentage points among 14-year-olds, to five points among 16-year-olds, to seven among 18-year-olds. Similarly, Smith and Denton (2005) reported that, compared to adolescent boys, adolescent girls aged 13–17 years old were more religious on a broad spectrum of indices, as girls were more likely to: attend religious services, see religion as shaping their daily lives, have made a personal commitment to God, be involved in religious youth groups, pray alone, and feel closer to God. These differences remained after accounting for youths’ social backgrounds.

Consistent with national data on adults, African American adolescents were more likely than European American ones to report that religion played a very important role in their lives (ChildTrends, 2013). In 2010, 46% of

African American 18-year-olds reported that religion was very important whereas only 24% of European American adolescents did. Differences in lower grades were smaller but consistent. Latino 16-year-olds were slightly more likely than European American 10th graders to report that religion plays a very important role in their lives, but Latino students of other ages were not significantly different from European American students. Similarly, African American students reported higher rates of regular attendance than European American students, though the gap decreased with age. Compared to their European American peers, 14-year-old Latina/o American students reported lower rates of regular attendance but no significant attendance differences in 16- and 18-year-olds.

HISTORY OF THE STUDY OF CHILD AND ADOLESCENT RELIGION AND SPIRITUALITY

In light of the role of religion and spirituality among contemporary children and adolescents, it is disconcerting that religion and spirituality have been so neglected within developmental science as contexts and domains of development. As we will indicate, these contexts seem to have a strong impact on child and adolescent well-being, prosocial and antisocial behavior, coping, values, sense of purpose, and identity. Fortunately, we have witnessed a surge of interest during the past 15 years in religion and spirituality in child and youth development.

At one end of the scholarly pipeline, dissertations on children and spirituality have increased, with most appearing since 2000, and a four-fold increase in the number of dissertations from 2007 to 2012. At the other end of the pipeline, of the peer-reviewed articles published in six top-tier developmental journals¹ from 1990 to 2012, the percentage on religion and spirituality increased by more than 50% from 1990–2002 to 2003–2012, with 1.4% of all articles addressing this topic (Benson, Roehlkepartain, & Rude, 2003). In addition, many major volumes have recently appeared, including the *Handbook of Spiritual Development in Childhood and Adolescence* (Roehlkepartain et al., 2006), with 34 chapters on a broad spectrum of contexts and developmental domains within spiritual development. Other recent publications have included

an encyclopedia of religious and spiritual development (Dowling & Scarlett, 2006), and edited books focusing on cognitive-developmental issues (e.g., Rosengren, Johnson, & Harris, 2000) and spirituality and thriving (Lerner, Roeser, & Phelps, 2008; Warren, Lerner, & Phelps, 2012). The past decade has also seen a spate of special journal issues on religious and spiritual development (Boyatzis, 2003), religion and spirituality in the family (Boyatzis, 2006a), and religion and spirituality in adolescence (Benson, Roehlkepartain, & Hong, 2008; Boyatzis & Hambrick-Dixon, 2008; King & Boyatzis, 2004). As noted earlier, the 2006 edition of the *Handbook of Child Psychology* for the first time included a chapter on religious and spiritual development (Oser et al., 2006). Prior to 2000, there were no edited volumes, handbooks, handbook chapters, or special issues on child and adolescent religious and spiritual development in the developmental sciences.

It is clear that research in this field has not only grown in quantity but improved in quality. Recent studies have advanced beyond the typical earlier study that tested for correlations between a single religiousness variable (often parents' worship attendance) and a child outcome. While this correlational approach is still common in the field, recent studies feature more complex conceptualizations of variables, more sophisticated quantitative approaches, and more in-depth qualitative approaches.

DEFINITIONS OF RELIGIOUS AND SPIRITUAL DEVELOPMENT IN CHILDHOOD AND ADOLESCENCE

A recent proliferation of descriptive approaches to defining religiousness and spirituality has characterized the field of psychology of religion and spirituality (see Pargament et al., 2013). Initially, in psychology the terms *religion* and *spirituality* were used synonymously (see James, 1902/1982). Until recently this area of study has been plagued by conflation and confusion of terms, but we are now moving toward more clarity. As the field has evolved, the concepts of religion and spirituality have begun to diverge both in scholarship and popular culture (Koenig, McCullough, & Larson, 2001). For example, young people are increasingly identifying as "spiritual, but not religious" (Smith & Denton, 2005). In the literature, religion is increasingly conceptualized as an organized socio-cultural-historical system, and spirituality as an individual's personal quest for meaning, satisfaction,

¹Child Development, Developmental Psychology, International Journal of Behavioral Development, Journal of Adolescent Research, Journal of Early Adolescence, and Journal of Research on Adolescence.

and wisdom. For instance, a widely used definition of religion is:

... an organized system of beliefs, practices, rituals, and symbols that serve (a) to facilitate individuals' closeness to the sacred or transcendent other (i.e., God, higher power, ultimate truth) and (b) to bring about an understanding of an individual's relationship and responsibility to others living together in community. (Koenig et al., 2001, p. 18)

From this perspective, religiousness refers to the extent to which an individual has a relationship with a particular institutionalized religion's approach to ultimate reality. This relationship occurs through affiliation with an organized religion, participation in its prescribed rituals and practices, and reflection or embrace of its espoused beliefs. Religious development would then entail the qualitative change and growth in the engagement in and understanding of the religious community and its rituals, creeds, sacred texts, and beliefs.

In contrast, Koenig et al. (2001) defined spirituality as "a personal quest for understanding answers to ultimate questions about life, about meaning, and about relationship to the sacred or transcendent, which may (or may not) lead to or arise from the development of religious rituals and the formation of community" (p. 18). This conception aligns with the view of personal religiousness or spirituality as a "search for the sacred" in which the sacred is an individual's concept of God, the divine, and transcendent reality, as well as other aspects of life that take on divine character or are imbued with divine-like qualities, such as transcendence, immanence, boundlessness, and ultimacy (Pargament et al., 2013). It is also consistent with definitions from the field of youth development that emphasize a capacity for self-transcendence and goals of awareness, connectedness, meaning, purpose, and contribution (Benson et al., 2012; Good, Willoughby, & Busseri, 2011; King, Clardy, & Ramos, in press; Lerner et al., 2008).

From a youth development perspective spiritual development was initially understood as growth in "the intrinsic capacity for self-transcendence, in which the self is embedded in something greater than the self, including the sacred... shaped both within and outside of religious traditions, beliefs, and practices" (Benson et al., 2003, pp. 205–206). Recent research suggests that spiritual development involves "transactions that are characterized by transcendence leading to a clarity and commitment of beliefs and identity resulting in behaviors that contribute to the self and society" (King, et al., in press). This definition's latter thrust—that spiritual development results

in contributions to self or society—is typically absent in notions of children's spiritual development (e.g., Hay & Nye, 1998) but is more prevalent in the adolescent literature (e.g., Benson et al., 2012). Other scholars have asserted that spirituality is intrinsic to human beings and is "a self-transcending awareness that is biologically structured into the human species" (Hay, Reich, & Utsch, 2006, p. 50).

These definitions offer helpful starting points in this emerging field and characterize spirituality as (a) a human propensity; (b) socialized and shaped by multiple experiences, sometimes within organized religion but also outside it in multiple social and natural contexts; and (c) characterized by a sense of connectedness and *relationality* to what is beyond the self. We use the term *relationality* to emphasize the centrality of relating to another or others for human development (Kuczynski & De Mol, Chapter 9, this *Handbook*, Volume 1; Lerner, 2006; Overton, 2013) in general and in spiritual development in particular (King, Ramos, & Clardy, 2013; Mahoney, 2010, 2013). Spirituality, then, is not restricted to a particular religious doctrine or sacred entity; God or a theistic version thereof is not *a priori* the only transcendent entity with which children or teens could experience relationships. These definitions also suggest that children's spiritual and relational consciousness emerge prior to religious socialization (Hay & Nye, 1998). The positing of a spiritual propensity in very young children presupposes that children are spiritual beings first and then are acculturated (or not) within a religious tradition that channels inchoate spirituality into particular institutional expressions (rituals, creeds, etc.). These definitions also convey that children's spirituality is subject to many influences, including family and culture.

One proposal (C. N. Johnson & Boyatzis, 2006) is that spiritual development proceeds from intuitive understanding to increasingly reflective thought about what is beyond the self. Children possess powerful inference mechanisms for intuitively sorting out reality and the supernatural. Such intuition is integrated with increasing reflection and is supported and scaffolded by cultural practices that orient the child to cultural modes of spiritual knowing and being. Thus, spiritual development arises not from mere acquisition of knowledge about the transcendent but from increasingly meaningful and organized experiential connections of the self to, in James's (1902/1982) words, the "something more." These connections transform the self by shaping beliefs, values, identity, fidelity, and actions.

Although an emphasis on personal as opposed to institutional levels may clarify the distinctions between religion and spirituality, there is considerable overlap between

them. Religion ought not be viewed as purely institutional; important individual-level processes such as interpreting and constructing religious worldviews are central to child and adolescent religiousness. Conversely, when spirituality is treated too narrowly as an individual phenomenon, the varied ways that spirituality grows and expresses itself in intimate relationships, families, congregations, and cultures may be overlooked. Indeed, many personal spiritual expressions are embedded in larger religious or social contexts. Religion and spirituality are multidimensional constructs with diverse cognitions, feelings, behaviors, experiences, and relationships and must be considered multilevel from theoretical and methodological vantages. Given the increasing conceptual clarity in the field, we try to distinctly use “religion” and “spirituality” based on the constructs under discussion. However, these terms are still often conflated in the literature and when unable to draw distinctions we will refer to “religiousness and spirituality” or to “religious and spiritual development.”

As we turn to theory, in our view there is no satisfactory “grand theory” of religious and spiritual development. Although some extant theories elucidate specific areas of religious and spiritual development, it is unclear whether they can capture the breadth and complexity of religious and spiritual development. As stated by King and Roeser (2009, p. 439):

The study of religion and spirituality in developmental science hinges upon whether it is possible to formulate *good* theories from which scientists derive clear and scientifically tractable definitions of what religion and spirituality *are* substantively, what they *do* functionally...and how they *develop* systematically.

THEORIES OF RELIGIOUS AND SPIRITUAL DEVELOPMENT IN CHILDHOOD AND ADOLESCENCE

Although an exhaustive review of theories related to religious and spiritual development is beyond the scope of this empirically focused chapter (see King & Roeser, 2009; Oser et al., 2006), we review theories within development science that are helpful to understanding the nature and function of religion and spirituality in development.

Psychoanalytic and Attachment Approaches

Due to space limitations, we combine psychoanalytic and attachment accounts of religious development. According

to object relations theory, individuals internalize affectively charged representations of their relationships with significant others such as parents as “psychic objects.” These images of parents serve as “templates” for God images (Rizzuto, 1979). In this theory, God images are posited to serve as “transitional objects” that can reduce attachment insecurity as children develop independence from caregivers and in the face of significant change and stress. Rizzuto emphasized that one’s private, subjective, “living” God is often different from any “official” God of organized religion. Developmentally, this private, living God emerges prior to formal religious socialization, developing in early childhood as a transitional object based on emotion-laden images of both parents and of self. This focus on the vital link between the child’s early experiences with one’s parents and the child’s God image has much in common with attachment theory.

Attachment theory is an important framework in the study of religious development. Building on Bowlby’s theory (e.g., 1988), Kirkpatrick and Shaver (1990), and Granqvist (e.g., Granqvist & Dickie, 2006) have likened individuals’ relationships with God to their relational attachments to parents. The fundamental tenet is that the internal working model of the parent-child relationship is used as an internal working model for the individual’s image of and relationship with God. Throughout life, the activation of the attachment system leads the individual to seek comfort (or not) from God in times of stress, as the child would (or not) from a parent. The models most often tested are the correspondence model and the compensation model.

The *correspondence model* posits that individuals’ internal working models of their attachments to their parents serve as the basis for the God attachment: those securely attached to their parents would have secure attachments to God, and those insecurely attached to parents would have insecure attachments to God. In contrast, the *compensation model* posits that an early insecure attachment with an earthly parent does not seal one’s fate with a divine parent but that one can develop an attachment to God as a substitute attachment figure, due to God’s perceived responsive and consistent loving, forgiving, and protective functions. There is evidence for both processes in adults but in children there is only limited evidence for correspondence, as the compensation process may not emerge until adolescence or later (Richert & Granqvist, 2013).

Nevertheless, the correspondence hypothesis is supported by some work on children. When asked to place a symbolic God figure on a felt board near a child figure

in an attachment-activating scenario, children who were securely attached to their mothers placed the God figure closer to the child than did children who were insecurely attached; this pattern occurred in Swedish 5- to 7-year-olds (Granqvist, Ljungdahl, & Dickie, 2007) and Italian 6- to 8-year-old children (Cassiba, Granqvist, & Costantini, 2013). Adolescents with secure attachments to parents are likely to adopt the faith and God images (or lack thereof) of their parents (e.g., Hertel & Donahue, 1995). The compensation process has received support in other studies. Children were more likely to describe a loving, present God if their fathers were absent from the home (Dickie et al., 1997). Adolescents with insecure attachments were likely to seek security by joining religious organizations and others rejected their parents' religion due to their distant or difficult relationships with parents (Smith, 2003b).

Across childhood and adolescence, attachment theorists would suggest that children begin with a "living God" representation based on the relationship with their parents, and across childhood and adolescence increasingly view God in relational and interpersonal terms. Thus, explicitly conscious relational images of God may become more salient during adolescence. This trend is manifested in adolescents' prayer concepts that show a move from children's concrete instrumental view of prayer as "talking to" God toward the adolescent view that prayer is more conversational "talking with" God (Scarlett & Perriello, 1991). In sum, attachment theory may elucidate many aspects of religious and spiritual development though better measures are needed to capture children's more implicit content and functions of the God image and attachment at nonconscious, physical, and nonverbal levels (E. B. Davis, Moriarty, & Mauch, 2013).

Cognitive-Developmental Approaches

To a considerable extent the study of children's religious and spiritual development has been the study of children's thinking about religious concepts (e.g., God, prayer), and thus has reflected developmental psychology's broader Piagetian-cognitive hegemony. Cognitive-developmentalism posits several tenets of cognitive development applied to religious cognition: qualitatively distinct stages of thinking that are yoked to a specific age range, a progression from concrete to abstract understanding, and the march from immature thought to the *telos* of mature abstract and rational thought.

In the 1960s, David Elkind conducted a series of important studies in the Piagetian cognitive-developmental

tradition on children's religious cognition (e.g., Elkind, 1961). Elkind's work on children's prayer concepts (Long, Elkind, & Spilka, 1967) and his broader theoretical explication (Elkind, 1970) are exemplary accounts of that era's approach. His work confirmed theoretical expectations that children's religious thinking showed stage-like progress from concrete and egocentric to more abstract and socio-centric thought. Religious cognition was merely a specific case of a generic conceptual process.

A new wave of cognitive-developmentalism in the 1980s ushered in a rejection of global stages that characterized, at any one age, all of a child's thinking and replaced them with models of domain-specificity, viewing the child as a builder of naive folk theories of specific domains (e.g., Carey, 1985). By the 1990s, domain specificity and research on children's theory of mind had become so central in the field that scientists viewed children's religious concepts (e.g., God) as part of the general growth of understanding of the mind, agency, and mental-physical causality. Children's religious cognitions were understood to operate under the same tendencies of children's everyday cognition but within specific domains of thought (Boyer, 1994).

In the case of beliefs about God, the anthropomorphic God images common to children and adults arise from the natural extension and application of an intuitive folk psychology (used to understand people) to supernatural figures. These ontologies possess several key features. First, they include counterintuitive beliefs (i.e., they violate ordinary expectations, as in the case of spiritual entities who are immortal or omniscient). Second, counterintuitive religious beliefs operate within the implicit backdrop of theory of mind that equips children with a prepared set of qualities to extend to religious agents (e.g., "My supernatural God has wishes and thoughts and worries [just like all beings with minds do]"). Third, the combination of the agents' counterintuitiveness with the judgment that such agents are *real* make the beliefs more salient to those who hold them, and their salience enhances their likelihood that they will be transmitted to others.

Another revision is the claim that children's and adults' thinking may not be altogether different. Magical thinking and rational thinking, "ordinary" and "extraordinary" reality, and other thought processes that seemingly compete with each other may in fact all coexist in the minds of children and adults. As Woolley (2000) put it, "children's minds are not inherently one way or another—not inherently magical nor inherently rational" (pp. 126–127). Such claims shake the venerable views of the child as cognitively

immature and cognitive growth as an invariant, stage-like march from irrational fantasy toward the *telos* of rational logic. This new characterization has been supported by a review of children's and adults' thinking about origins of life, death, and illness. Legare, Evans, Rosengren, and Harris (2012) concluded that as children get older they do not "lose" early intuitive thought processes but instead develop a coexistence model that integrates their previous intuitive and often supernatural accounts with later-developing scientific explanations. Legare et al. found that supernatural explanations were used more often by adults than younger children. Thus, supernatural beliefs—in developing and industrialized countries—do not diminish with age and with exposure to scientific knowledge from education or culture. Cognitive-developmental theories of religion and spirituality will surely evolve in relation to our broader accounts of cognitive development.

Faith Development Theory

Perhaps the most comprehensive stage theory was James Fowler's (1981) Faith Development Theory, a synthesis of the stage theories of Erikson, Piaget, and Kohlberg to explain the ontogeny of faith development. Fowler asserted that faith is a relational construct, incorporating the self in relation to others and in relation to some shared center of transcendent value or significance that exerts an ordering significance on one's life. This center of value in major religions is God or some transcendent reality, though one's center of value and thus faith need not be religious; Fowler claims that one's center of value could be an ideology or cause (e.g., nationalism, environmentalism) or a personal priority (e.g., career, money). One's faith, then, reflects and shapes one's deepest values, beliefs, and meanings and reflects "the human quest for relation to transcendence" (p. 14) and to the universal.

Here we describe the two stages of faith that correspond to the age range of interest in this chapter. During middle childhood (corresponding to Erikson's stage of industry versus inferiority and Piaget's stage of concrete operations), children are in a "mythic-literal" stage. Religious principles are taken at face value with a moral realism to them, and symbols are one-dimensional, with little conceptual or symbolic analysis. Faith is built around concrete story-like narratives whose meanings come from culturally available meaning systems. A challenge late in this stage is reconciling narratives from different sociocultural sources that would lead to conflict or dissonance (e.g., reconciling Biblical and evolutionary accounts of human origins).

With the onset of early formal operational thinking, young adolescents enter a "synthetic-conventional" stage in which they adopt the shared centers of values of others (conventional) without much reflection or analysis (hence synthetic). At this time, young adolescents' ability to be aware of what other people think can make youth sensitive to others' judgments of them and be susceptible to the "tyranny of the they" and a herd mentality regarding the shared centers of value they may adopt. Thus, adolescents are prone to embrace shared centers of value that could be profoundly different, ranging from love and justice to hate or nihilism. The adolescent synthetic-conventional faith is an "absorbed" and tacit one that is conformist rather than critically scrutinized. These more introspective processes emerge in later adolescence, corresponding to the faith stage Fowler labeled "individuative-reflective," when youth move from an absorbed tacit faith to an examined explicit faith orientation that is more truly one's own.

Although some agree with the proposed general stage progression, Fowler's theory has been criticized for its structural and cognitive basis and for its suggestion that children are limited to less mature forms of faith (e.g., Balswick, King, & Reimer, 2005). At most chronological ages, even the subjects in Fowler's original study showed striking individual variation (see Boyatzis, 2005, 2013, on these problems). Thus, psychologists of religion have criticized stage theory for failing to capture the diversity of faith at any one age, especially the unevenness and nonlinear nature of faith progression (Hood, Hill, & Spilka, 2009), just as developmentalists have rejected traditional stage theories for failing to capture variation in development at any one particular age.

Relational Developmental Systems Perspectives

As empirical challenges have highlighted the limitations of stage theories, relational developmental systems perspectives are increasing in popularity. These theories emphasize that ontogeny occurs through mutually influential relations between individuals and the many levels of the bioecology in which they are embedded across time (Lerner, 2006; Overton, 2013). Development occurs at all levels of the system—biological, psychological, social, cultural, and so forth. As such, relational developmental systems theory provides a meta-framework consistent with bioecological theory (Bronfenbrenner, 1974), sociocultural theory (Vygotsky, 1978), and social transaction models (Kuczynski, 2003).

From a relational developmental systems perspective, religious and spiritual development occur through ongoing transactions between individuals and their multiple socio-cultural contexts (Lerner, Dowling, & Anderson, 2003). Religious development can be described as the systematic changes in how one understands and participates in the doctrines, practices, and rituals of religious institutions. Thus, from a relational developmental systems approach, as a young person interacts with friends, family, faith community, and so forth, he or she will change in beliefs, commitments, and engagement in religion. This process is well recognized. Less clarity exists regarding the nature of spiritual development. Scholars are now addressing what exactly develops in spiritual development (Benson et al., 2012; Good et al., 2011; King et al., in press; Warren et al., 2012).

Recent theoretical and empirical literature suggests that relationality is central to spirituality. These systemic approaches highlight bidirectional relations, or reciprocity, between young people and their world. From this perspective, it is not just the interactions that influence spiritual development, but the interactions themselves, the capacity for transcendence, and the young persons' responses are central to spiritual development.

Transcendence involves a shifting of a young person's cognitive and emotional orientation from one's self to another in such a way that it provides ultimate value and meaning beyond the mundane and material, shapes identity, and motivates an active response (Lerner et al., 2008). When a young person experiences a meaningful connection with something of significance beyond him or herself, he or she may become aware of and feel connected to peers, nature, God or a divine entity, a sense of all of humanity, or a specific religious community.

However, not all transactions are transcendent. Specifically, those transactions between an individual and another (e.g., God, nature, community) promote transcendence when the interaction informs beliefs, meaning, identity, purpose, and/or fidelity and serves to motivate contribution to the well-being of the world beyond themselves. This contribution does not necessitate a public interaction, but research on adolescents suggests that spirituality involves living and acting consistently with one's beliefs (Benson et al., 2012; Dowling et al., 2004; King et al., in press; Warren et al., 2012).

Consequently, spiritual development involves transcendence, transformation, and action. We must note that these latter processes would be more readily apparent in older youth than younger children. One implication is that

spiritual development at any age would share fundamental characteristics (e.g., a relational connectedness to what is beyond the self) but have different manifestations and effects at different ages.

Although an expression of the divine is not needed to instigate spiritual development, the forces that stimulate spiritual growth are imbued with divine-like qualities, such as immanence, boundlessness, and ultimacy (Pargament et al., 2013). This spiritual transcendence instigates, as James (1902/1982) described, systematic changes within the self and leads to increases in one's awareness (Benson et al., 2012), identity (Templeton & Eccles, 2006), fidelity (King et al., in press, 2013), purpose (Damon, Menon, & Bronk, 2003), and action (King & Benson, 2006).

To summarize, relational developmental systems theories are framed within a relational meta-model that provides a set of person-context processes useful for exploring the complexity of spiritual development. For instance, relational developmental systems theories point to the plasticity of human development (Overton, 2013) and the resulting capacity for change and growth in development generally, and in spirituality specifically. Such approaches also emphasize the reciprocity of interactions between young persons and their world, highlighting that spiritual development is an active process and involves relating and responding. Such personal transformation or growth and contribution or service to the greater good is reflected in many spiritual and religious traditions. The relational developmental systems theories' emphasis on diversity and the interactions *within* the individual and *between* individual and context acknowledges the complexity of spiritual development. As such, religious and spiritual development are linked to processes in other developmental domains, as highlighted by our discussion of attachment and cognitive-developmental approaches and, as we discuss later, identity and moral development.

Relational developmental systems may be the most current formulation of understanding adolescent spiritual development. Although the meta-model provides a promising lens through which to view and investigate religious and spiritual development, empirical research has only begun. The research presented in this volume points to other studies indicating that spiritual development is an active process and not only involves transcendence but personal transformation as evidenced by identity, fidelity, and actions consistent with one's beliefs. Relational developmental systems theory provides an integrative approach to human development and helps us see how spirituality interacts with all of the levels within the developmental system.

Accordingly, our discussions in this chapter explore many systems that shape religious and spiritual development as well as how religion and spirituality influence child and adolescent development. However, before reviewing existing literature on child and adolescent religious and spiritual development, we examine reciprocating spirituality in order to emphasize the importance of bidirectional relationships between young persons and their context that contribute to religious and spiritual development.

Reciprocating Spirituality

Collectively, these relational-systems frameworks articulate a view of spiritual development that involves the development of key psychological processes (e.g., attachment, cognition, and—as we shall argue—identity) that emerge and grow as young persons interact with their surrounding environment. Relationality is key to our understanding of spirituality, and signifies the importance of attachment, whether young people attach to a transcendent other out of prescriptive internal working models or a need to compensate because of deficient working models. Though recent conceptualizations have emphasized relational spirituality (King et al., 2013; Mahoney, 2010), we propose *reciprocating spirituality* as a more appropriate formulation that conveys the relational and active processes in spiritual development.

Spiritual development involves the growing capacity to transcend the self, requiring the increase of cognitive and emotional capacities to be aware of and grasp that which is beyond the self, while reciprocally growing in self knowledge and understanding. This process requires the development of identity, purpose, values, meaning-systems, and eventually results in fidelity to an ideology. Further reciprocity is evident as the young person then responds to transcendence out of a sense of fidelity with actions that are consistent with their beliefs, values, and self-concept. Such actions are characterized by contribution, compassion, and leadership and require prosocial, moral, and civic development (Lerner et al., 2003). Spirituality is more than a feeling of transcendence, but a growing sense of identity or awareness that motivates or propels young people to care for themselves and to contribute to the greater good (King et al., 2013).

No doubt this description paints a picture of mature spirituality that is characterized by connection, commitment, and coherence (King et al., in press). As in all domains of development, this process takes place in the ongoing bidirectional interactions between individuals and their

context. This process is not linear. Research has noted that children's imagination and lack of analytical skills enable them to engage in spiritual emotions of wonder and awe (Roehlkepartain et al., 2006), and be more open to spiritual experience, whether through nature or religion (Fowler, 1981). Furthermore, loss, challenge, and doubt may also deepen faith by making meaning out of difficult situations and by renewed devotion or commitment to spiritual ideals.

Consequently, we recognize that spiritual development varies across individuals depending on their development and integration of the various psychological processes involved. For example, younger children may not have the reflective skills necessary to consciously integrate their experiences of the sacred or their beliefs with their identity and actions. Mentally handicapped children's spiritual development may be more based on their relational capacities than cognitive capacities. We believe that the spiritual development trajectory is unique for all people based on their individual (e.g., biological, psychological) factors and their relations with their contexts (e.g., cultural, religious). Despite these diverse expressions, we argue that the developmental trajectory of reciprocating spirituality is toward coherence of transcendence, fidelity, and contribution. As such we propose the notion of reciprocating spirituality to capture the complexity and richness of this developmental process. We next discuss the development of religion and spirituality and their roles in childhood and adolescence.

CHILDHOOD AND RELIGION AND SPIRITUALITY

This section integrates theory and research on different topics in children's religious and spiritual development and focuses on the most current and rigorous research. We have chosen these specific topics because they have clearly dominated, for decades, the research on children. In addition, the research has described the emergence of the cognitive and relational capacities necessary for reciprocating spirituality. One area of research reflects cognitive-developmental approaches to children's thinking about religious concepts; this work posits that there are cognitive-maturational processes that shape such thinking. A different but related approach is a sociocultural and social ecology view that examines how children's thinking about religious and spiritual topics is associated with the beliefs of their parents or other socializing agents. This work often tests the degree to which children's religious

cognition corresponds to or is independent from their parents' religious cognition. Another focus is on socialization dynamics and parent-child relationships that may affect children's religiousness or spirituality. A relatively new area of work examines links between children's behaviors and specific constellations of their parents' religiousness and parenting; an important lesson from that body of work is that the interactions between these variables are particularly revealing about how religion "works" in the family. After that, we address religion and children's well-being to learn whether the available evidence supports the notion that religion and spirituality are "good" for children. In that section, we offer important caveats about avoiding simplistic interpretations and conclusions and instead urge researchers to recognize the complex and nuanced relationships between religiousness and child outcomes. Finally, we offer important new directions for research on children.

Cognitive-Developmental Approaches to Religious Cognition

The venerable emphasis in developmental psychology on children's thinking is abundantly evident in work on children, religion, and spirituality. This section provides an overview of the major specific domains of children's religious cognition.

Children's Concepts of God

The longest-studied religious-cognition topic is children's thinking about God. This focus is not surprising, given that God and the relationship with God is the central component of most organized religions and that most research has been done by Westerners in Western settings, where monotheism predominates. The most robust conclusion from this work is that children think about God in anthropomorphic terms. Studies on religiously diverse samples have found widespread anthropomorphism with some denominational variation. In his collection of school-children's drawings, Coles (1990) found that 87% depicted God's face. Pitts (1976) sampled 6- to 10-year-old children and found the most anthropomorphic God drawings by Mormon, Mennonite, and Lutheran children and the least by Jewish and Unitarian children, consistent with the God imagery in their religions. Heller (1986) also found that Hindu children, more than Jewish, Baptist, or Roman Catholic children, described a multifaceted God who feels close and like a person in some ways yet is also an abstract and intangible form of energy. Hindu children's beliefs

reflect their doctrine about different gods with different natures and functions. Taken together, these studies show that many children anthropomorphize God but also that children in different religions and cultures conceptualize God in diverse and often nonanthropomorphic ways that reflect the impact of sociocultural influences.

The anthropomorphizing tendency has been typically explained by cognitive-developmentalists as resulting from an extension of an intuitive folk psychology to supernatural figures (Boyer, 2001). However, research by J. L. Barrett et al. challenges this view of the child's God as a personified God. J. L. Barrett and Keil (1996) and J. L. Barrett and Richert (2003) have studied young children to test whether they equate God's qualities with human qualities (i.e., think about God anthropomorphically). They have offered an alternative, "preparedness" hypothesis, which posits that children are prepared conceptually at young ages to think about God's *unique qualities*—not only those shared with humans. In one study (J. L. Barrett, Newman, & Richert, 2003) 5-year-olds claimed that God, but not their mothers, would immediately understand ambiguous drawings. In another (J. L. Barrett, Richert, & Driesenga, 2001), 3- to 7-year-old children claimed that God but not their mothers would know the contents of a cracker box that actually contained rocks. A study (Wigger, Paxson, & Ryan, 2013) of 3- to 8-year-old children challenged the anthropomorphism hypothesis because, with age, children made increasingly appropriate attributions of knowledge to real friends, imaginary friends, and dogs, but their claims of God's knowledge did not change with age—God was omniscient at all ages. Provocatively, while imaginary companions were less knowing than God, they were more knowing than real friends or dogs. N. Knight (2008) found somewhat similar results with Yukatek Mayan children in Mexico, who viewed the "Catholic God" as more knowing than other figures including people, animals, the Sun God, and forest spirits. As in the Wigger et al. study, these latter invisible entities were endowed with more knowledge than humans or animals.

However, in an excellent study, Lane, Wellman, and Evans (2010) addressed the preparedness argument. They tested young children's beliefs about ordinary characters (mom, a girl) and extraordinary ones (God) using a false belief task. The young preschoolers (40- to 52-month-olds) failed to attribute false beliefs to any characters; all characters including God would know a crayon box had marbles, hence God was not special in this knowledge. Children in the middle age group (53- to 59-month-olds) said that ordinary characters and God would have false beliefs, hence

God was not omniscient. In the oldest group (59+ months) children said that ordinary characters would mistakenly think the box held crayons but God would know it held marbles. These data suggest that young children are prepared to first think about God in anthropomorphic terms and only later, around age 5, adapt and overcome those propensities to appreciate God's counterintuitive, special abilities. Lane et al. note that their interpretation is supported by other studies. For example, in one study of Greek Orthodox children, 3- and 4-year-olds claimed that both a young girl and God would be ignorant of the hidden contents of a box; only at the age of 5 did children believe that God would have unique knowledge of the box's contents (Makris & Pnevmatikos, 2007). Thus, both hypotheses—that God is an anthropomorphized figure and that children are prepared to recognize God's uniqueness—have received support, and future research must determine under what testing and sociocultural conditions children seem to endorse one over the other. For example, we need more evidence on children from families (from atheist to fundamentalist) and religions (monotheistic to polytheistic) that vary widely in their theistic views.

Children's Concepts of the Soul and Afterlife

Although children's thoughts about the soul have received less empirical attention than God concepts, more scientists are exploring how children think about death, the soul, and the afterlife. Contemporary cognitive-developmental work indicates that children's beliefs about the afterlife are related to children's early distinction between minds and bodies (Bering & Bjorklund, 2004; Richert & Harris, 2006). Children know that physical/biological functions cease at death; however, children do not clearly see that death terminates all mental and emotional processes.

Bering, Blasi, and Bjorklund (2005) used a clever task involving a mouse (puppet) eaten by a hungry alligator to study afterlife beliefs in 5- to 12-year-old secular and Catholic children in Spain. Results showed that children, especially younger ones and children who attended a religious school, understand that biological processes cease at death but that psychological processes continue in the afterlife. If children hold early intuitions about the afterlife, they are reified and scaffolded by surrounding familial and cultural practices that provide ample testimony and rituals. As Bering et al. (2005, p. 600) stated, in a socialization milieu that regularly espouses the continued spiritual life of the deceased, "biological reasoning about the psychological status of dead agents may be set aside

in favor of explicit religious ideas that defy naturalistic principles." Richert and Harris (2006) have claimed that, rather than thinking of people as dualists in the traditional body/mind or body/soul dichotomy, humans may think more along a tripartite model of fundamental essences—of the body, mind, and soul—and while body and mind die the "soul" persists after death. Such concepts would arise, Richert and Harris claim, from surrounding testimony that commonly draws such distinctions. For example, children would be unlikely to hear phrases such as "the mind lives on" but would commonly hear "the soul (or spirit) lives on." Future research must learn more precisely how testimony from parents and organized religion about the soul/afterlife affects how children understand death and afterlife.

Children's Understanding of Prayer

William James (1902/1982) claimed that prayer is the "very soul and essence of religion" (p. 464) and that prayer is a central ritual in many religions. Perhaps the earliest study of how children understand prayer was by Long et al. (1967). Younger children (5 to 7 years of age) described prayer as an emotionally neutral, perfunctory act at specific times and locations. Prayers were said by all children, prayers came from heaven and God, and God had to process prayers one at a time. In the early elementary school years (7 to 9 years of age), prayer was seen as a specific act motivated by a desire (often to ask God for material objects). Prayers were not said by all children because some were too sleepy to pray and some did not "want anything." In later school years (9 to 12), prayer became a mental, private activity to communicate with God. Prayer was no longer yoked to ritual events, and beliefs motivated prayer: Those who didn't believe in God didn't pray. Older children saw prayer as a means to ask God to respond to more abstract, humanitarian needs such as peace, and a coping function was evident because children said negative emotions could lead to prayer.

Scarlett and Perriello (1991) explored concepts of prayer in adolescents who were asked to write prayers they would make in response to hypothetical vignettes (e.g., a friend was ill with cancer). Age trends emerged in the content and functions of prayers, as 13-year-olds made petitions to God to help the friend get well, 15-year-olds asked God to give the friend strength for her struggles, and college students expressed a search for meaning amidst doubt. When describing the nature and function of prayer, subjects' responses progressed with age from objective concerns (asking God for things) to subjective issues

(coping with feelings) to becoming closer to God. Other analyses revealed that young people's beliefs progressed from thinking of prayer as "talking to" God to "talking with" God, reflecting increased maturity in both the breadth and depth of relationality with the transcendent.

Subsequent research corroborated and refined the developmental patterns. Bamford and Lagattuta (2010) tested 4-, 6-, and 8-year-olds and adults on a variety of measures. Interview questions included "Can prayer be done in the head or do you have to say words?" and "Is prayer the same thing as talking to God?" After being given a story and vignette, children were asked how the characters' diverse feelings might inspire the characters to pray and how praying might help their feelings. With increasing age, children better understood that prayer is a mental activity done in one's head (endorsed by 45% of 4-year-olds but 84% of older children) and that prayer and talking to God are the same thing (43% of 4-year-olds but 90% and 94% of 6- and 8-year-olds). Children also came to better appreciate the role of emotions in prayers. Four- and 6-year-olds believed that positive emotions more than negative ones would cause people to pray, whereas 8-year-olds believed that both kinds of emotions would similarly inspire prayer. From 6 to 8 years of age there were significant increases in beliefs that negative emotions would lead to prayer and declines in beliefs that positive emotions would. As for the emotional benefits of praying, children felt that people would feel better after praying.

Bamford and Lagattuta (2010) also tested two alternative hypotheses: a *religious socialization model* in which children's knowledge of prayer (tapped by the questions described above) would be associated with their level of religious experience and education, and a *cognitive maturation model* in which children's prayer concepts would reflect age-related cognitive constraints. Parents provided data on children's religious activities (e.g., prayer with others, discussion about religion with parents, etc.). Although children's understanding of prayer was positively correlated with religious activity in the two younger ages, on most measures there were no relationships between children's religious activity and their prayer knowledge. Only 4-year-olds showed a link between religious activity and prayer knowledge but this association emerged on a minority of measures. Thus, this study does not support the socialization hypothesis, and neither did another study on parents' religiosity and their young children's comprehension of prayer (Woolley & Phelps, 2001). Bamford and Lagattuta noted that there may be other ways, not addressed in their study, that socialization could influence children's

prayer sophistication, but overall the results supported the cognitive maturation model in early childhood.

Summary of Cognitive-Developmental Approaches

The above review shows that exciting work has investigated how children think about entities and processes that are central to world religions and children's sociocultural contexts. This work reflects a Piagetian-infused focus on structural change in children's thinking as well as a more contemporary understanding of how children recruit both endogenous cognitive processes and cultural inputs to shape their thoughts. A sociocultural account of children's religious cognition underscores the fact that children's (and adults') thinking takes place in a rich social milieu. In our view, a key goal for future work is to synthesize methods and interpretive frameworks from cognitive-developmental and sociocultural approaches into a more helpful multilevel analysis of children's religious and spiritual cognition and growth in order to understand how cognitive abilities contribute to more fully developed spirituality. Future research must also correct an imbalance in the literature: We know much about *how children think* about God, prayer, and the afterlife, but less about *how do children feel* about such issues, and whether it matters? More work (perhaps informed by attachment theory) is needed on children's affect and emotion-laden responses to God, prayer, and the afterlife. How are children's personal feelings about God related to their own self-esteem, anxiety, or depression? Do these outcomes differ for children who believe in God and those who do not? What kinds of feelings about God motivate young children's prosocial behavior? We touch on some pertinent work below, but we know little about these questions that might illuminate more fully how personal religion "matters" for children.

A Social-Ecology Approach to Children's Religious and Spiritual Development

Several frameworks organize our thinking about the myriad social influences on children's religious and spiritual development. A bioecological model (Bronfenbrenner & Morris, 2006) posits multiple interrelated contexts of influence on children's development. These contexts range from proximal *microsystems* (e.g., family, school, peer group, religious community) to more distal *macrosystems* (e.g., dominant cultural values and ideologies). Thus, it takes a village to raise a religious or spiritual child but the family is the "first village" (Boyatzis, 2005, 2013). In this section we focus on the family because this context has received

by far the most empirical attention. The adolescent section below addresses the family as well as additional contexts (for an extensive treatment of sociocultural contexts, see Roehlkepartain et al., 2006).

A sociocultural model emphasizes the influence of knowledgeable adults and peers who scaffold children in culturally meaningful practices to help young apprentices move to higher competence (Rogoff, 2003; Vygotsky, 1978). Hence, parents, relatives, clergy, educators, older siblings, and knowledgeable friends can act as mentors. Such mentors can guide children to more advanced levels of spiritual connectedness to the sacred and, in religious contexts, greater understanding and engagement in rituals, creeds, and worship. A sociocultural perspective suggests that parents' practices and beliefs give children "cognitive anchors" (Ozorak, 1989).

Another framework for family processes (Kuczynski, 2003) is a transactional model positing that children and parents influence each other in bidirectional, reciprocal exchanges. This conception, which is associated with relational developmental systems theories (see Kuczynski & De Mol, Chapter 9, this *Handbook*, Volume 1), departs from the traditional view that parents shape children in a unilateral Parent→Child fashion. That "transmission" model long dominated religious socialization research but, as we discuss below, and again reflecting relational developmental systems ideas, scholars now endorse a more dynamic conceptualization of multidirectional influences (see Boyatzis, 2005; Boyatzis, Dollahite, & Marks, 2006).

Children's religious and spiritual beliefs and attitudes may be shaped and influenced in various ways within the family through induction of beliefs (from subtle persuasion to dogmatic insistence), narrative, rewards and punishments, and behavioral modeling. Children may revise their implicit religious theories and beliefs when exposed to conflicting parental testimony or experiences that support alternate accounts (P. L. Harris & Koenig, 2006) or as "secondary adjustments" brought about through "third-party discussions" in the family (Kuczynski, 2003, p. 10) about religious and spiritual issues. In addition, the earlier section on religious cognitions makes clear that whatever input or testimony children receive from their families must be processed through the child's inherent cognitive structures. For example, in studies of adolescents, children's own religious beliefs are more strongly related to their perception of what their parents believe than what the parents themselves report believing (Bao, Whitbeck, Hoyt, & Conger, 1999; Okagaki & Bevis, 1999).

Communication and Beliefs About Religion and Spirituality in the Family

One challenge in studying the family context is to identify immediate, proximal processes within parent-child relationships that go beyond measures of relationship quality (Mahoney & Tarakeshwar, 2005). A good candidate for such a proximal process is parent-child conversation about religion, which may be an important mechanism through which parents socialize their children. In a study of Christian families (Boyatzis & Janicki, 2003) with children aged 3 to 12, parents completed a religious-conversation diary for 2 weeks as well as survey measures on the topics, frequency, setting, and processes involved in such conversations. Parents (overwhelmingly mothers) and children discussed religious and spiritual issues close to three times per week; the most common topics in this Christian sample were God, Jesus, and prayer. Analyses of diary conversations revealed that children were active participants in conversations—they initiated and terminated about half the conversations, spoke as much as parents did, and frequently asked questions and offered their own views.

These data suggest that, in family discourse about religion, children are active participants rather than passive recipients of ideas "transmitted" by parents, and that, in many families, a bidirectional style is more prominent than a uni-lateral parent-to-child dynamic. For instance, Flor and Knapp (2001) assessed Christian families with school-age children in the rural U.S. South. Regression analyses revealed that frequent bidirectional communication about religion predicted the importance of religion and belief in God for children. These patterns were especially apparent in same-sex dyads (mother-daughter, father-son). Thus, an open communication style between parents and children may influence children's religious development. (The later adolescent section describes additional work that confirms these bidirectional processes.) Future work should examine how different parenting styles and parental religiosity variables (e.g., fundamentalism) interact to shape parents' communication style and impact on children.

A study by Braswell, Rosengren, and Berenbaum (2011) studied Midwestern Protestant and Catholic parents' beliefs about religion (and magic and science) and whether they encouraged their children to hold such beliefs. Parents felt it was important for their children to learn about religion (M of 4.4 out of 5) though they felt it was more important for them to learn about science (M = 4.6). Interestingly, parents felt that it was important for their children to learn

about religion at a significantly younger age (4.9 years) than about science (5.4 years). When asked to choose different mechanisms through which their children should learn about religion, parents almost never chose "on their own" but 31% chose "with help" and 64% "on their own with help." The strength of parents' religious beliefs was highly related ($r = .76$, $p < .001$) to the belief that they should encourage such beliefs in their children.

Parents' endorsement of mythical, culturally salient characters such as Santa Claus, the Easter Bunny, and the Tooth Fairy is sometimes related to their children's belief in them (Prentice, Manosevitz, & Hubbs, 1978; Rosengren, Kalish, Hickling, & Gelman, 1994), but correspondence between parents and children is not so strong as to suggest children think what their parents want them to. When parents encouraged their children to believe in the Easter Bunny, 23% did *not* believe, and when parents discouraged belief, fully 47% of their children *did* believe in the Easter Bunny (Prentice et al., 1978). These findings attenuate the notion that parents somehow "transmit" their beliefs to children in some simple uni-directional fashion.

Taylor and Carlson (2000) reported parents' attitudes about children's fantasy play through ethnographies and interviews. Parents' religious views influenced their reactions to children's fantasy and engagement with imaginary companions. Mennonite parents had strongly negative reactions to imaginary companions whereas Hindu parents often reacted positively, perhaps believing that communication with invisible companions may be a way for children to interact with spirits from a past life. This interpretation reflects their religious tradition of belief in reincarnated and metaphysical entities.

Evans (2000) compared the beliefs about origins (Creationist or evolutionist accounts) of children in secular families and in fundamentalist Christian families, who also attended religious schools or were home-schooled. To some degree, family type did matter—fundamentalist Christian children overwhelmingly embraced Creationist views with virtually no endorsement of evolutionist ones. However, even young children (7 to 9 years of age) from *secular* homes embraced Creationist views, and not until early adolescence did youth in secular homes begin to consistently share their families' evolutionist cosmologies. Evans notes that in even a "saturated" belief environment, sociocultural messages are filtered through the child's intuitive belief system.

Overall, family research indicates that both cognitive-developmental and sociocultural theories are informative. The evidence is limited on just how similar or "anchored"

children's beliefs are relative to their parents', but the available data make clear that the independence and distinctiveness of children's thoughts refutes simplistic models portraying children as passive recipients of parental beliefs and instead highlights children's active roles in their religious and spiritual development (for more on children's agency, see Boyatzis, 2011).

While parent-child communication has long been a topic of mainstream family research, developmental scientists have given scant attention to parent-child communication about religion and spirituality. We believe that future work will prove this family dynamic to be a crucial locus of children's (and parents') religious and spiritual growth. However, further research is needed to more fully understand how parents' beliefs are conveyed in their *actual* behavior and communication; this is a crucial missing piece of the religion and family puzzle. More data are also needed on what "mix" or balance of parents' verbal communication about religion and their overt behaviors (e.g., praying with or attending worship with children) constitutes the most "saturated" or effective context for religious socialization. Such work will be most informative if it bridges the dominant cognitive-developmental and sociocultural models of religious and spiritual development.

RELIGION IN THE FAMILY: THE VALUE OF MULTIPLE VARIABLES AND INTERACTION EFFECTS

Although religiousness is recognized as highly multidimensional, more than three quarters of studies on religion and family from the past three decades measured religiosity with only one or two items (Mahoney, 2010). As Boyatzis (2006b) noted, family research would benefit from the study of diverse populations with measurement of multiple dimensions of religiousness, parenting, and child outcome, using multiple informants. Here we highlight several studies that capture some of these qualities and illustrate the value of measuring multiple variables and the interactions of both parent religiousness and parenting behavior.

One of the most important and challenging dimensions of parenting is discipline, which is related to parents' religiousness in complicated ways. For example, parents with conservative Protestant affiliations endorse and use spanking more than other parents (Gershoff, Miller, & Holden, 1999). However, a stronger predictor is a continuous psychological variable—parents' theological conservatism

and belief in Biblical literalism and inerrancy (Gershoff et al., 1999). Building on this finding, Murray-Swank, Mahoney, and Pargament (2006) tested mothers' use of spanking in relation to their theological conservatism in interaction with their sanctification of being a parent, that is, how much they imbued their parent role with sacred and divine qualities and saw parenting as "God's work." Conservatism and sanctification were not related independently to mothers' spanking, but the interaction between mothers' conservatism and sanctification predicted spanking. Specifically, theologically conservative mothers were more likely (than other conservative mothers) to spank their children if they also viewed their parental role as sanctified, sacred, and holy; in contrast, mothers who were theologically liberal were less likely (than other liberal mothers) to spank if they also viewed their role as sacred and holy.

Volling, Mahoney, and Rauer (2009) measured parents' disciplinary strategies and sanctification of parenting in relation to their preschool children's moral conduct. The more parents sanctified their role, the more they used induction (e.g., focusing on consequences of children's wrongdoing) and positive socialization techniques (e.g., approving good behavior). A key finding was that parents' positive techniques combined with sanctification of parenting to predict children's conscience development. A similar interaction obtained for children's affective discomfort: After misbehaving, children's apologizing and concern for others was highest when parents used positive socialization techniques *and* were high in sanctification of parenting.

In another study, Dumas and Nissley-Tsiopinis (2006) analyzed a diverse sample of families with preschoolers. Parents reported on sanctification of parenting and style of religious coping in response to children's defiant behavior. Sanctification did not predict children's behavior, but oppositional behavior increased when parents' religiousness was low and when mothers used negative religious coping (e.g., expressing anger at God, feeling abandoned by God). Thus, children's defiant behavior was most evident at the intersection of different facets of religiosity.

Summary of Research on the Social-Ecology of the Family

To understand the family's influence on child religious and spiritual development, new methods and designs are needed to elucidate the dynamics of parent-child relationships. Too many studies rely on parental self-reports. Future work could employ additional measures, such as direct observation of parents and children discussing

spiritual issues or engaging in shared religious rituals or practices. Another constraint in the literature is the correlational nature of designs. Future work could use longitudinal and cross-lagged designs to test whether parent-child spiritual discourse at Time 1 is causally related to youth religiousness or spirituality at Time 2. Many questions remain and it will help to use multiple measures of parenting and of proximal constructs (e.g., sanctification) rather than more global ones (e.g., religious affiliation, church attendance) (Mahoney, 2010). We now turn to work on other dimensions of well-being in children.

Children's Religiousness, Spirituality, and Well-Being

A core question in the psychological study of religion and spirituality is whether and how these constructs are related to well-being (Koenig et al., 2001; Pargament, 1997). These issues have been explored in samples of normal children on outcome variables ranging from attachment to internalizing/externalizing symptoms to psychosocial constructs. Other studies have explored religious and spiritual elements in coping and outcomes in children facing acute or chronic challenges ranging from family dysfunction to medical problems to surrounding violence.

Given the generally positive role of religion and spirituality in myriad adult outcomes (Koenig et al., 2001; Pargament, 1997), an underlying hypothesis motivating this work on children is to test whether religiosity would serve positive functions, buffering children from stress or conflict in problematic situations or simply promoting positive adjustment in more optimal conditions. The research demonstrates that religion and spirituality do not have simple or direct effects in any monolithic, positive manner. Nevertheless, it is extremely rare to find any negative or undesirable links with children's outcomes. However, many studies show that religion and spirituality are associated in complicated, nuanced ways with various outcomes in various populations of children. This corpus of work on children affirms the wisdom of Pargament's (1997) admonition that asking if religion is good for people is too simplistic and that the more fruitful and valid question is, what dimensions of religion and spirituality are related to which outcomes in which populations?

Religion and Coping by Children in Difficult Circumstances

K. A. Davis and Epkins (2009) examined whether 11- to 12-year-olds' private religious practices such as prayer, scripture reading, and listening to religious programs

would buffer them against the impact of family conflict. The children's religious practices showed no direct association with their depressive and anxiety symptoms, but they did moderate relations between family conflict and the children's anxiety and depression. Specifically, family conflict was more related to young people's depression and anxiety when youth were low (as opposed to high) in private religious practices. Similarly, school-age children who prayed frequently were significantly higher in protective resources such as social connectedness and a sense of humor (Rew, Wong, & Sternglanz, 2004).

Two studies have measured how sick children use religion to cope. A qualitative study of children with cystic fibrosis (Pendleton, Cavalli, Pargament, & Nasr, 2002) found that children described 11 different religious coping strategies, including petitioning God to intercede, working with God to cope with their struggles, and expressing discontent with God or their congregation. Children felt that most of these strategies helped them with their illness. In a study of children with asthma, Benore, Pargament, and Pendleton (2008) found that the quality of children's lives and asthma severity were largely unrelated to the importance of religion and religious activities reported by parents (e.g., children's prayer/attendance frequency, religious education). In regressions that controlled for secular coping and the importance of religion, positive religious coping (e.g., "I think God is watching over me") did not predict unique variance in most outcomes, although it did predict—paradoxically—more worrying by children when they were hospitalized (which may have triggered greater use of positive religious coping). However, negative religious coping (feeling abandoned by God or feeling angry at God) during hospitalization predicted lower quality of life related to asthma, higher depression, and higher anxiety. One month later, negative coping predicted higher anxiety whereas children who used more positive coping came to feel closer to God and their faith communities.

To learn if religion has a protective buffering effect for abused children, J. Kim, McCullough, and Cicchetti (2009) examined normal and maltreated children from low-income families. This study was the first, the authors claimed, to test whether parental religiousness would be related to adjustment outcomes in maltreated children. Results showed parents' religiousness was protective for nonmaltreated children but not for maltreated children. An important pattern to emerge from this study was that different dimensions of both parents' and nonmaltreated children's religiousness interacted to predict child

outcomes. Specifically, parents' higher worship attendance predicted fewer internalizing symptoms in children who did not attend worship frequently (but not in children who did attend frequently). Also, higher importance of faith to parents predicted lower internalizing and externalizing problems in children who were low in faith (but not in children high in faith).

Another study has found that mothers' religiousness is related to better child adjustment in regions of Northern Ireland that have suffered chronic conflict between Catholics and Protestants (Goeke-Morey et al., 2013). In this study, mothers' religiousness was an aggregate score based on church attendance, importance of religion, and endorsement of Christian beliefs. Children's (M age = 12 years) psychological adjustment was assessed using an aggregate score based on mothers' and children's reports of the children's emotional problems, conduct problems, peer difficulties, and impulsivity. Results showed that higher maternal religiousness predicted many positive outcomes: healthier psychological adjustment in the children, stronger (more secure) child-mother attachments, and higher rates of personal disclosure to the mothers. In other analyses, several significant interactions highlighted the protective benefits conferred by mothers' religiousness. First, mothers' behavioral control was related to stronger attachment security in children when mothers were more religious but not less; second, higher family cohesion was related to strong attachment in children when mothers were more religious but not less; and third, mothers' own mental health problems were related to children's lower attachment security when mothers were less religious but not more. This study suggests that religion serves as a family asset that enhances child and family well-being in numerous ways.

Another study assessed how church attendance and private religiousness (e.g., prayer, reading the Bible) was related to aggression in African American children between 7 and 12 years of age who had previously been identified as moderately to highly aggressive (Holmes & Lochman, 2012). In regressions testing the full model of parent and child organizational and private religiousness and SES, the only predictor of children's lower aggressiveness was the parents' church attendance. An interaction between children's private religious practices and SES emerged, as the children highest in aggression were low in SES and high in private religious practices whereas the children lowest in aggression were low in both SES and private religious practices. While causality is unclear, the authors suggested that highly aggressive poor children

may pray or read Scripture to help self-regulate or control their aggression. An alternative explanation would be that such youth may seek comfort in prayer or find justification in scripture for their aggression (e.g., the Old Testament adage of “an eye for an eye”).

In sum, the small but growing literature on religion, coping, and outcomes for children suggests that religion may often, but not always, function as a personal or family asset. However, the findings do not consistently point to this conclusion, as religion did not seem to buffer abused children (J. Kim et al., 2009) or aggressive children (Holmes & Lochman, 2012); some desirable outcomes emerged only from some informants’ but not others’ reports, and some only from the interaction of certain parent and child qualities but not others. While evidence points generally to a positive role of religion in children’s lives, the findings are nuanced and complicated and confirm the need to identify which dimensions of religiousness are associated with which parenting or child variables leading to particular outcomes in particular populations. For example, because several of the studies reviewed above (Goeke-Moray et al., 2013; Holmes & Lochman, 2012; J. Kim et al., 2009) had samples with mostly single-mother families, additional research is needed to learn how religion and spirituality may operate in various family structures.

Religion and Children’s Well-Being

Here we focus on two studies of children in normal circumstances. We elaborate on these two in particular because their designs are more complex than those in other studies, and these studies present data from multiple informants on multiple dimensions of religiousness or spirituality in relation to multiple child outcomes, making the studies especially informative. One study focuses on religious variables, the other study on spirituality dimensions.

Holder, Coleman, and Wallace (2010) assessed happiness in 320 eight- to twelve-year-old children from public and private religious schools. The authors posited that children’s happiness would be enhanced through religion and spirituality through the provision of social support, relationship with the divine, and a sense of meaning. Children’s happiness was assessed on four similar measures (e.g., a smiley-face task in which children chose the expression that matched how they felt), some reported by children themselves and some by their mothers. Children’s religiousness was indexed by a survey on religious practices (e.g., prayer frequency) and religious beliefs (e.g., desire to be closer to a higher power) and spirituality on a Spiritual Well-Being Questionnaire that indexed four

dimensions of self-reported spirituality: *personal*, or the value and meaning in one’s life; *communal*, or quality and depth of relationships with others; *environmental*, or a sense of awe for nature; and *transcendental*, or faith in and relationship with something or someone beyond the human level (Holder et al., 2010, p. 136).

Holder and colleagues (2010) found that children’s happiness was not related to religiosity (defined as involvement in organized religion). In contrast, happiness was correlated with some measures of spirituality, albeit with low r s (.12–.21). In subsequent regression analyses that controlled for children’s gender, school type, and temperament, personal and communal spirituality predicted significant variance in children’s happiness. That is, children were happier the more they had a positive sense of self and better relationships with others. One might argue that these dimensions do not reflect spirituality as much as constructs such as self-esteem and social acceptance. However, if spirituality is understood as connectedness to what is beyond the self, then relationships with peers may be an important early expression of a “horizontal” spirituality in childhood. In contrast, the more “vertical” forms of spirituality were not relevant: Children’s sense of awe for the environment did not predict any happiness outcomes and transcendental connection predicted only one of four outcomes (and only 1% of the variance at that). These last findings on the minor impact of transcendental connection are noteworthy in part because this sense of connectedness is integral to most definitions of spirituality. However, from the framework of reciprocating spirituality, perhaps what is especially crucial in childhood is the development of an interpersonal or horizontal spirituality, which may function as a foundation for the development of a relationship with more transcendent entities such as nature or the supernatural. This interpretation seems consistent with theories of faith development, attachment, and relational spirituality already described earlier, and we return to this idea later.

In a large national study, Bartkowski, Xu, and Levin (2008) used data from one wave (N = approximately 17,000 children) of a representative sample of kindergarten and first-grade children and their parents and teachers. This study measured several aspects of family religiosity—mothers’ and fathers’ worship attendance, frequency of discussion with the child about religion, and frequency of spousal arguing about religion. Outcomes included children’s psychological and psychosocial functioning, some rated by parents and teachers and others by only one group of informants. Regression analyses with

demographic controls showed that frequency of worship attendance by mothers and fathers (separately and together) was widely associated with children's positive outcomes (self-control, social skills) and lower levels of undesirable outcomes (internalizing and externalizing problems), as rated by parents and teachers. These findings suggest potential benefits of involvement in organized religion for different types of outcomes in children. How often parents discussed religion with the children was less influential. Of the 10 possible outcomes, this measure was significantly linked to only 3 (better self-control, approaches to learning, and interaction with peers). We want to highlight that these significant findings emerged only with parents' reports of children's outcomes; none of the teacher-reported child outcomes were significantly predicted.

Collectively, these two studies confirm that simple conclusions about the benefits of religion or spirituality are unwarranted; some dimensions of religion or spirituality are related to some outcomes in some populations. The findings reviewed thus far demonstrate that, in a research literature of modest size, religion and spirituality and children's well-being are linked in complex and nuanced ways. This conclusion contrasts with the pattern in adolescence, where religion and spirituality clearly act as positive assets.

In sum, researchers should employ more developmental designs, micro-genetic or longitudinal, to learn how religiousness and spirituality actually develop and change. Such designs will also inform us about how childhood religiousness predicts later religiousness, how earlier religiousness and spirituality relate to child outcomes at later ages, and whether certain childhood psychological profiles set the stage for particular religious or spiritual outcomes later in life. Some longitudinal work shows that infants who were high-reactive and easily stressed were more religious as adolescents (Kagan, Snidman, Kahn, & Towsley, 2007). What other childhood temperamental or psychological profiles are associated with religious outcomes? What childhood qualities and environments lead to adolescent spiritual curiosity as opposed to defensive and dogmatic closure? We have much to learn.

ADOLESCENCE AND RELIGIOUS AND SPIRITUAL DEVELOPMENT

Although adolescence has long been recognized as a critical phase of development for religiousness and spirituality (Erikson, 1968; Hall, 1904), empirical research on it has blossomed only recently. In this section, we discuss why

spiritual and religious development are especially prevalent during adolescence and review the recent growing body of research that attempts to identify, conceptualize, and measure religious and spiritual issues and processes in adolescence. Such inquiry has been undertaken to identify what constitutes spiritual development during adolescence, delineate distinctions between religious and spiritual development, and discern how religious and/or spiritual development are resources for positive development.

Adolescent Development and Religion and Spirituality

In the last decade, scholars have brought to light how the marked physical, psychological, and social changes during adolescence enable young people to be developmentally poised for qualitative changes in their religious and spiritual development (Good & Willoughby, 2008; King & Roeser, 2009; King et al., 2013; Warren et al., 2012). Recognizing that youth are malleable and have the potential for growth, the following section describes how the many changes happening at different levels of the developmental system (e.g., biological, psychological, social) are germane to religion and spirituality during adolescence.

Growing evidence points to a role for biological-level variables on religious and spiritual development. Some studies have begun to examine neural correlates of religious and spiritual beliefs (see S. Harris et al., 2009). The evidence suggests that adolescent brain maturation, particularly the pruning of neural connections and increases in white matter, facilitates increased abstract reasoning that may be associated with spirituality (S. B. Johnson, Blum, & Giedd, 2009). Future research also needs to test the notion that heightened emotionality in adolescence due to maturation of the limbic system might enable adolescents to be engaged by the emotional aspects of religiousness and spirituality (see DeHaan, Yonker, & Affholter, 2011) and to experience the conviction of conversion (Smith & Denton, 2005). Insights into brain maturation during adolescence call for a multilevel future agenda to test potential influences on adolescent religious and spiritual development, ranging from neurological to psychological to family and culture (see Warren et al., 2012).

In addition, recent epigenetic research underscores the need to explore how certain genotypes interact with particular personality tendencies or childhood experiences that may lead to different religious and spiritual outcomes (see Slavich & Cole, 2013). For example, in their review of human social genomics, Slavich and Cole (2013) present growing evidence for the influence of

social context on genetic expression, including evidence for effects of spiritual practices (e.g., meditation) on genome-regulating effects. In addition, positive states associated with spirituality and religion such as gratitude, peace, and connectedness may influence genetic transcription. All of these processes illuminate how environments and experiences affect genetic and biological processes. The work by Slavich and Cole highlights the notion that spiritual and religious experience or feelings may not only influence brain process and function but genetic expression in such a way that has significant implications for adolescent health and even genomic evolution.

These biological changes may parallel cognitive and emotional developments that facilitate one of the main developmental tasks of adolescence—identity formation, in which religiousness and spirituality can play a vital role as youth endeavor to establish self-definition and belonging (Erikson, 1968; King, 2003). In striving toward identity cohesion, young people actively search for a sense of self. In this process of seeking to form a meaningful identity, adolescents are exposed to a variety of beliefs, values and roles, and they begin to ask existential questions and search for purpose (Damon, Menon, & Bronk, 2003; King, 2003, 2008; Mariano & Damon, 2008; Markstrom, 1999). These processes may reflect a quest for a philosophy of life by youth that comprise much of the religious and spiritual life. Adolescents are maturationally ready to embark on this psychological endeavor to consolidate and understand their experience of self and the world, as well as to identify themselves in terms of familial, vocational, societal, existential, and spiritual roles. Religious and spiritual communities may also be helpful to adolescents as they explore ultimate beliefs and as their relationships begin to shift.

Given the psychological growth indicative of adolescence, teenagers are developmentally prepared for deeper and broader engagement with the world beyond themselves due to emerging cognitive and emotional capacities that allow for more abstract reasoning, self-reflection on their beliefs and their place in their expanding social worlds, and more astute awareness of others and their perspectives (Warren et al., 2012) that cause them to engage in spiritual endeavors as they attempt to make sense of their world, ask existential questions and wrestle with doubt (Hunsberger, Pratt, & Pancer, 2002), seek belonging, and construct a sense of self. Given the potential import of religion and spirituality for adolescents, we turn to more recent distinctions between definitions of religiousness and spirituality in adolescents.

Adolescent Religious Development

Religious development involves the changes in a young person's engagement in and understanding of a religion's beliefs, rituals, and community. However, until recently the vast majority of empirical studies have employed measures of more simplistic religiousness variables, such as single-item variables that measure frequency of religious attendance and level of importance of religion. In hopes of deepening an understanding of adolescent religiousness or religious development, scholars have recently moved beyond these measures to more refined constructs such as religious commitment and religious identity. The following section highlights some promising new directions.

A recent meta-analysis of empirical articles published from 1990 to 2010 demonstrates the beginning of this shift. DeHaan et al. (2011) examined theoretical underpinnings, methodologies, and operational definitions of religion, spirituality, and faith that were used in studies of adolescents and young adults. Their analysis of 119 studies revealed four categories of conceptualizations and measures of religiosity: religious attendance (i.e., how often one attends church), religious behaviors (e.g., prayer), salience of beliefs (e.g., importance of religion or God), and religious searching (e.g., the extent to which religious beliefs have changed, readiness to face existential questions). The meta-analysis revealed that, although many researchers mentioned the intention to study religion and spirituality, few actually distinguished between these concepts in their operational definitions and measures. Most used measures tied to traditional religious traditions. This finding is of special interest in light of the growing concerns with creating operational definitions and measures of spirituality independent of religious tradition. This issue seems all the more important given the “rise of the nones,” those who claim no religious affiliation, in adolescence (Pew Forum, 2012; Smith & Denton, 2005).

In their secondary analysis of the NYSR data, L. D. Pearce and Denton (2011) proposed a more nuanced understanding of adolescent religiousness. Using three dimensions of religiousness, *content* (specific beliefs), *conduct* (the nature and frequency of religious practices), and *centrality* (the degree to which religion is salient in one's life), they used latent class analysis to identify five different religious profiles that remained stable over-time. Two types are clearly identifiable and internally coherent—“atheists” and religious “abiders.” They comprise 3%–5% and 20%–22% of U.S. teenagers, respectively. In addition, they found “avoiders” (17%–24% of U.S. youth who

resist identification as atheist or religious), “assenters” (20%–28% who are extrinsically oriented), and “adapters” (30%–31% who are intrinsically oriented to faith but not consistently affiliated). The analysis of the three additional types demonstrated the benefit of a person-centered approach as well as the complexity of internal and external factors that contribute to adolescent religiousness.

A recent qualitative study of Christian, Jewish, and Muslim adolescents used grounded theory to explore religious commitment beyond the typical attitudinal and behavioral measures employed to index adolescent religiousness. Exploring how adolescents talk about their religious commitments, Layton, Dollahite, and Hardy (2011) found seven “anchors” with which youth grounded their religious commitments—religious traditions, rituals, and laws; God; faith traditions or denominations; faith community members; parents; scriptures or sacred texts; and religious leaders. Consistent with other scholarship (King et al., 2013; Mahoney, 2010), these findings emphasize that “relational pathways are at work in the domain of adolescent religious commitment” (Layton et al., 2011, p. 407). The concept of “religious anchor” is a multidimensional relational construct that points to the specific ways that young people connect to religion. Youth are related to their faith not only through living people but also through God, ideals, teachings, practices, and stories in sacred texts and traditions. Interestingly, youth spoke of changes in the relative importance of different faith anchors at different points in their lives. Further research is needed to understand whether different anchors are more pertinent at different ages and in differing circumstances, religious traditions, and cultures. As we suggested previously, perhaps more concrete anchors (e.g. youth leaders, rules) are more accessible to young children or adolescents, whereas more abstract anchors (e.g. God, solidarity with previous and future believers) may be more meaningful to older youth. Furthermore, examining interactions between different anchors would illuminate the nature and content of the contexts that buoy religious commitments. A study of Moroccan-Dutch Muslim youth in the Netherlands exemplifies the complex interplay between adolescents’ religious and national traditions and cultures (Verkuyten, Thijs, & Stevens, 2012). For early adolescents, their parents’ identification with their religious group predicted the young people’s religious and ethnic/national identification, but by middle adolescence these associations were no longer significant.

In turn, understanding self-concept or identity in relation to religion has gained attention (Templeton & Eccles,

2006) due to the notion that religion, like any salient domain of social experience, constitutes an important source of individual differences in the social-cognitive-affective self-schemas that are elaborated across development. Roeser, Issac, Abo-Zena, Brittain, and Peck (2008) suggested that religious identity is a personal identification with a social collective or group characterized by a particular religious tradition. Individuals who claim membership in a particular tradition share in common with other group members’ collective sacred worldviews and associated beliefs, practices, rituals, and symbols.

In a longitudinal study, Lopez, Huynh, and Fuligni (2011) demonstrated the stability and coherence of adolescent religious identity and its connection to family and ethnic identity. Other studies have shown that religious importance and participation interact to promote religious identity (Hardy, Pratt, Pancer, Olsen, & Lawford, 2011). Commitment and exploration continue to be the two major constructs used in the study of religious identity, and Layton and colleagues (2011) found that specific “anchors” of commitment served as distinct components of adolescents’ religious identity inasmuch as identity is understood in terms of religious commitments made and maintained.

These studies advance understanding and assessment of adolescent religiousness. They highlight that religiousness is a multidimensional construct that involves beliefs, participation, commitment, and relationships. Research is needed to learn whether adolescent religious identity is a construct distinct from religiousness and, if so, how it illuminates the nature and function of religion in the lives of adolescents. In the next section, we discuss conceptualizations and measurement of spiritual development as distinct from religious development.

Adolescent Spiritual Development

In addition to studying religiousness, scholars have pursued a nuanced conceptualization and measurement of adolescent spirituality. Since 2010, scholars have made a concerted effort to understand the multifaceted nature of adolescent spirituality. The following section reviews empirical work on spirituality and spiritual development in the adolescent literature.

In a rare longitudinal study, involving 756 predominantly Canadian-born adolescents, Good, Willoughby, and Busseri (2011) examined intraindividual stability and change in spirituality and religiousness between 17 and 18 years of age. They included measures that were either more personal or institutional and more affective

or behavioral. These measures included religious activity involvement, wondering about spiritual issues, perceptions of transcendence, frequency of prayers, and frequency of meditation. Results of a cluster-analysis revealed five clusters with varying degrees of personal and institutional involvement and of affect and behavior. With the exception of the high institutional and personal cluster, the clusters remained stable over two time points. There also was strong intraindividual stability in all clusters, though a significant proportion of individuals classified as high institutional and personal at Time 1 moved into the primarily personal cluster at Time 2. This study illustrates the complexity and interrelatedness of adolescent religious and spiritual development. Some youth are committed at the institutional and personal level, while others are committed at only one or neither level. In addition, although institutional engagement may decline in later adolescence, personal modes of religiousness and spirituality are prevalent and relatively stable among adolescents.

In addition to operationalizing spirituality and religiosity distinctly, scholars have investigated spiritual identity as distinct from religious identity. In contrast to religious identity, Roeser et al. (2008) posited that the core of adolescent *spiritual identity* is a personal identification with that which is *pan-human* and *transcultural*, a solidarity with others, and values, ethics, and wisdom concerning life's ultimate existential questions relevant to all human beings. Although scholars have suggested that spiritual identity is salient in adolescence (Templeton & Eccles, 2006), there has been no empirical research on such an identity construct. Such data are needed to illuminate the potentially unique role of spiritual identity in young people. Just as identity achievement is linked to positive outcomes for youth, spiritual identity may help youth thrive and may facilitate the transition into meaningful and productive adulthood (Trommsdorff & Chen, 2012).

In addition to identity, recent attempts to elucidate spiritual development have emphasized constructs such as transcendence, awareness, connection, and contribution. In an exploratory study, the Search Institute conducted a quantitative study of 6,725 youth aged 12 to 25 from eight countries² (Benson et al., 2012). Items for an online survey were generated to explore spiritual development, drawing core spirituality constructs from numerous sources: a literature review, an international focus group study, a qualitative spiritual exemplar study, and a Delphi study

of expert practitioners and scholars of adolescent spirituality. Exploratory factor analysis was conducted on two sets of items from the online survey. The first set was intended to measure aspects of spirituality that were hypothesized to be more universal. Four psychological processes potentially integral to spiritual development were identified: connecting with others through prosocial beliefs and actions, discovering meaning, mindfulness, and alignment of values with action. The other set of items was intended to measure religious and spiritual engagement and yielded the following factors that were valid across the religions and countries represented in the sample: apprehension of God/Force, spiritual practices, religious practices, and spiritual experiences. Benson et al. then used a person-centered analysis to explore profiles of the unique ways spirituality manifested itself in the sample of diverse youth. Latent class analysis yielded six types of spiritual development involving different combinations of religious variables (e.g., attending congregation, reading sacred texts), spiritual variables (e.g., praying, experiencing God or the supernatural), and the four psychological processes described above.

Although preliminary, these Benson et al. (2012) findings suggest that spirituality is relevant for many youth from different cultural and religious backgrounds. Although the study was not longitudinal, the findings highlight important directions for future study. For instance, the researchers found that even though they did not report regular engagement with religious activities, the majority of youth reported connecting with other people through prosocial activities, seeking a sense of meaning, being mindful, and intentionally living lives aligned with their personal values. The study suggests potentially important links between youth and the ideological narratives, people, institutions, and cultures that surround them. Studies like this point toward the complexity of spirituality and psychological and behavioral components.

Another cross-cultural study explored dimensions of spiritual development in a sample of 30 culturally and religiously diverse youth from six countries³ who had been nominated by an international board of scholars and practitioners of adolescent spirituality as "spiritual exemplars" for living with profound spirituality in their culture (King et al., 2013). Using consensual qualitative research methods, structured analyses of participants' narratives of their experiences of spirituality yielded a view of spirituality as

²Australia, Great Britain, Canada, Cameroon, India, Thailand, Ukraine, and the United States.

³Kenya, India, Jordan, Peru, United Kingdom, and the United States.

based on transcendence, fidelity, and action. The findings suggested that spiritual development occurs when a young person's interactions with others are linked to a deeper connection to something beyond the self (transcendence), which can lead to a growing clarity and commitment to beliefs, values, and purpose (fidelity) that motivates a way of living that benefits others (action). The adolescent participants all described meaningful connections with God, their faith community, nature, or absolute truth. Perhaps one of the most interesting findings was that awareness and experience of God, absolute truth, or humanity informed the way these youth understood the world and themselves. These young people articulated clear beliefs and a genuine commitment to ideology—to the extent that they attempted to intentionally live in a manner consistent with their beliefs and values. In other words, these young people reported profound experiences of transcendence, were able to articulate a clarity and devotion to their beliefs, and participated in spiritual leadership or service.

In regards to measuring spirituality, transcendence is the construct that has received the most empirical attention. For example, the Spiritual Transcendence Index (STI; Seidlitz et al., 2003) has eight items (e.g., "My spirituality gives me a feeling of fulfillment," "I experience a deep communion with God") that measure subjective experiences of the sacred and their effects on one's self-perception, feelings, goals, and ability to overcome difficulties. The scale examines how one's daily experiences are interpreted in terms of spirituality, and it has been utilized with Canadian adolescents (Good, Willoughby, & Busseri, 2011) and among U.S. evangelical youth (Schnitker, Felke, Barrett, & Emmons, in 2014). Although the STI has strong psychometrics when used in adolescent populations, it is limited to a theistic expression of transcendence and spirituality. Other empirical studies have operationalized transcendence through adolescent self-perception of awareness of God, desire for closeness with God, and connection with others (see Desrosiers, Kelly, & Miller, 2011; Dowling et al., 2004; Warren et al., 2012).

The studies reviewed above suggest that a simple conceptualization and assessment of adolescent religious and spiritual development is neither available nor appropriate. However, there is growing consensus regarding the complexity of these constructs, as researchers are moving beyond simple operational definitions of religiousness and spirituality (e.g., frequency of attendance, degree of importance). Furthermore, the exploration of spiritual development has brought attention to the significance of concepts such as religious commitment and

religious identity, as well as transcendence, awareness, meaning-making, purpose, fidelity, and actions. These findings are consistent with the growing body of research that suggests that spiritual development is a domain of human development that pertains to finding significance, meaning, and the sacred through connection to self and other. In this light, we reaffirm the concept of *reciprocal spirituality* as a vital construct for a deeper and more comprehensive grasp of the active developmental process of transcending the self; of transforming personal beliefs, commitments, and meaning; and of living consistently with those beliefs. In the next section, we investigate different features of the adolescent developmental ecosystem to more fully understand relational influences on adolescent religiousness and spirituality.

Social Ecology of Influences on Adolescent Religiousness and Spirituality

From a relational developmental systems perspective, religious and spiritual development, like other areas of development, are embedded within networks of social relationships in different settings across the life span. In the following section, we describe what is understood regarding the social ecologies in which religion and spiritual development occur. First we examine research on how relationships with parents and peers, and experiences in schools and with mentors, shape religious and spiritual development during adolescence. In addition, given that religious traditions are closely connected to ethnicity and cultures, we review relationships between these broader contexts and the religious and spiritual development of youth.

Family Influences

Like research on other aspects of socialization, parents are viewed as the key socializers of adolescents' religion and spirituality. As described earlier, parental beliefs and practices are assumed to provide the foundation for young people's own religious beliefs and practices (Ozorak, 1989), directly through explicit socialization practices and indirectly through the influence of religion on parenting behaviors (Hood et al., 2009).

The quality of the parent-adolescent relationship is central to religious socialization. Parent-child relationships characterized by frequent interaction and trust enhance religious socialization (King & Furrow, 2004), and warm, close relationships are linked to greater correspondence of offspring's religious beliefs with those of their parents

(Hoge, Petrillo, & Smith, 1982) and less religious rebellion by teens (Wilson & Sherkat, 1994). Bao et al. (1999) found that parental acceptance mediated the socialization of religious beliefs and practices, with greater acceptance leading to greater influence. Thus, warm and supportive relationships with religious parents seem to enhance the religious and spiritual development of adolescents in U.S. populations (Hardy, White, Zhang, & Ruchty, 2011) as well as Indonesian Muslim populations (French et al., 2013). In a multigenerational study, Spilman, Neppl, Donnellan, Schofield, and Conger (2013) found that parents' religiousness in one generation predicted more positive relationships between parents and adolescent children in that generation as well as higher religiousness in adolescence and adulthood.

Other research indicates that mothers and fathers have distinct roles in promoting their adolescents' spirituality. Desrosiers et al. (2011) measured a large ethnically and religiously diverse sample in the northeast United States to learn how adolescents' relational spirituality (operationalized by daily spiritual experiences, forgiveness, and positive religious coping) was related to mothers' and fathers' care and concern for their children as well as spiritual support of their children's spirituality; support was operationalized as parents' interest in and frequency of discussing spiritual and religious issues. Mothers and fathers appeared to play different roles: Adolescents' spirituality was predicted by mothers' spiritual support and dialogue (but not general care and concern), whereas adolescents' spirituality was predicted by fathers' general care and concern (but not spiritual support and dialogue). The authors suggested that mothers seem especially important because they "supply the scaffolding for the spiritual individuation process in adolescents" (p. 49), which may help their children explore spiritual dialogue with friends; having an emotionally close relationship with fathers may provide a broad, secure foundation that is more important than specific interactions around religious topics.

Family socialization of adolescents in the religious domain is comprised in large part of family rituals and conversations about religion. Results of the NSYR (Smith & Denton, 2005) showed that 54% of U.S. families engage in "giving thanks before or after meals" and 44% of youth said they talked with their families about God, scripture, prayer, or religious and spiritual matters one or more days a week. Dollahite and Marks (2005) found that families foster religious and spiritual development in children through processes such as formal teaching, parent-child discussion, role modeling, and coparticipation in prayer and other

rituals. Dollahite and Thatcher (2008) surveyed and interviewed parents and adolescents in highly religious Jewish, Christian, and Muslim families, who described various techniques to shape young people's religiousness including family devotions, worship attendance, and praying with children. In interviews, parents and adolescents both cited conversations more frequently (more than 75% of each group) than any other method. In particular, they found "youth-centered" conversations were especially effective and meaningful. In these discussions parents focused on adolescents' spiritual needs and issues in contrast to "parent-centered" conversations that emphasized parents talking rather than listening to children and not taking adolescents' concerns as priorities. The youth-centered model is akin to the bidirectional parent↔child dynamic (Boyatzis & Janicki, 2003; Flor & Knapp, 2001). In the Dollahite and Thatcher (2008) study, youth-centered conversations were described by both adolescents and parents as more positive experiences. This style may help youth adopt parents' religious values as well as strengthen parent-child relationships.

Family prayer is common in conservative Protestant, African-American Protestant, and Mormon families and likely is one major way that these American parents socialize religious practices in their offspring (e.g., Ozorak, 1989). In a national Seventh-Day Adventist population, family worship patterns that involved a high degree of adolescent participation were positively linked with stronger adolescent faith (Lee, Rice, & Gillespie, 1997). Erickson (1992) found that parental religious participation with adolescents was more efficacious than mere parental religiousness. Another study on Protestant youth found that talking with parents about religious issues and participating in religious activities together predicted adolescents' experience of God and their report of the importance of religion (King, Furrow, & Roth, 2002). In a study of African-American families, there was no main effect of parents' religiosity or parenting style on their young people's religiosity, but a significant interaction emerged as higher authoritative parenting combined with higher parental religiosity to predict modest but unique variance in young people's religiosity (Abar, Carter, & Winsler, 2009).

The dearth of longitudinal studies on this topic precludes any strong inferences about the long-term effects of parenting on the religion of offspring, especially given the considerable fluctuation of religious affiliations noted earlier (e.g., Pew Forum, 2012). In addition, other sources of influence in the family, including siblings, aunts and uncles, and grandparents are important to consider in the

religious development of youth. This larger group of family members may be especially salient for ethnic minority families that live in close proximity to their extended family and who have religious homogeneity across generations.

One study demonstrated a plethora of social influences. Regnerus, Smith, and Smith (2004) analyzed data from the National Longitudinal Study of Adolescent Health, a database focused on youth 12 to 18 years of age. The survey included two religiosity outcomes for youth: worship attendance and importance of religion. Relative influences were computed for the religiosity of parents, peers, the young people's schools, and local county norms (for worship attendance). Teens' worship attendance was related most strongly to their parents' attendance, but peers' religiosity and local county worship norms were also strong predictors of youth attendance. Interestingly, the overall importance of religion in the young people's schools was the strongest predictor of the importance that the adolescents themselves placed on religion. Together, these studies confirm the value of a social-ecology approach that analyzes multiple influences and links between them.

Peer Influences

According to NSYR results (Smith & Denton, 2005), American youth generally report having peers who share their religious beliefs. Of their five closest friends, between two to three of these friends are on average said to "hold similar religious beliefs" and about one of these friends is said to "be involved in the same religious group." Conservative African-American Protestant and Mormon teens were more likely to have friends in their same religious group (Smith & Denton, 2005). King and Furrow (2004) found that religious youth, compared to their less religious peers, reported higher levels of positive social interaction, shared values, and trust with their closest friends.

These findings illustrate two important facets of adolescent religious and spiritual development: selection effects, in that youth pick peers who are religiously similar to themselves; and socialization effects, in that peers seem to shape each other. For instance, a longitudinal study of children from 7 to 22 years of age showed that the best childhood and adolescent predictors of religiosity during early adulthood were ethnicity and peers' church attendance during high school (Gunnroe & Moore, 2002). Desmond, Morgan, and Kikuchi (2010) used growth curve modeling to examine the influence of parents and peers on adolescent religious attendance and religious importance using five waves (eight years) of the National Youth Survey (1979–1987). Compared to adolescents with low peer

attachment, adolescents with high peer attachment were more likely to attend religious services initially and to believe that religion is important, although their religious service attendance and belief in the importance of religion decreased more rapidly over time.

Additional research points to how friends may influence each other's religious and spiritual development. Not surprisingly, adolescents who have friends who talk about religion and spirituality have higher self-reported religious beliefs and commitment than adolescents whose friends did not talk about their faith (Schwartz, Bukowski, & Aoki, 2006). In a large sample of Christian adolescents, perceived faith support and spiritual modeling of Christian friends were among the most important predictors of the adolescents' own faith (Schwartz, 2006). A striking finding from this study was that these peer factors mediated the influence of parents on adolescents' religiousness. Similarly, King et al. (2002) found that talking with friends about religion and participating with friends in informal religious activities (e.g., studying religious texts, attending religious camp) explained significant variance in religious commitment over and above parental influences. Desrosiers et al. (2011) found that friends' spiritual support—measured by how comfortably and how frequently adolescents reported discussing spirituality with their friends—predicted significantly higher relational spirituality in adolescents. Together these studies confirm that the peer group is a key context for religious and spiritual development.

School and Mentor Influences

Studies of school effects are typically divided into those assessing direct effects of attending religious schools on student academic development and on how the student body's religious composition may exert indirect effects on adolescents' religious lives. Studying an African-American Muslim school, Nasir (2004) found that teachers viewed students as spiritual beings waiting to be developed. This social positioning based on a spiritual ideology afforded these young people a unique set of supports and identity position to promote their religious and spiritual development. Similarly, J. B. Barrett, Pearson, Muller, and Frank (2007) suggested that the private religiosity of popular schoolmates may foster a community in which religious matters are normative and valued and in turn promote personal religiosity.

A small body of literature examines the roles of adult mentors in adolescent religious and spiritual development and has documented that the relational quality of mentoring relationships is linked to their impact on spiritual

development. In a study of over 3,000 Christian adolescents, participants who described their relationship with their youth pastors as instructive, imitative, and intimate also reported that these relationships contributed significantly to their spiritual development (Schwartz, 2006). Another study found that relationships between youth pastors and their youth that are characterized by both relational intentionality and spiritual focus result in spiritual development, as indicated by outcomes such as a personal relationship with God, moral responsibility, hopeful and positive attitudes, and engaging in mission and service (Strommen & Hardel, 2000). King and Furrow (2004) also found that for religious youth, relationships with adults that were characterized by higher levels of social interaction, trust, and shared values had more influence on adolescent moral outcomes than adults who were less engaged.

Thus, intimate and interactive relationships with spiritual mentors may provide inspiration for spiritual development, showing how nonparental role models matter in adolescent religious and spiritual development. Not only are relationships important to religious and spiritual development, but institutions play an important part as well.

Immigration

Given the high levels of immigration around the world, and the fact that immigrants are often more traditional peoples with historical ties to their religions and religious communities (e.g., Latinos to the Catholic Church, Turks to Islam), religious institutions serve as primary “contexts of reception” for immigrant adolescents. Such institutions afford them refuge, resources, and means for bonding with their ethnic community and mainstream culture through service and other activities (Jensen, 2008). Research on immigrant youth has revealed that congregations create opportunities for maintaining and building religious and ethnic identification and preservation (Suárez-Orozco, Singh, Abo-Zena, Du, & Roeser, 2012). In a study on acculturation, Güngör, Bornstein, and Phalet (2012) found that, when comparing acculturating Turkish-Belgian adolescents in Belgium to those living in their heritage culture (e.g., Turkish youth in Turkey, Belgian youth in Belgium), religious reaffirmation was higher among acculturating youth and was related to the cultural values of interdependence, maintenance of one’s heritage culture, and ethnic identification.

Race and Ethnicity

Religions reflect myriad geographical, historical, national, and ethnic/racial influences and are thus deeply cultural

in nature, so studying religious and spiritual development apart from culture misses something fundamental about their origins and manifestations (Mattis, Ahluwalia, Cowie, & Kirkland-Harris, 2006). Initial research confirms that spiritual development in any cultural context entails a deepening and intensifying sense of connectedness to the transcendent, even if the nature of the transcendent varies dramatically across cultures (see Benson et al., 2012; King et al., *in press*). However, culturally and developmentally sensitive methods are needed to understand the complexity of religious and spiritual development in diverse populations. For example, in cultures where religious rites of passage align with transitions to adulthood (e.g., bar mitzvah, confirmation), communal rituals help consolidate identity more effectively than in cultures where movement into the adult working world no longer accompanies these rites (Trommsdorff & Chen, 2012). Qualitative work in London has examined young adolescents’ “bowing” to their parents (Thanissaro, 2010). This act of bowing that has some religious significance to the individual and family occurred in more than a fifth of youth across diverse religions and ethnic groups but mainly in Buddhist and Muslim families and very rarely in nonreligious families or Christian ones. Religion and ethnicity interact to either promote or impede bowing. For example, Pakistani Muslim youth in London would not bow due to religious reasons but other Muslim youth from the Indian subcontinent would bow frequently. Clearly, adolescent religious practice occurs at the intersection of complex racial, ethnic, and religious traditions. An overview of existing research on the major racial and ethnic minority populations in the United States further demonstrates the nuances of the practice and function of religiousness in different groups.

African-American Adolescents. As discussed previously, African-American youth are more religious than other ethnicities (ChildTrends, 2013; Smith & Denton, 2005). African-American adolescents participate in various religions including Catholicism, Islam, and other forms of Protestantism. As the mainstay of African-American culture, the church plays an important role in the identity formation process of its adolescents by serving as a refuge and support system, and outside the family the church is one of the strongest social influences within African-American communities (Mattis et al., 2006). Several studies have shown positive associations with religiosity among African-American youth. For example, African-American students who were more religious were less likely to appropriate derogatory societal messages

regarding the African-American community (Brega & Coleman, 1999). Brittian and Spencer (2012) found that religious and ethnic identity correlated with less risk behavior for African-American youth. Highly religious African-American students perform well academically, study better, and engage in fewer risky behaviors than youth less committed to religion (Abar et al., 2009; Regnerus & Elder, 2003).

Asian-American Adolescents. Asian-American youth, in general, tend to be less religious than youth from other racial and ethnic groups (Smith & Denton, 2005), although variation exists. Despite low levels of religion and spirituality among Asian-American youth, religion and spirituality play significant roles in some of their lives and is related to their life satisfaction (S. Kim, Miles-Mason, Kim, & Esquivel, 2013). Religious youth groups may also provide Asian-American adolescents with a sense of community and religious identity that often supersedes cultural identity. In a longitudinal study of religious identity, Lopez et al. (2011) found that Asian-American and Latino youth reported higher levels of religious identity than Caucasian youth and this identity was stable over three years of high school.

Latino/a-American Adolescents. Given the adherence to the Catholic Church, it is not surprising that, in the United States, Latino/a youth are more religious than Caucasian youth. In the Lopez et al. (2011) study, Latino/a youth reported higher levels of religious identity than Caucasians and also reported higher levels of religious participation than the students from Asian and European backgrounds.

Latino and Latina youth tend to identify the family and home as contexts in which they learn spiritual practices that affirm their identities and offer spiritual support (M. Knight, Author, Bentley, & Dixon, 2004). Specifically, spirituality is sustained and developed in family pedagogies by using *cuentos* (stories) and *consejos* (advice) (Norton, 2006). For example, Lopez et al. (2011) found that young Latino/a American's religious identity was linked to family identity. Research has also documented that young Latino/a American's religious involvement is linked to lower drug use and spirituality to less marijuana and hard drug use (Hodge, Cardenas, & Montoya, 2001).

Summary of the Social-Ecology of Adolescent Religiousness and Spirituality

We need to learn more about how adolescent religious and spiritual development are influenced by the features

of social and cultural contexts. In addition to the methods most often employed to identify cultural universals, cultural developmental approaches are also warranted to understand differences in spiritual and religious development within populations (Jensen, 2012). For example, it is important to note that children grow up in different nations and cultures that may promote, incorporate, or tolerate organized religion to varying degrees. For example, in the United Kingdom "spirituality" is a required curriculum topic although religion, *per se*, seems not to have such a prominent place in public and political discourse, whereas, in the United States religious issues are often raised in public discourse, but religion and spirituality are excluded from government-funded education. A social ecology approach needs to include these broader public and political macrosystem factors.

In addition, exploring potential moderating or mediating effects of different relationships would shed further light on the social ecology of spiritual development. For example, does the frequent "spiritual growth" of adolescents renew or challenge their parents' spirituality, and would such effects vary by ethnicity? Do clear and consistent norms and accountability across contexts (e.g., family, school, congregation) influence changes in religious and spiritual development? Furthermore, given the increasing prominence of social media and technology in the lives of adolescents and the lack of existing research on technology and youth spirituality, research that investigates the impact of these environments on religious and spiritual development is required. We do not know how adolescent immersion in social media and technology may impede or promote their experiences of spirituality. Social media undoubtedly can increase the breadth of social contacts, but do these kinds of connection "beyond the self" promote a sense of transcendence that results in personal transformation and contribution to the greater good? Are some kinds of social media more beneficial than others?

Just as in other domains of development, the social ecologies that shape adolescent religious and spiritual development are increasingly complex as youth explore and affiliate more intensely and frequently outside the family. Longitudinal designs are needed to model or clarify causal influences on adolescent religious and spiritual development. Such designs will inform the nature of bidirectional relations between young people and the environments in which they live. For example, longitudinal designs may reveal under what conditions and through what mechanisms parents or peers promote religious and

spiritual development, or how adolescent religiousness or spirituality may influence their relationships.

Potential Influences of Religion and Spirituality on Adolescent Development

Empirical studies have turned toward understanding mechanisms that explain how religion and spirituality are potentially “fertile grounds” or important “anchors” for adolescent development (King, 2003; 2008). We have categorized existing studies to discuss the prominent roles of the ideological, social, and transcendent resources within religious and spiritual contexts. It behooves us to note that the large majority of studies are correlational and thus preclude any causal certainty. In addition, while many researchers presume that directionality flows from religious involvement to some positive quality in youth, the reverse directionality may apply: There may be selection effects, with youth who are higher in certain values or beliefs or more inclined to civic action or healthy behavior seeking out religious contexts that are consistent with their values and behaviors. Thus, the direction of causality in this work remains uncertain and underscores the need for designs that model or directly test causal influences.

Ideological Context

Young people strive to make sense of the world and to assert their place in it. The beliefs, worldviews, and values of religious and spiritual traditions provide an ideological context in which young people can generate a sense of meaning, order, and place in the world that is crucial to adolescent development (King, 2003; 2008). Erikson (1965) pointed to religion as an important aspect of the socio-historical matrix in which identity takes shape. He argued that religion is the oldest and most lasting institution that promotes fidelity. Religion intentionally offers beliefs, moral codes, and values from which youth can build personal belief systems (Smith, 2003b). Adolescents’ spirituality entails the intentional identification and integration of beliefs, narrative, and values in the process of making meaning. Whether this process is one of personal construction or socialization, the intentional act of relying on personal, religious, or cultural ideology is central to spirituality and crucial to the development of identity, meaning, and purpose (Damon et al., 2003).

Religion may help youth to internalize a set of beliefs and morals. In a large sample of 10- to 18-year-olds, religious commitment and religious involvement interacted to promote moral identity (Hardy, Walker, Rackham, &

Olsen, 2012). Similarly, in studies of individuals nominated for moral excellence, participants frequently reported that religion served as a foundation for their moral identity and action (Colby & Damon, 1999; Hart & Fegley, 1995). Larson, Hansen, and Moneta (2006) found that youth involved in faith-based youth programs tended to have stronger senses of identity than youth not engaged in faith-based programs. Furthermore, they found that 75% of youth in faith-based programs reported discussing morals and values, in comparison with 24% of youth involved in other types of organized youth programs. King and Furrow (2004) found that adolescents higher in religiousness had more shared beliefs, values, and expectations with parents, friends, and adults. In addition to providing ideology, religious traditions and forms of spirituality involve communities. Below we describe processes that clarify how youth may be socially influenced by religion and spirituality.

Social Context

Religion and spirituality do more than provide a belief system and a moral code. At their best, community members embody religious and spiritual ideological norms and serve as role models for youth (Erikson, 1968). Although religion and spirituality do not exclusively provide these social resources, ample research documents that they may be particularly effective in offering social capital, social support, and mentors. Religious influence is complex and is more thoroughly understood by the network of relationships, opportunities, and shared values common to religious congregations. It is useful to illustrate here a few different conceptions of how religion and religious settings may influence youth.

Social Capital. Social capital models posit that the constructive influence of religion on young people is due to the quantity and nature of relationships it provides. For instance, religious involvement strengthens young people’s access to intergenerational relationships, which are rich sources of social capital (King & Furrow, 2004; Smith, 2003a). Few other social institutions afford the opportunity that religious ones do to build trustworthy cross-generational relationships and give youth direct interaction with sources of helpful information, resources, and opportunities. For example, Benson, Scales, & Syvertsen (2011) provided an account of the resources available through religious and spiritual involvement. Structural equation modeling demonstrated that positive benefits of adolescent religiousness were partially mediated through

developmental resources available to these youth (Wagener, Furrow, King, Leffert, & Benson, 2003). In short, religious involvement provided youth with access to resources such as supportive adults and positive peer relationships, demonstrating the rich social milieu of religious participation.

Social Channeling. Religious institutions offer opportunities for social channeling, the conscious process on the part of adults to steer their children toward particular individuals positioned to discourage negative behaviors and promote positive life practices (Smith, 2003b). Social channeling in congregations promotes spiritual development, academic achievement, and generally positive development (Martin, White, & Perlman, 2001; Regnerus & Elder, 2003). Religious institutions and the relationships they engender also provide forms of social support that are particularly important to adolescent coping, resilience, and well-being. For example, youths' perceptions of social support from religious communities strongly predicted fewer depressive symptoms (Miller & Gur, 2002), whereas youth who perceived that their congregations were critical of them had more depressive symptoms (M. J. Pearce, Little, & Perez, 2003). It appears, then, that religious communities can be sources of social support or stress based on how youth feel about how adults in those communities perceive and treat the youth.

Spiritual Modeling. Based on social learning theory, spiritual modeling refers to emulating another in order to grow spiritually (Oman, 2013). Spiritual modeling emphasizes how adults may socialize young people's religious and spiritual identities to align with the beliefs, norms, and expectations of particular religious groups. A foundation of this approach is the notion that the people with whom we regularly associate shape the behavioral patterns that will be repeatedly observed and learned most thoroughly. Spiritual modeling is often provided by parents or by intentional mentors. Religious and spiritual groups are often intentional about mentoring younger members. For example, the Hindu tradition has gurus and the Christian tradition disciples. Through these relationships, adults connect youth to a larger whole, enabling them to identify with greater religious communities.

Spiritual Scaffolding. We suggest the term "spiritual scaffolding" to emphasize the value of an optimal balance of monitoring, interest, and support for youth in their pursuit of religious and spiritual exploration. Such scaffolding fits well with the sociocultural models described earlier. Exploration requires freedom within reasonable

boundaries to facilitate discovery and scrutiny of spiritual beliefs, engagement, and commitments. Scaffolding conducive to exploration is warm and supportive and needs to provide appropriate distance and autonomy. For example, a study of highly religious parents revealed that parental efforts to control their adolescent sons' problem behavior sometimes backfired whereas such strategies were more effective with daughters (Mahoney & Tarakeshwar, 2005). As noted in the section on family influences, children's religious beliefs are more similar to their parents' when the parents are perceived by children to be warm and accepting. These findings suggest that controlling parenting practices, in conjunction with religious teachings, may be problematic, particularly with adolescent sons, whereas autonomy support and warmth may facilitate religious socialization in sons and daughters equally in adolescence.

In summary, research confirms the importance of the social milieu associated with religion and spirituality. Religious communities teach, reinforce, and support religious and spiritual development and seem to influence other developmental outcomes. As measurement and methods become more sophisticated, research could investigate factors that determine the effectiveness of religious social engagement (e.g., religious attendance, youth group participation, mentoring) and more personal religious and/or spiritual factors. What types of spiritual scaffolding most effectively support healthy development? What religious and spiritual modeling allows for optimal identity exploration and commitment? Longitudinal designs will clarify developmental processes and trends and elucidate person-centered profiles of spiritual development. Finally, we note that our discussion is rather Western in its assumptions of autonomy and exploration as normative processes; in cultures with different presuppositions about human development, such processes may show different trajectories with different outcomes and influences on them.

Transcendent Context

Religion and spirituality provide important ideological resources and social relationships that may nurture adolescent development and also foster valuable opportunities for transcendent experiences. Transcendence—connecting with something beyond the self in ways that bring about deeper awareness of one's self and others—is often intentionally nurtured in religious and spiritual communities (Roehlkepartain & Patel, 2006). Experiences of transcendence can affirm one's own sense of identity and

self-worth through a profound sense of connection to a divine or human other. In a qualitative study on spiritual youth, a Christian boy from Kenya described this sentiment: "Knowing that I'm actually a child of the Most High God, I find that I'm actually a bit special" (King et al., in press). In an affiliated quantitative study of youth, initial findings suggested that awareness of one's inherent value and strength is a common aspect of spirituality among youth from eight different countries (Benson, Scales, et al., 2012). In addition, youth may experience transcendence through connection to religious communities. An American adolescent explained, "Well, we're [the Jews] a people who suffer. That's who we are and what we do. I get my social consciousness, my beliefs, my view of humanity from my Jewish traditions" (King et al., in press).

Ritual, worship, spiritual practices, and rites of passage can promote transcendence. Ongoing rituals may promote awareness of the Divine or human other, as well as confirm youths' places in communities. In the exemplar study, a Hindu boy from India talked about rituals in this way: "It's because of the ceremonies, which are held, and it makes people come together . . . and then sometimes you get a connection with God, a special time with God" (King et al., in press). Rites of passage are unique events that intentionally celebrate and affirm a young person's sense of identity as a religious or spiritual person, in addition to recognizing his or her place within the faith community, which may contribute to the youth's sense of maturity and commitment to something larger than the self.

Spiritual practices may promote experiences of transcendence. Meditation and prayer are spiritual practices, and in a nationally representative study of American youth, Smith and Denton (2005) found that 10% reported doing religious or spiritual meditation in the prior year. Meditation is associated with prefrontal cortex activation and self-regulation of pleasant emotions during cognitive reappraisals (Urry, Roeser, Lazar, & Poey, 2012). Serving the poor may be a spiritual practice because it may allow youths to experience others in different circumstances (e.g., cultural or socioeconomic) from themselves, promote civic engagement (Beyerlein, Trinitapoli, & Adler, 2011; Youniss, McLellan, & Yates, 1999) and teach the value of self-sacrifice. Such experiences are spiritual insofar as they inspire positive action and deepen the sense of connection to what is beyond the self. Of course, many "service" experiences may involve merely "going through the motions" to meet requirements for youth groups or schools, and we would presume that such experiences would not have salutary spiritual effects.

Summary of Religious and Spiritual Influences

Religion and spirituality may spur adolescent development when they offer ideology, social resources, and transcendent spiritual experiences. These facets are not unique to religion and spirituality but are often characteristic of them. Perhaps the most unique aspect of religious and spiritual contexts is the potential for transcendence. Many youth programs and organizations offer ideology and rich social environments; however, not many intentionally promote experiences of transcendence where young people are encouraged and expected to acutely experience an entity beyond themselves in ways that transform their ideological commitments, inspire devotion, and shape generative behavior. Consistent with a relational developmental systems approach, it would be important to learn in future research what characteristics of the experience and context combine with characteristics of youth to result in the greatest spiritual growth. Future research that tests diverse resources within religion and spirituality could reveal how they may be beneficial—or deleterious—to youth. An important question is how the perception by youth of the supernatural is related to their development. In addition, operationalizing different experiences of transcendence would clarify the nature and role of transcendence in young people's lives, especially in relation to contribution to the common good. In the next section, we discuss how religion and spirituality may function in the lives of youth and examine existing research on religiousness and spirituality on positive youth development.

Positive Youth Development and Adolescent Religiousness and Spirituality

Given the role of plasticity and developmental regulation in RDST approaches, the field of positive youth development has emerged (see Lerner, Lerner, Bowers, & Geldhof, Chapter 16, this *Handbook*, Volume 1) and emphasizes what can go right with young people rather than what can go wrong. This emphasis on thriving, rather than the traditional mental health emphasis on pathology, reorients a discussion of youth outcomes to explore optimal development as well as risk factors. However, much of the research in this field is still concerned with risk factors and thus our review attempts to capture both approaches. Several comprehensive syntheses of the literature that examines the dual role of religion and spirituality as protective factors inhibiting risk-taking behavior while promoting well-being, resilience, and thriving have been published

(Bridges & Moore, 2002; King & Benson, 2006; King & Roeser, 2009). Consequently, the following discussion highlights studies that clarify how religion and spirituality function in the lives of adolescents.

A recent meta-analysis of 75 studies (Yonker, Schnabelrauch, & DeHaan, 2012) included measures of adolescent and young adult religiousness and/or spirituality, risk behaviors, well-being outcomes, and personality variables. Using a broad conceptualization of religiousness and spirituality, this analysis was able to assess the relationships between more conventional measures of religiousness (e.g. religious attendance, behaviors, salience) and also more personal measure of spirituality (e.g. searching). Looking across religious and spiritual variables, the authors reported the relatively modest main effect sizes. Specifically, religiousness and spirituality were moderately correlated with risk behaviors (−.17), depression, (−.11), well-being (.16), self-esteem (.11), and the personality traits of Conscientiousness (.19), Agreeableness (.18), and Openness (.14). The direction and magnitude of these findings indicate that religiousness and spirituality seem to have a positive but modest role in the well-being of youth.

Of particular interest was their finding that the conventional measures of religious service attendance and religious salience provided the greatest number of significant associations with beneficial outcomes, compared to measures assessing more personal forms of spirituality. This finding is important and calls into question the relevance of spirituality, at least as represented as a personal quest for the sacred or existential meaning, in predicting behavioral outcomes among adolescents and emerging adults. The NYSR Study similarly found that the minority of U.S. youths claimed to be spiritual and not religious (Smith & Denton, 2005).

The findings described above suggest that religion and spirituality may indeed have positive though modest roles in the positive development of youth. They also indicate that additional work is needed to clarify how religion and spirituality may offer distinct contributions to positive development in adolescence. For example, in line with the discussion in the previous section, these findings highlight the potential importance of the ideological and social context of religions. Attendance and salience do not reveal what particular resources are available to youth through religious participation or in religious commitment. In addition, these findings raise the question of whether transcendence that is experienced within the context of a religious congregation or community functions differently than more individual quests for meaning and transcendence.

Thriving and Positive Youth Development

Research on adolescent spiritual development has evolved alongside the study of positive youth development (i.e., King & Benson, 2006; Lerner et al., 2003, 2008). It is not surprising, then, that there is a burgeoning literature examining relationships between religion, spirituality, and thriving. A noteworthy work on this topic is Warren et al.'s (2012) edited volume, *Thriving and Spirituality Among Youth*, which presents a variety of studies (many reviewed in this chapter) from mixed-method approaches that consider biological, psychological, social, and cultural factors involved with spirituality and thriving. One of the earliest studies to distinguish the roles of religion and spirituality in relation to thriving was conducted by Dowling et al. (2004). In this secondary analysis of the Search Institute's "Youth and their Parents" data set, spirituality was operationalized by: experiencing transcendence, defining the self in relationship to others, having genuine concern for others; religiousness by affiliation and participation in a religious tradition and doctrine; and thriving was defined by prosocial contributions to others. Results indicated that spirituality and religion both had direct effects on thriving, and that religion mediated the effects of spirituality on thriving. This study demonstrated that spirituality has an influence on youth thriving beyond religion and also points to the potentially important and constructive role of religious institutions.

Health. Many studies suggest that religion and spirituality are linked to better adolescent physical health. Church attendance predicts health-enhancing behaviors such as exercise, diet, dental hygiene, and seatbelt use (Jessor, Turbin, & Costa, 1998). In a nationally representative sample of high school seniors, religious youth were more likely to use healthy nutrition, exercise, and rest, and less likely to engage in health-compromising behaviors (Wallace & Forman, 1998). In a sample of Jewish adolescents, Benjamins (2012) found, after controlling for age, gender, and weight, that religious beliefs about health behaviors predicted behaviors related to physical activity. In adjusted regression models, the adolescents who reported that their religious beliefs influenced decisions about being physically active were active more days per week than those who said their religious beliefs did not influence such decisions.

Mental Health and Coping. Religion provides adolescents with resources for well-being, mental health, and coping (Mahoney, Pendleton, & Ihrke, 2006). Those

adolescents who valued church attendance and religion in general experienced fewer feelings of depression, loneliness, and hopelessness (M. J. Pearce, Jones, Schwab-Stone & Ruchkin, 2003; Sinha, Cnaan, & Gelles, 2007). In a longitudinal study on relationships between Australian adolescents' religious sentiment and psychological adjustment (Ciarrochi & Heaven, 2012), religiousness and hope were inversely related to psychoticism and neuroticism at both time points studied. After controlling for personality, structural equation modeling revealed that religious values at Age 17 did not predict improvements in self-esteem at Age 18, but they did predict improvements in hope. In addition, a longitudinal study with adolescent, parent, and teacher ratings of spirituality and religiousness found generally positive associations between Indonesian Muslim adolescents' religion and spirituality and adjustment (Sallquist, Eisenberg, French, Purwono, & Suryanti, 2010). Findings from this study indicated that, in that setting, where culture and religion were closely aligned, spirituality and religious practices were best represented as one latent construct, rather than two distinct constructs. In addition, although findings indicated that religion and spirituality had the predicted positive associations with adjustment and negative associations with maladjustment across a year, there was also some evidence that maladjustment predicted religiousness and spirituality over time, demonstrating the complex nature of the relationship between spirituality and religion and socioemotional functioning.

Religion and spirituality can serve as a resource for better coping when conceptualized in a positive manner (e.g., viewing God as benevolent) (see Mahoney et al., 2006), whereas negative forms of religious or spiritual coping (e.g., feeling punished by God) are often associated with negative outcomes. For example, one study found that Jewish youth used three distinct religious coping strategies. They tended to reframe their difficulties from a spiritual perspective, draw on their Jewish cultural relationships, and pray to God (Dubow, Pargament, Boxer, & Tarakeshwar, 2000). Among youth with diabetes and cystic fibrosis, Reynolds, Mrug, and Guion (2013) found that positive spiritual coping was associated with fewer internalizing and externalizing problems; whereas negative spiritual coping was related to more externalizing problems for youths with diabetes and cystic fibrosis. Among youths with cystic fibrosis, negative spiritual coping was also associated with internalizing problems as well, suggesting that youths with progressive, life-threatening illnesses may be more vulnerable to negative spiritual coping. In study of

youths at religious schools, Carpenter, Laney, and Mezulis (2012) found that negative religious coping significantly moderated the effects of stress on depressive symptoms in a 12-week study, with depressive symptoms being highest among adolescents exposed to high stress who reported high negative religious coping.

Besides protective qualities, religiosity and spirituality may promote positive mental health, although this relation is suggested only tentatively because the literature has been dominated by correlational designs. A positive relation between religiosity and spirituality and psychological well-being has been found in communities with different religious and spiritual traditions. For example, Kelley and Miller (2007) found that, among a diverse sample of U.S. adolescents, life satisfaction was associated with several dimensions of spirituality (e.g., daily spiritual experiences, forgiveness, positive religious coping, congregational support). Spirituality was similarly associated with life satisfaction in Korean-American Catholic adolescents (S. Kim et al., 2013). The strongest predictors of their life satisfaction were daily spiritual experiences (e.g., feeling the closeness of God), followed by their ability to forgive (others and oneself), and their sense of support from their congregations; worship attendance was not related to life satisfaction. In Muslim Kuwaiti adolescents, higher religiosity was associated with greater happiness (Abdel-Khalek, 2007). In another international study, Sabatier, Mayer, Friedlmeier, Lubiewska, and Trommsdorff (2011) found that family and country were linked in complex ways to adolescents' life satisfaction. Specifically, family orientation mediated the relationship between religiosity and life satisfaction. Higher religiosity in youth predicted higher life satisfaction, but this effect was mediated by family orientation; this effect was more salient for youths in countries with higher levels of religiosity (United States, Poland) than in those lower in national importance of religion (France, Germany). This last study illustrates the importance of a social-ecology approach to understanding how religion and spirituality may function in youths' lives.

Academic Achievement. Religious attendance and salience are modestly associated with better academic performance in adolescence. Youth in urban, low-income neighborhoods who are involved with their churches are more likely to stay on track academically than are peers who are not involved in their churches (Regnerus & Elder, 2003), perhaps because church attendance channels youths into relationships with people who support academics,

academic competencies, and commitments. Along those lines, Milot and Ludden (2009) found that adolescents who reported that religion was important in their lives reported less school misbehavior and higher motivation; those with high religious attendance had higher grades. Interaction effects indicated that religious importance particularly enhanced school bonding and self-efficacy in males. McKune and Hoffman (2009) found that adolescents' highest achievement occurred when parents and adolescents reported similar levels of religiosity, whereas the lowest occurred when parents reported high religiosity and adolescents reported low religiosity.

Civic Engagement and Moral Development. Many studies show that religion and spirituality are linked to community service, prosocial involvement, and altruism. Several studies show that more religious youth are significantly more likely to be involved in forms of civic engagement than their less religious peers (see Roehlkepartain et al., 2006). One reason may be, as one study found, that involvement in a faith-based context with a moral and value-laden framework promotes youth dialogue and self-reflection on religious justifications for one's actions (Youniss et al., 1999). In a longitudinal study, Kerestes, Youniss, and Metz (2004) tracked students' religious development from 14 to 18 along four trajectories based on being low or high in religiosity at Ages 14 and 18. Thus, there were four groups: low religiosity at both times, high religiosity at both times, low religiosity at Age 14 and high at Age 18, and high religiosity at 14 and low at 18. Participation in civic activities, extracurricular activities, and willingness to perform volunteer service was highest in the students who were high in religiosity at both times; most interestingly, civic engagement increased dramatically in students who changed from low to high religiosity across the 2 years. In a secondary analysis of data from Wave 1 of the NYSR dataset, participating in a short-term mission trip still increased the likelihood of adolescents' later participation in many forms of civic activity but particularly religious-based volunteering after controlling for demographic background, religiousness, parent religiousness, and attitudes toward the poor (Beyerlein et al., 2011).

Youth educated in Protestant secondary schools were more likely than other youth to continue to volunteer even accounting for potential influences such as parent religiousness, whereas youth schooled at home or in private nonreligious settings were significantly less likely to continue volunteering (Hill & den Dulk, 2013). The

study emphasizes the importance of the religious context through which the service was conducted. A study in the Netherlands found that both Christian and Muslim religious adolescents had more developed democratic competencies than nonreligious adolescents (Grundel & Maliepaard, 2012), again demonstrating the potential positive socializing effects of religion.

In a study on diverse U.S. youth, King and Furrow (2004) found that religious salience and religious attendance were related to altruism and empathy, and that religious youth engaged in volunteer service more often than their less religious peers. Structural equation models revealed that social capital resources (operationalized as social interaction, trust, and shared values with parents, peers, and adults) mediated the effects of religion on these moral outcomes, demonstrating the significance of the religious social context for adolescent moral and civic development. Another study demonstrated through structural equation modeling that youths who reported having a religious identity (assessed by self-report on prototypical descriptors) had more ideological frameworks for life and prosocial concerns for others (Furrow, King, & White, 2004). Adolescent youth nominated for their consistent caring behaviors toward family or community members were found to have salient moral identities and also described religion as an important influence on their moral commitments (Hart & Fegley, 1995). In the adolescent spiritual exemplar study mentioned previously, highly spiritual youth from around the world described that being moral and engaging in acts of compassion, service, justice, and leadership were central to their experience of being spiritual (King et al., in press). In another study on U.S. youth, religiosity was a significant positive predictor of kindness as well as compliant, anonymous, and altruistic prosocial behavior (Hardy & Carlo, 2005); interestingly, associations between religiosity and both compliant and altruistic prosocial behaviors were mediated by kindness, indicating that religious youth may be helpful, caring, and kind for different religious motivations. A later study (Hardy et al., 2012) of 10- to 18-year-olds found that religious commitment was indirectly related to empathy as mediated by moral identity.

In sum, this review suggests that young people who identify as religious or who are involved with institutional religion show greater prosocial behavior on a variety of measures. (In some cases, of course, there can be a "dark side" to youth involvement in religion and we address this point below.) Additional work is needed to clarify what causal mechanisms are at work and whether selection

effects (i.e., prosocial youth seek out religious organizations) explain these links, but one mechanism may be that religious involvement and commitment enhance a sense of moral identity which then leads to more prosocial action.

Identity. Religion and spirituality can contribute to psychosocial identity development and the broader search for purpose, meaning, and fidelity characteristic of adolescence (Damon et al., 2003; King, 2003; Templeton & Eccles, 2006). As noted previously, Lopez et al. (2011) found that Latino/a American and Asian American youths reported higher levels of religious identity than European-American youths even after controlling for ethnic differences in religious affiliation, socioeconomic background, and generational status. Although adolescents' religious identity remained mostly stable across 3 years of high school, changes in ethnic and family identities were linked to changes in their religious identity, suggesting that family, ethnic, and religious identity were closely tied for these ethnic minority youth.

Research using Marcia's (1966) identity status paradigm has yielded less conclusive findings. Youths' church attendance has been positively related to higher identity achievement, yet also foreclosure and identity diffusion have been linked to lower levels of religious importance and more orthodox Christian beliefs (Markstrom-Adams, Hofstra, & Dougher, 1994). Other researchers have shown that intrinsically religiously motivated youth (those who try to internalize and live by their faith) were most likely to have attained identity achievement (Markstrom-Adams & Smith, 1996). However, Hunsberger et al. (2001) found weak associations between religious commitment and achieved identity status in a Canadian sample.

One study of highly religious adolescents (Puffer et al., 2008) found that religious doubt was higher in youths with identity moratorium and achievement, whereas youths lower in doubt were more likely to be in identity foreclosure and diffusion. These findings could mean that youths in moratorium may experience doubt as both cause and effect of their "holding pattern" in identity, whereas youths with achieved identity may be more comfortable questioning their beliefs because they have explored and committed to ideologies. Using latent growth curve modeling and collecting data over four occasions, Hardy et al. (2011) found that late adolescents' change in religious involvement correlated negatively with identity diffusion and moratorium and positively with foreclosure. The results of cross-lagged panel analyses demonstrated effects in the expected direction from involvement to identity as

well as some, but to a lesser extent, reciprocal effects. Overall, the findings provided longitudinal evidence demonstrating that adolescents involved in communities with more cohesive norms and social structure tended to experience greater identity maturity than those who were less involved.

It is not surprising that religion has been shown to have a positive impact on adolescents' development of a sense of personal meaning and purpose (Damon et al., 2003). For instance, in a national probability sample of U.S. adolescents, religious and spiritual commitments were positively associated with their overall sense of meaning and hope for the future (Smith & Denton, 2005). Youths reporting strong religious identity (versus weak religious identity) were more likely to have a meaning framework that added direction and purpose to their lives (Furrow et al., 2004). Adolescents had greater sense of purpose and commitment to personal philosophy when they participated in religious communities (Markstrom, 1999). In addition, a qualitative study found that spirituality and religiosity appeared to guide some adolescents toward character development, service, and life purposes (Mariano & Damon, 2008).

Risk-Taking Behaviors

Ample research shows that religion and spirituality may buffer against risk-taking behavior such as delinquency, substance abuse, sexual activity, substance use, and suicide (see King & Roeser, 2009). Studies have revealed important nuances in the relations between religiousness and spirituality and risk-taking behaviors. For example, Desrosiers and Miller (2008) tested a large mixed-ethnicity sample to tease apart the effects associated with congregational religious factors from more personal spiritual ones; these spiritual constructs were derived from the Brief Multidimensional Measure of Religiousness/Spirituality. Lower alcohol use was predicted by higher scores on subscales of "personal spirituality," which included forgiveness, daily spiritual experience, and positive religious coping and by higher scores on public religion variables, such as perceived support from one's congregation. However, when youths perceived their congregations to be critical of them, they scored higher in anxiety.

In a large study, Salas-Wright, Vaughn, Hodge, and Perron (2012) categorized 17,705 U.S. youths as religious regulars (40.85%), religiously devoted (18.25%), religiously infrequent (23.59%), privately religious (6.55%), or religiously disengaged (10.76%). The religiously devoted group members engaged in less substance use, less fighting, and less theft. To a lesser extent, the religious

regulars were less likely to use substances or fight, whereas the religiously infrequent and privately religious groups only used marijuana less.

Taken together these studies begin to map out different dimensions of religious and spiritual development related to positive and undesirable outcomes. Although causal certainty has not yet been attained, this approach helps us grasp the complex constellation of ideological, social, and transcendent factors involved in youth behavior. The following studies shed additional light on these issues.

Delinquency. The inverse relationship between religiosity and delinquent behavior among adolescents has been well established. For instance, a 2004 study on U.S. teens found that youths who perceived religion as important and who participated in religious activities reported fewer risk behaviors such as smoking, truancy, marijuana use, and depression (Sinha et al., 2007). Similarly, after controlling for sociodemographic backgrounds, higher adolescent religiosity was negatively correlated with attitudes toward delinquent behaviors, association with delinquent peers, and engagement in delinquent behaviors (B. R. Johnson, Jang, Larson, & De Li, 2001). In African American preadolescents who had been previously identified as being moderate to high in aggression, parent religious attendance and preadolescent intrinsic religiosity predicted lower aggression and the relation between preadolescent private religious activities and aggression was moderated by socioeconomic status (Holmes & Lochman, 2012). Frequent exposure to religious content (e.g. reading, watching, or hearing religious information) decreased the likelihood of antisocial practices, witnessing violence, or being the victim of violence (M. J. Pearce, Jones, et al., 2003). In a study of how spiritual beliefs and experiences moderated the effects of exposure to violence in urban African-American adolescents, Shannon, Oakes, Scheers, Richardson, and Stills (2013) found that more frequent daily spiritual experiences and positive religious coping predicted unique variance in life satisfaction and positive mood beyond effects of demographic factors and family support. In a nationally representative sample of youths aged 12 to 18 years, Regnerus and Elder (2003) found that religiosity was related to a slight decrease in delinquent behaviors in early adolescence, disappeared as a predictor of delinquent behaviors during middle adolescence, and emerged as a strong negative predictor in late adolescence.

Substance Use. Studies consistently show a protective role for religion in adolescent drug use. In a national U.S.

sample, religious adolescents were less likely than their nonreligious peers to drink in excess, smoke cigarettes, drink alcohol weekly, or smoke marijuana (Sinha et al., 2007). More recent studies shed light on this consistent relationship. Arguing that religious involvement provides more than social capital, Longest and Vaisey (2008) demonstrated through secondary analysis of the nationally representative longitudinal data from the NYSR that valuing religion predicted abstinence from marijuana use more than mere social control or involvement in religious institutions did. Their findings reveal the complexity of religion as a developmental context by demonstrating that a young person's commitment and value of religion catalyzes the impact of the social norms and relationships available through religious involvement.

Similarly, in another nationally representative sample of 12- to 18-year-olds, Nonnemaker, McNeely, and Blum (2006) found that adolescents' decisions to experiment with smoking tobacco were influenced by their individual practice of religion and by their participation in religious communities. Private religiousness was protective against initiation of regular smoking among nonsmokers. It also protected against initiation of experimental smoking but only when the young people frequently attended religious services or religious youth groups. However, public, not private religiousness predicted reduction and cessation of cigarette use among regular smokers. Taken together, these findings demonstrate the multifaceted influence of religion on young people's lives and make clear that religion must be examined as individual and communal as well as in terms of beliefs, attitudes, and behaviors.

Desmond, Soper, and Kraus (2011) found that three measures of peer influence—peer attitudes, behaviors, and pressure—had weaker effects on substance use in religious adolescents. Thus, even when religious youth are exposed to peers who encourage substance use, religiousness may serve as a protective factor that reduces the deleterious effect of peers. However, one study found that religiousness in heterosexual but not gay, lesbian, and transgendered youth was linked to lower substance use (Rostosky, Danner, & Riggle, 2007).

Sexual Activity. There is no clear link between religiosity and sexual activity. In some studies, adolescents who attended church regularly and valued religion were more likely to assent to the importance of sexual abstinence until marriage than nonreligious peers, even though their beliefs were not always congruent with their actions (Smith & Denton, 2005). Despite the higher prevalence of

beliefs in the importance of sexual abstinence, religious youths were still likely to be sexually active, though to a lesser degree than peers for whom religion was not salient (Lammers, Ireland, Resnick, & Blum, 2000). For example, adolescent identification with religion at the age of 15 predicted delayed sexual activity at ages 15 and 21 (Rostosky, Regnerus, & Wright, 2003). However, Leonard and Scott-Jones (2010) found that no measures of religiousness in 18-year-olds were correlated with age of first intercourse or frequency of sex. Furthermore, a composite score of religious variables did not predict sexual activity, and the students' sexual activity was not predicted by their beliefs regarding premarital sexual activity.

Summary of Outcomes and Adolescent Religiousness and Spirituality

For many outcomes in adolescent behavior (e.g., civic engagement, delinquency), the research paints a clear picture of a positive relationship with adolescent religiosity and spirituality. These links would appear to benefit the adolescent and society. For other outcomes (e.g., sexual activity), the picture is murkier. We believe that the data support the admonition (Pargament, 1997) that, instead of assuming that religion and spirituality have some monolithic relations with outcomes, different dimensions of religiosity or spirituality should be related in different ways to different outcomes in different populations. As we have stated at various points, caution is needed in assuming any simple causal links between religion and outcomes. Finally, we see a clear need for more research closely examining person-environment matches and clarifying how religious and spiritual resources may work together to promote well-being and prevent risk and other challenges common in adolescence.

NEGATIVE ASPECTS OF RELIGION AND SPIRITUALITY

As we have shown, religion and spirituality seem to function as positive resources in child and adolescent development. Many of the previous sections build the argument that connections to the transcendent are beneficial. However, religion and spirituality are multivalent constructs that do not necessarily promote well-being and thriving. Holding negative worldviews and negative perceptions of God can cause significant personal distress (Mahoney et al., 2006; Wagener & Maloney, 2006). For

example, adolescents who attributed their illnesses or stresses to God's punitive nature reported more externalizing problems than those youths who held more positive God images (Carpenter et al., 2012; Reynolds et al., 2013). In terms of social context, some religious connections or spiritual experiences can inhibit personal growth or inculcate a negative sense of identity. For example, cults may elevate the identity and needs of the group while devaluing the individual. Religious environments that impede adolescent exploration, questioning, and expression of religious doubt may thwart optimal development. History tells us that organized religion and some manifestations of transcendence and connectedness have inspired hatred and violence, hate groups, and terrorism. We see how religion can be a negative force when it causes detriment to individual or societal well-being. At this time, there is little psychological evidence available on these processes in children and adolescents.

Thriving is also dependent on a prosocial ideology that nurtures a sense of moral and civic identity (Lerner et al., 2003). If the sources of transcendence do not engender a commitment to contribution to the greater good, they might be negative spiritual influences. For example, environments that use religion to encourage violence through ideology and example do not promote thriving (King, 2008). Religious expressions that encourage an "in-group" and promote suspicion of or hostilities toward others may also undermine positive youth development (Templeton & Eccles, 2006). In addition, experiences of religion and spirituality that promote personal quests for meaning and satisfaction but not contributions beyond the self may not promote thriving and social well-being. The relational developmental systems perspective proposed in this chapter provides a lens through which to understand when religion and spirituality may be deleterious.

Specifically, we advocate for a conceptualization of spirituality that emphasizes beneficial reciprocating relationships between individuals and the many contexts in which they live. Religion or spirituality are not always conducive to thriving and can cause harm to individuals (e.g., religiously inspired child abuse, suicide bombing, oppression) or can cause individuals to do harm to the greater good (e.g., discrimination, terrorism). Just as existing research demonstrates the potential benefits of religion and spirituality, history demonstrates the potential dangers (Oser et al., 2006). Both the good and bad point to the potency of religion and spirituality for children, adolescents, and society.

INTEGRATIVE COMMENTS AND FUTURE DIRECTIONS

The inclusion of this chapter in a research volume of the *Handbook* marks a historical moment for the field of child and adolescent religious and spiritual development. The depth and breadth of empirical work discussed in this chapter demonstrates that the study of the nature and function of religion and spirituality in development is moving from its earlier periphery and neglect to the mainstream of developmental psychology. We hope that this chapter is the most comprehensive and current review of these topics to date. To close, we offer some conceptual perspectives that will, we hope, promote richer understanding of the foci of this chapter.

Relational and Reciprocating Spirituality

A major theme we have emphasized is that religious and spiritual development occurs in relationships—to individuals, communities, nature, all humanity, or the supernatural. This sense of relationality is at the heart of transcendence—moving beyond the self to the discovery of meaning and transformation. Spiritual development stems from the transactions one has with transcendence. A combination of maturational constraints and sociocultural influences will shape this experience. For some the transcendent entity may be a parent, peers, a religious community, a political party, solidarity with all of humanity, or God. It is probable that the more one views the object of transcendence as sacred or meaningful, the greater the influence on the self (King et al., 2013).

This idea is supported by a study of adolescent spiritual exemplars who described various experiences of transcendence—some with God, Allah, nature, and absolute truth, for example. Because these forms of “another beyond the self” were perceived as ultimate and boundless, they had great impact on shaping the beliefs, world-view, identity, commitments, devotion, and actions of these young people. Spiritual development does not stem from *any* positive relationality but those transactions that are marked by transcendence that bring about meaning and beliefs that motivate and sustain a commitment to contributing to self and others.

From this vantage we have proposed revising the term *relational spirituality* (Mahoney, 2010; King et al., 2013) to *reciprocating spirituality*. This nuance emphasizes that spiritual development entails not only relationships but responding and contributing to the greater good. This

bidirectional movement is evident in studies that examine broad conceptualizations of spirituality (Benson et al., 2012; King et al., in press). The studies reviewed in this chapter confirm this sense of reciprocating spirituality. It has been noted that religiousness and spirituality are linked to bidirectional effects between young people and their worlds—whether parents, schools, or God. Religion and spirituality are clearly linked to identity, fidelity, and contribution—especially during adolescence. From this perspective, the heart of spiritual development lies in the interaction between the self and another that informs one’s beliefs and commitments, and motivates the young person to live in a manner mindful of others. Further research is warranted to understand the mechanisms through which transcendence may promote transformation, action, and well-being.

Are Religion and Spirituality Good for Children and Adolescents?

Based on the research we have reviewed, one of the most important conclusions we can offer is this: Simple conclusions about whether religion or spirituality are good or bad for children and adolescents are inappropriate. In contrast, it seems prudent to ask: What dimensions of religion or spirituality are related to which outcomes in which populations, and based on data from which informants? Such a cautious and more meticulous approach is needed in research on religion or spirituality and *children’s* well-being, where the findings are nuanced. However, the literature on religion/spirituality and adolescents provides a more consistent and robust pattern of evidence suggesting that religion and spirituality promote adolescent well-being. At this time, research points to the added benefits of both personal variables such as salience, experiences of transcendence, clearly defined morals and values, as well as more social or institutional variables such as religious participation and social capital. That said, further research is needed to clarify causal directions and under what circumstances the resources available through religion and spirituality are most helpful to young people.

Children’s “Horizontal” Spirituality and Growth Toward Reciprocal Relationality

Some transcendent relationships may be more pertinent or meaningful at different ages. Clearly, children are often *raised* as if they have relationships with the supernatural, and the social contexts they are raised in—family,

church or temple, community, and culture—can certainly strengthen those relationships. Perhaps, though, it is most important that young children develop relations with earthly others—developing “horizontal” spirituality in these social contexts. These experiences may well provide a foundation for the development of reciprocal relationality with that which is “further beyond” the self. This more “vertical” spirituality may become more salient in later childhood and adolescence. We emphasize here that young children’s spirituality is merely different from—not “less than” or “deficient” from—older children’s and adolescents’. The notion that young children’s spirituality would be particularly horizontal and grounded in human relationships seems plausible in light of many theories of development, from object relations and attachment theory to cognitive-developmental theory to faith development theory to psychosocial perspectives, that emphasize early trust as integral to the later development of spirituality and faith.

We believe that this conclusion is preliminary, because relatively little empirical data on children’s relationality with the transcendent is available. With very few exceptions, far more studies of children have measured their parents’ religiousness than have attempted to examine any deep facets of children’s spirituality. In addition, developmental scientists do not typically treat children as experts or authorities on their own experience, a tradition that must change if we are to obtain a deeper understanding of children’s spiritual relationality of all kinds, especially vertical (see Boyatzis, 2011). These constructs call for the development and use of new tools.

Building a Better Mousetrap: Improving Our Methodologies

Throughout the chapter we have offered many suggestions for future research. But a more fundamental issue is methodology. The measures and methods typically used by developmentalists may simply be inadequate for the task of assessing young children’s spirituality. Our methods may offer too crude an approach, too blunt an instrument, to capture the complexity of children’s transcendent relationality; we need better mousetraps. Even if we have faith in our measures, it behooves us to realize that “the map is not the territory.” William James (1902/1982) asserted that one of spirituality’s defining qualities was its “ineffability”—its resistance to being described. This would be all the more true for young children whose

communication abilities may be inadequate for describing transcendent connectedness.

Our understanding of religious and spiritual development would benefit from the use of multimethod approaches (see Tolan & Deutsch, Chapter 19, this *Handbook*, Volume 1). While quantitative approaches have been invaluable for measuring and charting links between constructs, qualitative approaches would help us understand more of the “how and why” of religious and spiritual development. Robert Coles’ (1990) work, *The Spiritual Life of Children*, was a stellar example of a qualitative approach. Coles talked with school-age children from Christian, Muslim, Jewish, and other backgrounds within the United States and outside it—at length, on many occasions, in various locations comfortable to the children. In his attempts to create authenticity and rapport, Coles made clear to them that, in their conversations (not “interviews”), he viewed the children as his teachers. This time-consuming personal approach may not work for all researchers or to answer all questions, nor would it be appropriate for children who are too young or too developmentally challenged for this heavily verbal approach. But it seems likely that the depths of children’s spiritual struggle and search for transcendent meaning would be revealed best using qualitative methods. Gersch’s work on “listening to children” in London is a rich example (Gersch, Dowling, Panagiotaki, & Potton, 2008). In the United States, Jennifer Beste (2012) studied Roman Catholic children’s experience with the sacrament of reconciliation or penance. She spent ample time in the children’s religious settings and acknowledged children as authorities on their own experience. As Beste asserted, “Interviewing children about what they think about their religious experiences, participation in religious rituals, religious communities, and relationship with God may very well alter or even shatter our dominant assumptions about children’s intellectual, religious, moral, and spiritual capacities, allowing us greater understanding of the actual children in our midst” (p. 170).

In their study of adolescent spiritual exemplars, King et al. (in press) traveled around the world to listen to the stories of youths who had been recognized in their communities for having “highly developed” spirituality. As nominated exemplars, these youths were viewed as expert informants who shared their experiences, opinions, and meanings about spirituality and their experiences of the transcendent. Hearing their stories and the meaning of them through in-depth interviews allowed more complex constructs like fidelity and coherence among their beliefs, identity, and actions to emerge. Without their

life narratives, these more recently recognized aspects of spiritual development would not have been evident.

In addition to qualitative methods, more advanced quantitative approaches are needed. Perhaps one of the most valuable new directions would involve using person-centered approaches rather than, or to complement, variable-centered approaches. Longitudinal designs are needed to track these personal intraindividual changes from childhood to adolescence and from adolescence to adulthood; such designs would help us identify the individual, psychological, social, and cultural factors that promote or impede religious and spiritual development and to learn how religious and spiritual development may contribute to development in other domains. Many of the developmental issues raised in this chapter could be elucidated by such longitudinal work. For example, how does the development of metacognition affect the capacity for transcendence? In addition, further research is warranted to understand how and under what circumstances experiences of transcendence bring about personal transformation and fidelity. Does fidelity based on a religious or spiritual identity sustain more generative contributions than other forms of fidelity? Which childhood antecedents of these tendencies are apparent during adolescence? Furthermore, existing research is based on assumptions of normative development. Research is needed to investigate the ontogeny of religious and spirituality development in children and adolescents who experience cognitive or emotional impairments.

Much research is needed to understand the relations between religion, spirituality, culture, and development. For example, do religious or spiritual identities function differently for youth who do not subscribe to the same beliefs and values dominant in their cultural context? Although initial research suggests consistencies across diverse religious groups (see Benson et al., 2012; King et al., in press; Trommsdorff & Chen, 2012), cultural-developmental or indigenous explorations are required to gain a more nuanced understanding of potentially different developmental trajectories among diverse expressions of spirituality or religious traditions.

It is important to note here that, consistent with a relational developmental systems perspective, spiritual development is linked to processes in other developmental domains. This interdependence creates a synergy in which spiritual development contributes to and is influenced by other changes in other developmental domains. Thus, longitudinal designs and methods to measure biological, psychological, social, cultural, and perhaps even

supervenient level variables may clarify the relations between spiritual development and other domains such as cognition, emotion, identity, moral, and civic development. Such research will give further insight into both the nature and function of spirituality in lives of children and adolescents.

It will be helpful if developmental scientists recognize that hundreds of millions of children and adolescents worldwide are raised in faith traditions, engaged and embedded in religious and spiritual communities, rituals, sacraments, scripture, practices, creeds, music, art, and proscribed and prescribed behaviors. In addition we need to learn about children growing up in atheist families or those with no ties to organized religion. An interesting qualitative study of atheist and agnostic scientists at elite U.S. universities (Ecklund & Lee, 2011) explored their plans and goals for involving religion in raising their children. The scientists revealed a striking disinterest in spirituality of any form but these same adults emphasized that exposing their children to religion was important and consistent with their value of free thinking: Involving their children in religion "was a way to expose them to diverse religious ideas so that they (the parents) do *not* inadvertently indoctrinate them with atheism" (p. 736). These groups are intriguing ones to study, and it will be interesting to learn how trajectories differ for children from atheist and religious homes (see Evans, 2000).

Why Not Organized Religion?

Developmental science has plumbed the depths of many microsystems of development, from the family to peer group to school to others. Why not organized religion? Given that so many children worldwide are raised within organized religious traditions, it is curious, if not a serious omission, that religious institutions remain "unexamined crucibles" for children's growth (Roehlkepartain & Patel, 2006). Developmental science would benefit from learning how children and adolescents understand and experience many aspects of the organized religions in which they grow up. These include forgiveness, sin and salvation, distinction between faith and good works, reincarnation, charity, grace and redemption, the Eucharist, karma, confirmation ceremonies, the Trinity, the power of divine figures to heal and punish, and so on. Other questions abound: How do Jewish children make sense of the Passover seder or the broader call for *tikkun olam*, to put together a broken world? What do Roman Catholic children feel and think when they are praying to a saint or statue of the Virgin Mary? How do

Hindu youth make sense of their polytheistic tradition (especially if they live in a monotheistic culture)? How are Muslim children transformed by the *hajj* to Mecca? How do children make sense of their religion's call to help the poor, or the mandates of dietary restrictions? How are children affected by the gendered nature of their gods or gender divisions in religions? What role does youths' cognitive level and family context, for example, play in these matters?

These questions and topics touch on many essential components of world religions. Many of these components are used as mechanisms to socialize children into religious conceptions of the good and moral life, appropriate notions of the self and of others, and to help children cultivate connectedness to the tradition's sacred transcendent entities and the human faith community around the children. We believe these are matters of profound importance, and think that, if more developmental scientists could take the bold step of studying these topics and questions, our field would take enormous leaps in understanding how religion plays a role in children's and adolescents' lives.

CONCLUSIONS

Over a century ago, William James noted that the function of personal religion (which, today, he would probably label spirituality) was to motivate individuals to realize a more satisfying existence: "Not God, but life, more life, a larger, richer, more satisfying life, is, in the last analysis, the end of religion. The love of life, at any and every level of development, is the religious impulse" (1902/1982, p. 453). For James, the core of spirituality at the personal level was "fundamentally about being whole, being wholly human, and being part of the whole that is existence" (King & Roeser, 2009, p. 449). We posit that spiritual development is the domain of development through which individuals experience their wholeness and their uniqueness most fully as they transcend themselves in relation to what is greater than the self and to the extent that they are contributing to the world beyond themselves. Religious development is a more specific domain in which young people undergo qualitative change of increasing differentiation and integration in their understanding and experience of the practices, beliefs, doctrines, and communal practices of their faith community.

To ignore this area of study within human development, which has been the case until recently, is to ignore a central aspect of child and adolescent psychological development and the global challenges of our day and age. Religion

and spirituality are increasingly viewed as basic human capacities, and religious and spiritual development are increasingly visible domains of developmental science. The concept of reciprocating spirituality emphasizes how religious and spiritual development take place through the interactions between young people and the many contexts in which they live. At its best, religious and spiritual development may be able to facilitate both individual and societal well-being. Religion and spirituality potentially offer youth a host of developmental resources from the intrapersonal to social to ideological to transcendent. Let us continue to learn how these dimensions of young people's lives develop and how they may contribute in good ways (and bad) to young people's growth, thriving, and flourishing.

As developmental scientists who have studied religious and spiritual development and the roles of religion and spirituality in children's and adolescents' lives for many years, we understand that some developmentalists may find these constructs too new, unfamiliar, or broad to confidently move toward studying them. However, developmental scientists have always faced the challenge of operationally defining and measuring dimensions of development that we have come to view as central (e.g., infant emotion, attachment, adolescent identity), yet long ago may have seemed amorphous or elusive. It is axiomatic that the more we study developmental phenomena the clearer they become and the more we come to understand them—while at the same time deeper questions and mysteries are revealed. We are confident this will be the way of this field as well, that the more developmentalists examine religious and spiritual development phenomena, the clearer they will become and the more important in development they will seem.

Subject Index

- Abandonment trauma, 267
Abuse, 133–136. *See also* Child abuse; Child maltreatment
Academic achievement, religion/spirituality and, 1006–1007
Academic experiences, academic processes and, 771–772
Academic outcomes, “theory of mind” and, 597–599
Acculturation, mediation/moderation and, 350–351
ACE model, 42
Achenbach System of Empirically Based Assessments (ASEBA), 33, 34
Achievement motivation. *See* Motivation, achievement
Acquiescence, 485
Adaptive calibration model (ACM), 122–123, 125
Adaptive functioning, 290–291
Adaptive phenotypic plasticity, 182
Add Health study, 431, 433, 435, 454
ADHD. *See* Attention-deficit hyperactivity disorder (ADHD)
Adjustment:
 culture and, 188–190
 positive adaptation and, 248–249
 reactivity/inhibition and, 173–174
 school, 225–226
 self-regulation, control and, 174–175
Adolescence:
 aggressive behaviors and, 48, 809–810
 HPA system and, 119–120
 questionnaires and, 34
Adolescence, religious/spiritual development and, 993–1010
 adolescent development and, 993–994
 adolescent religious development, 994–995
 adolescent spiritual development, 995–997
 social ecology of influences and, 997–1002
Adolescent(s):
 employment of, 388–389
 parenting by, 965
Adolescent sexual behavior, 895–902
 coitus, 897–900
 intercourse experiences, quality of, 900–901
 masturbation, adolescent, 895–896
 partnered sexual activity, 896–897
 pregnancy, STIs and, 901–902
Adopted children, 135, 209, 255, 445. *See also* Orphanages
Adrenocorticotropic hormone (ACTH), 72, 108
Adulthood:
 conceptions of, 371–378
 criteria for, beliefs about, 372–373
 emerging, 367–368
 identity, subjective adult (*see* Subjective adult identity)
 transitions, optimal timing and, 373–374
 transition to, employment and, 387
Adult status, beliefs about criteria for, 372–373
Adult transitions, optimal timing and, 373–378
Advantage/disadvantage, cumulative, 369
Adverse childhood experiences (ACE), 536
Adverse Childhood Experiences (ACE) Study, 89–90, 514
Adversity:
 about, 125–136
 economic, 545
 high-risk conditions and, 248
 resilience and (*see* Resilience)
Affect, negative, 348
Affect differentiation, child maltreatment and, 519–522
African-Americans:
 academics and, 331, 333, 342, 343
 child welfare system and, 543
 depression and, 382, 383
 discrimination and, 333, 336, 341, 343, 344, 346, 347, 348, 350, 352, 353, 356
 domestic abuse and, 267
 ethnic identity and, 328, 329
 maltreatment and, 515, 533, 542
 prenatal toxin studies and, 82, 83
 racism and, 345
 religion/spirituality and, 1000–1001
 single mothers and, 422
 social anxiety and, 186
Agency:
 early attributions of, 219
 expectations of, 132
 goal-oriented, 220
Aggression. *See also* Violence
 about, 794–795
 as adaptive behavior, 796–797
 biology of, 812–815, 831
 bullying and (*see* Bullying and victimization)
 bystanders and, 826
 causality/reciprocal processes, 801
 cognitive and emotional functioning and, 815–817
 defined, 795–796
 developmental taxonomies, 800
 development of, 799–802
 epidemiology of (*see* Epidemiology of aggression)
 family functioning and, 821–824
 future directions/challenges, 830–832
 genetics and, 831
 macro-level dynamics/individual development and, 827–830
 moral development and, 817–821
 morality and, 831–832
 origins of, 796–798
 peer relations and, 48, 824–827
 population heterogeneity and, 799–800
 as psychopathology, 797–798
 psychophysiological correlates of, 814
 right and wrong, morality and, 801–802

- Aggression (*cont'd.*)
 sex differences in, 810–811
 state dependence and, 799–800
 subtypes of (*see* Subtypes of aggression)
 time, situational/developmental and, 800–801
 turning points and, 800
- Aggression and antisocial behavior:
 externalizing problems and, 640–641
 perceived discrimination and, 347–348
- Aggressive behavior, defined, 795
- Alcohol. *See* Substance use
- Alcoholics Anonymous (AA), 276
- Allegations, reluctance in making, 492
- Alleles:
 “beneficial,” 210
 “risk,” 214
- Allostatic load (AL):
 allostasis and, 120–122
 chronic stress and, 208
 temperament and, 137
- Allostatic load model (ALM), 120–122, 125
- ALSPAC, 85
- Altruism, 268, 276, 610, 615, 616, 618, 620, 630, 634, 636, 637
- American Indians. *See* Native Americans
- Amnesia, infantile, 468–469
- Amygdala:
 functioning, deficits in, 800
 reactivity of, 138
- Amygdala sensitivity hypothesis in temperamental inhibition, 166
- Androgen exposure:
 2D:4D approach and, 852
 atypical, 850
 CAH disorder and, 853, 858
 early, 859, 861, 866, 867, 872, 875
 at puberty, 860, 864
 variability in, 851
- Androgen insensitivity syndrome (AIS), 850
- Anemia, 76
- Animal research:
 depression and, 139–140
 deprivation of parental care, 114
 early life stress and, 125–126
 epigenetics and, 44
 fairness and, 712, 713
 “farm fox experiment,” 61
 fetal brain development, 74–75
 gendered play, 855
 genotype expressions and, 210
 HPA axis and, 76, 123
 social imitation and, 218
 stress/stressors and, 138–139, 183, 212–213
 temperament and, 155–156
 testosterone and, 848, 849
- Antecedents, educational attainment, 398–404
 friendships, 400–401, 409
 institutional agents, relationships with, 402–403
 mentoring relationships, 402, 409
 parental factors, 398–399
 school structures, 403–404
- Antero-ventral periventricular nucleus (AVPV), 849
- Anti-immigrant propaganda, 349
- Antisocial behavior, 800. *See also* Aggression and antisocial behavior
- Antisocial personality disorder, 531
- Anxiety:
 attachment figure and, 118
 cardiovascular measures and, 169
 CRH levels and, 89
 environmental insults during pregnancy and, 76, 82
 inhibition and, 177, 180
 losing a parent during childhood and, 128
- maternal, 128, 130, 131
 oxytocin (OT) and, 114
 parental involvement and, 178
 peer relationships and, 181
 pregnancy-specific, 88, 90, 130
 prenatal maternal, 72, 75
 serotonin and, 170
 social situations and, 137, 172
- Anxiety disorders:
 comorbidity and, 141
 development of, 137
 temperament and, 137
- Approval seeking, 483
- Arguments, violent, 132
- Aristotle, 57, 59
- ASD. *See* Autism spectrum disorders (ASD)
- ASEBA. *See* Achenbach System of Empirically Based Assessments (ASEBA)
- Asian-Americans:
 academics and, 397, 403
 collectivistic orientation of, 372
 discrimination and, 352, 353
 ethnic identity and, 330
 religion/spirituality and, 1001
- Aspirations, 390–391
- Assessment, temperament, personality and, 163–165
 autonomic measures, 164–165
 behavioral observations, 163–164
 electrocortical measures, 164
 neuroendocrine measures, 165
 physiological measures, 164–165
 subjective reports, 163
- Assisted reproduction families, 437–446
 about, 437–438
 donor conception families (*see* Donor conception families)
 “high-tech” families (*see* IVF and ICSI families)
- Assisted reproductive technologies (ART), 87–88, 437
- Association of Intellectual and Developmental Disabilities (AAIDD), 290
- At-risk children, 215, 253, 254, 258, 270–271
- Attachment:
 aggression and, 821–822
 child maltreatment and, 525
 infancy and, 943
 intervention studies and, 255
 low-income children and, 254
 as protective force, 252–254
 security of, 216, 546 (*see also* Security of attachment)
 sensitive periods in early, 253
 theory, 420
- Attachment and Biobehavioral Catch-Up (ABC), 496, 546–547
- Attachment-based interventions in schools, 261–262
- Attachment relationships:
 child maltreatment and, 524–525
 legal contexts and, 481–482
 mental working models of, 226–228
