In this study, Fairburn, Cooper, et al. (2009) compared CBT-Ef with CBT-Eb and a waiting-list control condition in the treatment of 154 patients with BN or EDNOS. Consistent with previous research on BN, the waiting-list control condition showed little change. Both forms of CBT-E resulted in significant improvement at post-treatment and at a 60-week follow-up. More than half of the overall sample had a level of eating disorder psychopathology, assessed via the Eating Disorder Examination (EDE; Fairburn & Cooper, 1993), less than 1 standard deviation above the community mean. The rate of remission from both binge eating and purging in the BN patients was 45.6% at follow-up, a figure higher than that obtained with the earlier version of CBT (e.g., Agras et al., 2000). Treatment outcome was comparable for both BN and EDNOS patients. In a novel finding, exploratory moderator analyses indicated that CBT-Eb, as predicted, appeared to be more effective than CBT-Ef with patients characterized by at least two of the hypothesized maintaining mechanisms of mood intolerance, perfectionism, low self-esteem, and interpersonal difficulties. By contrast, the reverse pattern was obtained in the remaining patients. These promising results suggest that CBT-E is broadly effective with a range of eating disorders other than BN itself.

## Binge Eating Disorder

The provisional criteria for BED in DSM-IV characterize this disorder as recurrent binge eating, but without the regular use of inappropriate compensatory weight control methods that are required in BN. Several behavioral indicators are described by the diagnostic criteria to help evaluate a patient's subjective sense of loss of control during binge episode, in addition to the requirement that the overeating consists of large quantities of food. The criteria also require that the binge eating is associated with emotional distress, occurs regularly (at least 2 days per week), and is persistent (at least 6 months). Unlike AN and BN, there is no diagnostic criterion requiring undue influence of body weight or shape on self-evaluation; however, a growing body of research has shown that patients with BED have similar levels of overvaluation as those with BN, and that overvaluation signals a more disturbed variant of this disorder (Goldschmidt et al., 2010; Grilo et al., 2008). On the basis of these findings, some experts have recommended that the overvaluation of body weight and shape be included as a diagnostic specifier for BED in DSM-5 (e.g., Grilo, Masheb, & White, 2010).

Binge eating disorder has several features in common with other eating disorders, such as binge eating and overvaluation of body weight and shape (see earlier discussion). Evidence for BED as a distinctive and valid clinical category comes from well-documented differences between individuals with BED and other eating disorders. Compared with other eating disorders, BED is marked by less dietary restraint, a significant association with obesity, different gender and racial distributions, and diagnostic stability and response to treatment (Wonderlich, Gordon, Mitchell, Crosby, & Engel, 2009). Although closely linked with obesity, BED differs from weight-matched individuals without BED on several counts. For example, individuals with BED consume more calories in single eating episodes, have significantly more eating disorder psychopathology and psychiatric comorbidity in general, and have a lower quality of life (Wonderlich et al., 2009). The prevalence of BED (estimated to be roughly 3% of adults) also appears higher than the prevalence documented for AN or BN.

## Comorbidities

Individuals with BED have multiple comorbid problems, including depression, anxiety, personality disorders, and low self-esteem. The severity of co-occurring problems is often comparable to that found in AN and BN (Striegel-Moore & Franko, 2007; Wonderlich et al., 2009).

## Treatment Efficacy

### SPECIALTY PSYCHOLOGICAL TREATMENT

#### Cognitive Behavior Therapy

Research studies evaluating CBT for BED to date have typically been based on the Fairburn et al. (1993) manual developed for BN. The NICE (National Institute for Clinical Excellence, 2004) guidelines specify that CBT is the treatment of choice for BED, and this clinical recommendation was assigned a methodological grade of A, indicating strong empirical support from RCTs. In general, studies have shown that manual-based CBT results in remission rates in binge eating of between 55% and 70% at post-treatment that are generally well-maintained at a 1-year follow-up. The treatment also reliably results in a reduction in specific eating disorders and general psychopathology (Wilson et al., 2007).

Cognitive-behavioral therapy has proved more effective than pharmacological treatments for the treatment of BED. For example, a study by Grilo, Masheb, and Wilson (2005) found that CBT was significantly more effective than either fluoxetine or pill placebo, with remission rates of 61% for CBT plus pill placebo compared with 22% for fluoxetine. Using a different design, Devlin et al. (2005) showed that a combination of CBT with behavioral weight loss (BWL) treatment was more effective than adding fluoxetine to BWL.

Cognitive-behavioral therapy has also been shown to be superior to BWL treatment. A well-controlled study by Grilo et al. (2007) found that, at post-treatment, CBT was associated with a significantly greater binge eating remission rate (60%) than was BWL (31%). At the 1-year follow-up, the rates were 51% and 36%, respectively. Munsch et al. (2007) similarly showed that CBT for obese patients with BED was significantly more effective than BWL in producing remission from binge eating.

#### Interpersonal Psychotherapy

Two studies have shown that group manual-based IPT was as effective as CBT delivered in a group format (Wilfley et al., 1993, Wilfley et al., 2002). In the second of these studies, Wilfley et al. (2002) obtained remission rates of 79% and 73% for CBT and IPT, respectively, at post-treatment, and 59% and 62% at a 1-year follow-up. Both treatments produced significant reductions in eating disorder and associated general psychopathology. The equivalent effects of these two treatments for BED contrasts sharply with the findings observed among patients with BN (Agras et al., 2000). The NICE (2004) guidelines assigned a grade of B to IPT, presumably because of the limited empirical support for this type of treatment in comparison to the large number of studies on manual-based CBT by diverse groups of investigators in different countries.

In the largest controlled outcome study to date, Wilson, Wilfley, Agras, and Bryson (2010) compared 20 sessions of individual IPT to 20 sessions of BWL and to ten sessions of guided self-help based on cognitive-behavioral principles (CBTgsh). No differences were evident at post-treatment, but at 2-year follow-up both IPT and CBTgsh were significantly more effective than BWL in eliminating binge eating. A noteworthy finding was the very low attrition rate in IPT (7%) versus the other treatments (28% and 30%, respectively). Exploratory moderator analyses indicated that BWL fared less well than IPT in patients with low self-esteem at the 2-year follow-up. Interpersonal therapy was also superior to CBTgsh in patients with low self-esteem and high global EDE scores. The finding that global

EDE scores moderated treatment outcome is consistent with a latent class and latent transition analysis of the BED patients, in which four different latent classes were observed within the sample, with two of the classes showing a differential treatment response (Sysko, Hildebrandt, Wilson, Wilfley, & Agras, in press). In this analysis, IPT was the most effective treatment for those patients characterized by the most severe specific eating disorder psychopathology.

*Guided Self-Help*

Similar to that previously described for BN, guided self-help based on the CBT model for BN and BED (CBTgsh), and using the Fairburn (1995) manual, has been studied extensively in the treatment of BED. The NICE guidelines assigned CBTgsh a methodological grade of B, recommending that it might be a good first-step treatment for many patients. Subsequent studies, however, have provided evidence that CBTgsh might be as effective as specialty psychological treatments, at least for a specific subset of patients. Specifically, Grilo and Masheb (2005) compared CBTgsh (Fairburn, 1995) to a guided-help program for weight loss derived from Brownell's (2000) LEARN manual and to a control condition, which consisted of self-monitoring of eating. CBTgsh resulted in a 50% remission rate, compared with less than 20% in either of the comparison conditions. A second study by Grilo, Masheb, and Salant (2005) replicated the efficacy of CBTgsh in eliminating binge eating in obese BED patients. In the Wilson et al. (2010) multisite study referenced earlier, ten sessions of CBTgsh administered by beginning clinical psychology graduate students with little therapy experience proved to be as effective as 20 sessions of IPT delivered by intensively trained and supervised doctoral-level clinical psychologists both at post-treatment and at 2-year follow-up. No differences between the treatments were observed on the EDE subscales or measures of depression and self-esteem, and both treatments were superior to BWL.

CBTgsh has also been evaluated in the treatment of patients with recurrent binge eating among a population of members of a large Health Maintenance Organization in the United States (Striegel-Moore, Wilson, DeBar et al., 2010). In a sample of 123 participants, 55 were diagnosed with BED, and 56 reported binge eating once a week on average for the previous 3 months. CBTgsh was significantly more effective than treatment-as-usual (TAU) in eliminating binge eating and in producing improvements on specific measures of eating disorder psychopathology,

depression, and quality of life at a 1-year follow-up. CBTgsh in this setting was very acceptable to participants and significantly more cost-effective than TAU (Lynch et al., 2010).

*Weight Loss in Overweight and Obese Binge Eating Disorder Patients*

As summarized earlier, specialty psychological therapies and CBTgsh are broadly effective in eliminating binge eating, reducing associated psychopathology, and improving quality of life. Neither, however, is effective in reducing body weight. Patients who cease binge eating by post-treatment typically show a statistically significant weight loss compared with those who continue to binge, although the magnitude is modest (Wilfley et al., 2002; Wilson et al., 2010).

The evidence is mixed as to whether the presence of BED predicts less short-term weight loss in obesity treatments (Wonderlich et al., 2009). Early studies of BWL treatment produced results ranging from no effect to a negative impact, but these studies were limited by small sample sizes and less-than-optimal assessments of binge eating. Recent studies have found that BWL results in disappointingly small weight losses compared with studies of obese non-BED patients (Grilo et al., 2007; Wilson et al., 2010). A meta-analysis in which studies of BED patients were matched with other studies of obese non-BED individuals showed that the presence of BED resulted in significantly less weight loss (Blaine & Rodman, 2007). A limitation of this meta-analysis is that BED and non-BED samples were not directly compared in the same study (Wonderlich et al., 2009).

PHARMACOLOGICAL TREATMENT

A variety of medications have been used in the treatment of BED, including antidepressants (e.g., fluoxetine), antiobesity drugs (e.g., sibutramine), and antiepileptic medications (e.g., topiramate). As described previously, CBT has been shown to be significantly more effective than fluoxetine in two well-controlled RCTs (Devlin et al., 2005; Grilo et al., 2005). A recent, comprehensive meta-analysis of available studies of the pharmacological treatment of BED indicated that medications do not differ from pill placebo in terms of attrition, but are significantly more effective in producing remission from binge eating (48.7% vs. 28.5%) and short-term weight loss, although the latter is minimal (Reas & Grilo, 2008). Combining medication with psychological treatment does not enhance outcome in terms of binge eating, although two specific drugs (orlistat and topiramate) may enhance weight loss to a modest degree.

Perhaps the most striking conclusion of the Reas and Grilo (2008) meta-analysis is the total absence of any long-term, controlled evaluation of the effects of pharmacological treatments. Given the absence of long-term data, and the evidence that both CBTgsh and specialty psychological therapies reliably result in sustained reductions in binge eating, pharmacological treatments cannot be recommended as a first-line therapy for BED.

## PREDICTORS AND MODERATORS OF TREATMENT OUTCOME

Manual-based CBT for BED produces more successful outcomes in the treatment of eating disorder symptoms for patients with BED than BN. Nevertheless, there is still room for improvement. Identifying predictors and, ideally, moderators of therapeutic change would allow for the development of more targeted and possibly effective treatments. No evidence of reliable pretreatment or of either predictors or moderators of pharmacological treatments are currently available; however, research has identified two pre-treatment predictors of outcome. One is negative affect, as measured by the Beck Depression Inventory (BDI; Beck & Steer, 1987). Higher ratings of negative affect resulted in worse outcomes for individuals receiving CBT (Stice et al., 2001) or CBTgsh (Masheb & Grilo, 2008; Wilson et al., 2010). In the latter two studies negative affect predicted the reduction in the frequency of binge eating episodes but not remission, the more important index of improvement. A second predictor is overvaluation of body shape and weight as measured by the EDE (Fairburn & Cooper, 1993). Higher scores on this variable have been shown to predict lower reductions in the frequency of binge eating in CBTgsh among patients with BED, and overvaluation of shape and weight (Masheb & Grilo, 2008) and significantly lower remission rates not only in CBT but also in BWL (Grilo, Masheb, & White, 2010).

Neither negative affect nor the overvaluation of body shape and weight moderate treatment outcome (Grilo, 2009), and the only evidence to date for moderators is based on exploratory analyses that found both self-esteem and a composite score of the EDE subscales moderated treatment outcome at the 2-year follow-up (Wilson et al., 2010). Low self-esteem undermined the effects of BWL in eliminating binge eating, but had no influence on IPT. CBTgsh was unaffected by low self-esteem in patients with low global EDE scores, but was less effective in interaction with high EDE scores. The finding that global EDE moderated treatment outcome is consistent with a latent class analysis of the same sample of patients. Sysko et al. (in press) found four different latent classes within the sample, and the class characterized by the most specific eating disorder psychopathology (i.e., most severe objective and subjective bulimic episodes and highest body shape and weight concerns), which would be reflected in high global EDE scores, responded the most to IPT. CBTgsh was the most effective treatment for the "pure" binge eating class. Should these findings be replicated, they would have important implications for future treatment. It may be that CBTgsh is the treatment of choice for that subset of BED patients with symptoms defined mainly by binge eating. However, those patients with severe associated eating disorder psychopathology, such as body shape and weight overconcern, would benefit from a specialty therapy like IPT or CBT. CBT-E has yet to be applied to BED patients, but as Fairburn, Cooper, and Waller (2008) propose, it might be well-suited to "those patients with obesity who have prominent eating disorder psychopathology such as mood-triggered eating or extreme concerns about appearance" (p. 254).

### RAPID RESPONSE

Similar to the findings regarding early response for BN, rapid response to treatment—defined as a quick and clinically meaningful change in symptoms—has been found to be a clinically significant predictor of treatment outcome in CBT and pharmacological therapy for patients with BED. Grilo et al. (2006) found that individuals experiencing a rapid response, defined by a 65% reduction in binge eating by the fourth week of treatment, had a different prognostic significance and time course across different treatments for BED. Rapid response predicted remission rates of 73% for manual-based CBT versus 46% for fluoxetine. Whereas rapid response to CBT predicted improvement that was sustained over the remaining course of treatment, in the fluoxetine condition some of the improvement eroded. Clinically important findings were also observed for patients without a rapid response to treatment. In CBT, patients without a rapid response showed a subsequent pattern of continued improvement throughout treatment, although it did not reach the high levels of improvement achieved by the rapid responders. Clinically, these findings suggest that continuing CBT for patients who are not rapid responders—rather than switching to another intervention—may be best. Consistent with this

conclusion, Eldredge et al. (1997) found that extending CBT for initial nonresponders was an effective option. In the case of antidepressant treatment, the absence of a rapid response to antidepressant pharmacotherapy for BED suggests that the patient is quite unlikely to eventually respond to that medication and may suggest the need to try a different intervention. Masheb and Grilo (2007) similarly found that rapid response predicted greater improvement in overall eating psychopathology and depression in CBTgsh and guided self-help BWL (BWLgsh) for obese BED patients. In terms of binge eating, however, patients receiving CBTgsh, but not BWLgsh, did equally well regardless of whether they experienced rapid response.

### Future Directions

Reliably effective treatments for BED have been developed. Nonetheless, a significant minority of patients do not respond. A research priority must be the identification of moderators of treatment outcome—what specific treatment works for which subgroups of patients. Preliminary findings indicate that CBTgsh may be recommended as the first-step treatment for a majority of BED patients, but that specialty psychological treatments, such as IPT or full CBT, might be required for patients with more complex eating disorder psychopathology. The efficacy of CBT-E for BED remains to be evaluated. As a robust predictor of treatment outcome, rapid and early response will need additional experimental analysis, so that it is possible to capitalize on its implications for treatment planning. Finally, as with the other eating disorders, improved dissemination and implementation of evidence-based psychological treatments remains a priority.

Reviews of the BED literature typically conclude with calls for more effective means for producing weight loss. The problem, however, extends beyond just obese patients with an eating disorder. Effective treatments for producing long-term weight loss do not exist. The majority of individuals who lose weight in the short-term eventually relapse (Cooper et al., 2010). As this holds true for obese individuals free of any psychiatric comorbidity, it must be expected that obese patients with BED will fare at least as poorly. Future research must focus on improved methods for preventing and managing obesity in general.

### Conclusion

The next version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) is scheduled for publication in 2012. Modest (e.g., Attia & Roberto, 2009; Peat, Mitchell, Hoek, & Wonderlich, 2009; van Hoeken et al., 2009; Wilson & Sysko, 2009) and more substantial changes (e.g., Wonderlich et al., 2009; Walsh & Sysko, 2009) to the existing classification of eating disorders have been proposed. It is not yet known what alterations, if any, will be made to the nosology of eating disorders in DSM-5; however, it is clear that regardless of the specific form of the diagnoses, treatment research for any of these disorders should be a priority. For patients with AN, an effective treatment must be identified. Among individuals with BN or BED, the dissemination of existing effective treatments is needed. Recently, means for aiding treatment dissemination have been developed through innovative computer-assisted technology, including telemedicine (Mitchell et al., 2008) or Internet-based CBT (Andersson, 2009). Finally, as clinicians in the community begin to implement manual-based CBT for individuals with BN or BED more frequently, researchers will be able to obtain additional information regarding the generalizability of RCTs and better understand how existing manuals should be adapted and changed (Wilson, 2010a).

# Alcohol Use and Alcohol Use Disorders

Kenneth J. Sher, Julia A. Martinez, *and* Andrew K. Littlefield

**Abstract**

Alcohol use disorders (AUDs), alcohol abuse and alcohol dependence, are among the most prevalent mental disorders in the United States and elsewhere. Controversy exists with respect to the optimal way of classifying these disorders and the boundaries between normal and abnormal drinking. Although AUDs can occur over much of the life span, from an epidemiological perspective it is largely a disorder of adolescence and young adulthood. Many who experience AUDs "mature out" of them as they age and acquire adult roles and, perhaps, as a function of normal personality. However, a significant minority of individuals fails to mature out, and some individuals develop AUDs later in adulthood. There are a number of etiological pathways associated with developing an AUD; foremost among them is a pathway shared with other externalizing disorders such as conduct disorder, adult antisociality, and other substance dependence. However, pathways associated with internalizing disorders and with individual differences in alcohol effects also exist. All of these pathways likely involve major genetic and environmental determinants. Given the etiological pathways that have been documented, it is not surprising that AUDs are often comorbid with other mental disorders. A number of approaches to the prevention and treatment of AUDs have been developed that are effective. Additionally, basic research is setting the stage for further advances in both behavior and drug treatments of AUDs.

**Key Words:** Alcohol abuse, alcohol use disorders, assessment, comorbidity, epidemiology, etiology, personality, substance use disorders, treatment

## Alcohol Use and Alcohol Use Disorders

Alcohol use disorders (AUDs) are among the most prevalent mental disorders in the United States. They are associated with significant consequences for the drinker, his or her friends and family, employers, the community, and the nation. Additionally, AUDs are also frequently associated with other psychiatric and medical conditions and, thus, their consequences can be far reaching.

## Definitions of Alcohol-related Concepts
### Alcohol Use Disorder

The *Diagnostic and Statistical Manual of Mental disorders*, fourth edition, text revision (DSM-IV-TR; American Psychiatric Association, 2000) defines two major classes of substance use

disorders (SUDs): substance dependence and substance abuse. The diagnostic criteria for AUDs follow those for SUDs more generally with *alcohol dependence* defined as "a maladaptive pattern of use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following symptoms occurring at any time in the same 12-month period: (1) tolerance, (2) withdrawal, (3) the substance is often taken in larger amounts or over a longer period than intended, (4) a persistent desire or unsuccessful efforts to cut down or control substance use, (5) a great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects, (6) important social, occupational, or recreational activities are given up or reduced because of substance use, and

(7) the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance" (p. 197). The DSM-IV defines alcohol abuse as "a maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by one (or more) of the following occurring within a 12-month period: (1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home, (2) recurrent substance use in situations in which it is physically hazardous, (3) recurrent substance-related legal problems, and (4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance" (p. 198). According to the DSM-IV's diagnostic hierarchy, individuals who meet criteria for alcohol dependence do not receive diagnoses for alcohol abuse, implying that dependence is the more severe of the two AUDs.

The abuse/dependence distinction made its debut in the third edition of the DSM (DSM-III, American Psychiatric Association, 1980), reflecting, in part, the distinction introduced by Edwards and Gross (1976) between the alcohol dependence syndrome and alcohol-related disabilities, with the former construct reflecting the degree to which alcohol has come to dominate the drinker's life as evidenced by narrowing in the drinking repertoire, salience of drink-seeking behavior, increased tolerance to alcohol, repeated withdrawal symptoms, relief or avoidance of withdrawal symptoms by further drinking, subjective awareness of compulsion to drink, and/or reinstatement after abstinence. In contrast, the alcohol-related disabilities construct reflected the degree to which the drinker experienced a range of problems such as physical ailments (e.g., developing cirrhosis), occupational impairment, marital discord, and hazardous use (e.g., drinking and driving). Unlike Edwards and Gross's conceptualization of the dependence syndrome and alcohol-related disabilities as distinct but related dimensions, the categorical diagnostic approach embraced by the DSM to date viewed abuse and dependence as mutually exclusive categories with a dependence diagnosis representing the more severe condition and precluding the ostensibly less severe abuse diagnosis. In the DSM-III, alcohol dependence was conceived as physiological, indicated by tolerance or withdrawal and reflecting "neuroadaptation." This narrow concept of dependence was broadened in the revised criteria of DSM-III (DSM-III-R; American Psychiatric Association, 1987) and the DSM-IV to include behavioral signs of dependence such as loss of control (i.e., drinking in larger amounts or longer than intended), inability to abstain, and other symptoms reflecting compulsive use.

Despite the widespread acceptance of the abuse/dependence distinction since its introduction, accumulating data are challenging the validity of this distinction. For example, item-response theory (IRT) based analyses which conceptualize diagnostic criteria as indicators of a latent trait of AUD demonstrate that some dependence criteria (e.g., tolerance, impaired control) are prevalent and thus statistically "less severe" than are some abuse criteria, which are comparatively rare (e.g., legal difficulties; Kahler & Strong, 2006; Saha, Stinson, & Grant, 2007). These results are inconsistent with the notion that abuse is a less severe condition than dependence and may be prodromal to it. Moreover, although some early factor analyses suggested that abuse and dependence items formed statistically distinct (albeit highly correlated) factors (e.g., Hasin, Muthén, Wisnicki, & Grant, 1994; Muthén, Grant, & Hasin, 1993), more recent data further suggest either unifactorial solutions (e.g., Proudfoot, Baillie, & Teeson, 2006) or two factors that do not clearly map onto abuse and dependence (e.g., Harford & Muthen, 2001). Additionally, the DSM-IVs requirement of three or more dependence symptoms for a diagnosis of dependence but only one abuse symptom for a diagnosis of abuse leads to the problematic situation where someone who exhibits a pattern of hazardous use (which might reflect little more than a heedless drinking style) would meet criteria for an AUD but not someone who might experience one or two relatively severe dependence symptoms (Pollock & Martin, 1999). These "diagnostic orphans" pose a dilemma since they are likely more severe than individuals who have the single abuse criterion of hazardous use but, unlike those individuals, would not qualify for an AUD diagnosis.

The psychometric (i.e., IRT) analyses cited earlier indicate that DSM-IV AUD criteria oversample moderate levels of pathology and are less accurate in scaling mild and severe levels of alcohol-related problems. Those interested in improving diagnosis of AUDs must contend with findings questioning the empirical basis for the abuse/dependence distinction as well as the dimensional nature of AUDs, which are clearly graded in intensity from those who are high functioning and developmentally limited (Sher & Gotham, 1999; Zucker, 1987; Zucker, Fitzgerald, & Moses, 1995) to those with severe

and morbid courses. For these and other reasons, the validity of the DSM diagnostic system is coming under increasing criticism (Martin, Chung, & Langenbucher, 2008).

Martin et al. (2008) identify a number of additional problems regarding the DSM-IV substance use disorder criteria (including AUD criteria). Specifically, they note that the abuse category does not have a clear conceptual core and does not meet traditional standards for the concept of mental disorder (e.g., Spitzer, Endicott, & Robins, 1978; Wakefield, 1992) that is based, in part, upon the notion of dysfunction. For example, it is not immediately clear why repeated hazardous use (a behavior that would qualify someone for a diagnosis of alcohol abuse in DSM-IV) is necessarily indicative of a *disorder* as opposed to, say, mere *heedlessness*. They also note that there is a lack of empirical distinctions between exclusive criteria for substance abuse and dependence, and that these diagnostic algorithms produce unequal diagnostic coverage of those with similar levels of substance-problem severity.

Martin et al. (2008) suggested several solutions, including (1) abandoning the category of substance abuse and defining a single category of substance dependence using revised DSM-IV SUD criteria and new symptoms (e.g., consumption criteria); (2) revising the definition of tolerance to require a minimum level of use in addition to the change-based definition; (3) defining the physiological features subtype of substance dependence by withdrawal only; (4) emphasizing specificity over sensitivity by removing mild alcohol withdrawal subcriteria (e.g., anxiety and vomiting) and/or increasing the threshold for symptom assignment; (5) clarifying that frequency and duration of use is due to compulsive behavior and not merely due to social reasons; (6) splitting quit/cut down into two separate criteria; (7) removing hazardous use and legal problems as diagnostic criteria; (8) integrating categorical and dimensional approaches to diagnosis; and (9) grouping SUDs with an externalizing spectrum of psychopathology that includes other substance use disorders, conduct disorder, antisocial personality disorder, and closely related traits and conditions (e.g., Krueger, Markon, Patrick, & Iacono, 2005). Regardless of the merits of such extensive changes, the new DSM-5 AUD (and other SUDs) look quite similar to the DSM-IV version with a few important exceptions.

Specifically, DSM-5 abandoned the abuse/dependence distinction in favor of a single alcohol use disorder diagnosis that includes in its criteria set symptoms of both DSM-IV abuse and dependence. Major changes include the inclusion of craving (long considered a hallmark symptom of dependence but not included in DSM-IV) and the dropping of legal problems (a DSM-IV abuse symptom that has proven to be problematic). Under DSM-5, at least two of the eleven symptoms are required to make a diagnosis. (In DSM-IV, one abuse symptom was sufficient to make a diagnosis of substance abuse and, therefore, SUD.) Although DSM-5 SUD is ostensibly more severe at threshold than DSM-IV SUD in requiring a minimum of two symptoms, there is still concern that the new criteria remain too liberal and will yield artificially high prevalence rates (Martin, Steinley, Vergés, & Sher, 2011) with most diagnosed cases manifesting low levels of pathology. In addition, a number of critics (e.g., Martin, Sher, & Chung, 2011) do not believe that one of the most prevalent symptoms of SUD, hazardous use, should be included as a diagnostic criterion since it fails to resolve substance specificity (i.e., repeated heedless use that could reflect little more than incautious behavior that is simply being manifested by use of the substance but is not specific to it). That is, why should there be a "hazardous use" symptom of SUD but other hazardous behaviors (e.g., reckless driving) are not similarly pathologized? Despite these concerns on conceptual and clinical grounds, the new criteria were designed, in part, to yield prevalence rates roughly comparable to DSM-IV and, thus, may show little practical difference in epidemiology.

### Alcohol Consumption

It is important to note that current diagnostic criteria for AUDs fail to include direct measures of alcohol consumption despite health concerns based on alcohol consumption patterns. For example, the US government has recently, and for the first time, provided safe drinking guidelines as part of their Dietary Guidelines for Americans, 2005 (US Departments of Agriculture and of Health and Human Services, 2005). These guidelines discourage levels of consumption that exceed two drinks per day for men and one drink per day for women. Current estimates suggest that, among past-year drinkers 18 years of age and older, 46% of men and 32% of adult women in the United States exceed these safe drinking levels and are appropriate targets for interventions (Dawson, Grant, & Li, 2005).

In addition, there has been increasing concern in recent years over drinking patterns associated

with high levels of consumption on drinking days (i.e., "binge" drinking). The National Institute of Alcohol Abuse and Alcoholism (NIAAA, 2004) defined binge drinking as "a pattern of drinking alcohol that brings blood alcohol concentration (BAC) to 0.08 gram percent or above. For the typical adult, this pattern corresponds to consuming 5 or more drinks (male), or 4 or more drinks (female), in about 2 hours," noting that such patterns represent significant risk for the drinker and society. These consumption-based limits have not been included in formal diagnostic algorithms, although psychometric analyses suggest that their inclusion would be useful in measuring a latent construct of AUD that has better lower-end resolution than the DSM-IV (see Hasin, Hatzenbuehler, Keyes, & Ogburn, 2006; Saha, Stinson, & Grant, 2007).

## Epidemiology

Multiple population-based, epidemiological surveys indicate that the prevalence rates of AUDs are high, especially among those in late adolescence and early adulthood. Over the past 25 years, five large-scale, population-based epidemiological surveys using structured diagnostic interviews have provided estimates of AUDs in the United States. These include the Epidemiologic Catchment Area (ECA) Survey (Helzer, Burnam, & McEnvoy, 1991; Robins & Price 1991); the National Comorbidity Survey (NCS; Kessler, Crum, Warner, & Nelson, 1997; Kessler et al., 1994); the National Comorbidity Survey—Replication (NCS-R; Kessler, Berglund, Demler, Jin, & Walters, 2005; Kessler, Chiu, Demler, & Walters, 2005); the National Longitudinal Alcohol Epidemiologic Survey (NLAES; Grant, 1997; Grant et al., 1994; Grant & Pickering, 1996); and the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC; Grant, Dawson, et al., 2004; Grant, Stinson, et al., 2004). Each of these major studies indicates very high past-year and lifetime prevalence rates of AUDs in the US population (13.8% lifetime and 6.8% past year DSM-III in ECA; 23.5% lifetime and 7.7% past year DSM-IIIR in NCS; 18.2 % lifetime and 7.41% past year DSM-IV in NLAES; 30.3% lifetime and 8.46% past year DSM-IV in NESARC; 18.6% lifetime and 4.4% past year DSM-IV in NCS-R).

In general, men are much more likely to diagnose with past-year alcohol abuse (6.9%) or dependence (5.4%) than women (abuse: 2.6%; dependence: 2.3%; Grant, Dawson, et al., 2004). The prevalence of abuse is greater among Whites (5.1%) than among Blacks (3.3%), Asians (2.1%), and Hispanics (4.0%). The prevalence of dependence is higher in Whites (3.8%), Native Americans (6.4%), and Hispanics (4.0%) than Asians (2.4%).

### AUDs over the Life Course

If there is a single, salient phenomenon with respect to the epidemiology of AUDs, it is that their prevalence is highly age graded. Using data from the NESARC, Figure 20.1 illustrates the dramatic age gradient with peak prevalence rates for both abuse and dependence occurring early in the third decade

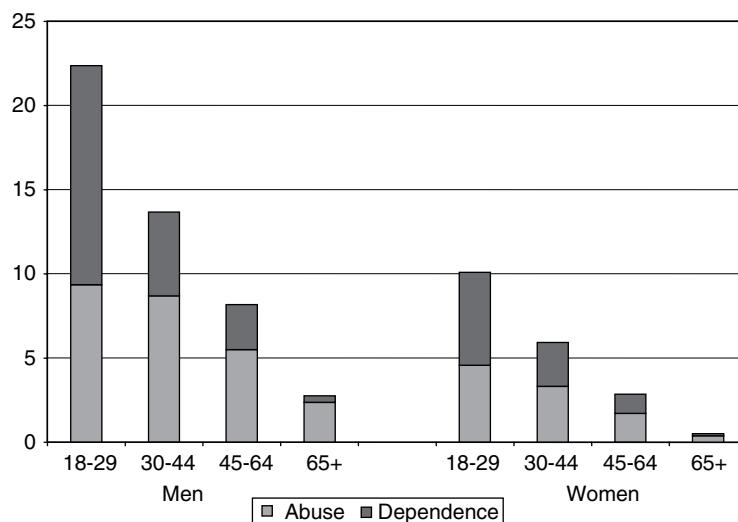

**Figure 20.1** Past 12-month prevalence of alcohol abuse and dependence for men and women (as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition; American Psychiatric Association, 1994). Data taken from the National Epidemiologic Survey on Alcohol and Related Conditions (Grant, Dawson, et al., 2004).

of life with large decreases in prevalence rates clearly evident by age 30. These changes in prevalence rates of AUDs over the life course argue for us to consider AUDs, in part, as developmental phenomena. The period intervening between adolescence and adulthood, known as "emerging adulthood" (Arnett, 2006), evidences the time when individuals are at the highest risk for manifesting an AUD with the peak hazard for onset for both alcohol abuse and alcohol dependence occurring around the age of 20 in the United States (Grant, Moore, & Kaplan, 2003; Li, Hewitt, & Grant, 2004). This heightened risk is thought to reflect a time when individuals are relatively free of adult responsibilities but unrestrained by parental influence. However, as individuals progress into adulthood, perhaps undertaking a number of novel adult responsibilities (e.g., marriage and parenthood), rates of AUDs typically decrease, a phenomenon which is known as "maturing out" (Arnett, 2006; Bachman, Wadsworth, O'Malley, Johnston, & Schulenberg, 1997; Donovan, Jessor, & Jessor, 1983; Littlefield & Sher, 2010; Winick, 1962; see Heyman, 2013, for a recent review).

It is important to note that there is notable cultural variation in these developmental patterns. In particular, African American men are likely to have later ages of onset of alcohol use disorder with increases during the third decade of life, while there is decreasing prevalence among Whites of the same age (Grant, Dawson, et al., 2004; Herd & Grube, 1996). These divergences in developmental paths may be due to cultural variation in education, labor market participation, drinking motives, and marriage and parenting (Cooper et al., 2008; Dawson, 1998).

## Alcohol as a Drug
### Acute Effects

The neuropharmacology of alcohol (specifically, ethanol, the form of alcohol contained in alcoholic beverages) is complex because it affects virtually all major neurotransmitter systems, especially at levels associated with intoxication. Indeed, alcohol operates both acutely and chronically with many central nervous system (CNS) neurotransmitter systems that play a key role in regulating cognition, affect, and behavior, as well as the subjective effects of alcohol, all of which may be factors in the development of alcohol addiction (Fromme & D'Amico, 1999; Vengeliene, Bilbao, Molander, & Spanagel, 2008). For purposes of discussion, the subjective and hedonic effects of alcohol can be separated into three broad classes: (1) positive reinforcing effects

(e.g., euphoric, arousing), (2) negative reinforcing effects (e.g., anxiolytic, antidepressant), and (3) punishing effects (e.g., depressant and acute discomfort such as flushing, nausea, and vomiting).

*Positively reinforcing effects of alcohol*, such as euphoria and increased arousal, are thought to be largely associated with enhanced monoaminergic (especially dopaminergic) effects and related opioid peptide activity (NIAAA, 1997). Opiate antagonists or blockers, in particular naltrexone and nalmefene, have been found to suppress the subjective stimulating effects of alcohol and also craving, both in social drinkers and non-treatment-seeking alcoholics (Drobes, Anton, Thomas, & Voronin, 2004).

*Negatively reinforcing acute subjective effects of alcohol*, including anxiolysis and possibly some antidepressant effects, are thought to be mediated by alcohol's effects on the gamma-aminobutyric acid (GABA$_A$) receptor. It has been known for more than 50 years that alcohol has reliable effects on passive avoidance in rodents in a way quite similar to classic anxiolytic drugs such as the benzodiazepines (Harris, Mihic, & Valenzuela, 1998). Further, neuropharmacological studies have shown that alcohol works to enhance GABAergic activity through its action on the GABA$_A$ receptor. Drugs that have the opposite effect on this receptor (i.e., inverse agonists such as RO 15-4513) appear to reverse anxiolytic and related effects (Lister & Nutt, 1988), perhaps by competing for the same GABA$_A$ receptors as ethanol (Hanchar et al., 2006).

Some of the *punishing acute subjective effects of alcohol* (e.g., flushing) appear to be due to intermediary by-products of ethanol metabolism (specifically acetaldehyde, which is a toxic metabolite of alcohol; Eriksson, 1983; Eriksson, Mizoi, & Fukunaga, 1982). Further, it appears that many of the effects of acetaldehyde are manifested in the periphery. Other presumably punishing effects (e.g., sedation) are likely mediated by central GABAergic mechanisms within the hippocampus, septum, cerebral cortex, and cerebellum and are more likely to be observed at high doses and on the descending limb of the blood alcohol curve (Fromme & D'Amico, 1999).

### Are Reinforcing and Punishing Effects of Alcohol Direct or Mediated via Cognitive Processes?

Until recently, there has been some disagreement as to the extent that alcohol has anxiolytic properties similar to the benzodiazepines. For example, Lang, Patrick, and Stritzke (1999) reviewed the available human literature on the effects of alcohol and

emotion and concluded that "evidence of intrinsic reward or selective stress reduction seems neither powerful enough nor reliable enough to account for the widespread appeal of alcohol and the prevalence of alcoholism" (p. 360). They also argued that most of alcohol's effects on affect and emotional responding were secondary to effects on cognition (and subsequent processing of relevant contextual cues and their bearing to the self).

One of the most influential cognitive processing theories of psychological vulnerability is Steele and Josephs's (1990) "alcohol myopia" theory, which proposes that the effect of alcohol is contingent upon information processing of more or less salient features of the drinking context. This theory has received support across multiple domains and can provide a coherent explanation as to how alcohol can lead to either an animated, euphoric, and celebratory experience (i.e., *reinforcement*) or to a depressive "crying in one's beer" experience (i.e., *punishment*). In several studies, Steele and colleagues have shown that alcohol consumption, followed by distracting pleasant or neutral stimuli, can attenuate stress responses. However, when no distraction is present, alcohol consumption either no longer reduces anxiety or produces anxiogenic effects (Josephs & Steele, 1990).

However, it has long been known that intermediate doses of alcohol have unpredictable effects on negative emotions, though as the dose of alcohol approaches those associated with "binge" levels of intoxication (e.g., BACs of approximately .08% or more), negatively and positively reinforcing effects tend to be observed reliably, independent of context (Sher, 1987). Consequently, it may be that it is only at intermediate doses where alcohol's effects are unreliable (Sher, 1987) and heavily dependent on context (Steele & Josephs, 1990) and appraisal (Sayette, 1993). This interpretation of the earlier literature is consistent with recent studies (e.g., Donohue, Curtin, Patrick, & Lang, 2007; Sher, Bartholow, Peuser, Erickson, & Wood, 2007) demonstrating nonconditional salutary effects on negative emotions across diverse measures and experimental paradigms. Thus, existing data suggest that, particularly at low and intermediate levels, many affective consequences of consumption are cognitively mediated. As a corollary, these affective consequences are heavily context dependent and moderated by individual differences related to appraisal processes. However, more direct effects of alcohol on brain centers responsible for mood and emotion are likely to be observed at higher doses.

## Biphasic Effects of Alcohol

The reinforcing effects of alcohol typically are experienced on the ascending limb of the blood alcohol concentration (BAC) curve (measured from the time that drinking is initiated until individuals reach their peak BAC), and the punishing effects typically occur on the descending limb of the BAC curve (measured at the time subsequent to that when individuals have reached their peak BAC), rendering the net effect of alcohol to be one that is biphasic (Sher, Wood, Richardson, & Jackson, 2005). These biphasic effects are observable in the laboratory, and individuals also report expecting to experience such effects prior to drinking (Earleywine, 1994; Earleywine & Martin, 1993). Notably, heavier drinkers have been found more likely to experience stronger stimulant effects relative to sedative effects, whereas lighter drinkers have been found to experience the opposite (Earleywine, 1994). The biphasic effects of alcohol are subject to individual differences (Newlin & Thomson, 1990) as well as dosage (Holdstock & de Wit, 1998).

## Chronic Adaptation to Alcohol

Heavy, chronic drinkers often experience a range of persistent changes relevant to acute withdrawal symptoms and resultant emotional functioning. First, alcohol withdrawal symptoms are often associated with affective disturbance, particularly anxiety (Sellers, Sullivan, Somer, & Sykora, 1991; Sullivan, Sykora, Schneiderman, Naranjo, & Sellers, 1989). These associations can potentially create a vicious cycle whereby chronic alcohol use leads to affective disturbance, which in turn motivates further drinking. Second, some forms of anxiety and mood disorders appear to be "alcohol induced" and, thus, differential diagnosis of substance-induced mood disorders is considered critical for nosology and treatment (American Psychiatric Association, 1994, 2000; Schuckit, 1994). Anxiety and mood disorders that remit spontaneously after a short period (less than a month) of abstinence and that only appear in the context of ongoing substance use should be considered substance induced and not "independent." Third, even ostensible "independent" anxiety and mood disorders often appear to temporally follow the occurrence of an alcohol use disorder (especially true in the case of depression; Kessler, Crum, Warner, & Nelson, 1997). For example, in a multinational pool of five epidemiological studies (Merikangas et al., 1996), it was found that, among those with co-occurring alcohol dependence and depression, 20% reported that the onset of the disorders occurred

together, 38% reported that depression came first, and 42% reported that alcohol dependence came first (the study did not compare order of onset for anxiety disorders and alcohol dependence).

A general perspective on changes associated with the chronic use of various drugs of abuse including alcohol is termed *allostasis* (i.e., adaptive homeostatic changes that occur in response to repeated drug challenges; e.g., Koob & LeMoal, 2001, 2008). According to this theory, an organism responds to drug challenges by producing counterdirectional (i.e., homeostatic) responses that increase over time. Thus, allostasis explains the phenomenon of acquired tolerance, the tendency for a given dose of a drug to elicit progressively less response over time, in a way similar to that proposed by Solomon and Corbit (1974) in their opponent-process theory and Siegel and colleagues (e.g., Siegel, Baptista, Kim, McDonald, & Weise-Kelly, 2000) in their Pavlovian account of tolerance development. However, the allostatic perspective goes further than these theories by specifically positing that repeated homeostatic challenges present an adaptive burden and result in a shift of a hedonic "set point" in the direction of the opponent process. Theoretically, such a process could explain intermediate- to long-term deviations in tonic emotional levels, resulting in a more depressed, irritable, and/or anxious alcohol-dependent person. Such a perspective is also consistent with the general principle that acute and chronic effects of alcohol are opposite in direction with respect to both neuropharmacological effects and their behavioral correlates. These allostatic, chronic adaptations are believed to be mediated by the hypothalamic-pituitary axis (HPA) via effects of corticotrophin-releasing factor (CRF) (Koob & LeMoal, 2001, 2008), and there are current drug development efforts that are targeting CRF antagonists to attempt to modulate these proposed allostatic influences.

## Genetic and Environmental Factors Associated with Alcohol Use and AUDs

The number of etiological factors contributing to alcohol use and AUDs are extensive and both genetic and environmental factors, broadly construed, have been implicated as well as their interactions.

### Genetic Vulnerability

The existence of significant genetic influences on AUDs (among individuals who drink) has been firmly established in adoption studies (Cadoret, Yates, Troughton, Woodworth, & Stewart, 1995; Cloninger, Bohman, & Sigvardsson, 1981; Goodwin, Schulsinger, Hermansen, Guze, & Winokur, 1973; McGue, 1994) that show strong effects of biological parents independent of being reared with them. Moreover, classical twin studies (Heath, 1995; Heath et al., 1997; McGue, 1999) that compare concordance of alcohol-related phenotypes between monozygotic ("identical") and dizygotic ("fraternal") twins consistently show genes accounting for approximately half of the variance in AUD prevalence. Although the new era of molecular genetics has moved the focus from establishing the importance of genetic factors to identifying specific genes that are important in AUD etiology (Dick, Rose, & Kaprio, 2006), these twin and adoption studies remain useful in demonstrating both: (1) common genetic influences on AUDs and comorbid conditions, and (2) the importance of gene × environment (G×E) interaction in the absence of knowledge of specific genes involved.

For example, Slutske et al. (1998) showed that much of the comorbidity between childhood conduct disorder and AUDs can be attributed to shared additive genetic effects and, further, that temperamental traits (especially those related to poor self-control) appear to represent common genetically mediated contributions to this disorder (Slutske et al., 2002). This suggests that rather than looking for pure "alcohol genes," it might be fruitful to look for genes contributing to multivariate, spectrum phenotypes (Dick et al., 2008; Uhl et al., 2008) as well as for genes specific to alcohol dependence.

Similarly, genetically informative samples can be useful for identifying the presence of certain forms of G×E interactions. In behavior-genetic rodent models of drinking, cross-fostering designs (where the genetic background and rearing environment are experimentally crossed) can be extremely informative (Randall & Lester, 1975). However, the comparable design in humans, the adoption design, is problematic for several reasons. Human adoptions tend to select for strong genetic effects (due to deviant biological parents) and low variance in rearing conditions (i.e., adoption agencies tend not to place adoptees in problem homes). Moreover, in the classic twin design, G×E interactions are confounded with additive genetic effects (in the case of genes × shared environment) and with unique environmental effects (in the case of genes × unique environment). However, extended twin-family designs that control for genetic background in parents while

examining differences in rearing conditions can elucidate where some G×E interactions might occur. Specifically, the absence of parental alcoholism (a protective environmental factor) can reduce the impact of high genetic risk for the development of AUDs in the offspring of (discordant) twins (Jacob et al., 2003; but see Slutske et al., 2008).

In recent years there have been increasing numbers of molecular genetic studies seeking to identify specific genes that confer risk. Much of this work focused on genes that play a role in alcohol metabolism, and subsequent subjective responses to alcohol. For example, variations in alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), two of the major enzymes involved in alcohol metabolism, have been linked to individual differences in subjective and physiological responses to alcohol (Chen et al., 1996; Luczak, Elvine-Kreis, Shea, Carr, & Wall, 2002; Nakamura et al., 1996). The most widely studied of these is allelic variation in a gene that encodes for ALDH2. Individuals with one or two copies of the ALDH*2 allele have impaired acetaldehyde metabolism resulting in elevated acetaldehyde levels that lead to an alcohol-induced flushing response (Higuchi, Matsushita, Murayama, Takagi, & Hayashida, 1995). This mutation, which is present in a large minority of several Asian groups, including Chinese, Japanese, and Koreans (but not Filipinos or Indians; Eng, Luczak, & Wall, 2007), is associated with a range of unpleasant effects, such as facial flushing, heart palpitations, and nausea, and is therefore thought to be protective against the development of alcohol dependence (Higuchi et al., 1995; Takeshita, Morimoto, Mao, Hashimoto, & Furuyama, 1994; Wall, Thomasson, Schuckit, & Ehlers, 1992). In a recent meta-analysis, Luczak, Glatt, and Wall (2006) found that presence of one (or two) copies of these alleles (that are linked with impaired acetaldehyde metabolism) were associated with a greatly reduced risk of alcohol dependence in Asian populations.

Although subjective response to alcohol as a function of variability in ADH genotypes has only just begun to be explored in alcohol challenge studies, there is evidence suggestive of etiologically relevant variability. Specifically, the presence of the ADH1B*2 allele leads to more rapid metabolism of alcohol to acetaldehyde (Crabb, 1995), which may generate an altered subjective response to drinking. This genotype occurs at a high base rate in Asians (esp. Chinese, Japanese, and Koreans; Eng et al., 2007) and is associated with lower rates of alcohol use disorders in these populations (Luczak et al.,

2006). The presence of at least one ADH1B*2 allele was also observed to be significantly more prevalent among young adult African Americans who do not have a family history of AUDs (Ehlers, Gilder, Harris, & Carr, 2001). Furthermore, in the same population, the presence of the ADH1B*2 allele was linked with higher levels of alcohol expectancies, which could be associated with greater subjective responses to alcohol as well.

Perhaps more relevant for understanding genetic influences in individuals of European descent, a number of genes associated with central brain neurotransmitter systems have been found to be associated with alcohol dependence. For example, GABA is a neurotransmitter involved in many of the anxiolytic and sedative effects of alcohol, and GABA receptors are involved in alcohol tolerance. Recent studies have established associations between $GABA_A$ receptor genes on chromosomes 4 (e.g., GABRA2, GABRB1) and 15 (e.g., GABRB3), and AUDs across human and animal studies (Dick & Beirut, 2006). Though genes associated with alcohol and acetaldehyde metabolism and the GABRA2 gene show replicable links to AUDs, there are a number of less consistent links with candidate genes associated with neurotransmitter function. Because of the possible role of some of these genes in comorbidity, it is worthwhile to mention them while noting the weaker empirical basis for some of these findings.

Serotonin is a neurotransmitter that is important in mood regulation, and it is associated with decreased alcohol consumption; however, the short 5-HTT allele is less efficient in transcription than the long allele, and thus it is thought to pose a risk for AUDs. There is also evidence for a relation between the short allele of the serotonin transporter (5-HTT) encoding gene and AUDs (Dick & Beirut, 2006; Dick & Feroud, 2003). Because interaction between this gene and childhood adversity has been shown in a primate model of drinking (Barr et al., 2004) and in human depression (Caspi et al., 2003), it seems likely that this gene in combination with early stressors predisposes individuals to a range of pathology associated with affective disturbance.

Because of the importance of the dopamine system to the rewarding properties of alcohol and other drugs of abuse, there has been interest in whether genotypes related to the dopamine system (e.g., polymorphisms related to dopamine receptors D2 and D4 and to the dopamine transporter) have also been linked to AUDs. Despite a number of

findings associated with allelic variation in D2 and, to a lesser extent, D4 receptor genes, data in this area are inconsistent (Dick & Beirut, 2006).

It should also be noted that there is increasing evidence that one of the genes associated with the acetylcholine muscarinic receptor (CHRM2) is associated with broad spectrum pathology, including AUDs, other drug use disorders, and related nonsubstance pathology (Dick et al., 2008; Luo et al., 2005).

At present, there are a number of large-scale genome-wide association studies under way that will likely reveal additional genes that are reliably associated with the AUD (or closely related) phenotypes. However, as is true for all psychological disorders (Kendler, 2005, 2006), it seems unlikely that any single gene will reveal a strong bivariate association with AUDs given the long and complex causal chain between gene action and the manifestation of alcohol-related pathology (Kendler, 2005, 2006; Sher, 1991) and the failure of genome-wide scans to identify strong single gene effects of complex disorders (Goldstein, 2009).

## Environmental Factors Associated with AUDs and Related Constructs

The range of potential environmental influences on the development of alcohol dependence is vast and ranges from the chemical environment (e.g., ethanol and other drug exposures) to broad social factors (e.g., cultural influences) to life-stage-specific factors (e.g., various social roles that vary over the life course).

### PRENATAL ALCOHOL EXPOSURE

From a developmental perspective, the first alcohol-related environment for the developing human is the womb. Prenatal alcohol exposure can cause fetal alcohol syndrome (FAS), which is a clinical syndrome characterized by growth retardation, facial dysmorphology, and CNS deficits, including tremors and visual irregularities (Larkby & Day 1997; Manning & Eugene-Hoyme, 2007). Studies examining school-aged outcomes for children affected by FAS reveal a range of cognitive and behavioral problems that often persist and/or worsen as children mature, leading to high rates of antisocial behavior and the development of AUDs (Baer, Sampson, Barr, Connor, & Streissguth, 2003; Steinhausen, Willms, & Spohr, 1993; Streissguth et al., 1994). These types of deficits and associated behavior problems are also common in children prenatally exposed to alcohol who are not diagnosed with full syndrome FAS (Streissguth, Barr, & Sampson, 1990; Testa, Quigley, & Eiden, 2003) but have some subsyndromal spectrum disorder. Animal models suggest that fetal exposure to alcohol may lead to the development of specific drug sensitivities and preferences that may contribute to the development of AUDs (Abel, Bush, & Dintcheff, 1981; Dominguez, Lopez, & Molin, 1998; Osborn, Yu, Gabriel, & Weinberg, 1998).

### ADOLESCENT ALCOHOL EXPOSURE

In addition to prenatal exposure to alcohol, there is increasing evidence to indicate that youth exposure to alcohol may also be relevant to the development of AUDs. Accumulating evidence suggests that adolescents may be exquisitely sensitive to the neurotoxic effects of alcohol. Heavy exposure to alcohol in adolescence has been associated with structural and functional brain deficits, and also deficits in cognitive functioning (Clark, Thatcher, & Tapert, 2008; De Bellis et al., 2000; Hargreaves, Quinn, Kashem, Matsumoto, & McGregor, 2009; Tapert, Brown, Baratta, & Brown, 2004; Zeigler et al., 2005). The seemingly heightened sensitivity of the adolescent brain to alcohol-related insult is thought to be associated with neurodevelopmental vulnerability to disruption of the extensive remodeling of the brain that takes place in adolescence (e.g., synaptic pruning; Clark et al., 2008). The associated neurocognitive deficits, especially those associated with deficits in executive functioning (Monti et al., 2005), could pose added risk for a range of externalizing behavior problems. Although a definite causal relation in humans has yet to be established, rodent models of adolescent ethanol exposure (Crews, Braun, Hoplight, Switzer, & Knapp, 2000; Spear, 2000; Swartzwelder, Wilson, & Tayyeb, 1995) demonstrate that adolescence appears to be a time of heightened sensitivity to persistent neurologic damage.

One of the most reliable findings in the epidemiology of AUDs is that early onset of drinking is associated with increased likelihood of developing an AUD (Grant & Dawson, 1997; Hingson, Heeren, & Winter, 2006). What is not clear at this point is the extent that these findings represent a clear causal mechanism (perhaps because of increased sensitivity of the brain to alcohol or alcohol-related cues) or are an artifact of a common "third variable" associated with both early deviant behavior and the development of AUDs. Currently the data are ambiguous, with some evidence suggesting that the early alcohol drinking–AUD link

is a spurious effect of correlated conduct problems (Prescott & Kendler, 1999), although it is unclear whether common third-variable causation is a sufficient explanation (McGue & Iacono, 2008; Odgers et al., 2008). Regardless of the mechanism of this association, early exposure, although associated with increased risk, does not appear to herald imminent alcohol dependence in younger adolescents. Indeed, Sartor, Lynskey, Heath, Jacob, and True (2007) and Hussong, Bauer, and Chassin (2008) found that in early adulthood, earlier exposure is associated with longer duration from first drinking to dependence. This is likely due to limited opportunities for access and use in mid-adolescence, which constrains the dependence process (Sher, 2007).

## PARENTAL INFLUENCE

Parental influences on drinking and AUDs are usually viewed along three dimensions: (1) modeling, (2) parenting practices (i.e., nurturance and control), and (3) abuse and neglect.

Alcoholic parents have been thought to inadvertently model their problematic drinking to their children, so that these children may emulate their parents' behavior as the children age (Ellis, Zucker, & Fitzgerald, 1997). Although there is poorer psychosocial adjustment in children of alcoholics (COAs) whose parents are actively drinking heavily versus those who are abstinent (Andreas & O'Farrell, 2007), the extent to which parents' modeling increases the risk of later AUDs in COAs is unclear (Chassin, Pitts, DeLucia, & Todd, 1999). For example, adoption and children-of-twins studies tend to show little evidence of modeling. That is, rates of alcoholism in the adoptive COAs do not appear to be elevated (Hopfer, Crowley, & Hewitt, 2003), and the offspring of twin pairs (that are discordant for AUDs) are not statistically different in their risk for AUDs after controlling for genetic and other environmental risk factors (Slutske et al., 2008).

Nonetheless, it might be less a matter of modeling and more a matter of general parenting practices that are of importance in considering the effects of parents on the development (or prevention) of AUDs. For example, parents who abuse alcohol are thought to demonstrate poor family management practices that are strongly linked with higher rates of internalizing and externalizing problems in children, such as lax and inconsistent discipline and inadequate supervision and monitoring. Also, poor parental monitoring puts children at risk for associating with substance-using peers. This peer association has been identified as a critical risk factor

for early alcohol initiation and the development of alcohol problems (Hawkins, Catalano, & Miller, 1992). In addition to monitoring, a range of other familial factors have been found relevant to familial transmission of AUDs. These include communication, cohesiveness, social support, parent and sibling attitudes toward alcohol use, familial conflict, parental loss through divorce or separation, disruption of family rituals, and unfair and harsh disciplinary practices (Leonard & Eiden, 2007).

In addition to these more general facets of parenting and their relation to the development of AUDs, child maltreatment and neglect are two risk factors for AUDs worth noting separately, given their increased severity as risk factors for a number of mental health issues. Child maltreatment is a correlate of substance use in families and poor parenting practices overall; thus, it is difficult to identify how maltreatment contributes to the development of AUDs beyond simply being an environmental risk factor (Locke & Newcomb, 2004). However, child neglect has been found to contribute to the development of AUDs by increasing children's vulnerability to be pressured by peers to use alcohol at early ages (Clark, Thatcher, & Maisto, 2004; Dunn et al., 2002; Leonard & Eiden, 2007).

## PEER INFLUENCE

Peer influence is considered one of the strongest predictors of alcohol use, particularly in adolescence, with data suggesting near perfect correlations between the alcohol use patterns of adolescent friends (Fowler et al., 2007). Peer influences on drinking may be stronger in adolescent girls than boys, although deviant peer associations have been found to exert influence on drinking behaviors in both boys and girls (Simons-Morton, Haynie, Crump, Eitel, & Saylor, 2001). This prompts the question of whether it is more often the case that peers socialize each other toward drinking behaviors, or whether it is more often that peers select into groups that are characterized by risky and heavy drinking behaviors (Sher, Grekin, & Williams, 2005). Data show that both selection and socialization effects are important aspects of peer influence on heavy drinking. Parental expectations moderate what types of peers children associate with and the amount to which the peers exert influence toward (or against) alcohol and substance use (Nash, McQueen, & Bray, 2005). As individuals move into adulthood, selection effects appear to become more important than socialization effects (Parra, Sher, Krull, & Jackson, 2007).

Because of assortative mating, heavier drinkers (including those who are alcohol dependent) often marry heavier drinkers, and spouses appear to influence each other's drinking and likelihood of having an AUD (Leonard & Eiden, 2007). Earlier reports suggest that husbands' drinking prior to marriage increases the likelihood of wives' drinking in the first year of marriage (Leonard & Eiden, 1999), though wives' heavy drinking has a longitudinal predictive effect of husbands' heavy drinking later in the course of marriage (Leonard & Mudar, 2004). More recent evidence (Leonard & Homish, 2008) suggests that, for both husbands and wives, spousal heavy drinking as well as postmarriage social networks (e.g., number of drinking buddies) are significant predictors of both partners' heavy drinking during the marriage. Decreased marital satisfaction and intimate partner violence are both causes and effects of heavy drinking in marriages, and heavy drinking has also typically been found to increase at the dissolution of a marriage (Leonard & Eiden, 2007). Further, higher levels of marital satisfaction appear to be protective against postmarital alcohol problems (Leonard & Homish, 2008). Thus, alcohol plays a role in the formation, maintenance, and dissolution of relationships, where inequalities in drinking between partners tend to forecast increases in discord in the relationship and continued or increased drinking. At a broader level, however, family systems' perspectives of alcoholism recognize decreases in heavy drinking specifically when spouses become parents (Leonard & Eiden, 2007).

### ADVERTISING AND MEDIA

Youths in the United States are heavily exposed to media promotions of alcohol. For example, it has been found that US youths aged 10–14 years are exposed to, on average, 5.6 hours of alcohol use and 243.8 alcohol brand appearances, mostly from the youth-rated movies that children report watching (Dal Cin, Worth, Dalton, & Sargent, 2008). The majority of media depictions of drinking show positive, rather than negative, consequences (Grube & Waiters, 2005). Thus, it is not surprising that modest associations have been found between exposure to television and magazine advertisements for beer and alcohol use in adolescents (Ellickson, Collins, Hambarsoomians, & McCaffrey, 2005). However, many studies are inconclusive or show very weak effects (Grube & Waiters, 2005). Thus, the extent that advertising has a causal influence on consumption levels remains an area of controversy.

### CULTURE

The prevalence of AUDs varies dramatically across nations and often equally dramatically across subcultural groups within countries. For example, a recent global status report on alcohol estimated the lifetime prevalence of alcohol dependence to be 0.2% in Egypt, 3.8% in China, 7.7% in the United States, 9.3% in Canada, 11.2% in Brazil, and 12.2% in Poland (World Health Organization, 2004). Perhaps due to this variation, culture has long been viewed as an important correlate of the development of AUDs, as certain societal cultures appear to be more permissive of alcohol than others, or have drinking customs that might relate to the development of AUDs (Engs, 2001; MacAndrew & Edgerton, 1969).

Indeed, some have argued that one of the reasons that alcohol problems are so prevalent in the United States in comparison to certain Mediterranean countries (e.g., Italy) is that, in the United States, there is a 21-year-old minimum legal drinking age (MLDA). This restriction is thought to preempt the ability of youth to learn how to drink in a healthy way and thus creates a "forbidden fruit" phenomenon that leads to excess (Amethyst Initiative, 2008; Main, 2009). However, recent research suggests rather comparable rates of drinking and alcohol problems in youths of different countries in Europe (which have lower MLDAs) and the United States (Grube, 2005), indicating that more research is necessary for understanding just how societal culture might play a role in the etiology of AUDs. In particular, with respect to effects of culture, the extent that alcohol is viewed as a drug versus a food stuff or that intoxication represents a socially sanctioned "time out" from normal roles and responsibilities (Aldridge, Measham, & Williams, 2011; MacAndrew & Edgerton, 1969) may be much more important than the age at which it is legal to consume alcohol (Heath, 1995).

## Psychological Individual Differences in Risk for AUDs

The genetic data cited earlier clearly indicate that there are important individual differences in susceptibility to AUDs. Some of this variability appears to be related to how ethanol and its metabolites are processed by individuals (e.g., pharmacokinetics). However, the link between AUDs and genes associated with major motivational systems suggests that some of these genetic effects are mediated by what are traditionally thought of as motivational and personality processes. Psychological individual

difference variables that have been implicated in AUD etiology are wide ranging and include neurocognitive processing, personality-related vulnerabilities, and alcohol expectancies and motives for use.

### Neurocognitive Deficits

Deficits in executive cognitive functioning (e.g., the regulation of goal-directed behavior, control of attention, planning, and cognitive flexibility) are associated with increased risk for AUDs (Giancola & Tarter, 1999). Such deficits are in evidence in children at elevated risk for alcoholism (Nigg et al., 2004). One particular endophenotypic measure of a neurocognitive deficit is reduced P300 amplitude, an electrophysiological index of inhibitory control. P300 amplitude has consistently been shown to be characteristic of individuals at high risk for AUDs (e.g., COAs) and is strongly associated with early-onset AUDs (Carlson, Iacono, & McGue, 2002; Carlson, McLarnon, & Iacono, 2007; Iacono, 1998), at least in boys and young men.

### Personality

Personality traits have long been considered an important feature of psychological theories of alcoholism. However, despite the apparent conceptual appeal of an "addictive personality," decades of empirical research have failed to identify a unique constellation of personality traits that characterize alcoholics. Rather, broad-based personality constructs appear to have etiologic relevance to alcohol abuse and dependence, particularly within the context of larger psychosocial models (Sher, Trull, Bartholow, & Vieth, 1999). Three broad-band personality dimensions have received particular attention: neuroticism/emotionality, impulsivity/disinhibition, and extraversion/sociability. For example, alcoholics exhibit significant elevations on measures of neuroticism/emotionality (Barnes, 1979, 1983; Sher et al., 1999), and many prospective studies have found neuroticism/emotionality to be predictive of subsequent alcohol involvement (Caspi et al., 1997; Chassin, Curran, Hussong, & Colder, 1996; Cloninger, Sigvardsson, & Bohman, 1988; Labouvie, Pandina, White, & Johnson, 1990; Sieber, 1981). More recent studies suggest that changes in traits related to impulsivity (including sensation seeking) and neuroticism relate to the course of alcohol involvement (e.g., Littlefield, Sher, & Wood, 2009; Quinn & Harden, 2013), though the functional relation between changes in personality and alcohol involvement is unclear (see Littlefield, Vergés, Wood, & Sher, 2012).

Impulsive/disinhibited traits appear to be some of the most etiologically significant personality dimensions for alcohol use and misuse, including such constructs as sensation seeking, aggressiveness, impulsivity, psychoticism, and novelty seeking (Sher & Trull, 1994). Prospective studies consistently indicate that traits such as aggression, conduct problems, impulsivity, unconventionality, and novelty seeking are strongly associated with the development of alcohol misuse, as well as other forms of substance misuse (Bates & Labouvie, 1995; Caspi et al., 1997; Cloninger et al., 1988; Hawkins et al., 1992; Pederson, 1991; Schuckit, 1998; Zucker et al., 1995). Whiteside and Lynam (2001) utilized factor analyses to identify four distinct personality facets associated with impulsive-like behavior: sensation seeking, lack of planning, lack of persistence, and urgency (acting rashly when distressed). Further work has distinguished among positive and negative urgency (Cyders et al., 2007), resulting in five personality facets of impulsivity. These facets were shown to account for different aspects of risky behaviors, such that sensation seeking appeared to relate to the frequency of engaging in risky behaviors, including drinking-related behaviors, whereas urgency (particularly positive urgency, the tendency to act rashly while in a positive mood; see Cyders, Flory, Rainer, & Smith, 2009) appeared to relate to problem levels of involvement in those behaviors (e.g., Smith et al., 2007; see Cyders & Smith, 2008).

Although extraversion/sociability is considered a major personality dimension, reviews of the literature suggest that extraversion/sociability does not reliably distinguish alcoholic and nonalcoholic individuals (Barnes, 1983; Sher et al., 1999). However, there is some evidence from longitudinal studies to suggest that extraversion/sociability predicts subsequent alcohol misuse (Jones, 1968; Kilbey, Downey, & Breslau, 1998; Sieber, 1981). Recent research (Park, Sher, Krull, & Wood, 2009) suggests that extraversion may be relevant to heavy consumption in late adolescence and early adulthood in that it is related to affiliation with certain types of highly sociable groups (e.g., Greek societies on college campuses) that often represent heavy drinking environments.

### Alcohol Outcome Expectancies

Another important aspect of psychological vulnerability is alcohol outcome expectancies. Alcohol outcome expectancies can be defined as beliefs that people have about the affective, cognitive, and behavioral effects of drinking alcohol (Goldman,

Brown, & Christiansen, 1987). Goldman, Del Boca, and Darkes (1999) suggest that outcome expectancies can be categorized along three basic dimensions: (a) positive versus negative expected outcomes (e.g., increased sociability versus increased aggressiveness); (b) positive versus negative reinforcement (e.g., social facilitation versus tension reduction); and (c) arousal versus sedation (e.g., stimulant versus depressant effects). Associations have been consistently found in cross-sectional studies between alcohol expectancies and both drinking behavior and drinking problems among children (Anderson et al., 2005; Dunn & Goldman, 2000), adolescents (Dunn & Goldman, 2000; Fromme & D'Amico, 2000), college students (Christiansen, Vik, & Jarchow, 2002; Palfai & Wood, 2001; Read, Wood, Lejuez, Palfai, & Slack, 2004), and adults (Lee, Greeley, & Oei, 1999; Pastor & Evans, 2003). These studies suggest that drinking behavior is positively associated with positive outcome expectancies (assessed both individually and as a composite) and negatively associated with negative outcome expectancies (assessed both individually and as a composite). Moreover, these associations are robust across a variety of drinking patterns and remain significant (although weaker) after controlling for demographics and previous drinking behavior (Carey, 1995; Jones, Corbin, & Fromme, 2001). Outcome expectancies tend to develop in childhood (Anderson et al., 2005; Christiansen, Goldman, & Inn, 1982; Dunn & Goldman, 2000; Jones, Corbin, & Fromme, 2001; Miller, Smith, & Goldman, 1990), strengthen during adolescence (Smith, Goldman, Greenbaum, & Christiansen, 1995), and weaken during early adulthood (presumably, following extended experience with drinking; Sher, Wood, Wood, & Raskin, 1996). Moreover, several prospective studies demonstrate that expectancies uniquely predict future drinking over extended time periods (Kilbey et al., 1998; Leonard & Mudar, 2000; Sher et al., 1996; Smith et al., 1995; Stacy, Newcomb, & Bentler, 1991). Although both cross-sectional and longitudinal studies suggest associations between expectancies and alcohol use, they do not necessarily implicate a causal relationship.

Longitudinal research (e.g., Sher et al., 1996) suggests reciprocal relations between alcohol outcome expectancies and drinking. Somewhat surprisingly, the question of how individual differences in alcohol expectancies relate to individual differences in alcohol effects has not yet been systematically explored (Sher et al., 2005). However, recent research focusing on individuals who possess

different genotypes associated with ALDH (e.g., Hahn et al., 2006), dopamine, and GABA receptors (e.g., Young, Lawford, Feeney, Ritchie, & Noble, 2004) suggests that pharmacogenomic interactions between ethanol and specific genotypes can contribute to individual differences in alcohol expectancies.

In recent years, there has been increasing interest in implicit cognitive processes and how they relate to alcohol involvement (Wiers & Stacy, 2006). In contrast to explicit alcohol expectancies that are assessed by self-report questionnaires and assume that these expectancies are conscious, implicit expectancies are assessed by any of a variety of behavioral tasks that are assumed to be automatic and largely unconscious. Both of these levels of cognition are thought to act in concert in "dual-process" models. Dual-process models predict that both more reflective, explicit and more reflexive, automatic implicit cognitive processes influence behavior (e.g., Fazio & Towles-Schwen, 1999). Implicit alcohol-related cognitions (e.g., implicit alcohol expectancies) are thought to represent individual differences in memory associations between alcohol-related cues, outcomes, and behavior (Thush et al., 2008). Recent work has provided support for the utility of a range of implicit assessments (e.g., Implicit Association Test; Greenwald, Nosek, & Banaji, 2003) of implicit alcohol-related cognitions by showing that these measures predict drinking behavior over and above the prediction afforded by explicit measures of similar constructs (e.g., Thush & Wiers, 2007). Dual-process models of addiction also posit that controlled self-regulatory processes interact with both implicit and explicit expectancies (e.g., Thush et al., 2008).

### Motivations for Use

Individuals report a range of motives for consuming alcohol, and factor analyses of self-reported reasons for drinking reliably yield a multidimensional, four-factor structure (Cooper, 1994) that can be described as (1) social motives (e.g., "to be sociable"), (2) enhancement motives (e.g., "to get high," "because it's fun"), (3) coping motives (e.g., "to forget your worries," "because it helps when you feel depressed or nervous"), and (4) conformity motives (e.g., "to fit in"). Notably, enhancement and coping motives (but not social or conformity motives) are strongly associated with drinking, heavy drinking, and drinking problems in both adolescents and results (Cooper, 1994; Cooper, Frone, Russell, & Mudar, 1995). A growing body of literature indicates that the personality traits of extraversion and sensation seeking tend to correlate

with enhancement motives, and the personality traits of neuroticism tend to correlate with coping motives (Kuntsche, Knibbe, Gmel, & Engels, 2006). Further, changes in coping motives appear to mediate the relation between both changes in impulsivity and neuroticism with alcohol-related problems (Littlefield, Sher, & Wood, 2010). These findings point to somewhat specific motivational pathways arising from individual differences in temperamental/personality traits and, thus, link broad dispositional traits to alcohol etiology.

## Multiple Etiological Pathways

The literature on alcohol use motivations documents that AUDs are clearly multifactorial disorders and that there appear to be multiple pathways leading to the manifestation of an AUD (i.e., equifinality). The pathways are discussed next: (1) *pharmacological vulnerability,* (2) *general externalizing behavior,* and (3) *affect regulation.* It is important to highlight the fact that these different pathways are not mutually exclusive and are likely additive or superadditive. In addition, they likely share common elements and so some constructs such as executive functioning could relate to all three of the pathways considered.

### Pharmacological Vulnerability

The *pharmacological vulnerability* model (Sher, 1991) proposes that individuals differ in their responses to the acute and/or chronic effects of alcohol and that these individual differences are etiologically relevant. The model itself incorporates several submodels that would appear to offer opposing predictions. For example, it can be hypothesized that some individuals are at risk for alcohol-related difficulties because they are especially sensitive to reinforcement (either positive or negative) and are therefore more likely to use alcohol because they get a comparatively greater effect from it (e.g., Finn & Pihl, 1987; Levenson, Oyama, & Meek, 1987). Alternatively, it can be hypothesized that some individuals are relatively insensitive to alcohol (either reinforcing or punishing effects). Such insensitivity can lead some individuals to higher consumption levels, either because they are seeking reinforcement or are less likely to be inhibited by punishing effects. These higher consumption levels are posited to increase the likelihood of inducing dependence processes (e.g., Schuckit & Smith, 2000).

### Generalized Externalizing Behavior

Another perspective on AUD etiology is that it is just one manifestation of the types of *generalized externalizing behavior* problems that first appear in childhood and adolescence (e.g., Achenbach & Edelbrock, 1978; Jessor & Jessor, 1977). As noted earlier, there is a strong genetic correlation between conduct disorder and alcohol dependence (e.g., Slutske et al., 1998). Additionally, prospective studies indicate, for men (and probably for women), that early conduct problems predict subsequent alcohol and drug disorders and antisocial personality disorder (Hawkins, Catalano, & Miller, 1992; Nathan, 1988; Zucker & Gomberg, 1986). Factor analytic approaches to psychopathology indicate that all externalizing disorders (e.g., conduct disorder, adult antisocial behavior, drug use disorders, and AUDs) are highly correlated and form a distinct psychopathological factor of "externalizing disorder" with common personality correlates (e.g., Krueger et al., 2005; Krueger & Markon, 2006, 2008). Although popular models of generalized externalizing behavior (e.g., Jessor, Donovan, & Costa, 1991; Patterson, Reid, & Dishion, 1992) tend to highlight the importance of parenting and deviant peer groups, both twin studies (e.g., Slutske et al., 1998) and molecular genetics studies (e.g., Dick, 2007) suggest that common genetic influences are also contributing factors.

### Affect Regulation

Another critical pathway involves using alcohol as an *affect regulation* strategy. Although the "self-medication" (e.g., Khantzian, 1985) view of the etiology of AUDs is widely held by both the lay public and many clinicians, the research literature indicates that alcohol can have variable effects on emotions and many, if not most, individuals do not drink to regulate negative moods. Some survey studies have found significant positive associations between stress and alcohol consumption and misuse (e.g., Cooper, Russell, Skinner, Frone, & Mudar, 1992; Scheier, Botvin, & Miller, 1999). Findings indicate that the association is stronger and more consistent with alcohol problems than alcohol consumption (McCreary & Sadava, 2000), suggesting the alcohol–stress relation is more relevant for pathological drinkers. However, many studies find small or nonexistent relationships (Perreira & Sloan, 2001; Rohsenow, 1982; Welte & Mirand, 1995). Moreover, some research suggests that much of the alcohol–stressful event relation can be attributed to aversive events that directly result from drinking (e.g., losing a job due to alcohol use; Hart & Fazaa, 2004; O'Doherty, 1991).

Perhaps most critically, the research literature suggests that the alcohol–stress relation is highly conditional upon many factors such as individuals' coping

styles, beliefs about the utility of alcohol as a coping device, and the availability of alternative coping strategies, among other things (e.g., Sher & Grekin, 2007). As noted earlier, individuals higher in neuroticism/negative affectivity tend to report drinking to regulate negative moods and the endorsement of such reasons for drinking suggest a high likelihood for both heavy consumption and alcohol-related problems (Kuntsch et al., 2006). In addition, the literature on psychiatric comorbidity (discussed later) indicates that individuals with high levels of negative affect (as indicated by mood and anxiety disorder) are at high risk for the development of AUDs and, thus, directly implicates negative affect regulation as an important pathway into AUDs.

## Psychiatric and Medical Comorbidity

Individuals who have AUDs frequently have multiple psychiatric diagnoses as well as various medical illnesses. Given the focus of this volume, we do not consider the myriad health-damaging (and some health-promoting) effects of alcohol consumption in any depth, but we do bring attention to this issue because it has important implications for providing adequate health services to those individuals who have problematic alcohol use and AUDs.

### Psychiatric Comorbidity

Individuals with AUDs are more than twice as likely to exhibit another psychiatric disorder than are persons without an alcohol abuse/dependence diagnosis (Regier et al., 1990), but the nature of these beyond-chance associations is difficult to assess. For example, (a) AUD can be secondary to a primary psychiatric disorder; (b) a psychiatric disorder can be secondary to primary AUD; (c) both disorders could arise from a common diathesis or underlying vulnerability; (d) bidirectional influence can occur; and (e) overlapping diagnostic criteria can create artifactual associations (Clark, Watson, & Reynolds, 1995; Schuckit, Irwin, & Brown, 1990; see Sher & Trull, 1996). Notably, comorbidity rates vary according to the population sampled, the diagnostic approach employed, and the specific comorbid condition under consideration, gender, and extent of other drug use (NIAAA, 1993; Ross, Glaser, & Stiasny, 1988). Next the comorbidity of AUDs with drug use disorders, mood/anxiety disorders, and personality disorders is discussed.

#### DRUG USE DISORDERS

Perhaps not surprisingly, the conditions that are most comorbid with AUDs are other drug use disorders. Although the co-occurrence of substance (alcohol or drug) use disorders (i.e., homotypic comorbidity) has been well documented in a number of large-scale surveys (e.g., the ECA Survey: Helzer, Burnam, & McEnvoy, 1991; Robins & Price, 1991; NCS: Kessler et al., 1994; Kessler, Crum, Warner, & Nelson, 1997; NLAES: Grant, 1997; Grant et al., 1994; Grant & Pickering, 1996), only recently has data been published regarding the 12-month comorbidity of AUDs and drug use disorders in the general US population. As shown in Table 20.1, data from Stinson et al. (2005) suggest that individuals with drug use disorders, compared to nondiagnosers, have significantly higher odds to meet criteria for an AUD. The magnitude of these associations is especially noteworthy, as illustrated by the strong association between cocaine dependence and AUDs (OR = 43.0, 95% CI = 17.83–103.49). The high comorbidity among substance use disorders is important clinically in that it is often the case that treatment of AUD is complicated by the presence of other substance use, abuse, and dependence (see later). This comorbidity is also important etiologically because it suggests that there may be common causes or influences across diverse forms of substance use disorders.

However, data suggest (Stinson et al., 2005) that sociodemographic and psychopathologic correlates differ between individuals that (1) only meet criteria for AUDs (AUD-only), (2) only meet criteria for drug use disorders (drug use disorder [DUD]-only), and (3) meet criteria for both AUDs and drug use disorders (comorbid AUD/DUD). Compared to the AUD-only group, DUD-only and comorbid AUD/DUD individuals are more likely to be young, male, never married, and of lower socioeconomic status. Furthermore, compared to the DUD-only group, comorbid AUD/DUD individuals were more likely to be male, young, and never married. Additionally, individuals in the AUD-only group were more likely to be White, 30–64 years old, and of higher socioeconomic status compared to those in the DUD-only and comorbid AUD/DUD groups, whereas Blacks were overrepresented in the DUD-only group when compared to those in the AUD-only group. Regarding treatment, individuals with comorbid AUD/DUD were more likely to seek treatment (21.76%) compared to DUD-only (15.63%) or AUD-only (6.06%) individuals, suggesting that combinations of alcohol and drug treatment services as well as prevention and intervention efforts may be profitable strategies for the management of substance use disorders. However, the study

**Table 20.1 Adjusted odds ratios of 12-month DSM-IV alcohol use disorder and 12-month specific drug use disorders**

| Drug use disorder | OR (95% CI)[a,b] |
|---|---|
| Any drug use disorder | 7.4 (6.00–9.03) |
| Any drug abuse | 5.7 (4.49–7.30) |
| Any drug dependence | 9.9 (6.47–15.01) |
| Sedative use disorder | 3.4 (1.89–6.29) |
| Sedative abuse | 5.3 (2.44–11.31) |
| Sedative dependence | 1.8 (0.65–4.93) |
| Tranquilizer use disorder | 5.7 (2.55–12.69) |
| Tranquilizer abuse | 7.1 (2.52–20.17) |
| Tranquilizer dependence | 4.0 (1.30–12.16) |
| Opioid use disorder | 7.7 (5.18–11.41) |
| Opioid abuse | 6.1 (3.76–9.91) |
| Opioid dependence | 12.9 (6.18–26.89) |
| Amphetamine use disorder | 8.8 (4.24–18.29) |
| Amphetamine abuse | 5.2 (2.14–12.59) |
| Amphetamine dependence | 20.3 (6.18–66.94) |
| Hallucinogen use disorder | 12.8 (5.18–31.49) |
| Hallucinogen abuse | 10.7 (4.24–26.80) |
| Hallucinogen dependence[c] | — |
| Cannabis use disorder | 6.8 (5.36–8.75) |
| Cannabis abuse | 6.2 (4.80–7.90) |
| Cannabis dependence | 7.3 (3.92–13.72) |
| Cocaine use disorder | 19.2 (10.71–34.56) |
| Cocaine abuse | 10.5 (4.85–22.56) |
| Cocaine dependence | 43.0 (17.83–103.49) |
| Solvent/inhalant abuse | 3.6 (0.52–25.82) |

[b] 95% CI: 95% confidence interval.
[c] Unable to calculate OR because all respondents with hallucinogen dependence also had an alcohol use disorder.
Data taken from the National Epidemiologic Survey on Alcohol and Related Conditions (Stinson et al., 2005). Reprinted from *Drug and Alcohol Dependence, 80*, Stinson, F.S., Grant, B.F., Dawson, D.A., Ruan, W.J., Huang, B., & Saha, T., Comorbidity between *DSM-IV* alcohol and specific drug use disorders in the United States: Results from the National Epidemiologic Survey on Alcohol and Related Conditions, Copyright 2005, with permission from Elsevier.

also revealed a new finding: AUD/DUD comorbidity did not significantly increase the likelihood of mood, anxiety, and personality disorder comorbidity above that found among DUD-only individuals.

This intriguing finding warrants further study and replication (Stinson et al., 2005).

Alcohol use most commonly co-occurs with tobacco use (e.g., Jackson, Sher, & Schulenberg, 2005). As noted by Jackson et al. (2005), individuals with AUDs are more likely to smoke than nondiagnosers (e.g., Martin, Kaczynski, Maisto, & Tarter, 1996), social drinkers are more likely to smoke than nondrinkers (Istvan & Matarazzo, 1984), and individuals with diagnosable tobacco use disorder exhibit greater risk for AUDs (Breslau, 1995). Further, concurrent alcohol and tobacco use appears to interact synergistically to produce elevated health risks (Bien & Burge, 1990), including oral (Blot et al., 1988), laryngeal (Flanders & Rothman, 1982), and esophageal (Muñoz & Day, 1996) cancers. Using nationally representative, prospective, multiwave data, Jackson et al. (2005) utilized a conjoint, developmental approach to examine alcohol-tobacco comorbidity and identified seven co-occurring trajectories of alcohol and tobacco use. Associations between trajectory classes and risk factors were unique to the substance being predicted. For example, the association of smoking with alcohol expectances and delinquency appeared to be attributed to smoking's comorbidity with drinking. These findings illustrate the ability of conjoint, developmental trajectory approaches to provide information regarding AUDs' co-occurrence with other psychiatric disorders that would otherwise remain "masked" by separately examining predictors of AUDs and other disorders. Such an approach could be applied to examine AUDs' co-occurrence with other substances (e.g., marijuana; Jackson, Sher, & Schulenberg, 2008) as well as other psychiatric disorders (e.g., mood/anxiety disorders, PDs).

### MOOD/ANXIETY DISORDERS

As with AUDs, mood and anxiety disorders are among the most prevalent psychiatric disorders in the United States, with prevalence rates of any 12-month DSM-IV independent mood (e.g., major depression) and anxiety (e.g., generalized anxiety disorder) disorders in the US population estimated at 9.2% and 11.1%, respectively (Grant, Stinson, et al., 2004). Moreover, AUDs and independent mood and anxiety disorders commonly co-occur. As exhibited in Table 20.2, associations between AUDs and independent mood and anxiety disorders are consistently positive and significant. Further, of individuals with a current AUD who sought treatment during the same period, approximately 41%

and 33% had at least one current independent mood or anxiety disorder, respectively (Grant, Stinson, et al., 2004), suggesting that mood and anxiety disorders should be addressed by substance abuse treatment providers.

At least one explanation of the significant co-occurrence between AUDs and mood/anxiety disorders are affect regulation models (see earlier) that posit that individuals may be motivated to use alcohol in order to regulate negative and/or anxious emotions commonly associated with depression and anxiety. However, it should be noted that the relation between AUDs and mood/anxiety disorders is complex and only a fraction of individuals with AUDs have a history of anxiety disorders (Schuckit & Hesselbrock, 1994). Indeed, in the NESARC data, only approximately 19% and 17% of individuals with a past-year AUD diagnosed with at least one mood and anxiety disorder, respectively. Thus, though individuals with an AUD are also more likely to diagnose with a mood or anxiety disorder compared to the general population, only a minority of individuals with AUDs experience co-occurring mood/anxiety disorder, suggesting that other factors (e.g., severity of AUD, motivation for alcohol use) may contribute to the likelihood of the co-occurrence of AUDs with mood/anxiety disorders.

### PERSONALITY DISORDERS

In the *Diagnosis and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM-IV-TR*), personality disorders (PDs) are organized into three clusters, Clusters A, B, and C, based on descriptive similarities. Cluster A (characterized as odd or eccentric) includes paranoid, schizoid, and schizotypal PDs. Cluster B (dramatic, emotional, erratic PDs) includes antisocial, borderline, histrionic, and narcissistic. Cluster C (fearful, anxious PDs) includes avoidant, dependent, and obsessive-compulsive PDs. Although several studies have examined the prevalence of PDs (notably antisocial PD) among individuals with AUDs (e.g., Verheul, van den Brink, & Hartgers, 1995; see Sher & Trull, 2002; Trull, Sher, Minks-Brown, Durbin, & Burr, 2000), it is only recently that data have become available that systematically document the co-occurrence of different PDs with AUDs in the general population. Data from NESARC (Grant, Hasin, et al. 2004; Grant et al., 2008; Trull et al., 2010) indicate that the co-occurrence of PDs with AUDs is pervasive in the US population. As shown in Table 20.3, individuals with alcohol dependence

are at increased risk to also meet diagnosis for a number of PDs, especially the Cluster B (the dramatic, emotional, erratic cluster) PDs such as antisocial, borderline, and histrionic PD. The strong relation between AUDs and Cluster B PDs is not surprising, given the association between impulsivity (see "Personality" section earlier) and affective instability and the Cluster B PDs (see Trull et al., 2000).

Although there are several models explaining the comorbidity between SUDs and PDs (see Sher & Trull, 2002; Trull et al., 2000), some research suggests that the development of PDs predicts the development of SUDs, including alcohol abuse and dependency symptoms (Cohen, Chen, Crawford, Brook, & Gordon, 2007; Stepp, Trull, & Sher, 2005), whereas other data suggest that adolescent AUDs predict later PDs (e.g., Thatcher, Cornelius, & Clark, 2005). With the perspective that certain PDs reflect extreme expressions of common personality traits (e.g., Widiger & Trull, 2007), recent research has posited and empirically examined drinking motives (see "Motivations for Use" section earlier) as mediators in the relation between PD symptoms and AUDs. Several studies (Tragesser, Sher, Trull, & Park, 2007; Tragesser, Trull, Sher, & Park, 2008) suggest that enhancement (but not coping) motives mediate the relation between AUDs and PD symptoms, especially in regard to Cluster B PDs. These findings suggest that treatment of comorbid AUDs and PDs should focus on both developing strategies for positive emotion regulation/maintenance as well as interventions aimed at managing features related to impulsive/sensation-seeking personality traits (Tragesser et al., 2008).

## Medical Consequences

Alcohol affects virtually all major organ systems, and there is considerable medical morbidity and mortality that is directly related to alcohol consumption (Rehm et al., 2003) from both diseases (including cardiovascular diseases, gastrointestinal diseases, cancer) and injury (both intentional and unintentional; Rehm, Greenfield, & Rogers, 2001; Rehm et al., 2003). Given the clinical psychology focus of this volume, we discuss two of these areas that are important with respect to the role of behavior: neurological disease and injury.

### NEUROLOGICAL DISEASE

Acute alcohol consumption has numerous effects on the brain (Peterson, Rothfleisch, Zelazo, & Pihl, 1990), including "blackouts" (a period of time when

**Table 20.2 Twelve-month odds of DSM-IV alcohol use disorders and independent mood and anxiety disorders**

| Comorbid disorder | Any alcohol use disorder | Alcohol abuse | Alcohol dependence |
|---|---|---|---|
| Any mood disorder | 2.6 (2.3–2.9) | 1.3 (1.1–1.6) | 4.1 (3.5–4.8) |
| Major depression | 2.3 (2.0–2.6) | 1.2 (1.0–1.5) | 3.7 (3.1–4.4) |
| Dysthymia | 1.7 (1.3–2.2) | 0.8 (0.5–1.3) | 2.8 (2.0–3.8) |
| Mania | 3.5 (2.8–4.4) | 1.4 (0.9–2.0) | 5.7 (4.4–7.4) |
| Hypomania | 3.5 (2.7–4.5) | 1.7 (1.1–2.7) | 5.2 (3.9–6.8) |
| Any anxiety disorder | 1.7 (1.5–2.0) | 1.1 (0.9–1.3) | 2.6 (2.2–3.0) |
| Panic disorder | | | |
| With agoraphobia | 2.5 (1.6–4.0) | 1.4 (0.8–2.6) | 3.6 (2.0–6.5) |
| W/o agoraphobia | 2.0 (1.5–2.6) | 0.8 (0.5–1.2) | 3.4 (2.5–4.7) |
| Social phobia | 1.7 (1.3–2.1) | 0.9 (0.7–1.3) | 2.5 (1.8–3.3) |
| Specific phobia | 1.6 (1.4–1.8) | 1.1 (0.9–1.3) | 2.2 (1.8–2.6) |
| Generalized anxiety disorder | 1.9 (1.5–2.5) | 0.9 (0.6–1.4) | 3.1 (2.3–4.1) |

Data are given as odds ratio (ORs) (95% confidence interval). The ORs represent the odds of having a specific mood or anxiety disorder among individuals with a specific substance use disorder relative to the odds of having a specific mood or anxiety disorder among individuals who do not have the specific substance use disorder.
Data taken from the National Epidemiologic Survey on Alcohol and Related Conditions (Grant, Stinson, Dawson et al. 2004).

recollection is impaired; Vinson, 1989). Although alcoholic blackouts have been thought to be an important early sign of alcoholism, research suggests that blackouts only modestly predict future AUDs (e.g., Anthenelli, Klein, Tsuang, Smith, & Schuckit, 1994) and that alcohol-induced blackouts are relatively common, especially among college students (Wechsler, Dowdall, Maenner, Gledhill-Hoyt, & Lee, 1998).

There is little evidence of any lingering impairment in neuropsychological tests following acute intoxication (Lemon, Chesher, Fox, Greeley, & Nabke, 1993; see Yesavage, Dolhert, & Taylor, 1994 for an exception), and most studies show little apparent effect among those who drink infrequently or moderately (Hebert et al., 1993; Parker, Parker, & Harford, 1991), especially when baseline neuropsychological performance is controlled (Arbuckle, Chaikelson, & Gold, 1994). However, neuropsychological impairment becomes increasingly likely with heavier drinking patterns (>21 standard drinks/week; Parsons & Nixon, 1998). Moreover, increasing evidence suggests that adolescents may be at especially high risk for alcohol-related neuropsychological impairments, perhaps because of the rapid rate of neurodevelopment occurring during this stage of life (Monti et al., 2005).

Despite these findings, alcoholism is associated with chronic brain diseases, such as Wernicke encephalopathy (characterized by neurological signs such as ataxia, nystagmus, and confusion) and Korsakoff psychosis (a combination of retrograde and anterograde amnesia; Victor, 1993, 1994). Wernicke and Korsakoff syndromes typically co-occur and are thought to be due to nutritional deficiency related to alcoholism rather than the direct toxic effects of alcohol itself (Victor, 1993). Some symptoms of Wernicke-Korsakoff syndrome will resolve with improved nutrition and abstinence from alcohol, though the amnesia (classic Korsakoff syndrome) will resolve in only about 20% of patients (Victor, 1993). Further, predicting which patients with Wernicke-Korsakoff syndrome will improve is difficult (Berglund, 1991).

Ischemic strokes, in which blood flow to a part of the brain is stopped by a clot within an artery, and hemorrhagic strokes, in which bleeding in or

**Table 20.3   Odds ratio (and 95% confidence interval) of personality disorders (PDs) and alcohol dependence in the NESARC**

| Personality disorder | NESARC-Original | NESARC-Strict |
|---|---|---|
| Any PD | 3.58(3.44–3.73) | 5.01(4.76–5.26) |
| Cluster A Paranoid | 3.75(3.47–4.05) | 4.53(4.11–4.99) |

around the brain occurs, are differentially related to alcohol. The association between alcohol and ischemic stroke risk appears to be J-shaped (Sacco et al., 1999), whereas the risk of hemorrhagic stroke increases monotonically with increasing alcohol consumption (Carmargo, 1989; Gorelick, 1989; Klatsky, Armstrong, & Friedman, 1989).

As noted in a recent review, the study of alcohol's effect on sleep dates back to the late 1930s (Roehrs & Roth, 2001). An extensive literature has been amassed since that time suggesting that alcohol has extensive effects on sleep as well as daytime sleepiness. Acute high alcohol doses disturb the sleep in healthy subjects, but lower doses of alcohol appear to be beneficial for insomniacs. However, tolerance to alcohol's sedative effects can develop rapidly, resulting in potentially excessive hypnotic use and, for insomniacs, potentially excessive daytime use (Roehrs & Roth, 2001). Further, recent prospective studies suggest that initial sleep problems are a risk factor for subsequent AUD onset and other alcohol-related consequences (Crum, Storr, Chan, & Ford, 2004; Wong, Brower, Fitzgerald, & Zucker, 2004). Additionally, results suggest that individuals with sleep disturbances and co-occurring anxiety disorders or dysphoria are at the highest risk to develop alcohol-related problems (Crum et al., 2004).

**INJURY**

Acute alcohol consumption also contributes to unintended and intended alcohol-related injuries. Vehicular crashes are some of the most common unintentional alcohol-related injuries, and indeed, it is estimated that approximately half of traffic deaths in college-age youths in the United States are alcohol related (see Hingson et al., 2003). Other unintentional injuries occur as a result of falling, fires, sports activities, being hit by or against something, being cut/pierced, overdosing, or being poisoned—all of which can happen repeatedly to individuals (Rehm et al., 2003; Watt, Purdie, Roche, & McClure, 2006). For example, there is some evidence that recurrent traumatic brain injuries are associated with the first injury being alcohol related (Winqvist et al., 2008).

Intentional alcohol-related injuries can be self-inflicted injuries, homicides, and wars, with self-inflicted injuries being the most common of these (Rehm et al., 2003). With regard to suicide, alcohol has been found to be involved in 10% to 69% of completed suicides, and 10% to 73% of suicide attempts (within literature published between 1991 and 2001; Cherpitel, Borges, & Wilcox, 2004). Homicides, in which alcohol is involved, are most likely to occur with the concurrent availability of firearms. Although stabbing and strangling are similarly common alcohol-related acts of violence, they are generally less fatal than alcohol-related shooting (Eckhardt & Pridemore, 2009; Roberts, 2009).

## Assessment
### Diagnostic Interviews

Several diagnostic interviews have been used to assess AUDs and other disorders in the United States as they are defined by the DSM-IV (1994). These include the Diagnostic Interview Schedule Version IV (DIS-IV: Robins, Cottler, Bucholz, & Compton, 1996), the Composite International Diagnostic Interview (WHO CIDI: Version 3.0: Kessler & Üstün, 2004), the Alcohol Use Disorder and Associated Disabilities Interview Schedule-IV (AUDADIS-IV: Grant and Dawson, 2000), the Semi-Structured Assessment for the Genetics of Alcoholism (SSAGA), and the Structured Clinical Interview for DSM-IV (SCID: First, Spitzer, Gibbon, & Williams, 2002).

Grant et al. (2003) assessed the test-retest reliability of selected DSM-IV diagnoses as well as (among others) modules for alcohol consumption, alcohol abuse, and alcohol dependence appearing in the National Institute on Alcohol Abuse and Alcoholism's (NIAAA) Web site. Based on their findings, Grant et al. (2003) suggest that alcohol consumption exhibited "good to excellent" reliability (intraclass correlation [ICC] = 0.69–0.84), whereas alcohol abuse and dependence exhibited "good reliability" (past year diagnosis: kappa = .74). Despite the high reliability associated with these interviews, a number of practical drawbacks exist, such as the personnel and time required for data gathering, leading researchers to employ other assessments, such as questionnaires.

### Assessment of Consumption

Drinking questionnaires account for the variation in drinking styles by focusing on both drinking frequency and quantity of consumption on a given drinking occasion. Because many individuals exhibit high intraindividual variability in drinking quantity, some researchers measure volume/variability in order to resolve drinking patterns further. More extensive assessments of drinking behavior, such as "graduated frequency" approaches (where individuals are queried as to how often they drink varying numbers of drinks/occasions [1–2 drinks, 3–4 drinks, 5–6 drinks, etc.], Greenfield, 2000) are often employed to have sufficient data to measure intraindividual variability in drinking patterns. Another strategy is to measure typical quantity/ frequency with supplementation using measures of heavy drinking to resolve drinking patterns that are likely to be associated with acute negative consequences, such as the 5/4 criteria (five drinks on

an occasion for men and four drinks on an occasion for women) promoted by Wechsler and Austin (1998) as a measure of "binge drinking." Although this distinction appears somewhat crude, evidence suggests that this measure roughly corresponds to the NIAAA's (2004) recent definition of a "binge" episode as drinking that yields a blood alcohol concentration (BAC) of .08% or more.

An alcohol timeline follow-back interview (TLFB: Sobell & Sobell, 1992, 1995, 2000, 2003) is a drinking assessment method that obtains detailed retrospective assessments of alcohol use. By utilizing a calendar and memory aids to enhance recall (e.g., key dates that serve as anchors for reporting drinking), individuals provide retrospective estimates of their daily drinking over a specified time period that can vary up to 12 months from the interview date. The Alcohol TLFB has been shown to have good psychometric characteristics with a variety of drinker groups and can be flexibly scored to provide a range of measures relevant to drinking and abstention patterns (Sobell, Brown, Leo, & Sobell, 1996). Although originally developed to be used in face-to-face assessments with a trained technician or clinician, both telephone and computer-based administrations have been shown to yield reliable results (Sobell et al., 1996).

### Daily Diary and Ecological Momentary Assessment Approaches

Most questionnaire-based assessments of alcohol are cross-sectional and rely on retrospective reports of drinking. Cross-sectional, retrospective data suffer from several shortcomings, including potential reporting bias and the inability to address questions about the temporal order of cause and effect relationships. Although some approaches, such as retrospective timeline follow-back assessments (Sobell & Sobell, 2003) and prospective panel studies resolve these issues to some degree, they fail to address shorter term, dynamic associations between drinking and other variables of interest.

To address these issues, daily diary and ecological momentary assessment (EMA) methodologies have been developed. Participants in daily diary studies are instructed to record events or feelings that occurred during the day on structured nightly recording forms (Carney, Tennen, Affleck, Del Boca, & Kranzler, 1998), by providing daily reports via the Internet (e.g., Park, Armeli, & Tennen, 2004) or interactive voice response via telephone (Collins, Kashdan, & Gollnisch, 2003; Perrine, Mundt, Searles, & Lester, 1995). In EMA studies,

however, drinkers are prompted several times per day to record drinking behaviors and other variables of interest in real time on palm-top computers. Thus, daily diary and EMA studies allow researchers to examine continually changing behaviors while utilizing naturalistic conditions and minimizing retrospective bias. In many clinical and research contexts, such assessments are burdensome but the value of obtaining real-time or near real-time data is increasingly recognized (Piasecki, Hufford, Solhan, & Trull, 2007).

### Biomarkers

Biomarkers of consumption derived from urine, blood, and expired air have traditionally been used to assess levels of alcohol use and treatment compliance (Allen, Litten, Strid, & Sillanauke, 2001; Lakshman & Tsutsumi, 2001; McClure, 2002), and biomarkers continue to be an active area of clinical research. Traditionally, blood markers such as mean corpuscular volume (MCV) and carbohydrate deficient transferring (CDT), and liver enzyme measures such as gamma glutamyl transferase (GGT), aspartate aminotransferase (AST), and alanine aminotransferase (ALT) have been the primary markers used both in clinical research, and to varying extent, in clinical practice (see Conigrave, Davies, Haber, & Whitfield, 2003). Existing blood markers of chronic exposure are limited in that they are relatively insensitive to many drinking patterns and can be nonspecific (Conigrave et al., 2003), thus lacking both sensitivity and specificity. Additionally, they are not necessarily useful for assessing changes in patterns of drinking.

In recent years there has been increasing interest in more direct assessment of alcohol consumption such as blood alcohol level (BAL). Although BAL can be reliably estimated via simple devices that measure breath alcohol levels (e.g., Alcosensor IV, Intoximeters, Inc., St. Louis, MO), breath testing is only useful for assessing consumption when alcohol is still in the bloodstream. Given that the half-life of alcohol in the bloodstream is relatively brief, a legally intoxicated individual may show no blood alcohol several hours after reaching his or her peak BAL, thus limiting its use.

Although still in its infancy, wearable electrochemical devices that estimate BAC based on concentration of alcohol in sweat, referred to as transdermal ethanol sensors, provide objective real-time measures of substance use (Sakai, Mikulich-Gilbertson, Long, & Crowley, 2006; Swift, 2000). These devices can store data over days and thus provide a quantitative, continuous measure of BAL levels over an extended time frame.

### Prevention

Alcohol prevention efforts can be categorized into universal, selective, and indicated prevention efforts. Universal prevention strategies seek to address an entire population (e.g., all adults in a community). Selective prevention strategies target subsets of the entire population that are thought to be at risk for problematic alcohol involvement (e.g., fraternity or sorority members). Indicated prevention efforts are designed to prevent the onset of a full-blown alcohol use disorder in individuals who indicate early signs of dependence (e.g., mandated college students involved in problematic drinking).

### Universal Prevention Approaches
#### POLICY INTERVENTIONS

Most public policies on alcohol are conceived and instituted with the express purpose of universally reducing alcohol use and related injuries and harms, either via penalties (sanctions) for risky behavior (e.g., drunk driving) or inducements (e.g., monetary appropriations) to support education and prevention efforts. Alcohol policies can be issued at federal, state, local, and institutional levels and most commonly affect the pricing of alcohol (e.g., taxes, restrictions on happy-hour sales), how it is sold and its general availability (e.g., days of the week and hours that alcohol can be sold), where it is consumed (e.g., public places), enforcement (e.g., compliance checks, drunk driving laws), and underage access (Toomey & Wagenaar, 1999). Policies concerning the *price/taxation* of alcohol appear to be particularly effective. For example, a report of 112 studies on alcohol tax show a consistent moderately strong association between higher taxes on alcohol and lower heavy drinking rates (Wagenaar, Salois, & Komro, 2009). Notably, taxation is a somewhat difficult policy for US citizens to endorse as it is viewed by some as "punishing" moderate drinkers as well as heavy drinkers. Thus, such policies render the need for complicated tax formulas to achieve an optimal and agreeable tax rate for the general public (Pogue & Sgontz, 1989). Even if alcohol is not highly taxed, however, restrictions on happy hours and alcohol specials (which utilize low alcohol prices as a means of increasing alcohol sales) can be effective in reducing heavy drinking in some populations such as college students, who are particularly receptive to such advertising (Kuo, Wechsler, Greenberg, & Lee, 2003).

Restrictions on the availability of alcohol are also common deterrents of immoderate and problematic use, both in the general and underage population (Gruenwald, Ponicki, & Holder, 1993). For example, local policies that are placed on the *days/hours of operation* of premises that sell alcohol have been particularly effective in reducing alcohol-related traffic crashes (Ashe, Jernigan, Kline, & Galaz, 2003; McMillan & Lapham, 2006). Additionally, because adolescents and young adults have been found to be more likely to use alcohol if there is a higher local alcohol *outlet density* in the area in which they reside (Gruenwald, Johnson, & Treno, 2002; Treno, Ponicki, Remer, & Gruenwald, 2008; Weitzman, Folkman, Lemieux-Folkman, & Wechsler, 2003), local zoning limits on the density of alcohol outlets can help prevent alcohol use in these populations. Additionally, *server liability laws* (in which servers become liable for not responsibly "cutting off" drinkers) have also been shown to be slightly effective in reducing alcohol-related traffic crashes (Wagenaar & Holder, 1991). *Server training* is often suggested by researchers as an important potential prevention step; however, these policies are often created at the institutional level, and thus there is less evidence of its generalizable effectiveness (Toomey & Wagenaar, 1999).

*Drunk driving laws* are also popular sanctions put in place to prevent both heavy drinking and also drinking and driving. BAC limit laws are common internationally and place a definable limit on one's BAC that is acceptable for driving (.08% in the United States). If the BAC is determined to be over this level, then the driver is punished, though the severity of such punishment differs widely by state (e.g., convictions, fines, and mandatory classes are common sanctions, though). Some states also institute zero-tolerance laws for underage drinkers, such that underage drivers are still liable for a BAC that is below .08%, yet over .02%, a law that has been found to be largely effective in reducing alcohol-related crashes (Voas, Tippetts, & Fell, 2003). With regard to punishment for repeat offenders, vehicle sanctions in particular (e.g., impoundment) have been shown to slightly reduce recidivism rates (Voas & DeYoung, 2002).

Perhaps one of the best-known underage alcohol policies is the National Minimum Drinking Age Act, instituted in 1984. The act withheld highway funding from states, which did not impose a minimum legal drinking age (MLDA) of 21, in effect making age 21 the standard MLDA across the nation. The age of 21 has historical value; it

was the age that individuals could vote at the time that alcohol prohibition was repealed in 1933, and thus most states deemed it as their MLDA (NIAAA, 2008a). When the voting age was lowered to 18, most states followed suit with their MLDA. Due to the high prevalence of alcohol-related traffic fatalities in youths, and research showing that states with higher MLDAs suffered fewer fatalities, the Minimum Drinking Age Act was passed (NIAAA, 2008a). However, there is recent interest to lower the MLDA, given that underage drinking continues to be a problem in the United States (Amethyst Initiative, 2008; Johnston, O'Malley, Bachman, & Schulenberg, 2007; Main, 2009), though underage heavy drinkers tend to want younger MLDAs whereas other underage youths do not report a preference (Martinez, Muñoz, & Sher, 2009). Insurance companies have suggested that if citizens want the MLDA to be lowered to 18, the driving age should simultaneously be *raised* to 18 (Rubin, 2008).

*School-based approaches* are usually aimed at educating elementary school youths and adolescents about the ill effects of alcohol and drugs, and how to resist peer pressure to use. School-based approaches can be affect based (i.e., focused on self-esteem and self-efficacy), skills based (i.e., focused on interpersonal interactions), and knowledge based (i.e., educating students about drugs and their effects), or a combination of the three (Tobler, 1986). Abstinence-only approaches that emphasize a "just say no" ideology toward alcohol consumption typically rely on education alone. Despite millions of dollars spent on programs that emphasize zero-tolerance approaches, such as Drug Abuse Resistance Education (D.A.R.E.), a consensus of empirical studies indicate that these approaches fail to reduce alcohol use and related consequences (Lynam et al., 1999; Moskowitz, 1989). Such programs, however, do successfully increase children's overall knowledge of drugs. Moreover, interventions that also incorporate skills training (e.g., Project ALERT) have been shown to reduce some hard drug use and also self-efficacy and general decision making (Faggiano et al., 2008).

*Community-based approaches* are community efforts to prevent and reduce alcohol use and related problems. Much of what can be accomplished in a community-based approach is dependent on funding, as well as the environmental risks and strengths of a particular community. Common elements in many community-based approaches are media campaigns, citizen monitoring, youth outreach programs, server training programs, brief screening

and/or counseling opportunities, and continuing education for professionals. Although evaluations of most of these locally based programs are unavailable, the evaluations that do exist show modest effectiveness (Giesbrecht & Haydon, 2006).

### Selective Approaches

Selective approaches are common in college populations, which have characteristically high binge drinking rates. *Social norms marketing* (where information is disseminated to correct misperceptions regarding peer drinking behavior) and *"expectancy challenge"* interventions (that focus on perceptions of alcohol's effects and provide accurate information) are two approaches that appear to have garnered empirical support (Cruz & Dunn, 2003; Perkins, Haines, & Rice, 2005), though results are somewhat mixed (Wechsler et al., 2003). Larimer and Cronce (2007) recently reviewed the literature on individual-focused prevention and treatment approaches for college drinking and found evidence for several similar efforts which appear to reduce drinking and/or related consequences, including normative reeducation programs, cognitive and behavioral skills-based interventions, motivational/feedback-based interventions, and brief motivational interventions. Notably, brief motivational interventions with personalized feedback were shown to be efficacious across a variety of modalities (e.g., delivered individually, in groups, or as stand-alone feedback with no in-person contact), highlighting the implemental flexibility of this approach.

In addition to these, *harm reduction approaches* (e.g., Marlatt & Gordon, 1985; Marlatt & Witkiewitz, 2002) promote strategies to avoid excessive levels of consumption and to minimize harmful consequences when intoxicated. Strategies that emphasize harm reduction approaches tailored to an individual's unique risk have been implemented for high school students, college students, and patients in medical settings (Neighbors, Larimer, Lostutter, & Woods, 2006). Interventions tailored for high school students incorporate aspects of normative information and skill development for reducing risks associated with alcohol (specifically drunk driving) are linked to reductions in risky drinking and negative consequences from alcohol (Shope, Copeland, Marcoux, & Kamp, 1996). Similar programs that focus on drinking moderation skills and behavioral alternatives to high-risk alcohol-related behaviors have also been shown to result in reductions in risky drinking (D'Amico & Fromme, 2002).

### Treatment Approaches

Depending upon the nature and extent of excessive consumption, physical dependence, and alcohol-related problems, a variety of treatment approaches to address these problems may be relevant. Beyond the treatment of AUDs and other behavioral aspects of drinking is the treatment of medical conditions that may be largely attributable to alcohol consumption (e.g., liver transplantation for alcohol cirrhosis; Beresford & Everson, 2000). Following we highlight those treatments that are of most relevant to clinical psychologists.

### Treatment of Alcohol Withdrawal

Withdrawal from alcohol in individuals with moderate to severe alcohol dependence is associated with a common abstinence syndrome characterized by cardiovascular overactivity, sweating, sleep problems, tremor, and anxiety (see Kosten & O'Connor, 2003). Detoxification treatment is designed to control the potential psychological and medical complications that may temporarily arise after a period of sustained, heavy use. Further, it is designed to do so in a way that is comfortable for the patient and prepare the patient to make arrangements for future treatment of his or her dependence (Bayard, McIntyre, Hill, & Woodside., 2004; Luty, 2006; Raistrick, 2000). A small minority of individuals who initially experience slight withdrawal reactions will progress to more severe reactions (e.g., alcohol withdrawal delirium, such as delirium tremens [Chick, 1989], hallucinosis, or seizure) that require skilled, hospital-based case.

Although the majority of individuals who are alcohol dependent can be withdrawn safely without medication (Whitfield et al., 1978), both human clinical and animal laboratory research suggests that there is a kindling-like process associated with withdrawal. That is, the likelihood of damage to certain brain regions (and corresponding behavioral deficits) increases with greater numbers of detoxifications (Becker, 1998), highlighting the potential value of medical treatments that dampen the withdrawal process or provide neuronal protection. Detoxification typically consists of monitoring withdrawal symptoms and responding with appropriate psychopharmacological interventions, such as benzodiazepines (Raistrick, 2000) and/or other drugs (e.g., antiepileptic drugs to treat seizures).

For many years it was assumed that medical detoxification (using benzodiazepines or similarly acting drugs) in an inpatient facility was necessary to avoid having patients progress to major

withdrawal. However, as discussed by Bischof, Richmond, and Case (2003), rising costs for inpatient treatment of alcohol abuse rose sharply during the 1980s, leading researchers to examine whether outpatient services were as effective (Finney, Han, & Moos, 1996). As many of these less expensive alternatives were found to be at least as effective as traditional inpatient detoxification (e.g., Alterman, Hayashida, & O'Brien, 1988; Bischof et al., 1991; Feldman, Pattison, Sobell, Graham, & Sobell, 1975; Hayashida et al., 1989; Stinnett, 1982; see Bischof, Rumpf, Hapke, Meyer, & John, 2003; Fleeman, 1997), other alternatives to hospital medical detoxification developed. These alternatives differed in both setting and in the use of medication. Some nonhospital medical detoxification programs moved treatment out of the more expensive hospital setting but continued to utilize medication routinely, whereas so-called social setting detoxification (Social Setting Detoxification, 1986) utilized a treatment process that provided a supportive, caring, and noninstitutional environment without the use of medication. Although several researchers concluded (based on empirical evidence) that social setting detoxification is an effective alternative to more costly hospital-based detoxification for most cases of withdrawal (e.g., O'Briant, Petersen, & Heacock, 1977), there may be concerns about the specific neurological sequelae of repeated unmedicated withdrawals.

### Brief Interventions

Brief interventions, which can be as short as 10 to 15 minutes (e.g., Fleming et al., 2000, 2002), are often used in primary care settings with drinkers having low levels of dependence and/or are unwilling to pursue more intensive treatment regimens. These interventions often involve motivational approaches designed to encourage drinkers to consider changing their drinking behavior (Wilk, Jensen, & Havighurst, 1997). Typically, the role of the clinician is to help the drinker set drinking goals, agree on a plan to reduce or stop consumption, and provide advice and educational materials. Follow-up sessions are scheduled to monitor progress and renegotiate drinking goals and strategies. Brief interventions can be administered by a wide variety of providers in a range of treatment modalities and are relatively less expensive than extended treatment (Heather, 1986). The NIAAA (2007) has developed a treatment manual, *Helping Patients Who Drink Too Much*, and supporting materials to encourage clinicians to screen and intervene with

patients they see in their practices. The NIAAA has also recently added online training materials (2008b).

Meta-analysis of controlled trials indicate that brief interventions reduce alcohol consumption and drinking-related outcomes (when compared to individuals who do not receive treatment) and appear to be as effective as extended treatment conditions (Moyer, Finney, Swearingen, & Vergun, 2002; Neighbors et al., 2006; Wilk et al., 1997). Further, these approaches appear to result in significant cost savings compared to the utilization of other health care services. Additionally, recent studies indicate that brief, motivational interventions delivered in an emergency room setting have been shown to reduce alcohol consumption, alcohol-related negative consequences, and recidivism, including among trauma patients (Bombardier & Rimmele, 1999; Gentilello, Ebel, Wickizer, Salkever, & Rivara, 2005; Monti et al., 1999). Thus, such brief motivational interventions are considered as a "best-practice" recommendation in the United States (Neighbors et al., 2006).

### Cognitive-Behavioral Approaches

Although numerous cognitive-behavioral interventions to treat alcohol dependence have been developed and assessed (Miller, Zweben, DiClemente, & Rychtarik, 1995), a predominant model of cognitive-behavioral therapy for AUDs is based on the work of Marlatt and Gordon (1985) regarding the relapse process. Marlatt's cognitive-behavioral model of relapse centers on high-risk situations and the individual's response in that situation (see Witkiewitz & Marlatt, 2004, 2008). Under this model, individuals who lack confidence to deal with the situation and/or lack an effective coping response are more likely to be tempted to drink. It is thought that the decision to use or not use is then mediated by the individual's outcome expectancies for the initial effects of using the substance (Jones et al., 2001). This model provides the basis for relapse prevention interventions that are designed to prevent and manage relapse by identifying potential high-risk situations for relapse and challenging the individual's expectations for the perceived positive effects of a substance (Witkiewitz & Marlatt, 2004, 2008). A meta-analysis conducted by Irvin, Bowers, Dunn, and Wang (1999) suggested that relapse prevention was a successful intervention for substance use and improving psychosocial adjustment, especially for individuals with alcohol problems.

A related component of cognitive-behavioral therapy (CBT) is social skills training (Monti & O'Leary, 1999). This approach assumes that increasing the repertoire of coping skills will reduce the stress of high-risk situations and provide alternatives to drinking. Techniques include assertiveness training and role-playing skills related to alcohol refusal. Several studies suggest social skills training is effective in reducing drinking (see Chambless & Ollendick, 2001).

Despite the apparent effectiveness of cognitive-behavioral approaches to treat AUDs, little is known about the cognitive-behavioral processes that underlie current definitions of coping (Morgenstern & Longabaugh, 2000; Witkiewitz & Marlatt, 2004, 2008). Although numerous studies have examined possible mediators (e.g., changes in coping skills) of cognitive-behavioral treatment for AUDs, there is little empirical support for the hypothesized mechanisms of action of CBT (Morgenstern & Longabaugh, 2000).

Based on the notion that alcohol-related cues (e.g., the sight and smell of an alcoholic beverage) can trigger a relapse for alcoholics, cue-exposure therapy repeatedly exposes patients to alcohol-related cues while preventing the usual response (drinking alcohol) with the desired outcome to reduce or eliminate urges to drink in response to cues (Monti & Rohsenow, 1999). Cue-exposure treatment draws from both classical learning models and social learning models of behavior. From the perspective of classical learning theory, environmental cues associated with past drinking elicit conditioned responses (e.g., Rohsenow et al., 1994) that are thought to play a role in relapse. As a corollary, repeated exposure to substance-associated cues should lead to an extinction of conditioned reactions, resulting in decreases in the likelihood of craving and relapse, and also extends time to first relapse. Social learning theory suggests that the presence of cues increases risk of relapse because cues increase the relevance (salience) to the drinker of positive effects of alcohol, thus leading the drinker to want to consume more alcohol (Monti & Rohsenow, 1999). Alcohol cues may also trigger cognitive and neurochemical reactions that undermine the drinker's ability to use coping skills and the drinker's beliefs surrounding the use of skills (Monti, Rohsenow, Colby, & Abrams, 1995). Various approaches to implement cue exposure exist (Rohsenow et al., 1994), with classical learning models that tend to focus on habituation and extinction of responses. Approaches based on social learning theory may

incorporate coping-skills training. Cue-exposure is listed as a probably efficacious treatment for AUDs (Chambless & Ollendick, 2001), though some researchers have questioned the effectiveness of cue exposure for treating substance use disorders (e.g., Conklin & Tiffany, 2002).

Although traditional cue-exposure techniques have focused on relatively passive exposures to alcohol cues (or various cues to drinking), it is possible that findings from recent research on implicit cognition in addiction can lead to techniques to enhance cue exposure (Wiers et al., 2008). For example, Fadardi and Cox (2007) showed that the tendency for alcohol cues to grab a drinker's attention can be altered by training excessive drinkers to gain more control over their attentional bias via behavioral training. Critically, these changes in attentional bias appear to correlate with changes in drinking behavior. Based on recent research on implicit cognition, other behavioral techniques that try to alter automatic reactions are also being evaluated. For example, Wiers et al. (2008) have exploited the finding that approach (pulling something toward oneself) and avoidance (pushing something away from oneself) are associated with more positive (pulling) and negative (pushing) emotions (e.g., Cacioppo, Priester, & Berntson, 1993). Specifically, they trained drinkers to "push" alcohol stimuli away. Preliminary data suggested reduced implicit positive attitudes toward alcohol as well as reduced craving.

It should also be noted that there is growing evidence from research on treatment of anxiety disorders that pharmacological manipulations can enhance exposure-based fear reduction (Norberg, Krystal, & Tolin, 2008). Specifically, D-cycloserine has been used to enhance extinction of alcohol seeking in rats (Vengeliene et al., 2008), suggesting that such pharmacological enhancement of exposure-based treatments could be useful clinically in the future. These innovative approaches that exploit new findings on implicit cognition and the pharmacology of learning potentially open up a new era of research on exposure-based approaches.

### Generalized Self-regulation Training

Based on the perspective that (lack of) self-regulation (or self-control) contributes to AUDs and in light of findings suggesting changes in impulsivity relate to changes in alcohol-related problems (Littlefield et al., 2009), some researchers have recently suggested strengthening self-regulation as a treatment approach (e.g., Sher & Martinez,

2009). Recent research suggests traits related to self-regulation, such as conscientiousness (Costa & McCrae, 1992), may be more mutable than previously thought (e.g., Roberts, Walton, & Viechtbauer, 2006). Experimental research has suggested that regular use of self-control will strengthen this attribute in a way akin to how muscles get stronger with regular use (Baumeister, Heatherton, & Tice, 1994; Muraven & Baumeister, 2000). This perspective provides novel approaches for training or rehabilitating self-control in persons suffering from substance use disorders. For example, self-control "exercises," such as dietary monitoring, regular physical exercise, money management planning, and working on improving study habits (Baumeister, Gailliot, DeWall, & Oaten, 2006), have led to improvements in other self-regulatory behaviors, such as smoking fewer cigarettes and drinking less alcohol. Thus, there is now increased interest in the treatment (and preventive) potential of self-control training for a range of externalizing behavior problems, including AUDs.

### The Question of Patient-Treatment Matching

It has long been recognized that individuals with AUDs are extremely heterogeneous with respect to etiology, symptomatology, and course of disorder. Because of this diversity, it has been speculated for many years that rather than a "one-size-fits-all" approach to alcohol treatment, treatment outcomes might be optimized if patients could be matched to specific treatments based on their personal characteristics. In a large, multisite, randomized control trial, this general hypothesis was put to the test by examining the interaction between three psychosocial treatments (i.e., twelve-step facilitation, cognitive-behavioral coping skills, or motivational enhancement therapy) and several individual difference variables hypothesized to be related to responsiveness to specific treatment approaches (e.g., sex, coping skills; Project MATCH Research Group, 1993). Although numerous papers and chapters have been published based on Project Match, the outcomes of the primary study hypotheses not only failed to find differences among treatments as a main effect but also failed to find much evidence for the hypothesized interactions (Project MATCH Research Group, 1997). It is possible that future research will provide more convincing evidence of patient-treatment matching strategies with psychological and behavioral treatments. For example, as discussed in the section on "Naltrexone,"

there appears to be evidence of patient-treatment matching for pharmacological treatments. It has also been suggested that the standard statistical approach to examining alcohol outcomes (e.g., relapse as a dichotomous outcome) may obscure important findings compared to more sophisticated approaches that conceptualize relapse as a nonlinear, dynamic process (Witkiewitz & Marlatt, 2007). Thus, although Project Match (and the theory underpinning it) has been popularly viewed as a failed approach, it is clearly premature to jettison patient-treatment matching as a viable strategy.

Indeed, other researchers (e.g., Conrod et al., 2000) have examined important individual differences, such as personality and drinking motives, in order to develop individually tailored treatments predominantly targeted at substance use motivations associated with different personality dimensions. Preliminary empirical evidence suggests that approaches that focus on individual differences in drinking motives related to personality delay the growth of adolescent drinking and binge drinking (Conrod, Castellanos, & Mackie, 2008).

### Marital and Family Approaches

AUDs often manifest themselves in the context of the family and have considerable consequences for spouses and other family members who often try to exert interpersonal influence over the drinker (Epstein & McCrady, 1998; Fals-Stewart, O'Farrell, Birchler, Cordova, & Kelley, 2005). Consequently, it is not surprising that a number of interventions involve couples and the family unit.

At the couples' level, the most extensively studied approach is behavioral couples therapy (BCT). In addition to sharing many features of traditional cognitive-behavioral treatment for the drinker, BCT also targets partners' coping with drinking situations reinforcing abstinence and on improving the dyadic relationship. A recent meta-analysis of BCT in substance use disorders (where 8 of the 12 studies reviewed were for treatment of AUDs; Powers, Vedel, & Emmelkamp, 2008) demonstrated that this treatment approach was more effective than control treatments in improving relationship satisfaction as well as substance-related outcomes. Interestingly, the comparatively stronger salutary effect of BCT on substance-related outcomes was not evident immediately after treatment when all treatments fared well but, rather, the couples' treatment effect strengthened relative to control treatments over time. This suggests that the improved interpersonal relationships fostered

better alcohol-related outcomes. Importantly, there was no relation between the number of sessions and outcomes, suggesting that BCT could be delivered as a relatively brief treatment.

A number of treatment approaches that target the entire family and larger social networks have also been developed (Copello, Velleman, & Templeton, 2005). Arguably the most systematically studied of these, the Community Reinforcement and Family Training approach (Smith & Meyers, 2004), is an extension of the Community Reinforcement Approach (CRA, Sisson & Azrin, 1986). Under this approach, a friend or family member (e.g., spouse) either provides or removes agreed reinforcers (e.g., television access) to reward periods of sobriety and punish drinking for the targeted individual. Further, the agreed-upon friend/family member may also encourage the alcohol dependent to enter treatment and supervise the use of disulfiram. Several studies suggest that CRA is an effective treatment for alcohol abuse and dependence (Carr, 2009; Chambless & Ollendick, 2001; Luty, 2006).

### Self-help Groups

Perhaps the most widely recognized treatment approach for AUDs is Alcoholics Anonymous (AA; AA World Services, 1978), a self-help movement that has now been in existence for 75 years. AA describes AA itself as (copyright © The AA Grapevine, Inc. Reprinted with permission):

> a fellowship of men and women who share their experience, strength and hope with each other that they may solve their common problem and help others to recover from alcoholism. The only requirement for membership is a desire to stop drinking. There are no dues or fees for AA membership; we are self-supporting through our own contributions. AA is not allied with any sect, denomination, politics, organization or institution; does not wish to engage in any controversy, neither endorses nor opposes any causes. Our primary purpose is to stay sober and help other alcoholics to achieve sobriety.

Based upon a "disease model" of alcoholism that posits that alcoholism is a relapsing illness that requires complete abstinence (Luty, 2006), new members are encouraged to recruit support from a sponsor (an AA member who has been sober for at least 1 year) and to attend 90 meetings in the first 90 days of treatment. Several studies suggest that AA is as effective as alternative treatments (Tonigan, Toscova, & Miller, 1996), though many studies are small, unrandomized, and fail to account for the fact that many AA members are often concurrently involved in other forms of treatment.

Other self-help approaches have been developed that do not rely on abstinence goals. Specifically, Moderation Management (MM; Kishline, 1994) is based on the assumption that some individuals are problem drinkers yet not alcohol dependent and can learn to drink in nonproblematic ways. As noted by Humphreys (2003), both AA and MM share some assumptions. For example, both suggest that there is a difference between individuals who are alcohol dependent and less likely to be able to drink moderately and those who may have problems with alcohol not due to an underlying dependence on alcohol. However, the two approaches differ to the extent that they believe the drinker is a good judge of how dependent he or she is and whether controlled drinking is a realistic outcome expectation. Specifically, AA and closely allied approaches embrace the notion that a hallmark symptom of alcoholism is denial (see Sher & Epler, 2004, for a discussion of this concept) and therefore an individual is unable to realistically appraise his or her drinking. MM, on the other hand, views the individual as capable of rationally evaluating the appropriateness of controlled drinking goals. Comparisons of those who affiliate with AA and MM suggest that the two approaches draw from very different subpopulations of those with AUDs, with MM affiliates being more socially stable and less alcohol dependent than those who affiliate with AA (Humphreys & Klaw, 2001). Thus, although there has been considerable antagonism between advocates of both AA and MM approaches, it appears that the two approaches are, to a large extent, serving different populations with different clinical needs and goals.

### Pharmacotherapy

One of the most dramatic changes in treatment of AUDs to have occurred in the past 15 years is the introduction of the pharmaceuticals to curb craving and compulsive alcohol use. Although disulfiram (Antabuse) has been marketed for the treatment of alcohol dependence for more than 60 years, this medication (which causes an intense adverse reaction when the drinker consumes alcohol by blocking the enzyme that breaks down acetaldehyde, leading to a buildup of this toxic metabolite in the bloodstream) has not been shown to be effective as a major treatment modality by itself (though it may be useful as part of behavioral contracting).

In 1994, naltrexone (Revia) was the first new medication to get FDA approval for the treatment of alcohol dependence since disulfiram. Naltrexone, which blocks opiate receptors in the brain, appears to be a fairly effective medication in reducing heavy consumption and reducing risk of relapse (Srisurapanont & Jarusuraisin, 2005). Despite its apparent efficacy and low profile of side effects, many believe it is underutilized, perhaps because of physicians' reluctance to use medications to treat substance dependence. A long-acting, injectable form (Vivitrol) has recently been approved and appears to be effective as well (Garbutt et al., 2005). This long-acting form might prove to be useful in individuals who have difficulty in complying with oral pharmacotherapy. Additionally, recent findings (Kranzler et al., 2003) suggest that naltrexone can be taken on a targeted, as-needed basis (e.g., when a drinker wants to abstain or limit his or her drinking on a given occasion).

There appear to be important, genetically based individual differences in response to naltrexone (e.g., Oslin, Berttini, & O'Brien, 2006). Specifically, allelic variation in the μ-opioid receptor moderates treatment response to naltrexone in alcohol-dependent individuals. This finding may herald a new "pharmacogenomic" chapter in the history of patient-treatment matching attempts (e.g., Edenberg & Kranzler, 2005). It is hoped by many that advances in both genomics and neurobiology will lead to other forms of "personalized medicine" (Zerhouni, 2006) in the treatment of alcohol dependence, where the characterization of one's own genetic makeup will guide treatment efforts.

It should also be noted that two other drugs have empirical support for their use in the treatment of alcoholism: acamprosate (Campral) and topiramate (Topomax). Acamprosate is FDA approved for the treatment of alcohol dependence and is thought to work by restoring normal NMDA receptor tone in glutamate systems in the brain (Kiefer & Mann, 2005). However, in one recent, large, multicenter clinical trial in the United States, acamprosate was not found to be effective (Anton et al., 2006). Consequently, it has been speculated that this treatment only shows effectiveness in trials with patients with relatively severe dependence. Although topiramate has not received an indication for alcohol dependence from the FDA (it is approved for other conditions), this antiepileptic drug has been shown to be effective in a large, multisite, randomized control trial (Johnson et al., 2007), presumably by facilitating GABAergic neurotransmission and inhibiting glutaminergic pathways in the brain and thus reducing alcohol-mediated reward. A number of drugs with different targets and methods of action are under investigation currently, and it seems likely that the range of treatment options for alcohol dependence will increase over the coming years

## Future Directions

It is difficult to imagine another health-related condition that provides more windows into varied aspects of the life sciences, the behavioral sciences, and the broader social sciences than alcohol use disorders. The noted 19th-century physician Sir William Osler is credited with claiming that to know syphilis was to know medicine, reflecting the diverse manifestations of this disease across multiple organ systems in the era before the introduction of antibiotics. In a sense, to know AUDs is to know about many things, including the genetics of individual differences, psychopharmacology, human development, psychopathology, varied physical ailments, and even the role of religion on personal behavior and social policy. Alcohol use, depending upon the intensity of use and when in the life course it is used, can be a significant risk factor for a number of psychological and physical disorders as well as having significant health benefits. Similarly, there are a number of adverse social consequences that stem from excessive alcohol use, but, when used in moderation, many in our society value beverage alcohol as a means of facilitating social interactions and enhancing major celebrations. It is probably safe to state that American society holds strongly ambivalent attitudes surrounding the use of alcohol because of its combination of many valued effects coupled with its (often devastatingly) damaging effects. This ambivalence is longstanding as evidenced by the Eighteenth Amendment to the United States Constitution, which, after passage in 1919, prohibited the manufacturing, sales, and transportation of beverage alcohol and the subsequent repeal of this prohibition 14 years later, the only amendment of the US Constitution to ever have been repealed.

There are many pressing areas for future alcohol research, a number of which have been discussed herein. One of the most basic ones concerns nosology, that is, how do we define disordered drinking and where is the line when drinking moves from merely being incautious, risky, or foolish to being a mental disorder. Research has uncovered a number of problems with our current diagnostic systems. As we continue to understand the dependence process better, we will be in a better position to take

this etiological knowledge to inform diagnosis with respect to developing better criteria sets and thresholds for meeting these criteria and perhaps even develop objective laboratory measures that assess core features of dependence reliably, even in those individuals who are currently abstinent (Sher, Wolf, & Martinez, 2009).

Another important area for research where we might expect to make significant progress in the coming years is in understanding the reasons why most individuals are able to drink alcohol in a way that poses minimal risk to themselves and others while some individuals are not and develop AUDs. A number of premorbid individual difference variables have been found to differentiate normal drinkers from those who have AUDs (e.g., certain genotypes, personality traits, and motives for use). Although sophisticated multivariate models have been put forth to describe how these individual difference variables might operate, we are still greatly limited in our ability to predict who will and who will not be able to control their consumption and how we might be able to intervene to prevent AUDs in those who are most vulnerable. The dream of "personalized medicine" that is "predictive, personalized and preemptive" (Zerhouni, 2008) remains an elusive goal, but we are clearly getting closer to identifying critical vulnerabilities and how they influence the course and development of AUDs and appropriate interventions will hopefully follow. As noted earlier, one area of "personalized" medicine that is much closer is selection of pharmacological treatment (i.e., naltrexone) based upon genetic testing (i.e., specific allele of the μ-opioid receptor). Presumably, the identification of more pharmacogenomic indications will continue to be an active research area and represent the next phase of patient-treatment matching. We also are moving toward developing and validating new treatment approaches that address both effortful self-regulatory processes (i.e., restraint or "will") and automatic approach tendencies (Sher & Martinez, 2009). Such new approaches hold the promise for having highly specific treatments that can be used individually or in combination with other behavioral and with pharmacological treatments based on an understanding of the motivational and regulatory structure of an individual's disordered drinking.

Although AUDs have been with human societies since antiquity and it seems likely that they will represent significant health problems for the foreseeable future, our ability to identify, prevent, and treat these conditions continues to show constant improvement. Continued improvement rests on our ability to use new and existing research to design more effective assessments and interventions and validate them rigorously.

# Sex and Gender Disorders

Andrea Bradford *and* Cindy M. Meston

**Abstract**

Sex and gender disorders are classified into three major categories. The *sexual dysfunctions* are problems that inhibit one's motivation or ability to engage in sexual activity. *Paraphilias* are recurrent patterns of sexual arousal and/or behavior involving inappropriate targets of sexual expression. *Gender identity disorder* is the experience of intense discomfort with one's assigned gender role, accompanied by the desire to live as a person of the opposite sex. Conceptualizations of sex and gender disorders are ever evolving in response to multiple cultural, scientific, political, and commercial influences. This chapter reviews current practice and emerging concepts in the diagnosis and treatment of sex and gender disorders, with emphasis on recent research findings and key unresolved questions.

**Key Words:** Gender dysphoria, gender identity disorder, orgasm, paraphilia, sexual arousal, sexual desire, sexual dysfunction

Although the behavior of many animal species suggests a "hard-wired," instinct-driven program for reproductive activity, other animals possess capabilities for a more flexible range of sexual behavior. The range of sexual behavior in humans is particularly diverse. As such, distinguishing "normal" from "abnormal" behavior for clinical purposes is problematic. The modern practice of classifying certain sexual behavior patterns as mental disorders has an ever-evolving and sometimes self-contradictory history. For example, although today the most common sexual dysfunction in women is a lack of sexual desire or interest, earlier versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) reflected clinical concern about excessive sexual interest in women (nymphomania), which is no longer a defined diagnosis. Another prominent example is the diagnosis of homosexuality as a mental disorder, which was restricted to "ego dystonic homosexuality" in the third edition of the DSM and later removed altogether. Clearly, as sociocultural norms for sexual behavior evolve, so do categories of psychopathology.

Classifying sexual behavior patterns as disorders has a variety of potential consequences. On one hand, viewing troublesome sexual behaviors as manifestations of clinical disorders rather than moral or volitional failings may open the door for education, support, and therapeutic intervention to improve the sufferer's quality of life. On the other hand, pathologizing sexual behavior that flouts cultural norms—however well-intentioned—may facilitate the stigmatization or exploitation of those with an identified "disorder." The tension between normative/affirming and pathologizing/medicalizing explanations of sexual and gender behavior is reflected even in the conventional nomenclature of the DSM, which makes most psychiatric diagnoses conditional upon personal distress or functional impairment associated with a sexual problem.

The goal of this chapter is to provide a brief overview of recent practices and theoretical perspectives on sex and gender disorders. Conventionally, these disorders are classified as

sexual dysfunctions (problems related to initiation or resolution of sexual activity, generally with a partner), paraphilias (problems related to inappropriate targets of sexual arousal and behavior), and gender disorders (discomfort with the gender role behavior of one's sex at birth). As emerging opinion emphasizes sex and gender differences in the etiology and assessment of sexual dysfunctions, sexual dysfunctions affecting men and women will be discussed separately.

## Sexual Dysfunctions in Women

The debut of sildenafil (Viagra) on the US market in 1998, followed quickly by competitors tadalafil (Cialis) and vardenafil (Levitra), was met with both commercial success and increased popular attention to male sexual disorders. The search for a corresponding product for women's sexual problems has been less successful. Enthusiasm for a "pink Viagra" has been tempered by unremarkable clinical trial outcomes and pointed opposition to the medicalization of women's sexual problems (e.g., Moynihan, 2003; Tiefer, 2002). Although development of medical treatments for women's sexual dysfunction is ongoing, a lesson learned from the Viagra era is that models of male sexual function and dysfunction may not be readily applicable to women.

In 1999, Laumann, Paik, and Rosen published figures from the National Health and Social Life Survey indicating that 43% of women complained of a sexual problem in the past year. This frequently cited figure has been a subject of criticism as this estimate does not take into account the presence of personal distress and inflates the prevalence of clinically significant problems. More recent and conservative estimates of female sexual dysfunction, which take into account personal distress, range from 5.8% (Shifren, Monz, Russo, Segreti, & Johannes, 2008) to 24.4% (Bancroft, Loftus, & Long, 2003; Burri & Spector, 2011; Shifren, Monz, Russo, Segreti, & Johannes, 2008).

Sexual dysfunctions in women are often comorbid and may be related to multiple etiological factors. Thus, a multidimensional assessment and treatment strategy is often warranted. In addition to the assessment of the nature, severity, and course of current symptoms, a comprehensive assessment of sexual concerns should include a psychosocial history, a discussion of sexual attitudes in the family and culture of origin, a history of early sexual experiences (including, if applicable, unwanted sexual contact), assessment of general functioning in the current relationship, and a medical and psychiatric history. Validated instruments to assess sexual dysfunction in women include the Brief Index of Sexual Functioning for Women (BISF-W; Taylor, Rosen, & Leiblum, 1994), the Changes in Sexual Functioning Questionnaire (CSFQ; Clayton, McGarvey, & Clavet, 1997), the Derogatis Interview for Sexual Functioning (DISF/DISF-SR; Derogatis, 1997), and the Female Sexual Function Index (FSFI; Rosen et al., 2000).

### Sexual Desire and Arousal Disorders

A persistent lack of interest in sexual activity is the most common presenting complaint among women seeking help for sexual difficulties. Historically, the conceptualization of low sexual desire as a mental disorder was informed by a model of sexual response introduced by Kaplan (1979; see also Masters & Johnson, 1966). In this model, desire is assumed to precede sexual arousal and orgasm in a unidirectional, sequential manner. However, this definition has elicited criticism (Basson et al., 2003) for its characterization of sexual fantasies as a primary trigger for sexual behavior in women. Although engaging in sexual fantasy may be characteristic of women in new relationships, research suggests that spontaneous sexual thoughts or fantasies occur far less frequently among women in longer-term relationships (e.g., Cawood & Bancroft, 1996). Basson (2001) proposed that, because women are often motivated to engage in sexual activity for reasons other than a desire for sexual stimulation, desire may follow *after* a woman has begun to experience sexual stimulation and arousal ("receptive" or "responsive" desire). Thus, there appears to be a close but not necessarily unidirectional association between sexual desire and sexual arousal in women. Laumann, Paik, and Rosen (1999) reported that 31% of women in the United States experienced a lack of interest in sex for at least several months during the prior year. Findings from clinic- and population-based studies indicated current prevalence rates of 10%–46% for sexual desire problems (Simons & Carey, 2001).

Commonly associated with low sexual desire is a lack of sexual arousal. Sexual arousal includes both feelings of subjective sexual excitement and physiological changes such as genital swelling and lubrication. However, genital changes may be a "reflexive" response to any sexual stimulus —whether welcomed and enjoyed or not—and

are therefore not necessarily congruent with the woman's subjective appraisal of the stimulus (Basson et al., 2003). Likewise, for various reasons a highly arousing stimulus may elicit strong subjectively experienced arousal without corresponding genital responses. Thus, low sexual arousal may be experienced as a lack of genital sensation, a lack of feeling mentally "turned on," or both. Shifren and colleagues (2008) estimated that roughly 1 in 4 women in the US experience difficulty with sexual arousal, but only 5% of women have a sexual arousal problem that is distressing to them. Sexual arousal concerns seldom present outside of the context of other sexual problems (Giraldi, Rellini, Pfaus, & Laan, 2013).

The DSM-5 defines female sexual interest/arousal disorder as a persistent problem with sexual interest, subjective arousal, and/or genital arousal in women that causes significant distress or impairment. This stands in contrast to previous versions of the DSM that classified desire and arousal disorders separately. Support for the single-diagnosis concept includes a high degree of comorbidity between sexual desire and arousal problems, consistently high correlations between self-report measures of sexual desire and arousal across studies, and the observation that women themselves seldom clearly distinguish sexual desire and sexual arousal (Brotto, Graham, Binik, Segraves, & Zucker, 2011). However, whereas some have argued that sexual desire and sexual arousal in women are manifestations of the same phenomenon, this proposition remains controversial (e.g., Sarin, Amsel, & Binik, in press).

Problems related to sexual desire and receptivity have been associated with negative or fearful beliefs and attitudes about sexuality and passive gender role identification (Nobre & Pinto-Gouveia, 2006; Sanchez, Crocker, & Boike, 2005). Assessment should include a psychosocial history to elicit family attitudes toward sexuality, early sexual experiences, and unwanted or otherwise upsetting sexual experiences. Depressed mood and anxiety are also associated with sexual desire and arousal difficulties and should be assessed. Anxiety that is specific to sexual concerns may play a central role in the development and maintenance of sexual arousal problems. Barlow (1986) proposed that the cognitive distraction of performance anxiety directs attention from sexual to nonsexual cues, interfering with arousal. Although performance anxiety in men is typically linked to the ability to attain and

maintain an erection, "performance concerns" in women are more likely related to perceived sexual attractiveness and desirability than to genital function (Dove & Wiederman, 2000). Recent work on the genetic epidemiology of sexual dysfunctions in women suggests a shared genetic vulnerability between anxiety sensitivity and sexual disorders, further supporting the role of anxiety as an important etiological factor (Burri, Spector, & Rahman, 2012).

Problems with sexual desire and arousal may reflect not only intrapsychic factors but also problems in the relationship with the sexual partner. A presenting complaint of low sexual desire or responsiveness in the woman should therefore trigger several clinical hypotheses about both partners. Sexual problems may be epiphenomena of unresolved problems in the relationship or interpersonal dynamics between partners. Low desire or arousal may also represent a normative response to an unskilled partner or unsatisfactory conditions specific to the couple's sex life. Finally, sexual desire and arousal concerns may develop secondary to a *partner's* sexual dysfunction and may resolve with successful treatment of the partner (Goldstein et al., 2005).

Women's sexual desire and arousal appear to be influenced by levels of sex steroid hormones, particularly androgens and estrogens. Endocrinological disorders interfere with these synthesis of these hormones and have been linked to problems with sexual desire and arousal (for review, see Guay & Spark 2006). Decreased ovarian function during the menopausal transition also results in lower estrogen production and has also been associated with sexual desire and arousal problems. Recent epidemiological studies indicate that "surgical menopause" induced by oophorectomy (surgical removal of the ovaries) is a more prominent risk factor for low sexual desire than natural menopause, particularly in younger cohorts (Dennerstein, Koochaki, Barton, & Graziottin, 2006; Leiblum, Koochaki, Rodenberg, Barton, & Rosen, 2006). However, recent evidence does not support a consistent relationship between endogenous sex steroid hormones and sexual arousal and desire disorders (Davis, Davison, Donath, & Bell, 2005; Heiman et al., 2011). Efficacy trials of androgen therapy for low sexual desire among surgically and naturally menopausal women have had conflicting results, and concerns about the long-term safety of these treatments linger. Other contributing biological factors include the effects of medications, particularly selective serotonin reuptake inhibitors (SSRIs), and fatigue or neurological problems related to chronic illnesses.

The psychological treatment literature reflects the historical separation of desire and arousal disorders in women, focusing primarily on the former. However, the behavioral sex therapy techniques pioneered by Masters and Johnson (1970) remain in widespread use among clinicians treating all types of sexual disorders. Traditional behavioral sex therapy emphasizes sexuality education, partner communication skills, and sensate focus exercises. Sensate focus is a core component of behavioral sex therapy and comprises a progressive series of touching exercises between partners (assigned as homework) to heighten partners' awareness of pleasurable experiences and enable communication of preferences for sexual touch. Prescribed sensate focus activities, completed by the couple at regular intervals throughout treatment, gradually progress from nongenital touching to mutual massage and masturbation to intercourse. An effectiveness study of behavioral sex therapy applied to couples in a real-world clinical setting demonstrated that these techniques were generally helpful across a range of sexual problems in both men and women (Sarwer & Durlak, 1997).

Despite early enthusiasm for Masters and Johnson's sex therapy program, contemporary sex therapies generally acknowledge the limitations of behavioral techniques for addressing the complex issues that often underlie sexual dysfunctions. Relationship problems, issues related to past sexual trauma, and primary psychiatric conditions are a few of many potential concerns that may complicate sex therapy. Therefore, the contemporary clinical literature overwhelmingly emphasizes an integrative approach to treatment of sexual desire and arousal disorders. These approaches most often incorporate traditional sex therapy concepts with systems and/or cognitive-behavioral conceptualizations, as well as biomedical factors. Cognitive-behavioral techniques are distinguished from other sex therapy components by the use of cognitive techniques to challenge beliefs that undermine sexual desire and arousal, such as unrealistic expectations of performance, exaggerated fears of undesirable outcomes, and the notion that one is "innately" dysfunctional. Recently, Brotto and others have expanded this paradigm with the incorporation of "third wave CBT" interventions including mindfulness and acceptance-based strategies (e.g., Brotto et al., 2012). Evidence from the relatively few systematic trials of psychotherapy for low sexual desire show varying levels of efficacy for both traditional sex therapy and cognitive-behavioral therapy (CBT) (Brotto, 2006). Limitations of the psychological treatment literature include heterogeneity of treatment methods and experimental designs that prevent the analysis of separate treatment components, precluding rigorous comparisons of studies. Evidence to support the efficacy of psychodynamic, systemic, and other types of treatment is at the level of clinical case reports. Thus, the relative efficacies of various psychosocial treatments for sexual desire and arousal disorders have not been clarified.

### Sexual Aversion Disorder

Sexual aversion, a strong aversion to and avoidance of sexual contact with a partner, is a poorly understood phenomenon for which there has been little systematic research. In view of the limited research on sexual aversion, the diagnosis was removed altogether from the DSM nomenclature in DSM-5. The clinical literature describes sexual aversion both etiologically and symptomatically in terms more congruent with anxiety disorders than sexual disorders (Kaplan, 1988; Kingsberg & Janata, 2003). It is not unusual for women with sexual aversion to report a history of unwanted sexual contact, but it should not be assumed that sexual abuse is an etiological factor in all cases of sexual aversion.

Case reports support the use of cognitive-behavioral techniques in the treatment of women with symptoms of sexual aversion. As with phobias and other anxiety disorders, a common approach to treatment involves gradual exposure and desensitization to a hierarchy of anxiety-provoking situations and stimuli. Although imaginal stimuli are often sufficient to provoke anxiety initially, the usual treatment goal is to enable the individual to engage in partnered sexual behaviors with minimal anxiety. Additional supportive treatment may be indicated for significant relationship or social problems resulting from sexual aversion.

### Female Orgasmic Disorder

For all its presumed importance in women's sexual lives, a precise definition of female orgasm is elusive. Even within the clinical and scientific literature, female orgasm is vaguely and variably defined, with over two dozen existing comprehensive definitions written by different authors (Mah & Binik, 2001). An attempt to clarify and reconcile definitions of female orgasm can be found in the report of the committee on female orgasm of the 2003 International Consultation on Urological Diseases as follows:

> An orgasm in the human female is a variable, transient peak sensation of intense pleasure, creating an altered state of consciousness, usually

accompanied by involuntary, rhythmic contractions of the pelvic, striated circumvaginal musculature often with concomitant uterine and anal contractions and myotonia that resolves the sexually-induced vasocongestion (sometimes only partially), usually with an induction of well-being and contentment. (*Meston, Hull, Levin, & Sipski*, 2004)

The DSM-5 defines female orgasmic disorder (FOD) as the persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase, which causes marked distress or interpersonal difficulty. The diagnosis requires clinician judgment and careful assessment to determine whether the woman's ability to experience orgasm is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives. Generally, a woman who can experience orgasm during intercourse with manual stimulation but not intercourse alone would not meet criteria for a clinical diagnosis unless her response pattern is a significant source of distress.

In the National Health and Social Life Survey, 24% of women reported a lack of orgasm in the past year for at least several months or more (Laumann, Gagnon, Michael, & Michaels, 1994). Clinic-based studies have yielded comparable prevalence estimates for orgasm difficulties. In a sample of 329 healthy women attending an outpatient gynecological clinic, Rosen, Taylor, Leiblum, and Bachmann (1993) found that 29% reported orgasm problems. Similarly, 23% of women were found to report orgasm problems in a sample of 104 general practice patients (Read, King, & Watson, 1997). Because attaining a sufficient degree of sexual arousal usually precedes orgasm, factors that contribute to sexual arousal problems are indirectly implicated in FOD.

Important clinical distinctions exist between women who meet criteria for lifelong, generalized FOD ("primary anorgasmia"), who report having never experienced orgasm or only ever having experienced orgasm infrequently and with difficulty, and women who are orgasmic at least part of the time. Anorgasmia is more common in younger women and may be related to limited sexual experience (e.g., having never or seldom masturbated) or limited opportunities for intense sexual arousal. Other demographic factors associated with anorgasmia include low educational level and high religiosity, although explanatory mechanisms are largely speculative (for further review, see Meston et al., 2004).

Women with situational and/or acquired orgasmic disorder make up a heterogeneous clinical population. For example, the definition is applicable to women who can experience orgasm through masturbation but not during sexual activity with a partner, women who were once able to experience orgasm but are no longer able to do so, or women who experience orgasm less frequently than desired. In general, treatment of this population is directed toward the factors that inhibit sexual arousal and/or orgasm in the particular contexts in which the dysfunction is present.

A well-studied and efficacious treatment for primary anorgasmia is directed masturbation, a multifaceted intervention that includes education, prescribed exploratory and experiential exercises in which a women learns to elicit pleasurable sensations through self-stimulation, and application of skills toward the attainment of orgasm. These experiences are first limited to the woman herself and are often facilitated with the use of aids such as vibrators, topical lubricants, and erotica. The partner is later included in the treatment once the woman has learned how to orgasm through solitary self-stimulation (for a detailed guide to directed masturbation, please refer to Heiman & LoPiccolo, 1988). Directed masturbation is efficacious in several treatment modalities including individual, group, and couples therapy and bibliotherapy (for review, see Meston, 2006). Directed masturbation for situational or acquired orgasmic disorders has received little study but appears to be less efficacious. Couple therapy, psychoeducation, and sex therapy techniques, such as those described in the previous section, may be of benefit in the case of situational or acquired orgasmic dysfunction. Anxiety reduction treatment may also be indicated in cases where sexual performance fears or similar concerns are present.

### Sexual Pain Disorders

Historically, sexual pain disorders in women have been classified as vaginismus and dyspareunia. The defining characteristic of vaginismus is an involuntary spasm of the outer portion of the vagina that interferes with vaginal intercourse or penetration. However, this definition has been challenged on the grounds that vaginal spasm is neither sensitive nor specific to women who report difficulty with vaginal penetration (Ressing, Binik, Khalifé, Cohen, & Amsel, 2004). Furthermore, although women diagnosed with vaginismus usually report pain (ter Kuile, van Lankveld, Vlieland, Willekes, &

Weijenborg, 2005), previous versions of the DSM have not specified pain as a diagnostic criterion. In contrast, the DSM-5 diagnosis of genito-pelvic pain/penetration disorder includes the key symptoms of vagnismus but without requiring vaginal muscle spasms as the specific cause of penetration difficulty.

In contrast to the DSM-IV-TR criteria, the proposed definition of vaginismus does not specify a muscle spasm localized exclusively to the vagina. The definition also emphasizes features of the disorder that suggest etiological mechanisms similar to those of anxiety disorders.

Dyspareunia is a broad term, not specific to psychiatry, used to describe genital pain associated with sexual activity. Whereas transient episodes of pain with sexual activity are common in women, dyspareunia generally refers to a recurrent pattern of symptoms. Dyspareunia is typically described as either superficial (e.g., associated with the vulva and/or vaginal entrance) or deep (perceived deep in the vagina, pelvis, or abdomen, usually provoked by penile thrusting); most presentations fall into the former category. Although previous versions of the DSM treated dyspareunia and vaginismus as mutually exclusive diagnoses, the common overlap in clinical presentations has raised concern as to whether it is valid to regard them as distinct disorders (Binik, 2010; de Kruiff, ter Kuile, Weijenborg, & van Lankveld, 2000; Reissing, Binik, & Khalifé, 1999). The two diagnoses are combined in the revised DSM-5 diagnosis of genito-pelvic pain/penetration disorder.

Epidemiological studies of sexual pain conditions vary and are not necessarily specific to diagnosis. Laumann et al. (1999) reported that approximately 16% of American women reported persistent or recurrent sexual pain in the past year, with older age associated with a lower likelihood of sexual pain. In a community-based survey of 303 women, 12% reported a chronic history of pain provoked by *any* genital contact (Harlow, Wise, & Stewart, 2001).

There are multiple etiologies for sexual pain, many of which are described in parallel literatures in the fields of general gynecology and urogynecology. For instance, the medical literature describes various presentations of "vulvodynia," a nonspecific term for genital pain in women. Many cases of superficial dyspareunia are associated with provoked vestibulodynia (PVD; formerly termed vulvar vestibulitis), a syndrome that includes sensitivity to touch and pressure of the tissues surrounding the vaginal entrance. PVD itself appears to have multiple etiologies (Sutton, Pukall, & Chamberlain, 2009). Vulvovaginal atrophy is another common cause of dyspareunia, mainly affecting postmenopausal women. There is scant psychological literature on pain associated with vulvovaginal atrophy, despite its relatively common presentation and association with psychosocial factors (Kao et al., 2012). Deep dyspareunia is less well understood and generally ill-defined in the literature. It is often attributed to gynecologic diseases such as endometriosis or, less often, to urinary or bowel syndromes (for review, see Weijmar Schultz et al., 2005).

Regardless of origin, pain may persist after its initial provocation via a number of mechanisms, including psychological and neurological changes. When conceptualized as a pain disorder rather than a sexual disorder, dyspareunia shares many etiological similarities with other chronic pain syndromes; pain-related fear and avoidance are both important maintaining factors and predictors of treatment outcome. To attempt to isolate the psychogenic and physiological components of chronic pain maintenance is a dubious exercise, as they are integral to one another. Research to date has not identified a reliable psychological "profile" associated with sexual pain disorders, although studies have reported increased anxiety and depressive symptoms, hostility, erotophobia, and psychotic features, albeit somewhat inconsistently, across the sexual pain disorders (Desrochers, Bergeron, Landry, & Jodoin, 2008; Weijmar Schultz et al., 2005). Although a past history of sexual trauma is commonly suspected as an etiological factor in the sexual pain disorders, findings are inconsistent and not sufficient to support a causal association (Desrochers et al., 2008; Weijmar Schultz et al., 2005).

Cognitive-behavioral interventions for sexual pain typically focus on psychoeducation; relaxation techniques; gradual desensitization to vaginal penetration, typically with the use of vaginal dilators; cognitive restructuring; and sex therapy techniques to enhance pleasure and normalize nonpenetrative sexual activities. Eight- to twelve-session protocols of CBT have been shown to significantly reduce genital pain in populations of women diagnosed with PVD, vaginismus, and unspecified vulvodynia (Bergeron et al., 2001; Desrochers, Bergeron, Khalifé, Dupuis, & Jodoin, 2010; Masheb, Kerns, Lozano, Minkin, & Richman, 2009; ter Kuile & Weijenborg, 2006; ter Kuile et al., 2007). Systematic desensitization alone has a relatively long history in the treatment of sexual pain conditions, particularly

vaginismus, but it has surprisingly little empirical support.

Glazer and colleagues, observing a relationship between PVD and abnormal responding of the pelvic floor musculature, developed a novel treatment approach using electromyography (EMG) biofeedback to reduce hypertonicity and increase the strength and stability of the pelvic floor (Glazer, Rodke, Swencionis, Hertz, & Young, 1995). Clinical trial data indicate that the pelvic floor training approach significantly reduces vestibular pain and may occasionally eliminate it altogether (Bergeron et al., 2001; Glazer et al., 1995, McKay et al., 2001). Further collaboration with a physical therapist can enhance psychophysiological treatment with hands-on techniques informed by expertise on the muscular and connective tissue of the pelvic floor (Backman, Widenbrant, Bohm-Starke, & Dahlof, 2008; Rosenbaum, 2005).

Topical anesthetics and other medications are sometimes used to alleviate genital pain in the short-term, but there is no evidence supporting the use of topical treatments in long-term management of sexual pain disorders. Likewise, limited data are available to support the use of antidepressants and anticonvulsants for pain relief (Weijmar Schultz et al., 2005). The efficacy of other medical, hormonal, and surgical treatments depends greatly on accurate diagnosis of the underlying problem. For instance, carefully selected patients with PVD may benefit substantially from surgical removal of vulvar vestibular tissue (Baggish, 2012; Goldstein & Goldstein, 2006). Increasingly, the clinical literature espouses a multimodal and multidisciplinary approach to treatment of sexual pain conditions. Across treatment modalities, greater severity of pain at presentation predicts a poorer prognosis (Bergeron, Khalifé, Glazer, & Binik, 2008).

## Sexual Dysfunctions in Men

In contrast to the conceptual shifts evident in emerging classifications of female sexual dysfunctions, the diagnostic classification of male sexual disorders has remained relatively uncontroversial in recent years. However, the clinical management of men's sexual problems was changed dramatically in 1998, with the advent of sildenafil (Viagra). The promise of Viagra is a safe, easy-to-use medical treatment for erectile dysfunction that requires no more than a trip to one's primary care physician—and little to no introspection. The reality is more complicated: a large minority (or perhaps even a majority) of men who are prescribed Viagra discontinue treatment, and the renewed ability to have a lasting erection may disrupt longstanding sexual equilibrium in a relationship (Leiblum, 2002; McCarthy & Fucito, 2005). Viewing erectile dysfunction strictly as a medical condition diverts attention from the contributing psychological factors that may continue to influence a man's sexual life. The relative ease of facilitating erection may also detract from assessment and treatment of more pervasive problems, such as diminished sexual interest or premature ejaculation. Moreover, a clinical focus on the attainment of erection reinforces narrow parameters and goals for sexual performance. Although sexologists have lamented a relative lack of data on women's sexual function, paradoxically, the failure of drug treatments for women's sexual dysfunctions has forced a more nuanced conceptualization of sexual problems that is not apparent in much of the literature on male sexual dysfunction. If today's theme is "women are complicated," it may be useful to add, "and so are men."

### *Hypoactive Sexual Desire Disorder*

Research on sexual interest among adults in the general population suggests that males tend to have a higher level of sexual drive than females. Compared to women, men report greater desire for sexual activity, masturbate more frequently, and endorse a greater number of lifetime sexual partners (Jones & Barlow, 1990; Laumann et al., 1994; Regan & Atkins, 2006). The notion of a robust male libido is also deeply imbedded within many popular concepts of masculinity. As such, men may experience a lack of sexual interest as highly abnormal or unnatural, if not embarrassing or shameful. Additionally, there are several aspects of sexual desire disorders in men that distinguish their presentation from those in women. Complaints of low sexual desire are less frequent overall among men (Laumann et al., 1994), and, unlike low sexual desire in women, the incidence shows a steady and reliable increase with age (Maurice, 2007).

Occasionally, low sexual desire in men is associated with pharmacologic treatments or medical conditions that affect testosterone. Male hypoactive sexual desire disorder (HSDD) in the setting of abnormally low testosterone levels is often responsive to testosterone supplementation (Buvat & Boujadoué, 2005). In contrast, men with HSDD and normal testosterone levels are unlikely to benefit from this treatment.

Although there is a compelling case to investigate hormonal or other medical causes of low sexual desire, particularly in older men, careful assessment may reveal important information about underlying psychological causes. Bass (1985) cautioned that self-diagnosed "low sexual desire" may often represent a faulty attribution for infrequent sexual activity within conditions that are inconsistent with the individual's sexual preferences. Attributing low sexual desire to an innate medical condition rather than, for instance, a lack of sexual attraction to one's partner or an unsatisfying sexual repertoire, may be less threatening. Similarly, a loss of interest in sexual activity may reflect avoidance of sexual performance problems associated with another primary sexual dysfunction, such as erectile disorder or premature ejaculation. It is also important to investigate other sexual outlets that are preferred to partnered sexual activity, particularly the use of sexually explicit web sites and other media for masturbation, which suggest a situational lack of sexual interest in the context of an otherwise intact sexual drive (Maurice, 2007; Polonsky, 2003). As in women, psychiatric conditions—particularly mood disorders—are risk factors for low sexual desire and should be assessed. Although these risk various factors may account for many cases of male HSDD, the disorder can exist independently of hormonal abnormalities, mood disturbance, or other sexual or gender disorders (DeRogatis et al., 2012).

The clinical literature offers little in the way of empirical study of psychotherapy for male hypoactive sexual desire disorder. The general consensus is that, as in women, sexual desire disorders in men are difficult to treat. Because low sexual desire is a symptom with multiple possible etiologies, a thorough assessment is necessary for appropriate treatment planning. Maurice (2007) recommends proceeding as follows:

• Men with lifelong, generalized low sexual interest have a poor prognosis in sex therapy and may be better served with supportive treatment to help the man and his partner adapt to his condition.
• Men with lifelong situational low sexual desire are unlikely to have a medical problem. Psychotherapy may be a treatment option, but there is little guidance from the empirical literature. Recent work suggests that restrictive sexual attitudes and dysfunctional sexual beliefs predict low sexual desire in men (Carvalho & Nobre, 2011), suggesting a potential role for cognitive-behavioral intervention.

• If low sexual desire is acquired and generalized, a review of possible medical causes is warranted, although the etiology may or may not be organic. In any case, further assessment is usually indicated.
• If the problem is both acquired and situational, there is a lesser likelihood of medical causes, and a course of individual or couple therapy (depending on etiology) is most likely to be appropriate.

### Erectile Disorder

Penile erection occurs when vascular smooth muscle relaxes and allows an increased volume of blood to flow into the corpora cavernosa. This process can be triggered by efferent or afferent nervous pathways. Older men tend to require a greater amount of tactile stimulation to attain an erection, whereas younger men more easily attain erection through fantasy or nontactile stimulation. Although a variety of chemical signals regulate erectile function, the most prominent effects on erectile function are mediated by the neurotransmitter nitric oxide. Nitric oxide is released from parasympathetic neurons in response to sexual stimulation and activates a metabolic pathway resulting in the production of cyclic guanosine monophosphate (cGMP), which in turn relaxes the vascular smooth muscle of the penis. Maintenance of the resulting erection depends on the ongoing production of nitric oxide, contingent on continued sexual stimulation. Normally, cGMP is broken down by enzymes known as phosphodiesterases (PDEs). However, this may be circumvented by inhibiting the activity of these enzymes. Viagra (sildenafil) and other drugs used to treat erectile disorder inhibit PDE type 5. In doing so, the PDE-5 inhibitors enhance the concentration of cGMP, allowing for greater smooth muscle relaxation and therefore improved erection.

Men of all ages have occasional difficulty obtaining or maintaining an erection. Common causes of transient erectile difficulty include fatigue, anxiety or other emotional distress, alcohol or drug intoxication, and (in older men) a long postejaculatory refractory period. Erectile disorder (ED) refers to persistent or recurrent episodes of difficulty in attaining or maintaining an erection that interfere with sexual activity and cause distress or impairment. (In the literature, the term *erectile dysfunction* is often used, although distress may be implied rather than explicitly assessed.) Although most cases of ED have an organic etiology, there is often a concurrent contribution of psychological or relation-

ship factors in the onset or maintenance of the disorder. Laumann et al. (1999) reported approximately 7% of men aged 18–29 years have erectile problems, whereas 18% of men aged 50–59 years experience difficulty with erection.

Barlow (1986) proposed a model of performance anxiety for psychogenic erectile dysfunction. The major psychological contributors to ED as identified by the model are anxiety, negative expectations, and spectatoring. In brief, men who are anxious about losing an erection tend to monitor the status of their erections and how they are "performing," which distracts from focusing on stimuli that are arousing and pleasurable. This "spectatoring" behavior is also associated with anxiety, which activates sympathetic nervous system arousal. Increased sympathetic activation inhibits the smooth muscle relaxation necessary for continued erection and contributes to continued negative affect and narrowed attentional focus on erectile performance. Eventually, the man is no longer able to maintain his erection, and the man's fears of not being able to perform are confirmed, thus increasing the likelihood that the process will repeat itself in subsequent sexual situations. Men without erectile dysfunction, on the other hand, tend to approach sexual situations with positive expectancies for performance and are able to focus on stimuli that are sexually arousing because they are not distracted by performance concerns. Consequently, these men become aroused easily and are able to obtain and sustain an erection. Repeated positive experiences shape expectancies for future sexual performance.

The assessment of ED includes identifying the situation(s) surrounding the onset of ED and the potential beliefs that were formed at that time. Beliefs may be specific to the relationship (i.e., a feeling of inadequacy with one specific partner) or may generalize to all situations. A medical evaluation is warranted when the problem is generalized or when the onset occurs in conjunction with an illness or medical treatment. Assays of free and bioavailable serum testosterone may be used to rule out abnormally low androgen levels. In cases where ED is the result of a vascular problem, laboratory assessments that measure genital blood inflow and outflow during sexual stimulation may be helpful. Measurement of nocturnal penile erections, which are expected to increase during the REM sleep cycle in sexually healthy men, is another commonly used technique for assessing potential vascular causes of ED.

There are now a range of treatments available for ED. One option is psychotherapy, the typical goals for which include setting realistic and positive expectations for sexual experiences, modifying dysfunctional beliefs, and enhancing sexual knowledge and skills. In cases of ED with a clear psychogenic component, psychotherapy should be the primary treatment modality and may be used in conjunction with medical treatment with good results (Melnik & Abdo, 2005). Although PDE-5 inhibitors are now in widespread use, they are not effective for all men. Use of PDE-5 inhibitors is also contraindicated in men taking nitrates and should be monitored carefully in men taking $\alpha$-blockers and certain other medications. Other medical treatments for erectile disorder include vacuum devices and constriction rings, intracavernosal injections, and intraurethral and topical pharmacotherapy. Lifestyle modifications, such as increasing exercise and eating a healthy diet, may also be useful adjuncts to treatment (Esposito et al., 2004). Penile implants are usually considered after other treatments have failed or when there is severe disease or damage to the penile tissue. In general, medical treatments for ED are best introduced in a setting that allows for both partners to participate in treatment. The addition of sex therapy to a medical treatment for ED may not always enhance erectile function per se but may nevertheless help to modify dysfunctional beliefs and improve the partner's satisfaction with treatment (Aubin, Heiman, Berger, Murallo, & Yung-Wen, 2009).

### Premature Ejaculation

Premature ejaculation (PE) is a persistent or recurrent pattern of orgasm and ejaculation occurring with minimal stimulation before or shortly after penetration and sooner than desired. Although the latency period from intromission (or onset of sexual stimulation) to ejaculation is variable, men with PE have markedly and reliably shorter latencies than do men without PE. Patrick et al. (2005), for example, found that the average time to ejaculation from the start to sexual intercourse was 1.8 minutes for men with PE and 7.3 for non–sexually dysfunctional controls. Interestingly, men with PE tend to have a longer ejaculatory latency during masturbation. Rapid ejaculation is the most commonly reported sexual complaint in men, affecting approximately 1 out of every 3 to 5 men at some point during their lives, although the prevalence of severe and persistent PE is likely to be considerably lower (Rowland et al., 2010). Prevalence estimates are somewhat unreliable across studies due to ambiguity in defining what exactly constitutes PE. Althof and Rowland

(2008) identified seven different published definitions of PE, all of which were generated by opinion leaders and/or consensus within professional organizations, and noted that most of these definitions lacked measurable operational criteria. In practice, an ejaculatory latency time of less than 1 minute and perceived poor control over ejaculation, combined with personal distress or functional impairment, constitute a reasonably sensitive set of criteria for detection of PE.

Ejaculation occurs when sperm is emitted into the vas deferens through sympathetically mediated contraction of smooth muscle in the epididymis. This process is accompanied by a subjective perception that ejaculation is inevitable and followed by rhythmic contractions of smooth muscle in the penis and the pelvic floor. These contractions are associated with the experience of orgasm. Most men experience ejaculation and orgasm as interconnected events, although some men may experience orgasm without ejaculation.

Historically, PE has been associated with psychological etiological factors, especially anxiety, which has been thought lower the stimulus threshold required to trigger ejaculation. Although this hypothesis is intuitively appealing, empirical support is inconsistent at best. Perceived control over ejaculation is increasingly recognized as an important psychological factor that distinguishes men with and without PE. Although men with and without PE show comparable degrees of erectile response to sexual stimulation, men with PE report significantly less control over their ejaculation and may report a greater subjective experience of sexual excitement. Physiological factors may also contribute to some cases of PE. Researchers have postulated that men with PE have a lower sensitivity threshold such that less stimulation is needed to attain ejaculation. This explanation cannot account for all cases of PE, however, as studies show that PE exists in both men with high and with low sensory thresholds. It has also been proposed that men with PE may respond with a higher level of arousal to sexual stimuli (hyperarousability). Again, though, this cannot account for all cases of PE. One psychophysiological study that measured penile rigidity in the laboratory showed that men with PE had a weaker genital response to visual stimuli compared to men with no sexual dysfunction, but had a comparable genital response to men with no sexual dysfunction during tactile plus visual stimuli (Rowland & Slob, 1997).

Assessment of PE should include measurements of ejaculatory latency (length of time from intromission to ejaculation), perceived control over ejaculation, and any distress or interpersonal difficulty associated with the problem. These may be assessed through retrospective self-report questionnaires or by interview, although sometimes the patient (or his partner) is asked to time the interval between intromission and ejaculation to estimate the man's ejaculatory latency. The history of the condition is also important to assess; lifelong, global PE has a relatively poor prognosis (Waldinger, 2008). PE is frequently comorbid with another sexual dysfunction, especially ED, and occasionally develops as a secondary sexual disorder (Rowland et al., 2010). Therefore, it is essential to assess other sexual disorders when PE is the presenting complaint.

The most commonly used psychotherapy techniques for increasing ejaculatory latency are the squeeze technique developed by Masters and Johnson (1970) and the pause technique (Kaplan, 1989). The squeeze technique consists of engaging in sexual stimulation alone or with a partner for as long as possible before ejaculation. Before reaching the "point of inevitable ejaculation," the man is instructed to stop the activity and apply tactile pressure to the glans to decrease the urge to ejaculate but not to the point that he completely loses his erection. When the urge has subsided, the man resumes masturbation or intercourse, stopping as many times as needed in order to delay ejaculation. The pause technique is similar to the squeeze technique with the exception that no pressure is applied to the penis. At times, clinicians may suggest using a PDE-5 inhibitor along with these techniques, so that the man can practice delaying ejaculation without worrying about maintaining an erection. Other goals of psychotherapy for PE include anxiety reduction, modification of dysfunctional beliefs, and enhancement of sexual communication and intimacy between partners.

One promising medical treatment for PE is the use of SSRIs to capitalize on their common side effect of delaying ejaculation. SSRIs may be used on-demand or daily, although outcomes may be superior with the latter (for review, see Rowland et al., 2010). Topical anesthetics can also be effective in delaying ejaculation, but they require use of a condom to prevent numbing in the partner and may therefore be less acceptable.

### Male Orgasmic Disorder

Delayed or inhibited ejaculation following normal sexual arousal and adequate sexual stimulation is less common than premature ejaculation. Results of

the National Health and Social Life Survey indicated that 3% of American men experience delay or difficulty in experiencing orgasm (Laumann et al., 1994). In a study of men over 40 in five English-speaking countries, the prevalence of this condition was estimated at 7% (Nicolosi et al., 2006).

A distinguishing feature of male orgasmic disorder is low subjectively perceived arousal during sexual stimulation despite an adequate erectile response (Rowland, Keeney, & Slob, 2004; Rowland, van Diest, Incrocci, & Slob, 2005). Impairments in orgasm and ejaculation have often been noted as a side effect of SSRI antidepressant use, and this has led some researchers to speculate that serotonin may play a role in the etiology of this disorder. Other medical causes of delayed orgasm or anorgasmia in men include spinal cord injury, diabetic neuropathy, infections of the genitourinary tract, and hypothyroidism (for review, see McMahon et al., 2004). In many cases, however, delayed or inhibited ejaculation is psychological rather than physiological in etiology. Like other sexual dysfunctions, male orgasmic disorder is commonly associated with relationship dissatisfaction and performance anxiety (Rowland et al., 2005). Poor sexual communication or discomfort between partners are typical relationship factors that may decrease enjoyment of sexual encounters and hinder attainment of high levels of arousal. Unlike other sexual dysfunctions, men with inhibited orgasm report better erections during masturbation than during intercourse with a partner and may strongly prefer masturbation to intercourse. Psychological treatment for delayed or inhibited ejaculation generally includes helping the couple to enhance sexual pleasure and intimacy, to address underlying hostility or other interpersonal problems, and to "retrain" the affected partner's sexual response using masturbation techniques that are more akin to the rhythm and intensity of intercourse.

### Dyspareunia

Male sexual pain conditions are relatively uncommon and seldom addressed in the clinical literature. A recent population-based study of Australian men indicated that 5% of men reported pain associated with sexual activity (Pitts, Ferris, Smith, Shelley, & Richters, 2008). Most cases of male sexual pain are related to an underlying medical condition, anatomical defects, or iatrogenic factors. Thus, treatment is usually aimed at correcting physical causes through medical or surgical intervention. Medical/physiological causes include sexually transmitted infections, other diseases of the genitourinary tract, and pelvic floor hypertonicity. Anatomical features associated with sexual pain include curvature of the penis (e.g., from Peyronie disease) and an unusually short frenulum (a thin strip of tissue that attaches the penile foreskin to the glans). Primary male dyspareunia in the absence of any detectable physical cause is a rare condition, and very little work has examined contributing psychological factors involved in male sexual pain. Kaplan (1993) described postejaculatory pain in terms of intrapsychic conflict precipitating involuntary muscle spasms. Pitts and colleagues (2008) reported that same-sex sexual experience and a history of experiencing sexual coercion were risk factors for male dyspareunia. The clinical literature on male dyspareunia is composed largely of case reports, and there are no published empirical studies of treatment for male sexual pain of presumed psychogenic origin.

### Paraphilias

All paraphilias share the key feature of intense sexual interest and/or behavior directed toward an atypical target, which may be an inanimate object, a child or other nonconsenting individual, or the suffering or humiliation of oneself or someone else. Paraphilic disorders are categorized in the DSM with a relatively high degree of specificity, but they appear to co-occur frequently. Although prevalence estimates are most likely influenced by reporting bias, studies to date suggest that a single paraphilia diagnosis (i.e., with no coexisting paraphilias) is the exception rather than the rule. Accordingly, some theories of psychopathology cluster paraphilias that are presumed to share common psychological features (e.g., the "courtship disorder" hypothesis; Freund & Blanchard, 1986). Because of the high degree of overlap among paraphilias, and the fact that clinical research samples are often heterogeneous with respect to diagnosis, general treatment considerations will be discussed in this section after defining the paraphilic disorders specifically.

Many paraphilic behaviors are subject to attention not only from mental health professionals but also from the criminal justice system. Because such behaviors are socially unacceptable, if not illegal, those who engage in these behaviors seldom present voluntarily for treatment. Rather, referral for treatment is usually a consequence of being discovered by a loved one and/or apprehended by law enforcement officials. In the case of behaviors that constitute sex offenses, assessment and treatment have not only clinical implications but also potentially profound effects on the legal consequences for the sex offender.

The Internet plays a notable role in the world of paraphilias, providing a relatively anonymous forum for those with paraphilias to engage in their sexual interests. The Internet is also a tool for detecting persons with similar interests. Durkin, Forsyth, and Quinn (2006) described the potential for Internet-based communities organized around atypical sexual interests to shape paraphilic interests and/or behaviors. Online communities may, for instance, facilitate exchange of sexually explicit media, normalize atypical behaviors by connecting members with common sexual interests, or distribute elaborately justified "manifestos" defending behaviors such as rape or sex with children or animals. On the other hand, the Internet may provide a safe outlet for sexual expression and satiety of sexual urges. The effects of sexually oriented Internet use on the development and course of paraphilias is unknown. The Internet has also greatly reduced barriers for access to sexually explicit materials, giving rise to a new generation of users whose exposure to these media has largely existed within the confines of their homes.

## Definitions and Features of the Paraphilias

### PEDOPHILIA

Pedophilia is the most prevalent disorder among the paraphilias and has attracted the greatest amount of attention from both the media and the scientific community. Pedophilia is defined as recurrent fantasies or desires involving sexual activity with a prepubescent child (usually 13 years or younger). The condition is diagnosed when the person acts on these urges or experiences distress or interpersonal difficulty related to these urges. The behavioral criterion is controversial as it can be misapplied in a criminal justice setting to any person who has engaged in sexual activity with a child, and meeting diagnostic criteria for a mental disorder may have legal implications in some jurisdictions (First & Frances, 2008).

Although many persons with pedophilia act upon their desires and engage in sexual behavior with children, sexual behavior with a child is not an absolute indicator of pedophilia. In other words, an incident of child molestation may or may not reflect a persistent sexual interest in children. Among those who have committed sexual offenses against children, only 30%–50% are considered pedophilic (Seto, 2004). Seto, Cantor, and Blanchard (2006) reported that, among sex offenders, a child pornography offense was a more reliable indicator of pedo-

philia than having committed a sexual offense against a child. Additionally, a person with pedophilia may or may not have concurrent sexual interest in adults. The targets of pedophilic interests may be male or female children, and this is not necessarily associated with the person's sexual preference for adult partners.

As with all of the paraphilias, the prevalence of pedophilia is difficult to estimate. The high prevalence of childhood sexual abuse suggests a significant number of adults who engage in sexual activity with children. In samples of college-aged men, 5–9% of respondents endorsed fantasizing about or desiring sex with young children (Briere & Runtz, 1989; Templeman & Stinnett, 1991). Although these figures indicate that adult–child sexual activity occurs frequently and that a small group of men are willing to endorse at least some degree of sexual interest in children, the numbers do little to help quantify the number of persons who have an enduring pattern of fantasies and urges that characterizes true pedophilia. It is known that pedophilia is largely a disorder of men, and female pedophiles are considered relatively uncommon. Data from sex offender samples indicates that victims are more often female than male, but Internet-based research with anonymous respondents does not reflect this trend.

Because assessment of pedophilia often occurs within a forensic setting, data gathered from interviews and other self-report assessment methods are interpreted with caution. The Clarke Sex History Questionnaire (Paitich, Langevin, Freeman, Mann, & Handy, 1977) and the Multiphasic Sex Inventory II (Nichols & Molinder, 2000), for instance, contain items expressly developed for the purpose of detecting socially desirable responding. Psychophysiological assessment methods are often used as adjuncts to the assessment process. Polygraph testing, in particular, is a popular method of authenticating sex offenders' self-reports despite a relatively weak evidence base and enduring concerns about its validity. Measurement of penile response (phallometry) is a controversial but common strategy used to measure men's sexual interest in stimuli depicting children and other types of people and activities. Phallometric devices measure either penile circumference (e.g., a strain gauge) or blood volume (e.g., a penile plethysmograph). Phallometry has been shown to distinguish between several types of sex offenders and men without a history of sexual offending (for review, see Seto, 2001), although its sensitivity for identifying sex offenders is modest.

Methodological issues, including a lack of standards for the use of penile plethysmography and similar techniques, raise legitimate questions about the reliability and validity of phallometry. Research has also demonstrated that men may consciously manipulate their own erectile responses using cognitive distraction, which further detracts from the validity of this technique. Less invasive alternatives to phallometric assessment include measurement of reaction times and viewing times to relevant stimuli (Abel, Huffman, Warberg, & Holland, 1998; Gress, Anderson, & Laws, 2013; Mokros, Dombert, Osterheider, Zappalà, & Santtila, 2010) and eye movement tracking (Fromberger et al., 2012). However, these techniques have not been widely adopted, and further study is needed to demonstrate the clinical utility of these measures in forensic settings.

Treatment of pedophilia and other sex offense–related paraphilias is distinguished from treatment of other sexual disorders in that the therapy is usually court-mandated (e.g., as a condition of probation or parole). Because typical limits of confidentiality do not hold when the client is an identified sex offender, the clinician adopts dual roles of both therapist and informant. Moreover, disclosure of sexual activity with children is generally not protected by confidentiality laws. Because of the unusual circumstances surrounding treatment, therapists working with sex offenders must be skilled in fostering trust and rapport. The development of a strong working alliance with court-referred sex offenders is a long-term and ongoing process.

### FETISHISM

The defining feature of fetishism is a recurrent pattern of sexual interest or arousal involving a specific nonliving object. The fetish object is often used in masturbation, or it may be incorporated into sexual activity with a partner (for instance, asking the partner to wear a particular item of clothing). As the fetish object is often required or strongly preferred for sexual arousal, functional problems may arise when the affected person is unable to consistently use his or her preferred stimulus, or when the repeated use of the fetish object is a source of interpersonal conflict. However, if no distress or functional impairment is present, a diagnosis is not given. Fetishism is less frequently associated with criminal behavior than pedophilia and is more likely to create problems related to occupational, interpersonal, or social functioning.

The prevalence of fetishism is unknown, although a proliferation of Internet forums devoted to fetishes suggests that at least subclinical fetishism is not rare. Scorolli and colleagues attempted to quantify the prevalence of various subtypes of fetishes according to the number of fetish-themed Internet discussion groups and the level of membership and activity associated with these groups. Their review of 381 such discussion groups indicated that the majority were devoted to themes of either body parts or objects associated with the body (such as articles of clothing). Within this category, the most common themes were feet or foot-related objects such as footwear (Scorolli, Ghirlanda, Enquist, Zattoni, & Jannini, 2007).

Conditioning has been theorized to be important in the development of sexual fetishes and perhaps other paraphilias. There is some experimental evidence to support this hypothesis. Rachman (1966) famously "trained" healthy adult males to experience erection in response to an image of women's boots by repeatedly pairing this image with pictures of nude women in a classical conditioning paradigm. Additional studies have confirmed that sexual arousal in men can be conditioned through repeated pairing of nonsexual and sexually arousing stimuli (e.g., Hoffman, Janssen, & Turner, 2004; Rachman & Hodgson, 1968). The results of similar studies in women have been inconclusive at best (Hoffmann et al., 1997; Letourneau & O'Donohue, 1997). Some clinical reports are undoubtedly consistent with the conditioning hypothesis of fetish development, whereas others are more complicated. Case reports of persons with fetishes often identify highly salient childhood memories involving the fetish object or activity (e.g., Abel, Coffey, & Osborn, 2008), but these are consistently associated with reports of sexual arousal at the time. The treatment literature specific to fetishism is sparse, and recent work is largely limited to case reports.

### TRANSVESTIC FETISHISM

Transvestic fetishism is a particular type of fetish-like behavior in which the affected person (generally, a heterosexual male) engages in or fantasizes about dressing in women's clothing for the purpose of sexual excitement. As with fetishism, the behavior must be persistent and must cause distress or functional impairment in order to be considered a disorder. Few data are available to estimate the prevalence of this condition. A survey of 18- to 60-year-old adults in the Swedish general population found

that 2.8% of men and 0.4% of women endorsed having ever experienced sexual arousal from cross-dressing (Långström & Zucker, 2005). The extent to which these behaviors would have met full diagnostic criteria, however, is unknown.

The etiology of transvestic fetishism is unclear, but it is notable that, in many cases, the cross-dressing behavior is accompanied by thoughts or fantasies of being a woman. This observation suggests that, at least in a portion of men, it is the adoption of a female identity, and not the feminine attire per se, that is sexually arousing. Blanchard (1989) labeled this behavior "autogynephilia"—the attraction to oneself as a woman—and has linked this pattern of sexual arousal to gender dysphoria and transsexualism (also see Lawrence, 2004). However, not all men with transvestic fetishism experience gender dysphoria, and not all male-to-female transsexuals endorse the autogynephilic arousal pattern (Veale, Clarke, & Lomax, 2008).

Treatment of men with transvestic fetishism should take into account the presence or absence of gender dysphoria, the functional areas that have been negatively affected by cross-dressing behavior (e.g., problems in the primary relationship), and the individual's goals for therapy. Cross-dressing in and of itself is not a disorder and is not associated with greater levels of psychopathology than in the general population. Thus, understanding the motivation for referral is key. Resolution of the problem may entail reducing or stopping cross-dressing behavior that is perceived as "out of control" or interfering with interpersonal relationships, in which case therapy is focused on achieving satisfaction with sexual expression as a male. Alternatively, the goal of therapy may be to help the man (and, if desired, his partner) incorporate his sexual preference more adaptively and attain greater comfort with cross-dressing activities. If gender dysphoria is persistent and continues despite greater acceptance and integration of cross-gender expression, more intensive treatment related to gender identity may be considered.

## THE "COURTSHIP DISORDERS": EXHIBITIONISM, VOYEURISM, FROTTEURISM

Exhibitionism, voyeurism, and frotteurism are separately defined disorders in the DSM-IV-TR that share a common feature of sexual arousal or contact in the presence of a nonconsenting person. Exhibitionism is characterized by fantasies or urges to expose one's genitals to a stranger, whereas voyeurism is characterized by the desire to observe an unsuspecting person while nude, in the act of undressing, or while engaging in sexual activity. Frotteurism is defined by the urge to rub one's genitals against a nonconsenting person or to touch a nonconsenting person in a sexual way (sometimes referred to separately as "toucheurism"). In each case, the behavior or fantasy must be experienced as sexually arousing. These conditions meet the criteria for a disorder either when the person has acted on the desire to engage in the behavior or when these interests cause distress or interpersonal difficulty. In a population-based study of over 2,450 Swedish adults, Långström and Seto (2006) found that 3.1% and 7.7% of survey respondents admitted to one or more instances of exhibitionistic or voyeuristic behavior, respectively. Both behaviors were associated with male gender, psychological problems, greater substance use, and a higher overall level of sexual activity.

Although these behaviors represent distinct disorders in the DSM, they often co-occur. Freund and Blanchard (1986) interpreted the high comorbidity of exhibitionism, voyeurism, and frotteurism as evidence for a common etiological pathway for these disorders. They speculated that these behaviors represent a disturbance in the typical courtship behavior sequence of initial appraisal of a potential sex partner, "pretactile interaction" (e.g., smiling, talking) with a prospective partner, tactile interaction, and genital contact. A preference for nonconsensual intercourse (the "preferential rape pattern") was also considered to be a manifestation of courtship disorder. In a clinical sample of over 1,500 heterosexual males referred for treatment of a paraphilia, Freund and Watson (1990) found that exhibitionism co-occurred in 82.4% of cases of voyeurism and in 73.1% of cases of frotteurism/toucheurism, and only in 25.0% of cases was exhibitionism reported in the absence of another paraphilia. Rates of voyeurism and frotteurism/toucheurism occurring alone were even lower (10.1% and 16.8%, respectively).

## SEXUAL SADISM AND MASOCHISM

Sexual sadism is characterized by experiencing sexual excitement from psychological or physical harm or humiliation of a victim. Phrased somewhat differently, sexual sadism—along with its counterpart, sexual masochism—can be viewed as the eroticized experience of a power differential between partners. To receive the diagnosis, the person must experience distress or interpersonal difficulty associated with sadism; alternatively, the diagnosis may be given when

the person engages in sexual sadism with a nonconsenting person. Sexual masochism, conversely, is diagnosed when sexually arousing fantasies or sexual acts involving experiences of one's own humiliation or pain cause distress or interpersonal impairment.

The clinical literature describes sexual sadism largely in the context of two distinct populations: persons who are involved in BSDM (bondage-discipline/dominance-submission/sado-masochism) cultures and sexual assault perpetrators who torture, mutilate, and/or kill their victims. The former group of sexual sadists typically engage in consensual sexual activities and are rarely distressed by their preferences. Thus, the formal diagnosis of sexual sadism is perhaps most relevant to forensic settings. Because sex offenders may not be inclined to disclose sadistic fantasies or behaviors, the diagnosis requires considerable inference from the clinician. Even among mental health professionals with forensic training, the diagnosis of sexual sadism is unreliable (Marshall & Yates, 2004).

Very little literature addresses the prevalence of consensual sadomasochism. A population-based study of sexual practices among over 19,000 Australian adults revealed that 1.8% of respondents had engaged in some form of BDSM activity in the past year (Richters, de Visser, Rissel, Grulich, & Smith, 2008). Concern has been raised about the appropriateness of pathologizing behavior that, while atypical, does not appear to be associated with harm (there is a notable exception in the case of asphyxiation used to enhance arousal and orgasmic intensity, which is associated with risk of accidental death). As a group, persons who practice BDSM tend to be relatively well adjusted, with no greater-than-average risk of sexual problems or psychological distress (Connolly, 2006; Richters et al., 2008). Persons who engage in consensual BDSM practices are vulnerable to stigmatization, even from mental health professionals, and some have called for the elimination of sexual sadism and sexual masochism from the DSM, noting that their inclusion as "disorders" may contribute to unnecessary pathologizing and discrimination of BDSM practitioners (for primers on psychotherapeutic issues in BDSM/kink populations, see Moser & Kleinplatz, 2007; Nichols, 2006).

### Hypersexuality
Sexual behavior that is typical in form or content may still be problematic when it occurs with atypical frequency or intensity or is subjectively diffi-

cult to control. Clinically, this behavior often manifests as unusually frequent engagement in "impersonal" sexual activities (e.g., casual sexual encounters, masturbation, use of pornography, visits to strip clubs, etc.), which may be sought in response to negative mood states or life events (Kafka, 2010). Although there is now a considerable literature on nonparaphilic hypersexuality, there is a lack of consensus about what constitutes a "disordered" frequency of sexual fantasies, urges, or behaviors. Indeed, the concept of hypersexuality as a disorder is not universally accepted. Although there is considerable clinical interest in hypersexual behavior patterns variously labeled as "sexual addiction," "out-of-control sexual behavior," "paraphilia-related behavior," and the like, no such disorder is defined in the DSM-5. Excessive use of Internet pornography, in particular, is now a common cause for referral to mental health professionals and appears to be a factor in a surprisingly large number of recent divorce cases (Manning, 2006).

Treatment options for hypersexuality include individual, couple, and group psychotherapy. Group treatment is a popular option, as evidenced by the virtual explosion of 12-step treatment programs for self-described "sex addicts" (e.g., Sex Addicts Anonymous, Sex and Love Addicts Anonymous, Sexual Compulsives Anonymous, etc.). These programs may be of substantial benefit to individuals who are able and willing to participate in regular group meetings, maintain a relationship with a sponsor, and commit to long-term "abstinence" as variously defined by different programs. In addition to the 12-step recovery model of treatment, cognitive-behavioral group treatment is also likely to be beneficial to motivated participants. Behavioral and psychopharmacological treatments used to treat the paraphilias, as described later, may also be adapted for use in some persons with paraphilia-related disorders.

### Treatment of Paraphilias
Unlike many individuals with mental disorders, persons with paraphilias and/or hypersexual behaviors do not necessarily wish to change their feelings or behavior. Some may desire change only after the consequences of their behavior have provoked a crisis, whereas others may not wish to change but are compelled by someone else to enter treatment. The individual's motivation for change is important to consider in treatment planning as it is a prognostic factor and may guide the goals of

therapy. Research on the treatment of paraphilias is complicated by the fact that many research samples are heterogeneous with respect to diagnosis and (in forensic samples) types of offenses. However, given the high comorbidity of paraphilias it is both pragmatic and ecologically valid to examine treatment effects in diagnostically diverse groups. Many of the techniques described in the following sections have shown efficacy in multiple disorders.

Several behavioral techniques have been developed to reduce problematic sexual thoughts or behaviors, particularly among sex offenders but also for individuals with various paraphilic sexual interests. Aversion therapy, for instance, involves delivering an unpleasant stimulus (such as an electric shock) in combination with a sexually arousing stimulus until the sexual stimulus no longer elicits a response. Although there is some evidence to support the effectiveness of this treatment, high relapse rates have limited the use of aversion therapy over time (Kilman, Sabalis, Gearing, Bukstel, & Scovern, 1982; Rice, Quinsey, & Harris, 1991). More recent work has examined covert sensitization, a variant of aversive conditioning in which the person is asked to repeatedly *imagine* a scenario in which the inappropriate behavior is linked to an aversive consequence (e.g., McKibben, Proulx, & Lussier, 2001; Plaud & Gaither, 1997). An alternative technique is a form of "reconditioning," in which the individual masturbates to the unwanted sexual stimulus just to the point of orgasm, at which time the fantasy is turned to a more appropriate or acceptable target of sexual stimulation (such as a spouse or partner). Finally, masturbatory satiation is a technique in which the person is asked to fantasize about the inappropriate sexual behavior during the postorgasmic period, during which further sexual arousal is very difficult to attain. Relatively little research has been done to examine the effectiveness of these and related techniques (Laws & Marshall, 1991).

Cognitive-behavioral therapy is the current standard of care for paraphilias. Cognitive distortions have been found to play an important role in the maintenance of pedophilia (for review, see Navathe, Ward, & Gannon, 2008) and other paraphilias. Typical beliefs include those that justify one's own inappropriate sexual behavior (e.g., sexual behavior is out of one's control), distort the unwanted nature of the act (e.g., the victim implicitly consented to or was gratified by the act), or minimize the negative consequences of the behavior (e.g., the victim suffered no harm as a result of

the act). Although cognitive distortions are acknowledged to be only one of multiple contributing factors for paraphilic behavior, they are an intensive focus of cognitive-behavioral treatment. Other goals of cognitive-behavioral treatment for pedophilia and other sex offenses are to accept responsibility for one's actions and their consequences, to foster improved social skills and relationships, to develop empathy toward victims and others (when applicable), and to better tolerate and cope with strong negative emotions that may precipitate inappropriate sexual behavior. Behavioral techniques such as those described in the preceding paragraph are also incorporated into therapy, and relapse prevention strategies may be used in long-term treatment. Much of the outcome research on CBT for paraphilias is conducted in populations of sex offenders, and there are few randomized clinical trials in this field, in part because of ethical problems involved in withholding treatment from willing participants. The evidence to date suggests that cognitive-behavioral treatment programs, often delivered in group format, have a modest positive effect on recidivism outcomes (Hanson et al., 2002; Lösel & Schmucker, 2005), but further research in this area is needed.

Pharmacological treatment is usually reserved for the more severe criminal manifestations of paraphilias. These treatments are less invasive and less permanent alternatives to surgical castration, which is effective in reducing recidivism rates but fraught with ethical and legal problems. Most commonly used treatments work by reducing levels of androgen and other sex hormones that affect sexual drive and arousability (for review, see Bourget & Bradford, 2008). Currently used pharmacological treatments include medroxyprogesterone acetate, cyproterone acetate, and leuteinizing hormone-releasing hormone (LHRH) agonists such as leuprolide. However, these treatments are associated with a number of side effects, and recidivism rates have been found to increase on discontinuation of treatment. Selective serotonin reuptake inhibitors have also been used in the treatment of paraphilias due to their effects on erectile function and sexual desire, and have shown some efficacy in reducing problematic sexual thoughts and behaviors.

## Gender Disorders

Although the terms *sex* and *gender* are frequently used interchangeably in lay language, they are distinct constructs. Whereas sex refers to genetic or anatomical features that define a person as male or

female, gender refers to the subjective, internal experience of being female or male. Although a categorical and dualistic view of gender predominates, there are both sociocultural and biological arguments for more flexible conceptualizations of sex and gender. For instance, the extent to which gender is polarized varies with culture, and some cultures recognize more than two definable gender identities. From a biological standpoint, the processes of sexual differentiation and maintaining sex-linked characteristics are not all-or-none phenomena. Thus, considering a spectrum of both physiological/anatomical sex characteristics and gender identification is often helpful in conceptualizing gender variance and gender expression.

### The Biological Basis of Sex and Gender

It is helpful to understand the multiple pathways that shape the development of sex-linked characteristics in the brain and elsewhere, and those that maintain sex differences in physiological function. At typical conception, the human egg contributes one X chromosome and the sperm cell contributes an X or Y chromosome. Females develop from a fertilized egg with two X chromosomes (XX) and males develop from a fertilized egg with an X and Y chromosome (XY), although other configurations of sex chromosomes such as XXY, XXX, XYY, and XX/XY mosaicism are possible. Regardless of chromosomal sex, human embryos begin development in a sexually undifferentiated state. Masculinization of the male embryo depends on the expression of Y chromosome genes that promote the development of the testes. The testosterone secreted from newly developed testes in turn influences the development of brain structures. If, for some reason, functional testes do not develop, or if the embryo's responsiveness to testosterone is abnormally low, a female-typical pattern of development results. These and other variations in development may affect the masculinization of brain structures including the hypothalamus, amygdala, and other areas of the limbic system (for review, see Keefe, 2002).

In addition to the early organizing effects of hormones (i.e., those that result in permanent developmental changes), circulating hormones continue to modify brain and nervous system pathways in reversible, temporary ways. Receptors for androgens and estrogens are located on the peripheral autonomic nerves, on nerves within the spinal cord, and in multiple structures in the brain. Sex hormones play a substantial role in regulating genital sexual function (Giuliano & Rampin, 2004; Min et al.,

2003) and in cognition and emotion associated with sexual behavior (e.g., Anderson, Bancroft, & Wu, 1992; O'Connor, Archer, & Wu, 2004; Redouté et al., 2005).

### Gender Dysphoria

The diagnosis of gender disorders has evolved with subsequent editions of the DSM. Between DSM-III and DSM-IV-TR, the diagnoses of transsexualism and gender identity disorder (GID) shared common key features of discomfort with one's sex or with the gender role assigned to that sex, along with a strong desire to live as and/or have characteristics of the opposite sex. The DSM-5 abandons these prior diagnoses in favor of the term "gender dysphoria." The change is not only semantic but reflects several significant shifts in conceptualization of the gender-related distress. First, the diagnosis of gender dysphoria in DSM-5 more strongly emphasizes the discrepancy between the individual's natal or assigned gender and the gender as experienced or expressed by the individual. Second, the diagnosis places less emphasis on a binary classification of gender. Third, diagnostic criteria allow for a broader range of psychological and behavioral manifestations of gender dysphoria. Fourth, diagnostic specifiers no longer reference sexual orientation due to dubious clinical utility and strong opposition from many transgender persons. Finally, the diagnosis of gender dysphoria is now described in its own chapter separate from the sexual disorders and paraphilias, again underscoring the distinction between gender and sexual expression. Separate criteria are specified for children and adolescents, with the former required to demonstrate a strong desire to be of the other gender. A chronic course of 6 months or greater and associated distress or impairment are required for the diagnosis. Gender atypical or nonconforming behavior, while of possible clinical relevance, is not a diagnostic criterion in itself.

Prevalence estimates for gender dysphoria are lacking and must be inferred from previous research on behaviors indicative of the condition (e.g., completed sex reassignment surgery). Given the relative infrequency of gender dysphoria and the stigma faced by gender-variant individuals, this research is sparse and challenging to conduct. Available data suggest that gender dysphoria is more common in natal males than females (APA Task Force on Gender Identity and Gender Variance, 2008). The prevalence of male-to-female transsexuals reported in the literature ranges from 1:36,000 in Germany (Weitze & Osburg, cited in Sohn & Bosinski, 2007)

to 1:2,900 in Singapore (Tsoi, 1988; cited in Sohn & Bosinski). The prevalence of female-to-male transsexuals ranges from 1:94,000 to 1:8,300 (Sohn & Boskinski). However, these rates clearly underestimate the full range of gender dysphoria presentations. Many gender-nonconforming people do not identify as transsexual or undergo sex reassignment surgery.

Referral patterns suggest a longitudinal trend toward increased help-seeking for gender dysphoric children (Hewitt et al., 2012; Wood et al., 2013). Zucker et al. (1999) reported that children who develop gender dysphoria tend to attain the concept of gender constancy, the understanding that gender is fixed and unchanging, later in development than is typical. Although children with gender dysphoria display elevated rates of psychopathology relative to the general population, with about half meeting criteria for another psychiatric disorder, they do not differ in the number or type of comorbid conditions compared to other clinic-referred populations, such as children with attention-deficit hyperactivity disorder (Wallien, Swaab, & Cohen-Kettenis, 2007). The extent to which psychiatric comorbidity is a function of adjustment difficulties and not gender dysphoria per se is unknown. Data from several studies suggest that gender dysphoria resolves for the majority of persons diagnosed as children. Children with gender dysphoria are substantially more likely than others to develop a bisexual or homosexual orientation in adulthood (Zucker, 2005). Many adults who present with gender dysphoria have exhibited gender-atypical behavior from a very young age but, for various reasons, did not present for treatment earlier in life.

The term *gender dysphoria*, replacing the former term *GID*, was selected with deliberate consideration of the stigma attached to the word *disorder*. Nevertheless, the diagnosis of gender dysphoria is controversial among clinicians and transgender advocates. Although transgender advocates generally view gender variance along a continuum of normative behavior, some support retention of a mental disorder diagnosis to provide a mechanism for medical referral and reimbursement. Others suggest that any disorder defined by atypical gender expression pathologizes the experience of gender-variant persons to their detriment. Of particular concern is the potential for health professionals to advocate "curing" gender dysphoria rather than affirming and supporting functional expressions of gender variance. Many advocates have drawn parallels between the diagnosis of gender dysphoria and the history of pathologizing homosexuality. Although the availability of a formal diagnosis may or may not change a mental health professional's approach to the care of a person with gender dysphoria, awareness of these issues is important due to their potential financial, legal, and professional ramifications.

Assessment of gender dysphoria at any age should include a history of gender identity from childhood to the present. Questionnaires such as the Gender Identity/Gender Dysphoria Questionnaire for Adolescents and Adults (Deogracias et al., 2007) and the Recalled Childhood Gender Questionnaire-Revised (Meyer-Bahlburg et al., 2006) may be useful tools to supplement a clinical interview. The person's past and current feelings about his or her own gender, cross-gender experiences and attempts to pass as the opposite sex, and desires regarding sex reassignment should also be assessed. It is also important for the mental health professional to determine early in the professional relationship whether the client with gender dysphoria intends to seek the provider's formal recommendation for hormone treatment and/or sex reassignment surgery. Although most individuals with gender dysphoria do not have an intersex condition or another underlying medical cause, a medical evaluation may be indicated to rule out these factors in some cases.

The World Professional Association for Transgender Health (WPATH), formerly known as the Harry Benjamin International Gender Dysphoria Association, publishes a comprehensive set of guidelines for the health care of persons who are gender dysphoric or who identify as transgender, transsexual, or otherwise gender-nonconforming. The most recent WPATH Standards of Care define basic competencies and several possible roles for the mental health professional in the care of this population (Coleman et al., 2011).

Psychotherapy can be an important tool for helping people with gender dysphoria find satisfaction with a gender identity, cope with gender-related stigma and psychosocial stressors; address concurrent mental health problems; and, if desired, transition to another gender identity (Coleman et al., 2011). Although one possible treatment goal is the ultimate acceptance of one's natal or assigned gender, this may be unrealistic for clients whose gender dysphoria has been lifelong (Carroll, 2007). The alternative approach is to provide guidance in self-examination and formation of goals for gender expression, including a careful exploration of the client's options and a realistic appraisal of their ram-

ifications. In some cases, the development of a "part-time" cross-gender role may best meet the client's needs, whereas in other cases the only satisfactory resolution of gender dysphoria is to undergo full sex reassignment through hormone treatment and surgery. It should be noted that these options are not defined simply, and their particulars vary on a case-by-case basis; for example, some clients may desire a "blended" gender identity and/or partial sex reassignment.

Mental health professionals may also be involved in the multidisciplinary care of gender dysphoric individuals who seek hormonal or surgical intervention. Although psychotherapy is not a requirement for hormone therapy or surgery, a psychosocial evaluation is generally indicated. The mental health professional's tasks in this case are to assess gender dysphoria and overall psychosocial adjustment, help the client understand options for gender expression and medical intervention, and help clients to be psychologically and practically prepared for the possible outcomes of medical treatments. The WPATH Standards of Care provide specific guidance for mental health professionals who are asked to recommend a client for hormone therapy or surgery. Separate guidelines are provided for the assessment of children and adolescents. Although medical interventions are generally withheld until puberty (Coleman et al., 2011; Shumer & Spack, 2013), a good working relationship with the child and his or her family may facilitate timely decision-making about early interventions such as the use of puberty-suppressing hormones.

## Conclusion

Psychological understanding of sex and gender disorders continues to evolve not only in response to research findings but also in concert with cultural and political shifts both internal and external to the behavioral sciences. Despite a tremendous amount of interest in sexual and gender disorders, the psychological treatment literature is somewhat sparse when compared to the body of work for many other types of mental health conditions. Political polarization among health-care professionals and researchers further complicates the outlook for advances in evidence-based approaches to psychological assessment and treatment. Thus, the small number of high-quality clinical trials of psychotherapy for sex and gender disorders does not represent the sizeable amount of clinical wisdom and theory currently circulating in this field. On the other hand, research in the sexual disorders has contributed a substantial

amount of data to guide the development of new treatments and the refinement of existing ones. Translation of laboratory and cross-sectional research to improved clinical care will be a major challenge in the coming decades.

### *Future Directions*
#### SEXUAL DYSFUNCTIONS
Research on the treatment of sexual dysfunctions is at an interesting crossroads as the limitations of the biomedical model of sexual function come to light. Meanwhile, there is a need for effective models of integrating medical and psychosocial treatments for certain disorders in both men and women. Emerging models of female sexual response, although intuitively appealing, have undergone little empirical scrutiny, and their ability to inform useful clinical practices remains unclear. Development of empirically supported treatments for low sexual desire in women is a particularly important priority area for future research given the high prevalence of this complaint.

#### PARAPHILIAS
Although hypersexuality is a frequent reason for seeking mental health treatment, large observational studies and clinical trials are needed to better define the etiological underpinnings of hypersexual behavior and the effect of treatment on functional outcomes and quality of life. A movement toward depathologizing "abnormal" but otherwise benign sexual behavior is likely to shape future standards of diagnosis and treatment. Meanwhile, sexual offenses against children and other vulnerable populations continue to occur at alarming frequencies, and systematic efforts to examine the outcomes of sex offender treatment programs should be strengthened. High-quality efficacy trials and comparative outcome studies are needed to better determine the relative strengths of different treatment approaches and to refine prognostic indicators.

#### GENDER DYSPHORIA
Gender dysphoria remains a topic of controversy, made more so by the many challenges to conducting high-quality research on the prevalence, diagnosis, and treatment of this condition. Prospective longitudinal studies of psychological and functional outcomes of psychotherapy and gender reassignment, particularly among younger cohorts, are needed to evaluate existing standards of care for gender-variant persons. It is also important to examine models for

broad dissemination of best practices in the assessment and treatment of gender dysphoria. Improving access to empirically supported care will likely go a long way toward repairing the transgender community's wary stance toward mental health care.

# Schizophrenia

Kim T. Mueser *and* Stephanie Marcello Duva

## Abstract

Schizophrenia is a severe mental illness marked by hallucinations, delusions, reduced social drive, apathy, and cognitive impairment. Schizophrenia tends to develop in early adulthood and has a major impact on all aspects of functioning, including work, school, social relationships, and self-care. The illness is thought to have a biological basis that interacts with environmental and psychological factors, including stress, social support, and social competence and coping skills. Schizophrenia was once thought to be a progressively deteriorating disorder. However, more recent perspectives on schizophrenia focus on helping people define the meaning of recovery for themselves, to set personally meaningful goals, and to become active participants in their own treatment. A broad range of effective treatments exist for schizophrenia, including antipsychotic medications and psychosocial interventions such as supported employment, family psychoeducation, social skills training, and cognitive-behavioral therapy for psychosis. Although most people with schizophrenia experience some symptoms and impairments throughout their lives, recent treatment advances enable them to live rewarding, fulfilling lives, and to make a contribution to society.

**Key Words:** Assertive Community Treatment, cognitive remediation, cognitive-behavioral therapy for psychosis, family psychoeducation, illness self-management, schizoaffective disorder, schizophrenia, schizophreniform disorder, schizotypal personality disorder social skills training, stress-vulnerability model, supported employment

Schizophrenia is a major psychiatric disorder that can have a profound effect on the individual, his or her family members, and society at large. Schizophrenia is characterized by a combination of psychotic symptoms, such as hallucinations and delusions, and negative (or deficit) symptoms, such as apathy, paranoia, and blunted affect. Although symptoms are critical to the diagnosis of schizophrenia, the hallmark of the disease is impaired functioning, including the ability to participate in meaningful and reciprocal relationships with others, to take care of oneself, and to function at work, school, or as a parent.

Because of the long-term impact of schizophrenia on functioning, and the episodic nature of psychotic symptoms that tend to vary in their presence and intensity—at times requiring temporary hospitalization to protect the individual or others—most people with schizophrenia rely on family members and disability benefits to meet their basic needs. The loss in functional capacity, combined with the intermittent need for inpatient psychiatric treatment, makes schizophrenia a costly disease to society (Rice, 1999; Samnaliev & Clark, 2008). In fact, due to the loss of productivity and premature death attributed to schizophrenia, it is considered one of the top 10

of all diseases in the world contributing to disability burden (Murray & Lopez, 1996).

Schizophrenia is a biologically based disease that interacts with environmental factors such as stress and social support. Although the precise causes of schizophrenia remain unknown, substantial advances in the treatment of the disorder have been made over the past several decades. With a combination of pharmacological and psychosocial treatments, it is now possible for many people with schizophrenia to live rewarding and productive lives, despite continuing to experience some of the symptoms and characteristic impairments of the disorder. In this chapter, we review what is known about the nature and causes of schizophrenia, and describe the growing evidence base for the treatment of the disorder.

## Epidemiology
### *Prevalence*
Schizophrenia affects approximately 1% of the world population. In the United States alone, 3.7 million Americans or approximately 0.7% (ranging between .3% and 1.6%, depending on the study) have the disease (McGrath, Saha, Welham, Saadi, MacCauley, & Chant, 2004). Due to the chronic nature of schizophrenia, health-care costs are significant. It is estimated that 10% of all disabled persons meet criteria for schizophrenia (Goldman & Manderscheid, 1987). A significant percentage of people with this disorder are unemployed and typically have a lower quality of life, when compared to the rest of the population (Marwaha et al., 2007; Warner, Girolamo, & Bellini, 1998). Furthermore, the economic costs are considerable: people diagnosed with schizophrenia account for 75% of mental health care costs and approximately 40% of Medicaid reimbursements (Murray & Lopez, 1996). It is estimated that the overall US cost of schizophrenia is $62.7 billion (Wu, Birnbaum, Shi, Ball, Kessler, & Moulis, 2005). This includes both the direct costs of treating the illness, as well as costs related to lost work productivity for clients and families, and costs associated with incarceration and the legal system. The substantial burden of the disease is a reflection of its early onset and persistent and fluctuating symptoms (American Psychiatric Association [APA], 2013).

### *Onset and Course*
Schizophrenia is typically diagnosed in late adolescence or early adulthood, and infrequently after the age of 45. However, schizophrenia does develop through the adult lifespan, including past the age of 50 (Almeida, Howard, Levy, & David, 1995a, 1995b). The disease characteristically has a gradual onset that takes place over 5 years, starting with negative and depressive symptoms, followed by cognitive and social impairment, which is then followed by the emergence of psychotic symptoms (Häfner & an der Heiden, 2008; Häfner, Löffler, Maurer, Hambrecht, & an der Heiden, 1999).

Schizophrenia is a chronic, disabling disorder and, once it has developed, some impairment is present throughout most of life, although clients might experience times of remission (Häfner & an der Heiden, 2003). Between 50% and 70% of cases are associated with a chronic course, relapses, and permanent disability. However, despite past negativity about prognosis, recent studies suggest that early intervention and great advances in treatment can improve outcomes (Perkins, Gu, Boteva, & Lieberman, 2005). For example, Loebel et al. (1992) found that, in a state-of-the-art treatment program, 74% of people recovering from their first episode had achieved complete remission. Also, at a specialized clinic for high-risk youth in Australia, 91% of people with recent-onset psychosis were in remission after 1 year of assertive community treatment, medication, and cognitive-behavioral therapy (CBT) (Edwards, Maude, McGorry, Harrigan, & Cocks, 1998). Even among clients with a more chronic and disabling course (e.g., clients who have spent years in state psychiatric hospitals), recovery rates over 15–25 years can be promising. For example, several long-term studies have shown that approximately 25%–40% of people with schizophrenia lead relatively independent lives, or are even completely recovered and off all medication, after many years of comprehensive treatment (Ciompi, 1980; Harding, Brooks, Ashikaga, Strauss, & Breier, 1987a, 1987b; Harrison et al., 2001; Tsuang & Winokur, 1975).

Poor outcome is predicted by gender (male), early age of onset, severity of negative and cognitive symptoms, substance abuse, and sudden discontinuation of psychiatric medications (Emsley, Chiliza, & Schoeman, 2008). Lack of insight is present in 50% to 80% of people with schizophrenia and often contributes to poor medication adherence (Amador & Gorman, 1998; Lysaker, Lancaster, Davis, & Clements, 2003; Smith et al., 2004). Also, a shorter duration of untreated psychosis is associated with greater response to treatment (Perkins et al., 2005).

### Gender, Ethnicity, and Cultural Factors

Schizophrenia occurs equally in men and women, although symptoms typically appear earlier in men (20–28 years) than in women (26–32 years) (Murray & Van Os, 1998). Women also tend to have a more benign course of illness, including fewer hospital admissions and better social functioning (Angermeyer, Kuhn, & Goldstein, 1990; Canuso & Pandina, 2007; Riecher-Rössler & Häfner, 2000). The better outcome of women with schizophrenia compared to men is hypothesized to be the result of estrogen, which has antipsychotic properties and is associated with a later age at onset of the disorder and better psychosocial functioning due to having passed through more developmental milestones (Häfner, Maurer, Löffler, & Riecher-Rössler, 1993).

Substantial variations in the prevalence of schizophrenia across different countries and cultural groups have been reported (Institute of Medicine, 2001b). However, these differences are reduced when diagnostic criteria is controlled for (Jablensky, 1997). Research by the World Health Organization indicates similar rates of schizophrenia across cultures and countries, including developed and developing nations (Jablensky et al., 1992).

### Risk Factors

Several forms of environmental stress and/or trauma may increase the likelihood of schizophrenia. Some research suggests that neglect and trauma during childhood increases the risk of developing this disorder later in life. The data indicate that childhood abuse is associated with increased rates of adult schizophrenia, and that high rates of neglect and physical and sexual abuse are found in the histories of people with schizophrenia (Read & Argyle, 1999; Read, van Os, Morrison, & Ross, 2005).

Some sociodemographic factors have been associated with increased risk for schizophrenia (van Os & Marcelis, 1998). Poverty (Bruce, Takeuchi, & Leaf, 1991), lower social class (Eaton, 1994; Hollingshead & Redlich, 1958), urban birth and upbringing (Torrey, Bowler, & Clark, 1997; Saha, Chant, Welham, & McGrath, 2005; van Os, 2004), and migration to urban areas are strongly correlated to higher rates of schizophrenia (Pedersen & Mortensen, 2001; van Os, 2004). Some hypotheses are that stressful environmental conditions increase the risk of schizophrenia, and schizophrenia results in a downward "social drift" due to a decline in social and occupational functioning (Fox, 1990). Although the incidence of the disorder is similar across different

ethnic groups (Jablensky, 1999), increased rates are present in some monitory populations, such as second-generation Afro-Caribbean people in the United Kingdom (Boydell et al., 2001), Dutch Antillean and Surinamese immigrants in Holland (Selten, Slaets, & Kahn, 1997), and African American people (Rabkin, 1979). An additional environmental factor is international migration. A recent meta-analysis review (Cantor-Graae, Zolkowska, & McNeil, 2005) provides evidence that migration to a new country is correlated with increased rates of schizophrenia.

There is evidence that the prenatal environment and obstetric complications are related to increased risk of developing schizophrenia (Byrne, Agerbo, Bennedsen, Eaton, & Mortensen, 2007; Cannon, Jones, & Murray, 2002). Obstetric complications may disrupt early brain development, and several factors have been association with increased risk of developing schizophrenia; for example, maternal infection (Brown et al., 2004), maternal starvation (Hoek, Brown, & Susser, 1998), late winter birth (Hultman, Sparén, Takei, Murray, & Cnattingius, 1998), birth asphyxia (Dalman et al., 2001), and being born too small (Jones, Rantakallio, Hartikainen, Isohanni, & Sipila, 1998). Despite this growing body of evidence of the association between obstetric complications and later development of schizophrenia, there are some conflicting results. Haukvik et al. (2009) found that the number or severity of obstetric complications were not associated with brain cortical thickness in people with schizophrenia. Previous studies have found that people with schizophrenia have thinner brain cortices compared to controls (DeLisi et al., 2006).

There is some evidence that cannabis use can actually precipitate the onset of schizophrenia. In a meta-analysis, Henquet et al. (2005) found that cannabis use more than doubles the risk of developing schizophrenia. The risk of developing schizophrenia appears to be higher for individuals who smoke cannabis relatively early in adolescence (e.g., before the age of 16), with dose of use also associated with increased vulnerability to the disorder (Arseneault, Cannon, Witton, & Murray, 2004; Corcoran et al., 2008).

## Psychopathology and Characteristic Impairments
### Symptoms

Three types of symptoms are characteristic of schizophrenia: psychotic symptoms, negative symptoms,

and disorganization symptoms. Common *psychotic symptoms* include delusions, hallucinations, and bizarre behavior. *Negative symptoms* are the absence or reduction of aspects of normal behavior, thinking, or feeling. Some examples are reduced facial emotional expressiveness (i.e., *flat affect*), poverty of speech (*alogia*), reduction in the experience of pleasure (*anhedonia*), and lack of motivation (*avolition, apathy*). Negative symptoms are sometimes subtyped into primary negative symptoms (symptoms that directly reflect a disease process) and secondary symptoms (symptoms due to the side effects of medication or other extraneous factors) (Carpenter, Heinrichs, & Wagman, 1988; Kirkpatrick & Galderisi, 2008; Mueser, Douglas, Bellack, & Morrison, 1991). Examples of disorganization symptoms include poorly planned behavior and difficult-to-understand speech due to disordered syntax (*word salad)* or making up new words (*neologisms*).

Depression in people with schizophrenia has been found to be more frequent and more severe than in the general population, and persistent over the course of the illness (Häfner et al., 1999). Depression during the acute phase of schizophrenia may be associated with a more favorable course and outcome (Vaillant, 1964), but during the chronic phase has been linked to greater risk of suicide (Cohen, 1995) and relapse (Johnson et al., 1998). The severity of depressive symptoms is correlated with positive symptoms and substance abuse, but not with age, gender, or negative symptoms (Brunette, Mueser, Xie, & Drake, 1997; Mueser et al., 1991b; Zisook et al., 1999).

Cognitive impairment is a core feature in people with schizophrenia that tends to remain stable after the onset of the disorder (Heaton et al., 1994). People with schizophrenia tend to show a broad spectrum of neurocognitive deficits, including in attention/vigilance, executive functioning, working memory, processing speed, verbal learning and memory, visual learning and memory, reasoning and problem solving, and social cognition. Large studies and meta-analyses suggest that neurocognitive functioning is compromised in a significantly large proportion of people with schizophrenia (Heinrichs & Zakzanis, 1998). Clinically, this is important because cognitive impairments in people with schizophrenia contribute to poor functional outcomes, including, difficulty maintaining work, independent living, and social networks, and reduced benefit from psychosocial treatments (Green, 1996, 2006; McGurk & Mueser, 2004; Mueser, 2000).

## Functional Impairments

Psychosocial dysfunction, including impaired social relationships and role functioning, and poor self-care, are core behavioral features that distinguish schizophrenia (APA, 1994). Negative symptoms are significant contributors to poor social functioning (Puig et al., 2008), and have higher predictive value than do positive symptoms (Addington, Young, & Addington, 2003). Both have a negative impact on the quality of life for both clients and families. Chronic symptoms and cognitive impairments are the strongest predictors of psychosocial functioning (Puig et al., 2008).

Unemployment rates are higher than 20% in people with schizophrenia and are much higher when compared to the general population (Marwaha & Johnson, 2004). However, most people with schizophrenia indicate a desire to work (Mueser, Salyers, & Mueser, 2001). Work is associated with numerous favorable outcomes, including improved self-esteem, less severe symptoms, financial gain, and improved sense of recovery (Arns & Linney, 1993; Mueser, Becker, et al., 1997).

Self-care and community survival skills, such as grooming and hygiene, cooking, laundry, and home maintenance, are commonly impaired in people with schizophrenia (Holmberg & Kane, 1999), frequently requiring the involvement of family in getting basic needs met. Housing is often substandard, with high rates of homelessness (Fischer, Drake, & Breakey, 1992; Olfson, Mechanic, Hansell, Boyer, & Walkup, 1999; Susser, Struening, & Conover, 1989). Incarceration is common, and is often related to lack of treatment (Munetz, Grande, & Chambers, 2001; Teplin, 1985; Teplin, Abram, & McClelland, 1996) or increased rates of aggression and violence (Arseneault, Moffitt, Caspi, Taylor, & Silva, 2000; Brennan, Mednick, & Hodgins, 2000). Although schizophrenia is associated with an increased risk of violence, individuals with the disorder are significantly more likely to be victims of crime than perpetrators (Bebbington et al., 2004; Hiday, Swartz, Swanson, Borum, & Wagner, 1999; Teplin, McClelland, Abram, & Weiner, 2005).

## Comorbidity

People with schizophrenia often have other comorbid psychiatric conditions or disorders. Depression is commonly found in people with this disorder. Lifetime estimates of clinically significant depression in people with schizophrenia range from 25% to 33% (Cohen, Talavera, & Hartung, 1996; Häfner

et al., 2005; Sands & Harrow, 1999). Suicide is the leading cause of early death in people with schizophrenia. About 4.9% of people with schizophrenia commit suicide, frequently near the onset of their symptoms (Palmer, Pankratz, & Bostwick, 2005).

Substance use disorders occur in approximately 50% of individuals with schizophrenia, compared to approximately 15% in the general population (Kessler et al., 1996; Mueser, Bennett, & Kushner, 1995; Regier et al., 1990). Rates of abuse tend to be highest among younger males with lower educational level, antisocial personality disorder, and a family history of addiction (Kavanagh et al., 2004; Mueser, Crocker, et al., 2006; Noordsy, Drake, Biesanz, & McHugo, 1994). As described later in this chapter, substance abuse in people with schizophrenia is of particular concern and is an important focus of treatment because it leads to increases in severity of positive symptoms, treatment noncompliance, violence, human immunodeficiency virus (HIV) infection, homelessness, higher medical costs, and potential involvement with the legal system (Drake & Brunette, 1998).

Rates of conduct disorder in childhood and antisocial personality disorder in adulthood are also increased in persons with schizophrenia (Hodgins, Toupin, & Côté, 1996; Robins, 1966; Robins, Tipp, & Przybeck, 1991). Higher rates of antisocial personality disorder have been linked to increased aggression (Hodgins, Hiscoke, & Freese, 2002; Hodgins, Tiihonen, & Ross, 2005; Tengström, Hodgins, Grann, Långström, & Kullgren, 2004) and substance use disorders (Mueser, Crocker, et al., 2006; Mueser et al., 1997; Mueser, Rosenberg, et al., 1999). Hodgins and colleagues have hypothesized that the increased rate of violence in schizophrenia can be subtyped into one group of "early starters," with conduct disorder and a pattern of aggression that precedes the onset of schizophrenia; and another group of "late starters," whose violence is related to psychotic symptoms (Crocker et al., 2005; Hodgins et al., 1996; Moran & Hodgins, 2004; Tengström, Hodgins, & Kullgren, 2001).

Anxiety disorders are significant clinical problems in many people with schizophrenia and include panic disorder (Argyle, 1990; Hofmann, 1999), obsessive-compulsive disorder (Hwang, Morgan, & Losconzey, 2000; Tibbo, Kroetsch, Chue, & Warneke, 2000), social phobia (Penn, Hope, Spaulding, & Kucera, 1994), and post-traumatic stress disorder (PTSD) (Mueser, Goodman et al., 1998; Mueser, Salyers et al., 2004). Of particular concern, estimates of exposure to traumatic events for people with schizophrenia range from 34% to 98% (Goodman, Dutton, & Harris, 1995; Hatters Friedman & Loue, 2007), with rates of PTSD in people with schizophrenia of between 29% and 43% (Mueser, Rosenberg, Goodman, & Trumbetta, 2002). It has been suggested that the frequency of trauma among people with schizophrenia may also be *under*estimated, due to clients' underreporting of traumatic experiences and insufficient assessments of traumatic events at mental health facilities (Rosenberg et al., 2001).

People with a serious mental illness die, on average (Pack, 2009), 25 years earlier than the general population, and medical comorbidity is largely to blame (Sokal et al., 2004). Suicide and injury account for about 30%–40% of deaths, but the high mortality and morbidity rates are not all accounted for by the higher rates of suicide (Harris & Barraclough, 1998). As many as 60% of premature deaths in people with schizophrenia are due to high rates of medical conditions, such as diabetes (Dixon et al., 2000), dyslipidemia (Meyer & Koro, 2004), obesity (Dickerson et al., 2006), cardiovascular and respiratory diseases (Druss, Bradford, Rosenheck, Radford, & Krumholz, 2000; Sokal et al., 2004), metabolic effects of antipsychotic medications (Meyer et al., 2008), and pulmonary and infectious diseases, such as hepatitis and acquired immune deficiency syndrome (AIDS) (Rosenberg et al., 2001). This is due to multiple factors including poor judgment about health needs (Felker, Yazel, & Short, 1996), receipt of fewer and poorer-quality health services (Desai, Rosenheck, Druss, & Perlin, 2002; Druss et al., 2000), poorer nutrition (Fontaine et al., 2001), high rates of smoking (de Leon & Diaz, 2005), lack of exercise (Daumit et al., 2005), "unsafe" sexual behavior (Cournos et al., 1994; Goodman & Fallot, 1998), and low socioeconomic standing and living in poor neighborhoods (Felker et al., 1996).

## Diagnostic Systems and History

The characterization of schizophrenia as a single disorder dates back to Emil Kraepelin (1919/1971), who coined the term *dementia praecox* to mean "early dementia." This disorder was distinguished from manic-depression (now called bipolar disorder), which had a relapsing and remitting course. To Kraepelin, dementia praecox was a progressive disease involving deterioration in cognitive functioning and increased disability over time. The word *schizophrenia* was introduced in the early 20th century by

the Swiss psychiatrist Eugen Bleuler (1911/1950). Bleuler changed the term because, he argued, many people with the disorder did recover, and, even when recovery did not occur, deterioration did not necessarily occur. The term *schizophrenia* is derived from the Greek words *skhiz* (split) and *phren* (mind), and refers to the fragmentation of thought, speech, emotion, and behavior found in the disorder. (It is often mistakenly assumed that people with schizophrenia have multiple personalities. However, that condition is known as dissociative identity disorder, and it is unrelated to schizophrenia [APA, 2013].)

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) (APA, 2013) and the *International Classification of Diseases*, 10th Edition (ICD-10) (World Health Organization, 1997) are the two sets of diagnostic criteria by which schizophrenia is most often diagnosed.

### Schizophrenia-Spectrum Disorders

The symptoms of schizophrenia have historically been used to form different subtypes, such as paranoid, disorganized, hebephrenic, undifferentiated, and catatonic (e.g., DSM-IV; APA, 1994). However, in the most recent version of the DSM (DSM-5), the subtypes of schizophrenia have been eliminated due to their limited diagnostic stability, low reliability, and poor validity.

Four disorders are commonly grouped together as schizophrenia-spectrum disorders based on family history, similarity in presenting symptoms, and response to available treatments: schizophrenia, schizoaffective disorder, schizophreniform disorder, and schizotypal personality disorder (Levinson & Mowry, 1991). In the DSM-5, schizophrenia is defined by the presence for 1 month or longer of at least two of the following five Criterion A symptoms: (1) hallucinations, (2) delusions, (3) disorganized speech, (4) grossly disorganized or catatonic behavior, and (5) negative symptoms, of which at least one must be hallucinations, delusions, or disorganized speech (APA, 2013). In addition, following the onset of symptoms the individual must have experienced significantly reduced functioning in the areas of work or school performance, social relationships, or self-care (Criterion B). Finally, the duration of disturbance must persist for at least 6 months (Criterion C). Schizophreniform disorder differs from schizophrenia mainly with respect to not requiring a 6-month duration of symptoms and associated impairment in functioning. Individuals who meet symptom and functional impairment criteria for schizophrenia (Criteria A and B), but do not

meet the 6 months' duration criterion, are diagnosed with schizophreniform disorder. Those whose symptoms and impaired functioning remit in less than a 6-month period are given the diagnosis of schizophreniform disorder in remission. Individuals with schizophreniform disorder who continue to be symptomatic or impaired are diagnosed with schizophreniform disorder (provisional), which is then changed to schizophrenia when the symptoms or impairment have been present for a minimum of 6 months.

Schizoaffective disorder is defined by the presence of clear and prominent mood syndromes (meeting criteria for either major depressive episodes or hypomanic or manic episodes) in people who otherwise meet the diagnostic criteria for schizophrenia. The diagnosis of schizoaffective disorder is based on two primary criteria. First, the person much have experienced episodes of depression, hypomania, or mania during significant proportions of his or her life in terms of the overall duration of his or her psychiatric disorder. Second, the individual must show at least some of the prominent symptoms of schizophrenia (e.g., hallucinations, delusions) during periods when he or she was not experiencing an episode of abnormal mood. Changes to the DSM-5 for schizoaffective disorder are the requirement that a major mood episode be present for the majority of the duration of Criterion A symptoms. This change was primarily implemented based on the diagnostic challenges of distinguishing between schizoaffective disorder and schizophrenia, and to increase the reliability and validity of this diagnosis. People who have psychotic symptoms only during a mood episode, but whose psychotic symptoms remit when the depression or mania remit, are diagnosed with a mood disorder (e.g., major depression, bipolar disorder) and are not classified with a schizophrenia-spectrum disorder (Pope & Lipinski, 1978).

Schizotypal personality disorder is defined by the long-term presence of milder symptoms of schizophrenia, including symptoms such as magical thinking, peculiar face-to-face report when interacting with others, social anxiety, and odd behavior. The symptoms of schizotypal personality disorder are typically milder and more stable compared to those in schizophrenia. Nevertheless, functioning is substantially impaired and often only marginally better than in schizophrenia (Ödéhn & Goulding, 2009). Paranoid personality disorder, which is characterized by suspiciousness and paranoid delusions, and schizoid personality disorder, which is defined in terms of aloofness and a lack of desire or need for

social relationships, are also sometimes included in the schizophrenia spectrum (Kendler et al., 2006).

## Etiology
### Genetic Factors
Genetic and environmental factors appear to play a role in the development of schizophrenia. Structural brain abnormalities have consistently been found in clients with schizophrenia (Shenton, Dickey, Frumin, & McCarley, 2001) and at least some of these brain changes are progressive (Pantelis et al., 2005). The cause of the brain changes is still unclear, but have been associated with poorer long-term outcomes (van Haren et al., 2008). It appears that the severity of the illness and the medication used to treat it influence the progressive brain volume changes (Lieberman et al., 2001). However, genes may also be involved with these progressive brain changes. Brans et al. (2008) found that progressive brain volume loss found in clients with schizophrenia and their unaffected twin sibling are partly attributable to genetic factors. Rates of developing schizophrenia are higher among relatives of clients when compared to the general population, and the hereditable nature schizophrenia is estimated to be around 80% (Sullivan, Kendler, & Neale, 2003). The genetic risk of developing the disorder increases with each affected relative, to nearly 50% when both parents are affected, and 60%–84% when a monozygotic twin has the illness (Cardno et al., 1999). Multiple genes have been shown to be associated with schizophrenia (Harrison & Owen, 2003; Jianxin Shi et al., 2009).

### Environmental Factors
Studies have found that higher rates of abuse and trauma (e.g., physical and sexual abuse) during childhood increase the chances of developing schizophrenia later in life (Read et al., 2005). Urban birth, upbringing, and migration to urban areas have been correlated with increased rates of developing schizophrenia (Torrey et al., 1997). Numerous studies have found that cannabis use more than doubles the risk of developing schizophrenia, with risk being highest in people with one variant of the COMT gene (Moore et al., 2008). Studies done in the Northern Hemisphere have shown small, but consistent correlations demonstrating that babies born in the winter and spring months develop schizophrenia to a greater extent than in the general population (Fritzsche & Schmidl, 2002). Data from the Southern Hemisphere, however, have not supported the hypotheses as consistently (McGrath & Welham, 1999).

The long-term effects of racism and stress associated with being an underprivileged minority are associated with the development of schizophrenia. Silverstein, Spalding, and Menditto (2006) suggest that, although social defeat is unlikely to be a sufficient cause of developing this disorder, it might interact with other factors to increase risk. For example, chronic stress can lead to anatomical changes in the hippocampus and produce biological changes that, in combination with other psychological, biological, and environmental factors, can facilitate expression of the illness.

Although the etiology of schizophrenia is unknown, several theories have gained support in the literature. Both biological and environmental factors can increase one's risk for developing schizophrenia. In people with a genetic predisposition, environmental factors can determine whether the person develops or does not develop the disorder. In people without a known family history, factors such as birth complications (Cannon et al., 2002; Geddes & Lawrie, 1995), viral infection of the mother during the second trimester of pregnancy (Brown et al., 2004), and paternal age of the father (Zammit et al., 2003) may create the same brain abnormalities associated with genetic forms of schizophrenia, thus increasing risk. Genetics have been found to contribute to 80% of the liability for developing schizophrenia, and eight chromosomal sites have been associated with increased risk. Having a parent with schizophrenia raises a person's risk from 1% to 10% of developing this disorder. Having an identical twin with the illness raises the risk to 50% (Gottesman, 1991). Three birth complications have been associated with increased risk for developing schizophrenia: pregnancy complications (e.g., bleeding), delivery complications (e.g., hypoxia), and abnormal fetal development (e.g., low birth weight) (Buchanan, 1995).

The dopamine hypothesis of schizophrenia attributes the disorder to a hyperactive dopaminergic system. It has been suggested that the dopamine pathways in the mesolimbic region may contribute to the positive symptoms of schizophrenia. The evidence to support this theory is the emergence of psychotic symptoms in people who used amphetamines, cocaine, and other drugs, which are known to increase dopamine in the brain, and the positive effects of antipsychotic medications, which block dopamine receptors and reduce psychotic symptoms of schizophrenia (Davis, Kahn, Ko, & Davidson, 1991). However, serotonin, γ-aminobutyric acid (GABA), glutamate, and other neurotransmitters have also been implicated in schizophrenia (Pantelis et al.,

2005). Therefore, rather than trying to isolate one neurotransmitter, focusing on the interactions among neurotransmitter systems is important for understanding schizophrenia.

## Stress–Vulnerability Model

The Stress–Vulnerability Model has become a framework for explaining how environmental factors interact with preexisting vulnerability in the etiology and course of schizophrenia (Liberman et al., 1986; Nuechterlein & Dawson, 1984; Zubin & Spring, 1977). The model posits that schizophrenia is caused by a psychobiological vulnerability, which is determined early in life by genetic and early environmental influences. Once the vulnerability is established, the onset and course of the illness is determined by both biological and psychosocial factors. An example of a biological factor that can worsen vulnerability is substance abuse, which can precipitate relapses and hospitalizations (Linszen, Dingemans, & Lenior, 1994). Stress, including normal or traumatic life events (Bebbington & Kuipers, 1992), exposure to high levels of interpersonal stress (Butzlaff & Hooley, 1998), or lack of meaningful structure (Wong et al., 1987) can impinge on vulnerability, precipitating relapses and contributing to impairments in other domains (e.g., social functioning). However, coping skills (e.g., social skills, problem-solving ability) and social support can minimize the effects of stress on relapse and functioning (Liberman et al., 1986; Norman et al., 2005).

The treatment implications of the Stress–Vulnerability Model are straightforward. The outcome of schizophrenia can be improved through interventions that reduce psychobiological vulnerability or stress, or that improve social support and coping skills. Increasing adherence to antipsychotic medication and reducing substance abuse can lower vulnerability and improve the course of the illness. Interventions that reduce stress in the environment and increase social support, such as family psychoeducation, can minimize relapses and improve functioning. Providing meaningful structured activities that are not overdemanding can also reduce environmental stress. Additionally, people can be taught skills to enhance their ability to deal with internal sources of stress (e.g., coping skills for anxiety, depression, persistent hallucinations), to handle external sources of stress (e.g., social skills for managing interpersonal conflict), or to achieve personal goals (e.g., social skills, problem-solving skills).

## Treatment

Because schizophrenia can have a major impact on all aspects of daily living, and the etiology of the illness remains a mystery, treatment is necessarily complex as it must address the broad range of different domains of functioning affected by the illness. In this section, we first address the recovery paradigm as a new model for conceptualizing the role of treatment and rehabilitation in the management of schizophrenia. We next discuss the targets of treatment in schizophrenia, followed by different systems of care involved in the treatment of the disorder. We then discuss the psychopharmacologic treatment of schizophrenia, followed by a review of evidence-based psychosocial treatment and rehabilitation approaches for schizophrenia.

## The Recovery Paradigm

Over the past 15 years, a gradual change has occurred in the conceptualization of the goals in treatment for schizophrenia. At the core of this change has been an evolution in how *recovery* from mental illness is understood and defined. Traditional medical definitions of recovery have emphasized the elimination of psychopathology and remission of symptoms and functional impairments (Andreasen et al., 2005; Liberman, Kopelowicz, Ventura, & Gutkind, 2002). Because early conceptualizations of schizophrenia posited that the disorder had a deteriorating course over the lifetime (Kraepelin, 1919/1971), most experts believed that recovery from schizophrenia was impossible. However, longitudinal research studies on the long-term outcome of schizophrenia published over the last three decades have conclusively refuted this assumption and have demonstrated that, in fact, a significant proportion of people with schizophrenia experience a medical recovery from the disorder over their lifetime (Häfner & an der Heiden, 2008). The fact that medical recovery from schizophrenia does occur has been important to challenging stereotypes about the chronicity and poor prognosis of the disorder previously held by many treatment providers.

Even more important than research showing that medical recovery from schizophrenia occurs over the long-term has been the rise of the *consumer movement* (i.e., individuals with schizophrenia or other severe mental illnesses) in advocating for a new, more personally meaningful, and more hopeful definition of recovery (Chamberlin, 1978). Newer definitions of recovery have challenged the emphasis of the medical definition on psychopathology, and instead view recovery as the process of coming to grips with having a mental illness and then moving forward with one's life despite the presence of any

continuing symptoms or impairments (Anthony, 1993; Corrigan, Giffort, Rashid, Leary, & Okeke, 1999; Davidson, Tondora, Lawless, O'Connell, & Rowe, 2009; Deegan, 1988; Ralph, Kidder, & Phillips, 2000; Silverstein & Bellack, 2008). When recovery is defined in this way, it is more akin to recovering something that one has lost, such as a sense of meaning and purpose in life, as opposed to recovery from a disease. Furthermore, the concept of recovery goes beyond coping and evokes personal growth, in which the experience of a mental illness presents an opportunity for personal transformation and development (Roe & Ben-Yishai, 1999; Roe & Chopra, 2003). Of greatest significance, this new definition means that recovery from schizophrenia is possible despite some persistent symptoms.

Defining recovery as a process involving the development of meaning and improved functioning has had dramatic effects on increasing the hope of clients, family members, and even professionals for improving the lives of people with this disease. As a result of this shift in the conceptualization of recovery, treatment approaches have also evolved to focus more on helping clients make personally meaningful changes in their lives and focus less on symptoms alone. In addition, since recovery is understood to be an individual process that varies from one person to the next, and that people differ in what they find meaningful and their personal goals, treatment approaches have been altered to be less prescriptive and hierarchical (i.e., "the doctor always knows best"), and based more on developing a collaborative relationship between treatment providers and clients and a shared-decision making approach to treatment decisions (Adams, Drake, & Wolford, 2007; Hamann, Leucht, & Kissling, 2003). Such an approach recognizes that the client is a vital participant in his or her own treatment and that treatment decisions are much more likely to be followed through on when they are arrived at in a collaborative fashion (Roe, Chopra, & Rudnick, 2004).

## Systems of Care

A variety of different systems of care are involved in the treatment of persons with schizophrenia. Temporary inpatient psychiatric treatment may be periodically necessary during acute symptom exacerbations to protect the person or others. Acute inpatient treatment typically lasts between several days and several months, and has the primary goal of stabilizing the individual's symptoms, so they no longer pose a threat to themselves or others and can therefore be treated on an outpatient basis. A rela-

tively small minority of people with schizophrenia have persistent symptoms that are so severe that they require long-term inpatient treatment, or treatment in residential facilities that provide close monitoring and ample assistance in getting daily needs met (Ciompi, 1980).

The most common system of care for people with schizophrenia is at local community mental health centers that serve geographic catchment areas and are publicly funded. These centers typically provide a wide range of services, including pharmacological treatment, psychosocial treatment and rehabilitation programs, housing supports, and assistance in obtaining disability benefits. Because of the complex array of needs and potential services, outpatients with schizophrenia are often provided case management at community mental health centers, which is aimed at identifying needs, providing services or connecting clients to other service providers, and evaluating receipt of services, improvement in targeted outcomes, and the need for further services (Kanter, 1989).

In addition to community mental health centers, a variety of other organizations or individuals may be involved in providing treatment to people with schizophrenia in the community. Freestanding psychiatric rehabilitation programs may provide an array of services to people who choose to use them. Psychosocial clubhouses that are based on the principles of self-help and responsibility for contributing to the program are another service in the community (Norman, 2006). In addition, people with schizophrenia may receive their treatment from private practitioners, including either primary care providers or psychiatrists, psychologists, or social workers.

Finally, because of the numerous social repercussions associated with schizophrenia, individuals with this disease are often involved in the criminal justice system (Abram, Teplin, & McClelland, 2003; Teplin, 1994) or are homeless (Susser et al., 1989). Although the criminal justice system was not designed to be a system of care, but rather to protect society from the transgressions of those who do not obey its laws, it has become a de facto system of care for many people with schizophrenia (Torrey, 1995). Similarly, services for homeless persons are needed to attend to the multiple needs of persons with severe mental illness because of their disproportionate numbers in this population (Peters, Kearns, Murrin, & Dolente, 1992).

## Pharmacological Treatment

Since the discovery of antipsychotic medications in the late 1950s, these medications have been the mainstay of treatment in schizophrenia. Extensive

research has shown that antipsychotic medications are effective at reducing the severity of psychotic symptoms of schizophrenia, and in preventing relapses and hospitalizations (Schatzberg, Cole, & DeBattista, 2007). However, antipsychotic medications do not have consistent effects on improving either negative symptoms or cognitive impairment in schizophrenia. Furthermore, these medications can produce a variety of undesirable side effects, such as tremors, involuntary movements, sedation, and restlessness.

Over the past 25 years, a variety of new antipsychotic medications have been developed with the intention of improving their efficacy and reducing the troubling side effects. Newer-generation antipsychotics have been successful at reducing some of the most subjectively distressing side effects of the traditional antipsychotics, but also tend to be associated with different problematic side effects, such as increased weight gain and other metabolic effects (Meyer et al., 2008). Research on the comparative efficacy of newer-generation and older antipsychotics indicates that they are of comparable efficacy in their impact on psychotic symptoms and preventing relapses, but do not significantly improve cognitive functioning or negative symptoms (Keefe et al., 2004; Lieberman et al., 2005).

One medication that should be distinguished from the other antipsychotics is clozapine, which was first developed in the 1970s (Matz, Rick, Thompson, & Gershon, 1974). Clozapine is more effective than other antipsychotics for the treatment of persistent psychotic symptoms and has also been shown to improve the severity of negative symptoms (Honigfeld, Patin, & Singer, 1984; Kane, Honigfeld, Singer, & Meltzer, 1988). Clozapine has also been shown to have a beneficial impact on suicidal thinking and behavior (Meltzer et al., 2003), to reduce aggression and violence (Volavka, 1999), and to reduce substance abuse (Drake, Xie, McHugo, & Green, 2000; Green, Zimmet, Strous, & Schildkraut, 1999; Volavka, 1999) in schizophrenia. The use of clozapine in schizophrenia needs to be carefully monitored because the medication can cause *agranulocytosis* (i.e., a lowering of white blood cells), which can be fatal if not detected and the medication reduced or withdrawn (de la Chapelle, Kari, Nurminen, & Hernberg, 1977). However, with appropriate monitoring of white blood cell count, clozapine can be a very safe and effective medication.

A wide range of other medications has been evaluated for the treatment of schizophrenia, especially antidepressants and mood stabilizers. Despite the widespread use of these medications, data from controlled trials do not support their efficacy at improving symptoms or reducing relapses in schizophrenia (Arey & Marder, 2008). Similarly, there has been a growing trend toward prescribing multiple classes of antipsychotic medication for schizophrenia (Clark, Bartels, Mellman, & Peacock, 2002), but data do not provide strong support for the efficacy of combining antipsychotics over the use of a single agent (Arey & Marder, 2008; Freudenreich & Goff, 2002).

Medication nonadherence is a common problem in schizophrenia that contributes to relapses and hospitalizations (Pratt, Mueser, Driscoll, Wolfe, & Bartels, 2006; Yamada et al., 2006). Several long-acting, injectable depot antipsychotic medications that can be administered every 2–4 weeks have been developed and shown to be clinically efficacious; these are viable alternatives for clients who forget to take oral medication but are willing to take injections (Kane et al., 2003; Schooler, 2003). A variety of other strategies have been developed and evaluated to improve medication adherence in schizophrenia (Zygmunt, Olfson, Boyer, & Mechanic, 2002), with illness self-management strategies and the Assertive Community Treatment model (described below) showing the most benefit.

### Psychosocial Treatment

In addition to medications, a wide range of psychosocial treatments have been demonstrated to improve the outcome of schizophrenia. In this section, we first summarize effective psychosocial interventions for schizophrenia with a well-established evidence base (i.e., supported by multiple controlled trials). For each intervention, we provide a brief rationale for the targeted domain of the treatment, followed by a description of the intervention, and then research supporting it.

#### SUPPORTED EMPLOYMENT

Difficulty sustaining competitive work is one of the diagnostic criteria for the functional impairment characteristic of schizophrenia (APA, 1994). Although problems working are by definition common among people with schizophrenia, the majority of individuals express a desire for competitive work (Mueser, Salyers et al., 2001; Rogers, Walsh, Masotta, & Danley, 1991). However, rates of competitive work are typically low, usually between 10% and 20%, including part-time work (Marwaha et al., 2007). For these reasons alone, improving the competitive employment outcomes has been a major goal in the treatment of schizophrenia.

There are a number of advantages of helping people with schizophrenia return to work, either part- or full-time. Work is associated with self-esteem, and clients with schizophrenia report improvements in self-esteem when they obtain jobs (Torrey, Mueser, & Drake, 2000). Work has also been associated with modest reductions in symptoms severity (Bell, Lysaker, & Milstein, 1996; Bond et al., 2001), supporting the old adage that "work is good therapy" (Harding, Strauss, Hafez, & Liberman, 1987). Work also provides clients with additional economic resources, an important consideration in light of the low incomes and need for disability entitlements that plague most people with schizophrenia. Finally, there is great social approval associated with work, and therefore helping people return to work can have destigmatizing effects both on how the individual sees himself or herself, as well as on how other people in society perceive the individual (Farina, 1998).

### Description

The principles of supported employment for persons with severe mental illness were first established and standardized by Becker and Drake in a program called Individual Placement and Support (Becker & Drake, 1993, 2003). The focus of supported employment is on helping clients find competitive jobs that pay competitive wages in the community. Involvement in supported employment programs should be the client's choice, with no other exclusion criteria required in order to receive vocational services.

Supported employment emphasizes rapid job search and placement in favor of prevocational training and extensive assessment. For most clients, the job search commences within 1 month of joining a supported employment program. The goal is not only to help clients get jobs, but to help them keep jobs, or to help them transition from one job to another. Therefore, in contrast to traditional vocational rehabilitation approaches, in supported employment, follow-along supports are provided after a job has been successfully obtained. The nature of these supports varies from one client to another, and can include on-the-job training, consultation or a liaison with the client's supervisor, behind-the-scenes problem solving or skills training to address interpersonal or job performance issues, and temporary transportation assistance.

Another important feature of supported employment programs is the role of client preferences. Preferences are critical both in the nature of jobs that are sought, as well as in the types of supports provided by the employment specialist. Research has shown that client who obtain jobs in their preferred area of interest have job tenures approximately twice as long as those whose jobs do not match their interest (Becker, Drake, Farabaugh, & Bond, 1996; Mueser, Becker, & Wolfe, 2001). Client preferences are also important in terms of whether the person chooses to disclose their psychiatric disorder to a prospective employer. A final component of supported employment programs is benefits counseling. All clients need information about how much they can work without loss of disability income, how much additional work will reduce their disability income, and the implications of work for maintaining insurance benefits.

### Research

Multiple randomized controlled trials (RCTs) have been conducted to evaluate the effects of supported employment programs compared to other vocational programs. Comparison programs include traditional sheltered workshop approaches, transitional employment, and group skills training approaches. Across the broad range of different vocational models that it has been compared to, supported employment has been found to result in significantly better vocational outcomes (Bond, Drake, & Becker, 2008). This includes a greater likelihood of obtaining a competitive job, earning more wages, and working more hours. Although most of the research on supported employment has been conducted in the United States, several recent studies have replicated the effectiveness of the approach abroad (Burns et al., 2007; Killackey, Jackson, & McGorry, 2008; Latimer et al., 2006). Research on the clinical benefits of participating in supported employment in obtaining work indicates that work is associated with increases in self-sufficiency, modest decreases in symptoms, and improved satisfaction with economic standing (Bond et al., 2001; Mueser et al., 1997).

Research is under way in improving the effectiveness of supported employment. One approach with some recent empirical support has been to provide cognitive remediation, targeting cognitive impairments that interfere with vocational functioning in schizophrenia (McGurk, Mueser, Feldman, Wolfe, & Pascaris, 2007; McGurk, Mueser, & Pascaris, 2005). Cognitive remediation approaches are described in greater detail later.

### SOCIAL SKILLS TRAINING

Similar to the reduced capacity to work, impairment in social relationships is a prominent feature of

schizophrenia. Poor premorbid social functioning is a common precursor to schizophrenia that is also associated with a worsening course of the psychiatric illness, including more impaired psychosocial functioning, as well more frequent relapses and hospitalizations (Mueser, Bellack, Morrison, & Wixted, 1990; Zigler & Glick, 1986). Social support is an important mediator of the course of schizophrenia due to its role as a buffer against stress-induced relapses (Buchanan, 1995). Improving social functioning is also an important quality-of-life issue. Many people with schizophrenia desire close, intimate, and rewarding relationships (Ralph, 2000). Thus, improving social functioning is an important goal in the treatment research, with social skills training currently enjoying the strongest empirical support.

*Description*

Social skills training is a systematic approach to teaching interpersonal skills. It involves breaking down complex behaviors into smaller constituent elements or steps, and then teaching these skills through a combination of modeling (demonstrating the skill), role play rehearsal, positive feedback, corrective feedback, additional role play rehearsal, and home assignments to practice the skill outside of the training session (Bellack, Mueser, Gingerich, & Agresta, 2004; Liberman, DeRisi, & Mueser, 1989). Social skills training is usually conducted in groups of five to eight clients, with sessions conducted at least once or twice per week. The duration of the program is between 3 months to over 1 year. Sessions follow the highly structured teaching approach described earlier, with a wide range of curriculum taught, depending on the clients' needs and goals. Common target areas for social skills training include conversational skills, friendship and dating skills, conflict-resolution skills, assertiveness, interpersonal skills for the workplace, alcohol and drug refusal skills, and independent living/self-care skills. Standardized curriculum has been developed to facilitate the teaching of social skills to people with schizophrenia and other severe mental illnesses (Bellack et al., 2004).

*Research*

Extensive research has been conducted on social research training since the standardization of skills training methods in the 1960s and 1970s and the development of curriculum specifically geared to the needs of people with severe mental illness. Social skills training is hypothesized to improve functioning by improving the individual's social competence

or ability to interact with others in a socially effective manner. Social skills training is also thought to improve the symptomatic outcome of schizophrenia, including relapses, through improved ability to cope with stress and increase social support (Liberman et al., 1986).

A recent meta-analysis confirmed the impact of social skills training on several different outcome domains (Kurtz & Mueser, 2008). As expected, social skills training had a large effect size on clients' mastery of the information taught in skills training groups. Social skills training also had a moderate effect size on both social skills performance in role-play tests and on measures of community functioning and social adjustment. Skills training also had a somewhat smaller, but nevertheless significant, effect on reducing negative symptoms. Finally, social skills training had a small but significant effect size on reducing other symptoms and preventing relapses. These findings are consistent with those from another recently completed meta-analysis of social skills training conducted by an independent group of researchers (Pfammatter, Junghan, & Brenner, 2006). Thus, research supports the beneficial effects of social skills training on social functioning in schizophrenia.

### FAMILY PSYCHOEDUCATION

Prior to the 1950s and the 1960s, some theories of the etiology of schizophrenia proposed that the origins of the disorder lay in disturbed family relationships characterized by problematic and contradictory communication patterns among the members (Fromm-Reichman, 1948). As family members were thought by many mental health professionals to be culprit in causing schizophrenia, collaborative relationships were rarely formed between treatment providers and the client's relatives, and families were usually left in the dark about the nature of the illness (Appleton, 1974).

However, psychogenic theories of the family causing schizophrenia were largely abandoned in the 1960s, for several reasons. First, research on the genetics of the disorder demonstrated that it was at least partly heritable, as indicated by facts such as the higher concordance rate of the disorder in monozygotic than dizygotic twins and increased rates of schizophrenia in the children of mothers with the disorder, even when they were raised by adoptive parents with no mental illness (Gottesman, 1991). Second, the dramatic effects of antipsychotic medications on the psychotic symptoms of schizophrenia made theories of the family as the causal

agent increasingly implausible. Third, family therapy approaches that attempted to correct family pathology thought to be at the root of schizophrenia were largely unsuccessful (Terkelsen, 1983).

The discovery of antipsychotic medications in the late 1950s and their widespread use in the 1960s led to the deinstitutionalization of many people with schizophrenia (Johnson, 1990), with many others never being institutionalized and instead receiving treatment for their disorder in the community. As a focus of the treatment for schizophrenia shifted from the hospital to the community, increasing numbers of clients either returned to their family's home or continued to live with them and depend on them for emotional and material support. Although families were heavily relied upon to provide support for a relative with schizophrenia, they were frequently ill-prepared to meet the challenge, and emotional turmoil was a common consequence. Research on family *express emotion* showed that the presence of strong negative emotional attitudes in the relatives of someone with schizophrenia acted as a stressor that could precipitate relapses and rehospitalizations (Butzlaff & Hooley, 1998). Furthermore, families began to demand better treatment from mental health professionals, both for themselves and their loved ones, thus giving birth to the family advocacy movement, as exemplified by organizations such as the National Alliance on Mental Illness (Hatfield & Lefley, 1993, 1987).

*Description*

Family psychoeducation programs were developed to address the needs of families to better understand the nature of schizophrenia and its treatment, to reduce stress in the family, and to foster a respectful and collaborative relationship with mental health treatment providers (Lefley, 2009). In the 1970s and the 1980s, several different models of family psychoeducation were developed and empirically validated (Anderson, Reiss, & Hogarty, 1986; Barrowclough & Tarrier, 1992; Falloon, Boyd, & McGill, 1984; Kuipers, Leff, & Lam, 2002; McFarlane, 2002; Mueser & Glynn, 1999). Although the programs differ in format (single family vs. multiple family groups), theoretical orientation (e.g., social learning, modified systems theory, etc.), and duration of treatment, they actually share more in common than they differ.

Effective family psychoeducation programs are led by professionals who assume a collaborative stance in working with families. In addition, family psychoeducation models for schizophrenia incorporate several other common characteristics, including (a) both the client and family members are included in treatment sessions; (b) the programs are long-term, lasting at least 9 months; (c) the focus of the programs is on the present and the future, rather than the past; (d) basic information is provided about schizophrenia, its treatment, and the role of the family in helping a loved one with the illness; (e) families are helped to develop strategies for addressing problems and reducing stress and conflict among members; (f) family members have access to the treatment team to alert them to changes in clinical status or express other concerns; and (g) families are involved in treatment planning with other members of the treatment team.

*Research*

Extensive research has been conducted on family psychoeducation programs over the past 25 years. The most consistent impact of family psychoeducation is on the reduction of relapses and rehospitalizations (Pitschel-Walz, Leucht, Bäuml, Kissling, & Engel, 2001). This is presumably accomplished through a combination of reducing the effects of stress in the family on precipitating relapses, and improved monitoring of the illness by the family in collaboration with the treatment team, thereby permitting rapid intervention at the early stages of a relapse and the prevention of full-blown symptom exacerbations. Other effects of family psychoeducation include improved client functioning and the reduction of family stress and burden (Lefley, 2009).

**ASSERTIVE COMMUNITY TREATMENT**

The deinstitutionalization movement described earlier resulted in a shift in the locus of care for most people with schizophrenia from long-term state hospitals to local community mental health centers. With this shift, a subgroup of people with schizophrenia and other severe mental illnesses failed to access community-based services and were consequently prone to frequent relapses and hospitalizations for the management of their disorders. In addition, these clients usually had extremely impaired psychosocial functioning and often lived in impoverished conditions. As awareness grew about this subgroup of clients who did not access community-based psychiatric services, a new term was invented to describe their pattern of going in and out of hospitals for the treatment of acute exacerbations of their disorders: the *revolving door patient* (Bachrach, 1981; Harris & Bergman, 1984). Because of the high cost of inpatient treatment, there was a strong interest in

developing a more effective approach to delivering mental health services to these clients.

## Description

To address the problem of frequent relapses and hospitalizations for this subgroup of clients, Stein and Test (1985) developed the Assertive Community Treatment (ACT) model, based on the rationale that if clients did not go to local community mental health centers to receive their mental health services, the same services could be brought to the client, wherever he or she was in the community. The ACT model is a team-based approach to delivering mental health services that differs from traditional approaches in several ways. Members of an ACT team have lower caseloads, typically about one clinician for every ten clients, as compared to usual services in which each clinician may be responsible for 30 or more clients. Rather than each clinician on an ACT team having his or her own personal caseload, members of ACT teams share the responsibility for all the clients carried by an ACT team, thereby reducing the burnout associated with individual-based case management (Cook, Pickett-Schenk, & Nageotte, 2000). Consistent with the philosophy of assertive outreach, the majority of the services provided by an ACT team are conducted in the community, rather than in treatment setting such as a community mental health center. ACT teams assume 24-hour responsibility for clients, with different members of the ACT team taking turns being available for emergency calls during evenings and weekends. Another unique feature of ACT teams is that they focus on the direct provision of services to clients, rather than brokering services to other treatment providers. There are no time limitations placed on receiving services from an ACT team, although clients graduate from ACT teams to less intensive services as they improve their illness self-management and independent living skills (Salyers, Masterton, Fekete, Picone, & Bond, 1998). The principles of act have been standardized in several manuals (Allness & Knoedler, 1998; Stein & Santos, 1998).

## Research

The ACT model has been extensively studied in RCTs. Most of the studies of ACT have been conducted in the United States, with the majority of participants including people with schizophrenia. Some successful replications of the ACT model have been reported from abroad (Rosen, Mueser, & Teeson, 2007), although there is also a question as to whether the ACT model is appropriate for some systems of care, such as in Great Britain (Johnson et al., 1998; McCrone et al., 1998; Thornicroft et al., 1998; Wykes, Leese, Taylor, & Phelan, 1998), where the fragmentation of services is not as great a problem as it is in the United States.

Research on ACT indicates that it has prominent effects on reducing hospitalizations and on stabilizing housing in people with schizophrenia (Bond, Drake, Mueser, & Latimer, 2001). The stabilization of housing is partly a reflection of reduced hospitalizations, but also reflects the effects of ACT on reducing homelessness in this population. Studies have found that clients express satisfaction with ACT services and report improved quality of life related to participation in the program. ACT treatment program have also been found to have modest effects on reducing symptom severity. However, the ACT model tends to have limited effects on social and vocational functioning, unless specific ACT team members are designated to focus on addressing these areas. For example, when an employment specialist is added to an ACT team to provide supported employment, competitive work outcomes improve (Gold et al., 2004).

## COGNITIVE-BEHAVIORAL THERAPY FOR PSYCHOSIS

Despite the growing variety of antipsychotic medications available for people with schizophrenia, a significant portion of clients continued to experience psychotic symptoms that are not the result of medication nonadherence. Estimates of the rate of persistent psychotic symptoms in people with schizophrenia vary, with most suggesting that between 20% and 35% of clients experience such symptoms (Mueser et al., 1991b; Silverstein & Harrow, 1978). Persistent psychotic symptoms are associated with high levels of distress (Mueser et al., 1991b), often related to the derogatory nature of auditory hallucinations or to the fear associated with paranoid delusions (Chadwick & Birchwood, 1994; Garety & Hemsley, 1994). In addition to the distress associated with psychosis, persistent psychotic symptoms increase vulnerability to relapses and contribute to poor psychosocial functioning (Racenstein et al., 2002). For these reasons, cognitive-behavioral therapy (CBT) for psychosis was developed to reduce the severity of psychotic symptoms or the distress associated with them.

## Description

CBT for psychosis is based on the application of the same approach to other disorders, such as mood

and anxiety disorders (Beck, Emery, & Greenberg, 1985; Beck, Rush, Shaw, & Emery, 1979). CBT for psychosis proposes that psychotic symptoms and associated distress in people with schizophrenia are related to clients' appraisals of events, which may be inaccurate due to illness-related biases in information processing, "normal" distortions in the interpretation of events, and significant personal life experiences that may have influenced the person's perception of themselves or the world (e.g., childhood physical or sexual abuse) (Garety & Hemsley, 1994; Hemsley, 1996; Maher, 1988). In CBT, clients are taught how to identify and evaluate the evidence for and against upsetting thoughts or beliefs related to their psychotic symptoms and to modify them when the evidence does not support them.

The first applications of CBT for psychosis actually predated the use of the approach for depression, as described in a single case treated by Aaron Beck more than half a century ago (Beck, 1952). Following this initial case, little systematic work examined the utility of CBT for psychosis over the next several decades. Then, in the late 1980s and early 1990s, systematic efforts to apply CBT to psychosis began, with preliminary reports indicated promising effects (Chadwick & Birchwood, 1994; Garety, Kuipers, Fowler, Chamberlain, & Dunn, 1994). Since the 1990s, a number of manuals for CBT for psychosis have been developed, which share a range of common elements (Chadwick, Birchwood, & Trower, 1996; Fowler, Garety, & Kuipers, 1995; Kingdon & Turkington, 2004; Morrison, Renton, Dunn, Williams, & Bentall, 2004; Nelson, 1997).

CBT for psychosis emphasizes the importance of establishing a collaborative relationship between the therapist and the client, and of establishing treatment goals to work toward together. Information about the nature of psychotic symptoms is usually provided to clients, seeking to normalize these experiences as common reactions or responses to stress (Kingdon & Turkington, 1991). This makes it easier for clients with psychotic symptoms to talk about their symptoms without feeling shameful or embarrassed. Coping strategies for dealing with psychotic symptoms are usually taught, such as listening to the radio or other distraction techniques for auditory hallucinations. The heart of CBT for psychosis is in the use of cognitive restructuring to help clients examine the evidence for and against psychotic or otherwise distressing thoughts or beliefs, and changing those thoughts when the evidence does not support them. The exploration of evidence for and against thoughts or beliefs is conducted in a collaborative, nonconfrontational manner to avoid inadvertently reinforcing beliefs through psychological reactance (Milton, Patwa, & Hafner, 1978). When insufficient evidence exists for determining the correctness of the thought or believe, behavioral experiments may be conducted in which the client obtains additional information bearing on the question at hand (Hagen & Nordahl, 2008). Most CBT for psychosis programs last at least 3–6 months, and sometimes longer.

*Research*

Extensive research has been conducted on CBT for psychosis over the past 15 years, with the great preponderance of studies conducted in Great Britain. The most recent meta-analysis of CBT for psychosis reported moderate effects sizes on reducing the severity of psychotic symptoms (Wykes, Steel, Everitt, & Tarrier, 2008). Furthermore, CBT for psychosis was found to have significant effects on reducing the severity of negative symptoms and improving psychosocial functioning.

The success of research on CBT for psychosis has led it to be recommended in treatment guidelines for schizophrenia both in Great Britain (National Collaborating Centre for Mental Health, 2009) and the United States (Dixon et al., 2010). This strong research supporting CBT for psychosis is in contrast to the relative lack of access to this intervention in the United States. There have been calls to increase the access to CBT for psychosis for people with schizophrenia in the United States (Turkington, Kingdon, & Weiden, 2006) and for increased involvement of psychologists in the treatment of schizophrenia in the community (Mueser & Noordsy, 2005).

## COGNITIVE REMEDIATION

Cognitive impairment increases the risk of developing schizophrenia (Zammit et al., 2004). Furthermore, the onset of schizophrenia is associated with a decline in cognitive functioning in almost all persons who develop the illness (Heaton et al., 1994). Cognitive impairment is strongly correlated with psychosocial functioning in schizophrenia (Green, 1996), and is predictive of an attenuated response to psychiatric rehabilitation approaches, such as supported employment (McGurk, Mueser, Harvey, Marder, & LaPuglia, 2003) and social skills training (Mueser, Bellack, Douglas, & Wade, 1991; Smith, Hull, Romanelli, Fertuck, & Weiss, 1999).

For these reasons, improving cognitive functioning in schizophrenia is an important treatment goal. The importance of this goal is also underscored by the fact that currently available antipsychotic medications do not improve cognitive functioning, and other cognition-enhancing drugs have yet to be discovered.

*Description*

A variety of different methods have been developed and employed to remediate cognitive functioning in schizophrenia. Most of the approaches that have been developed involve a combination of practice and teaching cognitive strategies designed to improve cognitive performance. In addition to focusing directly on improving the quality of cognitive functioning, some programs also teach clients coping or compensatory strategies for managing persistent cognitive impairments that interfere with functioning. Thus, cognitive remediation programs seek both to improve cognitive functioning and to reduce the interference caused by cognitive impairments in psychosocial functioning.

Programs vary with respect to the actual strategies employed to remediate cognitive functioning. Many approaches include computer programs designed to help clients practice specific cognitive skills, such as attention, psychomotor speed, memory, and problem solving (Bell, Bryson, Greig, Corcoran, & Wexler, 2001; McGurk et al., 2005). Other programs utilize paper-and-pencil exercises (Brenner et al., 1994; Wykes & Reeder, 2005). Some programs also include a group format in which people practice different cognitive exercises together (Hogarty & Flesher, 1999). The length and intensity of cognitive remediation program also varies significantly. Many programs provide at least two or three training sessions per week, and most programs last at least several months, with some lasting over a year.

One other potentially important distinction between different cognitive remediation programs is whether they are integrated with a psychiatric rehabilitation program. Some cognitive remediation programs focus on cognitive remediation alone and do not attempt to integrate cognitive training with other rehabilitation methods (Medalia, Revheim, & Herlands, 2009; Wykes & Reeder, 2005). Other approaches integrate cognitive remediation with other psychiatric rehabilitation methods, such as social skills training (Silverstein et al., 2005) or vocational rehabilitation (Bell, Fiszdon, Greig, Wexler, & Bryson, 2007; McGurk et al., 2005).

An alternative approach to the remediation of cognitive impairments or the teaching of coping skills to minimize the effects of impaired cognitive functioning on adaptation is to modify the client's environment, so that it cues appropriate self-care behavior. *Cognitive adaptive therapy* was developed to facilitate the community functioning of former state psychiatric inpatients who were discharged into the community (Velligan, Mueller et al., 2006). The program is implemented by staff members who regularly visit a client's apartment (e.g., weekly), and arrange his or her living space so that appropriate dressing, hygiene, and other self-care behaviors are cued by signs or other prompts. For example, the client's clothes may be selected for the following week with each day's clothes placed in a separate bag or plastic container. This approach to organizing the client's environment reduces the cognitive reserves necessary to sustain independent living in the community.

*Research*

Over the past several decades, numerous studies have been conducted on the effects of cognitive remediation. A meta-analysis of 26 studies of cognitive remediation in schizophrenia was recently completed (McGurk, Twamley, Sitzer, McHugo, & Mueser, 2007). This analysis found significant effects for cognitive remediation on improving cognitive functioning, psychosocial functioning, and negative symptoms. Exploration of possible factors that could influence the effect of cognitive remediation on cognitive functioning were not found. However, one significant factor was found to moderate the impact of cognitive remediation on psychosocial functioning. Specifically, cognitive remediation programs that provided adjunctive psychiatric rehabilitation had significant effects on improving psychosocial functioning, whereas cognitive remediation programs that were provided in isolation and did not provide ancillary psychiatric rehabilitation failed to demonstrate significant improvements in psychosocial functioning. The results are consistent with research showing that level of cognitive impairment is predictive of benefit from psychiatric rehabilitation (Bowen et al., 1994; Kern, Green, & Satz, 1992; Mueser et al., 1991a; Silverstein, Schenkel, Valone, & Nuernberger, 1998; Smith et al., 1999). These findings are in line with another meta-analysis that demonstrated significant effects on cognitive functioning and psychosocial adjustment of Integrated Psychological Therapy (Roder, Mueller, Mueser, & Brenner, 2006), a program developed in

Switzerland by Brenner and colleagues (1994) that integrates cognitive remediation using group exercises with social skills training. Thus, cognitive remediation may be an effective way of increasing the ability of clients with schizophrenia to benefit from psychiatric rehabilitation approaches such as supported employment and social skills training.

Research on cognitive adaptive therapy is still in the relatively early stages. However, two RCTs provide support for the effectiveness of the program at improving community functioning, as well as some evidence that it increases medication adherence (Velligan et al., 2000; Velligan et al., 2008; Velligan, Diamond et al., 2006; Velligan et al., 2002). These results are encouraging, and suggest that modifying the environment is a viable approach to the management of debilitating cognitive impairments that often result in long-term institutionalization.

## INTEGRATED TREATMENT FOR DUAL DISORDERS

Alcohol and drug use disorders are one of the most common comorbid disorders in people with schizophrenia, with approximately 50% of all clients meeting lifetime diagnostic criteria (Mueser, Bennett, & Kushner, 1995; Regier et al., 1990). Substance abuse is associated with a worse course of schizophrenia across the full spectrum of outcomes, including increased relapses and re hospitalizations, worse depression and suicidality, problems in social and role functioning, legal problems, housing problems, susceptibility to medical illnesses, and premature mortality. Thus, the treatment of substance abuse in people with schizophrenia is a high priority.

Traditional approaches to treating co-occurring psychiatric and substance use disorders (or dual disorders) have typically involved the provision of psychiatric and substance abuse services by different agencies and different clinicians who work either in a parallel or sequential fashion (Polcin, 1992). *Parallel treatment* involves the treatment of the psychiatric and the substance use disorders at the same time by different treatment providers. *Sequential treatment* involves attempting to first treat or stabilize one disorder before then attempting to treat or stabilize the other disorder. Research has clearly demonstrated that parallel or sequential treatment approaches for co-occurring disorders are ineffective (Ridgely, Goldman, & Willenbring, 1990). The most common problems with these approaches are the failure of clients to follow through on treatment referrals for their substance abuse due to a lack of insight into their substance use problems. Other problems with traditional treatment approaches include barriers to accessing both treatments, such as restrictive eligibility criteria, the use of confrontational and stressful treatment approaches in substance abuse programs (which can precipitate relapses in people with schizophrenia), high rates of dropout from either or both treatments due to lack of motivation, and the lack of integration between psychiatric and substance abuse treatment providers when both disorders are treated simultaneously. The failure of traditional approaches in treating co-occurring disorders has led to the development of integrated treatment models for these disorders.

### Description

*Integrated treatment* refers to the treatment of both the psychiatric and the substance use disorders at the same time, by the same treatment team, in which clinicians assume the responsibility for treating both disorders in an integrated fashion (Mueser, Noordsy, Drake, & Fox, 2003). The integration of substance abuse and psychiatric treatment in people with schizophrenia is important for schizophrenia because many of the symptoms and impairments related to the disorder contribute to the high vulnerability of clients for using and abusing substances. For example, common motives for using substances in people with schizophrenia include facilitating socialization, having something enjoyable to do, and coping with symptoms such as anxiety, depression, and demoralization (Addington & Duchak, 1997; Dixon, Haas, Weiden, Sweeney, & Frances, 1991; Mueser, Nishith, Tracy, DeGirolamo, & Molinaro, 1995). Effective integrated treatment for co-occurring disorders for people with schizophrenia involves both educating clients and their families about the effects of drugs and alcohol on the course of the illness, as well as using psychiatric rehabilitation approaches designed to address clients' motives for using (Mueser et al., 2003). For example, social skills training can be used to help clients develop more effective skills for establishing rewarding relationships with peers who do not abuse substances. Supported employment can enable clients to pursue their vocational goals and have something meaningful and purposeful to look forward to in their lives. Cognitive-behavioral therapy for psychosis or other approaches to helping clients cope with persistent symptoms can be used to reduce symptom distress and the motivation to use substances to cope with symptoms. Teaching clients new leisure and recreational skills can help them develop alternatives to drug and alcohol use as sources of pleasure.

A number of integrated treatment programs for co-occurring disorders have been developed over the past 15–20 years (Bellack, Bennet, & Gearon, 2007; Carey, 1996; Drake, Teague, & Warren, 1990; Minkoff, 1991; Mueser, Nishith et al., 1995; Roberts, Shaner, & Eckman, 1999). In addition to the shared focus on integration, effective treatment programs tend to incorporate similar elements as well. First, assertive outreach, which involves going into the community and meeting with individuals where they spend their time, such as in their apartments, a coffee shop, or a park, is a common practice used to engage those clients in treatment who do not otherwise come to mental health treatment settings. A second common feature of integrated treatment programs is the adoption of a harm reduction approach. *Harm reduction* refers to treatment that is initially aimed at reducing the harmful consequences of substance abuse without requiring the individual to endorse abstinence as a personal long-term goal (Marlatt, 1998). Harm reduction facilitates the development of a therapeutic relationship between the clinician and the client, and addresses immediately the most toxic effects of the client's substance abuse on health and functioning.

A third common feature of integrated treatment programs is the use of motivational enhancement strategies and the adoption of a stage-wise approach to treatment. People with schizophrenia often lack motivation to work on their substance use problems, and treatment must be geared according to the individual's level of motivation to change his or her behavior. The concept of *stages of change* has proven useful in developing treatments that are matched to the individual's motivation to change (DiClemente & Prochaska, 1998; Prochaska & DiClemente, 1984). The stages of change model posits that when people change their behavior, they progress through a series of discrete motivational states, including *pre-contemplation* (not thinking about change), *contemplation* (thinking about change), *preparation* (making plans to change), *action* (making changes), and *maintenance* (maintaining changes). The stages of change have been adapted to the *stages of treatment* for dual disorders, which describe the stages that individuals progress through when receiving professional treatment for their disorders, and identify treatment goals for each stage (Mueser et al., 2003; Osher & Kofoed, 1989). The stages of treatment include *engagement* (when the client is not receiving services for their co-occurring disorders, and the goal is to develop a therapeutic relationship with that person), *persuasion* (when a

therapeutic relationship has been established but the client is not motivated to address substance use problems, and the goal of treatment is to instill such motivation), *active treatment* (when the client has demonstrated motivation to work on substance use problems, and the goal of treatment is to reduce substance use or achieve abstinence), and *relapse prevention* (when the client no longer has an active substance use problem, and the goal is to maintain sobriety while extending recovery to other areas of functioning, such as work, school, health, and social relationships). The stages of treatment construct helps clinicians optimize treatment by matching specific interventions to the client's stage of motivation to change.

*Research*

Extensive research has been conducted on the effectiveness of integrated treatment programs for co-occurring disorders. Early research was marred by methodological weaknesses and treatment programs that only included selected components of integrated dual-disorder programs (Mercer-McFadden, Drake, Brown, & Fox, 1997). More recently, however, rigorous research has been conducted evaluating well-defined integrated treatment programs for co-occurring disorders. Research on integrated dual-disorder treatment programs indicate that they are effective at reducing the severity of substance abuse and associated consequences, such as impaired functioning and psychiatric symptoms and hospitalizations (Drake, Mueser, Brunette, & McHugo, 2004; Drake, O'Neal, & Wallach, 2008).

ILLNESS SELF-MANAGEMENT TRAINING

Despite significant advances over the past several decades in the pharmacological treatment and psychiatric rehabilitation of schizophrenia, clients often know little about their psychiatric disorder or the principles of its treatment, lack basic illness self-management skills for using medication effectively, and are challenged by coping with stress and persistent symptoms. Many people with schizophrenia are not actively involved in establishing their treatment goals or making decisions with clinicians and family members about their own care (Fenton, 2003). All too often, people play a passive role in their own treatment, sometimes lacking awareness of their right to participate, and thus leading to dependency on others and low self-esteem (Oades et al., 2005). This lack of involvement and poor illness self-management skills often leaves people with schizophrenia prone to medication nonadherence,

disruptive symptoms, and frequent relapses and rehospitalizations. Illness self-management programs have been developed to address these needs.

*Description*

Illness self-management programs are aimed at teaching people with schizophrenia information and skills that enable them to minimize their symptoms, reduce the distress and interference caused by persistent symptoms, and prevent or limit the severity of relapses and hospitalizations. Teaching illness self-management can foster the development of a mutually respectful, collaborative therapeutic relationship by empowering the client to take an active role in his or her treatment. Several programs have been developed in recent years to teach illness self-management skills to clients with schizophrenia and other severe mental illnesses, including personal therapy (Hogarty, 2002; Hogarty, Greenwald et al., 1997; Hogarty, Kornblith et al., 1997), the UCLA Social and Independent Living Skills modules on symptom self-management and medication management (Liberman, 2007), and the Illness Management and Recovery (IMR) program (Gingerich & Mueser, 2005). These programs overlap in much of the information and skills taught to clients. We briefly describe here the IMR program, which is the most comprehensive illness self-management program, and the only program based on a comprehensive review of research on the topic.

The basic rationale underlying the IMR program is that people with schizophrenia can be most effectively taught how to manage their mental illness in the context of setting and pursuing personally meaningful, functional goals. The IMR program was designed as a curriculum-based approach that explicitly incorporates empirically supported practices for illness self-management into a single cohesive program. The program was designed to incorporate five practices found to improve the outcome of severe mental illness in a comprehensive review of 40 RCTs (Mueser, Corrigan et al., 2002). This review indicated that *psychoeducation* significantly improves knowledge about mental illness, but does not affect medication adherence, reduce relapse, or improve functioning (Macpherson, Jerrom, & Hughes, 1996). Medication adherence programs that utilize cognitive-behavioral techniques such *behavioral tailoring* (i.e., teaching clients how to incorporate taking medication into their daily routines by pairing medication adherence with another activity such as brushing one's teach) improve clients' ability to take medication as prescribed (Azrin & Teichner, 1998;

Cramer & Rosenheck, 1999). Teaching *relapse prevention skills*, including identifying situations that have triggered relapses in the past, recognition of the early warning signs of relapse, and developing a written plan for responding to the early signs of relapse, have demonstrated decreases in relapses and rehospitalizations (Herz et al., 2000). Teaching people *coping skills* for how to manage symptoms such as hallucinations, depression, or anxiety has been shown to improve coping efficacy and to reduce the severity of symptoms or distress related to symptoms (Lecomte et al., 1999; Tarrier, Beckett, et al., 1993; Tarrier, Sharpe, et al., 1993). Finally, bolstering social support through *social skills training* can buffer the negative effects of stress on relapses and rehospitalizations (Bebbington & Kuipers, 1992; Kurtz & Mueser, 2008; Norman et al., 2005).

Motivation for learning how to manage one's illness in the IMR program is instilled by first helping individuals explore the concept of recovery, and then helping them develop personally meaningful goals based on what recovery means to them. Specific objectives are then set toward achieving these overall goals, with motivation to learn illness self-management harnessed by exploring how it could help them achieve their goals. The curriculum taught in the IMR program is organized into ten modules, including: Recovery Strategies, Practical Facts about Severe Mental Illness, Stress-Vulnerability Model and Treatment Strategies, Building Social Support, Using medications Effectively, Drug and Alcohol Use, Reducing Relapses, Coping with Stress, Coping with Problems and Persistent Symptoms, and Getting Your Needs Met in the Mental Health System. Between three and six sessions are usually spent teaching each module, in either an individual or group format, with the entire program requiring 9–10 months of weekly sessions (or 4–5 months of biweekly sessions) to complete.

*Research*

Limited research supports the efficacy of personal therapy (Hogarty, Greenwald et al., 1997; Hogarty et al., 1995; Hogarty, Kornblith et al., 1997) and the UCLA skills for independent living skills modules (Liberman, 2007) for improving the illness outcomes of schizophrenia. The feasibility and initial beneficial effects of the more recently developed IMR program were demonstrated in a three-site study conducted in the United States and Australia (Mueser et al., 2006), followed by a larger study demonstrating the feasibility of implementing the IMR program with good fidelity to the treatment model in 12 community

mental health centers over a 2-year implementation and follow-up period (McHugo et al., 2007). In addition, two RCTs have indicated that participation in IMR improves illness self-management, including symptom severity and community functioning (Hasson-Ohayon, Roe, & Kravetz, 2007; Levitt et al., 2009). Thus, a growing body of research supports the benefits of training people with schizophrenia in illness self-management.

## TOKEN ECONOMY

The role of inpatient treatment for schizophrenia has decreased dramatically since the discovery and widespread use of antipsychotics and the development of more effective approaches to outpatient management of the disorder, such as the ACT model. Inpatient treatment for the vast majority of persons with schizophrenia is limited to pharmacological intervention and stabilization for acute psychotic exacerbations, with most treatment episodes lasting 1–4 weeks. Despite the reduced role of inpatient treatment for schizophrenia, some clients with extremely severe symptoms, impaired psychosocial functioning, or aggression require intermediate or long-term inpatient treatment (Menditto, Baldwin, O'Neal, & Beck, 1991). The token economy was developed to address severely impaired social behavior in institutionalized persons with schizophrenia and other mental illnesses that are a barrier to community living.

### Description

The token economy is based on the systematic manipulation of contingencies in a specific milieu (e.g., the inpatient setting, group home) that control disruptive behaviors, as well as reward socially appropriate behaviors. Clients participating in a token economy are rewarded for appropriate behaviors with tokens or points that can be exchanged for valued items or activities, such as food, listening to music, clothes, or personal hygiene products (Ayllon, 1968). Based on the principle of sharing, complex social behaviors are broken down into smaller component behaviors, with tokens provided for small steps toward the larger goal. Token economies typically include a store that stocks a wide range of desirable items that can be purchased, with additional items added upon request. Inappropriate behaviors can be reduced through either ignoring the behavior (i.e., *extinction*), fining the client tokens, or by imposing time-outs. Specific target behaviors and rewards are individually developed for each client and modified regularly to ensure that the person is making progress toward treatment goals. Token economy programs are most effective when all stakeholders, including staff and clients, are involved in the design of the program (Corrigan, McCracken, Edwards, Kommana, & Simpatico, 1997).

### Research

The preponderance of research on the token economy was conducted in the 1960s and 1970s, when the deinstitutionalization movement was still largely under way. In a classic study conducted by Paul and Lentz (1977), "back ward" chronic patients were randomly assigned to one of three programs: an intensive token economy, an equally intensive milieu therapy program, and usual treatment. Clients who were randomized to the token economy program showed dramatically better improvements across a range of social and symptomatic behaviors, as well as better discharges into the community, compared to the two comparison programs.

In addition to the Paul and Lentz study, another 12 controlled studies have demonstrated the efficacy of the token economy for clients with schizophrenia and severely impaired social behavior (Dickerson, Tenhula, & Green-Paden, 2005). Although the token economy has been shown to be effective and is accepted as an evidence-based practice for schizophrenia (Dixon et al., 2010), the intervention is rarely used in inpatient treatment for schizophrenia, in part because it requires extensive coordination among the broad range of service providers in such settings (e.g., nurses, doctors, psychiatric technicians).

## EMERGING PRACTICES

There are a number of treatment approaches for schizophrenia that are currently under development or for which preliminary evaluations suggest promise for improving the long-term course of the illness. We briefly describe these practices here.

### Peer Support

There is a long history of peer support for persons with severe mental illness dating back to the Alleged Lunatic Friends Society in 1845 (Frese, 2008). More recently, in the 1940s, individuals who had been discharged from state psychiatric hospitals in New York City began to get together for mutual support and to talk about their experiences. From these meetings, the Psychosocial Clubhouse Model emerged as an approach to providing social support and assistance to people with severe mental illness in a context and setting in which individuals with mental illness themselves are involved in organizing and

running the services (Beard, Propst, & Malamud, 1982). Since the development of the first psychosocial clubhouse in New York City, Fountain House, the clubhouse model has been standardized (Macias, Barreira, Alden, & Boyd, 2001; Propst, 1992) and hundreds of clubhouses have been created throughout the United States and abroad.

Clubhouse programs offer a variety of services, such as a place to hang out and socialize, recreational activities, vocational rehabilitation, and a role in running the clubhouse. An important component of the clubhouse model is the *work ordered day*, in which participants (referred to as *members*) are expected to fulfill tasks in the clubhouse necessary to its operation, such as cooking, washing dishes, giving guests tours, and assisting in event planning. Participation in the work ordered day is typically followed by involvement in transitional employment programs, in which members work temporarily at competitive jobs in the community that are secured by the clubhouse to build their work experience and help them move on to obtaining their own competitive jobs (McKay, Johnsen, Banks, & Stein, 2006; Schonebaum, Boyd, & Dudek, 2006).

In addition to the growth of psychosocial clubhouses throughout the world, the consumer movement of the 1970s challenged traditional, hierarchical approaches to treatment and psychiatry, and advocated for more patient voice in decision-making, respect for mental health professionals, and advocacy for the basic rights of persons with psychiatric disorders (Davidson et al., 2009). As a result of the consumer movement, and the growing acceptance of the recovery paradigm, other approaches to involving peers in the treatment of severe mental illness began to emerge. For example, peers are sometimes employed as mental health treatment providers at community mental health centers, such as on ACT teams (Solomon & Draine, 1995). The involvement of peers in delivering services is based on the expectation that the unique experience of peers may put them in a valuable position for forming relationships with others who are struggling to manage their psychiatric illness.

Research on peer support services has proved difficult to evaluate because, by its very nature, self-help organizations are difficult to evaluate in a controlled fashion. Nevertheless, the available evidence on peer support services suggests that persons with severe mental illness appreciate access to peers with similar experiences, and derive social support from their involvement in peer support activities (Davidson et al., 2009).

## Supported Housing

Homelessness and poor housing conditions are significant problems for persons with schizophrenia and other severe mental illnesses (Lehman, 1983; Susser et al., 1989). Supported housing is an approach to addressing the housing needs of persons with severe mental illness, one that is aimed at helping clients obtain housing based on their personal preferences (Kloos, Zimmerman, Scrimenti, & Crusto, 2002; Siegel et al., 2006). Client choice with respect to roommates and type of housing situation is an important consideration, as such choice is expected to result in more stable long-term housing arrangements. In addition, supported housing approaches impose minimal exclusion criteria to obtain housing services, including substance abuse, with the expectation that stable housing is a critical ingredient for people with severe mental illness to learn how to more effectively manage their illness and to reduce their substance use habits.

Limited research has been conducted on supported housing approaches for people with severe mental illness. However, preliminary studies indicate that of supported housing has benefits, when compared to traditional approaches, in areas such as duration of time in stable housing in the community (McHugo et al., 2004; Rog, 2004; Tsemberis, Gulcur, & Nakae, 2004). More work is needed to evaluate the effectiveness of supported housing models and identify which clients are most likely to benefit from them.

## Trauma Treatment

Those with schizophrenia have high rates of trauma, both in childhood, adolescence, and throughout the lifespan (Goodman, Rosenberg, Mueser, & Drake, 1997; Read et al., 2005). As a result of these high rates of trauma, post-traumatic stress disorder (PTSD) is a common comorbid disorder (Frueh, Cusack, Grubaugh, Sauvageot, & Wells, 2006; Mueser et al., 2002). PTSD is associated with a worse course of illness, high levels of subjective distress, and increased utilization of high-cost services such as emergency room visits and hospitalizations for acute symptom exacerbations (Switzer et al., 1999). To reduce the distress associated with trauma experiences and PTSD, different approaches have been developed in recent years that focus on either trauma or PTSD.

One approach to the treatment of trauma-related problems in people with schizophrenia and other severe mental disorders has been the development of a cognitive-behavioral program for PTSD that was

specifically designed for persons with severe mental illness (Mueser, Rosenberg, & Rosenberg, 2009). This standardized, individual-based 12–16-week intervention was initially pilot tested in a sample of individuals with severe and persistent mental illness and found to be both feasible and associated with improvements PTSD and depression (Rosenberg, Mueser, Jankowski, Salyers, & Acker, 2004). The program incorporates three core elements of treatment commonly used in PTSD treatment programs in the general population: teaching breathing retraining as anxiety management skill; psychoeducation about trauma, PTSD, and associated problems; and cognitive restructuring. Cognitive restructuring is initially taught as a skill for managing negative feelings, with attention gradually shifting toward the identification and examination of thoughts and beliefs related to traumatic experiences that are believed to underlie PTSD symptoms. The treatment is coordinated with other treatments that the person is receiving in an integrated fashion. One RCT of this program was recently completed (Mueser, Rosenberg et al., 2008); it included 108 clients with severe mental illness (16% schizophrenia-spectrum) who were randomized to either the cognitive-behavioral treatment program for PTSD, or treatment as usual, with the assessments conducted at baseline, post-treatment, and at 3- and 6-month follow-ups. The results indicated high levels of retention in treatment for clients assigned to the cognitive-behavioral intervention, as well as greater improvement at post-treatment and at follow-ups in PTSD symptoms, depression, and other psychiatric symptoms. In addition, clients reported improvements in their working alliance with their case manager, who was different from the person who provided the treatment program. The findings provide encouragement for the treatment of PTSD in people with schizophrenia and other severe mental illnesses.

Several other treatment approaches for trauma and PTSD have been developed for people with severe mental illness. Frueh and colleagues (2004) have recently developed an intervention for people with schizophrenia and PTSD that involves first providing education and social skills training in a group format, followed by individual exposure-based methods (e.g., imaginal exposure). Preliminary work on the model supports its feasibility and suggests that it leads to clinical improvements in PTSD and related outcomes (Frueh et al., 2009). An alternative to the focus on treating PTSD symptoms in people with schizophrenia is to take a broader approach to addressing the consequences of trauma in this population, including skills deficits and poor self-esteem, such as the Trauma Recovery and Empowerment model developed by Harris and colleagues (1998).

*Social Cognition*
*Social cognition* refers to the cognitive processes involved in the recognition of emotions in other people, understanding the unwritten rules of social behavior, and *theory of mind,* or the ability to discern what is on another person's mind (Penn, Corrigan, Bentall, Racenstein, & Newman, 1997). Research on social cognition has demonstrated that it is both significantly associated with cognitive functioning and with social and community functioning, and that it mediates the relationship between the two (Addington & Addington, 2008; Brekke, Kay, Lee, & Green, 2005; Vauth, Rüsch, Wirtz, & Corrigan, 2004). Thus, treatment approaches aimed at improving social cognition skills have become a focus in recent years.

Social cognition interventions employ a variety of approaches to improving the ability of clients to recognize and understand important social information in different situations. Training in social cognition skills is typically done in groups, and employs a variety of exercises aimed at training social cognition skills. Preliminary research on social cognition programs indicate that they are feasible to conduct, and that clients who participate in such programs demonstrate expected improvements in social cognition skills (Combs et al., 2007; Penn et al., 2005).

## Conclusion
Schizophrenia is a severe adult psychiatric disorder that contributes to functional impairment across the broad range of different life domains. Schizophrenia represents a major burden to clients, family, and society, and therefore its treatment is a high priority. Although schizophrenia is believed to be a biologically based disease, it interacts with the environment, as well as with social factors such as stress, social support, and social competence or coping skills. In addition, schizophrenia is known to be improved by antipsychotic medications and worsened by drug and alcohol abuse. Thus, there are a variety of ways in which the course and outcome of schizophrenia can be improved, including through the use of medication, reduction of substance abuse, building clients' competence at managing stress and persistent symptoms, and increasing social support.

Previously bleak expectations about the chronic and deteriorating course of schizophrenia, and the impossibility of recovery, have been replaced by more positive and personally meaningful definitions of recovery that emphasize improved functioning, well-being, and self-determination. Substantial progress has been made in the treatment of schizophrenia over the past several decades. New medications for the disorder continue to be developed, and although it remains unclear as to whether these medications are clinically more effective than the traditional antipsychotic medications, each medication has its own unique side-effect profile and the greater variety provides more choice for clients and treatment providers. In addition to advances in medication, a number of psychosocial treatment approaches have been developed and shown to be effective in improving the course and outcome of schizophrenia. These treatment approaches include supported employment, family psychoeducation, social skills training, CBT for psychosis, cognitive remediation, training in illness self-management, integrated treatment for co-occurring substance abuse, and the ACT program. There is now realistic hope, supported by a burgeoning treatment technology, that it is possible to live a personally meaningful, rewarding life in which one makes a contribution to society, despite continuing to have some symptoms and impairments of the illness.

### Future Directions

A wide range of future research directions are possible for schizophrenia and its treatment. Extensive research is under way aimed at identifying the pathophysiological mechanisms that underlie the causes of schizophrenia and are responsible for its characteristic symptoms and impairments of the disorder. Drug development continues to be an active focus of research, primarily aimed at developing equally effective or more effective medications that have a more benign side-effect profile than those medications currently available. The discovery of medications that can ameliorate the severity of negative symptoms and cognitive impairment, for which effective medications do not currently exist, is also a high priority for research.

Psychosocial treatment development for schizophrenia is also needed, to address a variety of needs. Several promising treatment approaches were previously described, but many other treatments remain to be developed to address the stubborn features of schizophrenia. For example, although depression is one of the most consistent and debilitating features

of schizophrenia (Häfner et al., 1999), the field still lacks a standardized and empirically validated intervention that targets depression in the illness. Cognitive-behavioral therapy for psychosis has been found to improve depression in some studies (Wykes et al., 2008), but has yet to be applied to depression as the primary focus. Similarly, anxiety disorders such as PTSD, obsessive-compulsive disorder, panic disorder, and social phobia are common in schizophrenia. However, with the exception of recent work on treating PTSD (Frueh et al., 2009; Mueser et al., 2008), little work has focused on developing interventions that target other anxiety disorders in schizophrenia.

Another area in need of treatment development and research concerns the parenting needs of persons with schizophrenia. Although in Western countries the rate of fertility in men with schizophrenia is relatively low, among women with schizophrenia rates of fertility are close to that of the general population (Haukka, Suvisaari, & Lonnqvist, 2003; Howard, Kumar, Leese, & Thornicroft, 2002). However, women with schizophrenia often experience a broad range of problems in fulfilling their role as parent, and many must receive extensive help from relatives or give their children up for adoption or to foster care (Fox, 1999; Nicholson, Sweeney, & Geller, 1998). Because so many women with schizophrenia have children, the need exists to develop and standardized programs that address family planning (Coverdale & Grunebaum, 1998), as well as parent training programs designed to teach parenting skills to these women, potentially enabling them to continue to maintain their role as parents or to continue to have a positive role in relationship with their children who are being raised by another person or family.

Another potentially fruitful direction is the development of programs aimed at engaging in treatment those individuals experiencing their first episode of psychosis. People who are early in the stages of developing schizophrenia frequently have difficulty obtaining appropriate treatment, and in many cases remain untreated for years—until their behavior gets out of control and hospitalization is necessary. Strong evidence suggests that longer durations of untreated psychosis are associated with a reduced ability to successfully stabilize the key symptoms of the illness and lead to a worse overall prognosis (Perkins et al., 2005). Therefore, the identification and treatment of individuals in the early stages of psychosis has the potential to improve the long-term trajectory of schizophrenia.

Over the past 10–20 years, early psychosis identification and treatment programs have been developed in a number of countries (Addington, Van Mastrigt, Hutchinson, & Addington, 2002; Leavey et al., 2004; Petersen et al., 2005). Studies based on these programs indicate that they are successful in engaging clients and families in treatment, and that early treatment is associated with positive outcomes in terms of psychosocial functioning in the minimization of relapses and rehospitalizations (Penn, Waldheter, Mueser, Perkins, & Lieberman, 2005). However, well-controlled studies of the effectiveness of first-episode psychosis programs are limited at this point. Furthermore, no controlled studies of first-episode treatment programs have been conducted in the United States. Furthermore, most first-episode treatment programs developed in Europe and Australia are located in cities that serve a large population. These programs focus on recruiting clients into specialty first-episode clinics by drawing from the entire population in the city. In the United States., where mental health services are usually provided based on smaller geographic regions, there is a need to develop first-episode treatment approaches that can be implemented within the context of the US mental health system.

The final consideration for future directions is increasingly access to evidence-based practices (EBPs) in the treatment of persons of schizophrenia. Despite the multitude of empirically validated psychosocial interventions for schizophrenia previously reviewed in this chapter, most clients of schizophrenia are not able to access these services at their local community mental health centers (Institute of Medicine, 2001a; Lehman & Steinwachs, 1998; President's New Freedom Commission on Mental Health, 2003). The need exists to develop more effective methods for disseminating EBPs for the treatment of schizophrenia to a broad range of mental health providers who serve this population. Recent research on the implementation of EBPs for severe mental illness indicates that standardized interventions can be successfully implemented with good fidelity to their treatment models for up to 2 years using routine mental health treatment settings (McHugo et al., 2007). However, all implementation efforts require training and a commitment to new practice standards.

Finally, there is a critical need to realign funding mechanisms for the provision of mental health services, so that they provide the incentive necessary to mental health centers to implement EBPs for their mental health population, including clients with schizophrenia. Current funding for mental health services for schizophrenia is not consistent with the evidence base of effective interventions, and in the absence of a realignment, the widespread implementation of efficacious treatments for schizophrenia is likely to remain an elusive goal.

# Disorders of Impulse Control and Self-Harm

Matthew K. Nock, Christine B. Cha, *and* Halina J. Dour

## Abstract

Disorders of impulse-control and self-harm are dangerous clinical problems that often present significant challenges for scientists and clinicians. In this chapter, we provide a comprehensive review of each disorder on the impulse-control spectrum. We begin by describing the clinical presentation and epidemiology of each disorder. Next, we discuss what is currently known about the etiology of these disorders, summarizing recent research on genetic/neurobiological factors, environmental factors, and psychological factors that appear to influence these disorders. The assessment and treatment of disorders of impulse-control and self-harm is complicated by the relatively low base-rate of these disorders, as well as by their dangerous and sensitive nature. Nevertheless, several evidence-based approaches to assessment and treatment have been developed and also are reviewed here. We conclude with recommendations for future scientific and clinical efforts aimed at better understanding, predicting, and preventing disorders of impulse-control and self-harm.

**Key Word:**  suicide, self-injury, self-harm, impulse, impulsiveness, impulsivity

Everyone occasionally has an urge to do something that is harmful to himself, herself, or others. These urges may involve striking another person, taking something that does not belong to us, or even hurting oneself. Having an occasional urge, or even acting on such urges on rare occasions, is normal. However, some people have a problem inhibiting their behavior in response to such urges. When such failures of impulse control are severe, persistent, and impairing, they are considered to be a mental disorder. The harmful and potentially embarrassing or illegal nature of many of these behaviors often makes them difficult to study and treat. Fortunately, however, researchers and clinicians have been working to advance the understanding, assessment, and treatment of these challenging behavior problems. This chapter provides a review of what is currently

known about disorders of impulse-control or self-harm.[1]

## Descriptive Psychopathology
### *Definitions, Epidemiology, and Phenomenology*

The essential feature of impulse-control disorders (ICDs) is "the failure to resist an impulse, drive, or temptation to perform an act that is harmful to the person or to others" (American Psychiatric Association [APA], 2000, p. 663). In most cases, the behavior

---

[1] Although self-harm is not currently considered a disorder in the DSM, we use the term "disorders" in this chapter to refer to both ICDs and self-harm for ease of presentation.

is preceded by increased aversive arousal (i.e., "tension"), which dissipates following performance of the behavior. However, in many instances, the behavior is followed by the experience of pleasure or gratification, as we discuss in more detail later. The ICDs included in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) and reviewed in this chapter are trichotillomania, pathological gambling, pyromania, kleptomania, and intermittent explosive disorder.

The essential feature of self-harm (a term that includes both suicidal and nonsuicidal self-injury) is the performance of actions that are directly and deliberately harmful to the self. Self-harm is direct in that physical harm occurs without intervening steps (e.g., cutting oneself is direct, whereas cell death due to alcohol consumption is indirect). Such behaviors are deliberate, in that harm to the self is the intended outcome and is not incidental or accidental (e.g., accidentally cutting oneself while cooking). Like ICDs, self-harm can be conceptualized as resulting from a failure to resist an impulse, which in this case is an impulse to hurt oneself. Moreover, self-harm also is most often preceded by aversive arousal and followed by a tension release, and at times is followed by the experience of pleasure or gratification.

Although ICDs and self-harm appear to function quite similarly, they historically have been treated as two completely different classes of behaviors. Impulse-control disorders are included in the DSM-IV-TR, whereas self-harm behaviors are not. Literature on the two classes of behaviors has been fairly distinct and non-overlapping. Despite these historical differences, we propose that the similarities in function and in many other fundamental aspects of these behaviors support the placement of both ICDs and self-harm on a single impulse-control spectrum. We consider issues of classification and potential commonalities in etiology, assessment, and treatment later. However, before doing so, it is important to consider the definitions, epidemiology, and phenomenology of each of these behaviors.

In the following sections, we review each ICD and self-harm behavior and summarize what is known about their epidemiology and phenomenology. All of these disorders are characterized by a failure to control a harmful impulse—the outcome of which falls on a continuum representing "harm to self" on one end and "harm to others" on the other end. We begin by presenting each disorder in the order in which they appear on this continuum, starting with those that are directly harmful to the self (e.g., suicidal behaviors),

followed by those that are indirectly harmful to the self (e.g., pathological gambling) and others (e.g., kleptomania), and ultimately to those that are directly harmful to others (e.g., intermittent explosive disorder). Most important for clinicians and scientists to consider is the defining features, prevalence, average age of onset, course, and associated features (e.g., sex differences) of each disorder. These features are reviewed in detail below and summarized in Table 23.1.

### *Harm to Self*
#### SUICIDAL BEHAVIORS
##### *Defining Features and Subtypes*
The term *suicidal behaviors* refers to a broad class of nonlethal behaviors in which a person directly and deliberately acts in a way intended to end one's own life. Suicidal behaviors can be conceptualized as being on a continuum of severity that begins with thoughts of suicide and ends with death by suicide. *Suicide ideation* refers to thoughts of engaging in behavior intended to end one's own life. Merely having thoughts of death is not considered suicide ideation (although this is sometimes referred to as "passive suicide ideation"). Having a *suicide plan* refers to the formulation of a specific method through which one intends to kill oneself. This involves more than simply thinking about suicide, but means that one has stopped short of actually attempting to kill oneself. A *suicide attempt* refers to potentially self-injurious behavior in which a person has at least some (i.e., nonzero) intent to die. The importance of using these terms clearly and consistently has been written about extensively (O'Carroll et al., 1996; Silverman, Berman, Sanddal, O'Carroll, & Joiner, 2007a, 2007b). Two relatively new terms have been introduced to more carefully characterize and classify behaviors that fall between suicide plans and suicide attempts. *Preparatory acts toward imminent suicidal behavior* refers to instances in which a person has taken steps toward making a suicide attempt but stops himself or herself before the potential harm has begun (Posner, Oquendo, Gould, Stanley, & Davies, 2007). This includes *interrupted suicide attempts,* in which a third party stops the attempt before the injurious behavior is performed, and *aborted suicide attempts,* in which the person stops himself or herself immediately before the injurious behavior is performed (Marzuk, Tardiff, Leon, Portera, & Weiner, 1997; Posner et al., 2007).

##### *Prevalence*
Suicidal behaviors are among the leading causes of death worldwide (Nock, Borges, Bromet, Cha,

**Table 23.1  Characteristics of impulse control disorders and self-harm**

| | Definition | Prevalence | Sex difference | Average age of onset | Course |
|---|---|---|---|---|---|
| *Harmful to self* | | | | | |
| Suicidal behaviors | Direct, deliberate, nonlethal acts aimed at killing oneself | SI lifetime 8.0%–24.9% SP lifetime 1.5%–9.4% SA lifetime 1.3%–3.5% | F>M | Adolescence | 33.6% SI cases transition to SP 15.4% SI (no SP) transition to SA 56.0% SP cases transition to SA |
| NSSI behaviors | Direct, deliberate, nonlethal acts of hurting oneself in the absence of intent to die | SG lifetime 1.9% NSSI community adult lifetime 4.0% NSSI community adol., lifetime 13.9%–46.5% NSSI clinical adult lifetime 19.0%–25.0% NSSI clinical adol. lifetime 40.0%–61.2% | F=M | Early Adolescence | Increase of NSSI in adolescence, decrease throughout adulthood |
| Trichotillomania | Repetitive pulling out of one's own hair resulting in noticeable hair loss | Community sample lifetime 1.0%–3.0% Clinical sample lifetime 3.4%–4.4% | F>M | Early Adolescence | Typically intermittent course, but could persist up to 17–21 years |
| Gambling | Betting or risking money on a game of chance in excess, leading to moderate (problem) or significant (pathological) distress or impairment | Problem gambling lifetime 2.3%–9.2% Pathological gambling lifetime 0.4%–3.4% | M>F | Gambling problems, Mid 20s; Pathological gambling, Earlier onset | Problem gambling persists on average for 3.6–9.4 years Pathological gamblers practice preferred gambling method on average for 13.0 years |
| *Harmful to others* | | | | | |
| Pyromania | Repetitive, deliberate, and purposeful fire-setting in the absence of other motivations (e.g., vengeance, political belief) | Clinical/forensic sample current diagnosis approx. 0%–39.0% | M>F | 18.1 years | Course unknown. Fire-setting occurs approximately once every 6 weeks when present |
| Kleptomania | Repetitive, deliberate stealing, even though items are not needed for personal use or monetary value | General population <1% | F>M | Late adolescence, Early adulthood | Course unknown |
| IED | Repeated acts of assault and property destruction that are grossly out of proportion to precipitating triggers/events | Less severe IED    General population lifetime, 7.3% More severe IED    General population lifetime, 5.4%    Clinical sample lifetime, 6.2% | M>F (Less severe IED) | 14.8–18.3 years | Persists for 6.2–11.8 years |

et al., 2008; World Health Organization [WHO], 2008). Suicide is the 14th leading of cause of death worldwide, accounting for 1.5% of all deaths (Nock, Borges, Bromet, Cha, et al., 2008; WHO, 2008). Cross-national mortality data are maintained by the World Health Organization (WHO) and indicate that suicide rates vary significantly across different regions and countries around the world (WHO, 2008). In the United States, suicide is the 11th leading cause of death, the fifth leading cause of years of life lost, and accounts for more deaths than homicides and more than twice as many deaths than HIV/AIDS (Centers for Disease Control [CDC], 2008a; Knox & Caine, 2005; Kung, Hoyert, Xu, & Murphy, 2008; Nock, Borges, Bromet, Cha, et al., 2008).

Nonlethal suicidal behaviors produce less severe outcomes than do suicide, but they occur much more frequently. A recent systematic review of the literature on suicidal behaviors revealed that the lifetime prevalence estimates of suicide ideation (3.1%–56.0%; Interquartile range [IQR]=8.0%–24.9%), plan (0.9%–19.5%; IQR=1.5%–9.4%), and attempt (0.4%–5.1%, IQR=1.3%–3.5%) differ substantially across studies (Nock, Borges, Bromet, Cha, et al., 2008). Part of this variability is likely due to variations in the method through which suicidal behaviors were assessed in each study. Studies requiring actual thoughts of suicide (i.e., rather than merely thoughts of death) to define suicide ideation and actual intent to die (i.e., rather than self-injury performed to communicate with others) to define suicide attempts yield lower estimates of each behavior (Nock & Kessler, 2006). One recent study examined the lifetime prevalence of suicide ideation, plans, and attempts across 17 different countries using the exact same assessment methods (Nock, Borges, Bromet, Alonso, et al., 2008). Substantial cross-national differences in the rates of each suicidal behavior were still observed, but with much less variability than obtained when comparing across prior studies, resulting in lifetime prevalence estimates of 9.2% for suicide ideation, 3.1% for suicide plans, and 2.7% for suicide attempts.

## Onset and Course

Suicidal behaviors have been reported in children as young as 4 years of age (Pfeffer, 2001; Tishler, Reiss, & Rhodes, 2007), even though many authors suggest that children younger than 10 years of age are rarely capable of understanding the finality of death (Cuddy-Casey & Orvaschel, 1997; Pfeffer, 1997). Shortly after this point, at the onset of adolescence, the rates of each of the suicidal behaviors described

earlier increase dramatically. For instance, the rate of suicide death increases from 0.01 per 100,000 people per year among those 5–9 years of age to 1.29 in those 10–14 years old, and up to 12.35 among those 20–24 years old (CDC, 2008a). A similarly striking increase during adolescence is seen in the rates of suicide ideation, plans, and attempts (Kessler, Borges, & Walters, 1999; Nock, Borges, Bromet, Alonso, et al., 2008). Overall, adolescence is a time of significantly increased risk, and a major priority for research in this area is to better understand why this increased risk occurs during this particular developmental period.

Only a handful of studies have described the course of suicidal behaviors over time. Existing studies report that approximately 34% of people who experience suicide ideation go on to make a suicide plan, and 56% of those with a suicide plan go on to make an attempt, whereas only 15% of ideators without a plan go on to make an attempt (Nock, Borges, Bromet, Alonso, et al., 2008). Importantly, the majority of transitions from ideation to plan and attempt occur within the first year after the onset of suicide ideation (Nock, Borges, Bromet, Alonso, et al., 2008). Interestingly, the continued experience of suicide ideation in the absence of a suicide plan or attempt is associated with a *decreased* risk of suicide plan and attempt over time (Borges, Angst, Nock, Ruscio, & Kessler, 2008).

## Associated Features

Sex- and ethnicity/race-related influences on suicide and suicidal behaviors have been reported consistently across studies. Regarding sex, in virtually every country around the world for which suicide rates are available (with the exception of only China and India), the suicide rate for men significantly exceeds that for women by a ratio of approximately 4:1 (WHO, 2008). In contrast, the rates of suicide ideation, plans, and attempts are 40%–70% higher among women than men (Nock, Borges, Bromet, Alonso, et al., 2008; Weissman et al., 1999). It is generally believed that men die by suicide much more often than women due to men's use of more lethal means for suicide attempts. For instance, in the United States, men are significantly more likely than women to die by suicide using firearms, whereas women overdose on poison at a much higher rate than men—a behavior less likely to have a lethal outcome (CDC, 2008a). The reason for the higher rate of nonlethal suicidal behavior among women is not well understood and represents another important question for future research.

Ethnic/racial influences on suicidal behavior are difficult to study cross-nationally, due to the obvious variability in how ethnicity/race is defined across countries and what groups constitute a minority group in each country. In the United States, 90.5% of those who die by suicide are white, and 71.9% are white men (CDC, 2008a). In contrast, there are no significant ethnic/racial differences in the rates of suicide ideation, plans, or attempts (Kessler, Berglund, Borges, Nock, & Wang, 2005). In addition to sex- and ethnicity/race-related factors, several factors have emerged as consistent predictors of suicidal behaviors, including being younger, less educated, unmarried (i.e., never married, divorced, or widowed), and having a mental disorder (Nock, Borges, Bromet, Alonso, et al., 2008; Nock, Borges, Bromet, Cha, et al., 2008). The presence of a mental disorder is one of the most often-studied correlates of suicidal behaviors, and work in this area has shown that more than 90% of those who die by suicide had a diagnosable mental disorder at the time of their death (Cavanagh, Carson, Sharpe, & Lawrie, 2003). Potential explanations for why mental disorders are associated with ICDs and self-harm are reviewed in greater detail in the section "Influences on ICDs and Self-Harm," later in this chapter.

## NONSUICIDAL SELF-INJURY

### Defining Features and Subtypes

Nonsuicidal self-injurious thoughts (NSSI) and behaviors can be classified into several distinct categories. A *suicide gesture* is a behavior performed to lead others to believe that one intends to kill oneself when one really has no intention of doing so (Nock & Favazza, 2009; Nock & Kessler, 2006). These behaviors occur in approximately 2% of the general population (Nock & Kessler, 2006). The term "suicide gesture" was originally used to describe behaviors in which soldiers self-inflicted injuries in order to escape from active military duty (Fisch, 1954; Tucker & Gorman, 1967), and as a result this term carries a negative connotation among some clinicians and researchers. *Nonsuicidal self-injurious thoughts* refer to episodes in which people consider engaging in NSSI, serving as a parallel to suicide ideation but in this case lacking any intent to die. *Nonsuicidal self-injury* refers to the deliberate destruction of one's own body tissue in the absence of any intent to die. The most common forms of NSSI include cutting (i.e., most often with a razor, knife, or other sharp object), burning, inserting objects under the skin, and scratching oneself until bleeding occurs.

Although researchers and clinicians agree on this definition of NSSI, and most use these terms, some use different terms to describe this behavior, including self-mutilation, deliberate self-harm, and parasuicide. Notably, some researchers also use the last two terms to refer to self-injury more generally, regardless of whether the person has intent to die from their behavior. Given evidence that self-injury performed with intent to die is associated with more lethal injury (Beck, Beck, & Kovacs, 1975; Brown, Henriques, Sosdjan, & Beck, 2004) and with a greater likelihood of subsequent death (Harriss & Hawton, 2005; Lonnqvist & Ostamo, 1991; Ostamo et al., 1991), it is wise to distinguish between suicidal self-injury and NSSI. The following paragraphs review what is currently known about NSSI, given that this is the most injurious and concerning of these three behaviors and the one for which most research is available.

### Prevalence

As with suicidal behaviors, estimates of the rate of NSSI in the general population vary markedly across studies due to inconsistencies in the definitions and measurement methods used. In addition, because research on NSSI is relatively new, questions on NSSI have not been included in the large epidemiological studies that provide prevalence estimates for most mental disorders, such as the National Comorbidity Surveys (Kessler, Berglund, Demler, Jin, Merikangas, & Walters, 2005; Nock & Kessler, 2006) and the Epidemiologic Catchment Area Survey (Bourdon, Rae, Locke, Narrow, & Regier, 1992). These limitations notwithstanding, available studies suggest that 4% of adults (Briere & Gil, 1998; Klonsky, Oltmanns, & Turkheimer, 2003) and 13%–46% of adolescents (Lloyd-Richardson, Perrine, Dierker, & Kelley, 2007; Ross & Heath, 2002) in the community engage in NSSI at some point in their lifetime. The higher rates of NSSI among adolescents suggest that the rate of NSSI may be increasing, a fact also suggested by data from the Centers for Disease Control (CDC) on the increasing rate of nonfatal self-injury (although these figures include suicide attempts) (CDC, 2008b), or may reflect reporting biases among adults who deny their history of NSSI, or both. The rate of NSSI among clinical samples is much higher among both adults (outpatient rate=25%; inpatient rate=19%; combined=21%) (Briere & Gil, 1998) and adolescents (inpatient rate=40%–61%) (Darche, 1990; DiClemente, Ponton, & Hartley, 1991).

### Onset and Course

Nonsuicidal self-injurious behavior typically has its onset during early adolescence (Jacobson & Gould, 2007; Nock & Prinstein, 2004), but it is important to note that this behavior has been reported to occur in 7%–8% of preadolescents in the community (Hilt, Nock, Lloyd-Richardson, & Prinstein, 2008). Little is known about the course of NSSI due to the absence of long-term longitudinal studies; however, studies on NSSI across age groups suggest that the rates of NSSI show an increase in adolescence and young adulthood, followed by a steady decline throughout later adulthood.

### Associated Features

Nonsuicidal self-injurious behavior appears to occur at equal rates across different groups regardless of sex, ethnicity, or socioeconomic status (Hilt et al., 2008; Jacobson & Gould, 2007; Nock, Joiner, Gordon, Lloyd-Richardson, & Prinstein, 2006). People engaging in NSSI have significantly stronger family histories of suicide ideation, violence, and drug and alcohol abuse, but do not have higher rates of psychopathology more generally, thus suggesting that what may be transmitted within the family is a tendency to engage in impulsive aggression (Deliberto & Nock, 2008). Most people engaging in NSSI themselves meet criteria for a current mental disorder (87.6%), including internalizing disorders (51.7%), externalizing disorders (62.9%), substance use disorders (59.6%), and personality disorders (67.3%) (Nock et al., 2006). Self-injurers also are at significantly increased risk of suicidal behavior, as evidenced by the fact that 70% of self-injurious adolescents report at least one suicide attempt, and 55% report making multiple suicide attempts (Nock et al., 2006).

### TRICHOTILLOMANIA

#### Defining Features and Subtypes

Trichotillomania, the first behavior reviewed in this chapter that is formally classified as an ICD in DSM-IV-TR, refers to the repetitive pulling out of one's own hair, resulting in noticeable hair loss. According to the DSM, trichotillomania also is characterized by the experience of increased tension immediately prior to episodes of hair-pulling, as well as relief or pleasure following hair-pulling. Consistent with all mental disorders, this behavior must be associated with significant distress or impairment in social, occupational, or other important areas, and the behavior cannot be better

explained by some other mental or medical disorder (APA, 2000).

The form and function of trichotillomania are quite similar to NSSI, and in fact, many researchers include hair-pulling in their definition of NSSI. However, the build-up and release of anxiety and tension involved in trichotillomania have led some to argue that it would be more appropriately classified on an anxiety or obsessive-compulsive spectrum (Swedo & Rapoport, 1991). Others have argued against such a move given that (a) trichotillomania is not characterized by the persistent and intrusive thoughts that occur in obsessive-compulsive disorder, (b) those with trichotillomania are more focused on the topography of their behavior than on mitigating their anxious thoughts, and (c) obsessive-compulsive behaviors are rarely if ever described as gratifying, as is often the case in trichotillomania (Franklin, Tolin, & Diefenbach, 2006; Grant, Odlaug, & Potenza, 2007). It also has been suggested that trichotillomania would be better classified on a spectrum of "unwanted repetitive species-typical behaviors," which, in the case of trichotillomania, consists of pathological grooming behaviors (Swedo & Rapoport, 1991). However, researchers specializing in the study of ICDs argue that trichotillomania should remain on the impulse-control spectrum, given its similarity to other behaviors on this spectrum in terms of characteristics and treatment response (Grant, Odlaug, & Potenza, 2007).

Disagreements about where to classify trichotillomania notwithstanding, research studies have provided a consistent clinical description of this behavior. Hair-pulling in trichotillomania most often occurs on the scalp, eyebrows, and eyelashes, but can occur anywhere on the body on which hair grows (Reeve, Bernstein, & Christenson, 1992; Stanley, Borden, Bell, & Wagner, 1994). Most people with trichotillomania (64%–93%) report pulling hair from more than one place on their body (Christenson, Mackenzie, & Mitchell, 1991; du Toit, van Kradenburg, Niehaus, & Stein, 2001), and the average number of pulling episodes reported ranges from 15 to 36 episodes per week (Christenson, Mackenzie, & Mitchell, 1991, 1994). Hair-pulling occurs most often following the experience of negative affect but also can occur in the context of positive affect a smaller percentage of the time (du Toit et al., 2001). Interestingly though, approximately 17%–36% of those who display chronic hair-pulling do not report the tension release or gratification thought to be diagnostic of trichotillomania

(Christenson, Mackenzie, & Mitchell, 1991, 1994). Complicating reports of the experience of trichotillomania is the fact that hair-pulling episodes often are classified into two subtypes, one of which involves hair-pulling as a deliberate response to negative affect (i.e., "focused pulling"), and the other of which involves hair-pulling outside of conscious awareness (i.e., "automatic pulling") (Flessner et al., 2008; O'Sullivan et al., 1997). The fact that automatic pulling occurs outside of awareness during times of sedentary activities requiring focused attention (e.g., television watching, reading) introduces obvious problems with relying on self-report to determine the factors that influence this behavior.

People with trichotillomania typically report experiencing little or no pain during hair-pulling, suggesting that there often are not immediate negative consequences for this behavior (Christenson, Mackenzie, & Mitchell, 1991). However, this behavior often leads to impairments in social and occupational functioning (e.g., du Toit et al., 2001; Franklin et al., 2006) in the form of shame, embarrassment, and attempts to conceal excessive hair loss (Christenson, Mackenzie, & Mitchell, 1991; du Toit et al., 2001). Despite this distress and impairment, as many as 40% of people with trichotillomania go undiagnosed, and 58% never receive treatment for this condition (Lejoyeux, McLoughlin, & Ades, 2000).

### Prevalence

Studies of community and college student samples suggest that 1%–3% of people meet criteria for trichotillomania at some point in their lifetime (Christenson, Pyle, & Mitchell, 1991; King, Zohar, et al., 1995), with a slightly higher rate of 3.4%–4.4% obtained in inpatient psychiatric samples (Grant, Levine, Kim, & Potenza, 2005).

### Onset and Course

Trichotillomania typically has its onset at 12–15 years of age (Christenson et al., 1994); however, an early-onset subgroup has been described in several studies with a mean age of onset of 6–9 years (King, Scahill, et al., 1995; Reeve et al., 1992). Once begun, trichotillomania typically persists for 17–21 years (Christenson, Mackenzie, Mitchell, & Callies, 1991; du Toit et al., 2001), with an intermittent course in which symptoms wax and wane over time (Christenson et al., 1994; King, Scahill, et al., 1995).

### Associated Features

Trichotillomania typically is reported at higher rates among women than among men (Christenson, Pyle, et al., 1991; du Toit et al., 2001). However, this difference may be partially explained by an unwillingness to report this potentially embarrassing behavior and by the increased likelihood that men can attribute the hair loss to male pattern baldness (Christenson, Mackenzie, & Mitchell, 1991). Interestingly, trichotillomania is associated with increased rates of "pathological grooming behaviors" (e.g., nail biting, skin picking) and anxiety disorders (especially obsessive-compulsive disorder) among first-degree relatives (Lenane et al., 1992; Swedo & Leonard, 1992).

## PATHOLOGICAL GAMBLING

### Defining Features and Subtypes

*Gambling,* which refers to betting or risking money on a game of chance, is not pathological and, when performed in moderation, is referred to as *social gambling* or *recreational gambling*. Researchers and clinicians use the term *problem gambling* to denote a pattern of gambling behavior that leads to some moderate (i.e., subclinical) level of distress and functional impairment. *Pathological gambling*, by contrast, refers to a persistent and maladaptive pattern of gambling behavior resulting in significant distress and impairment (APA, 2000). Essential features of pathological gambling include preoccupations with gambling, the need to risk increased amounts of money to achieve the desired level of excitement, repeated unsuccessful attempts to control one's gambling, chasing behavior (i.e., following up losses with more gambling in an attempt to get even), and engagement in deceitful and/or illegal activities in an effort to continue and finance one's gambling (APA, 2000). These thoughts and behaviors should not be better accounted for by another psychiatric disorder (e.g., manic episode). The impairment experienced as a result of this behavior often includes the loss of important relationships, jobs, and finances (e.g., bankruptcy) (Lesieur, 1984, 1998; W. N. Thompson, Gazel, & Rickman, 1996). Other terms, such as *disordered gambling* (Shaffer, Hall, & Vanderbilt, 1999) and *compulsive gambling* (Jacobs et al., 1989) have been used in the literature but generally have been discouraged in favor of "problem gambling" and "pathological gambling" (Moran, 1970). The most common forms of gambling reported include games played at casinos, lotteries, on- and off-track betting on horse-racing, and Internet gambling (Potenza, Kosten, & Rounsaville, 2001).

### Prevalence

Approximately 80% of people in the U.S. general population report engaging in social/recreational

gambling at some point in their lifetime (Kessler et al., 2008). Rates of lifetime problem gambling (2.3%–9.2%) (Cunningham-Williams, Cottler, Compton, & Spitznagel, 1998; Kessler et al., 2008) and pathological gambling (0.4%–3.4%) (APA, 2000; Kessler et al., 2008; Shaffer et al., 1999) are much lower, but indicate that these are problems that occur in a significant number of people. Studies of adolescent (Shaffer et al., 1999) and clinical samples (Grant et al., 2005; Hall et al., 2000) suggest that the rates are even higher in these populations. In addition, the prevalence of pathological gambling appears to be increasing, perhaps due to greater social acceptability and accessibility of gambling in today's society (Petry & Armentano, 1999; Shaffer et al., 1999).

*Onset and Course*

Gambling problems typically begin in adolescence and early adulthood. A recent nationally representative survey of U.S. residents revealed that gambling problems typically begin during the mid-20s (Kessler et al., 2008). Age of onset is typically earlier for those who eventually develop pathological gambling, and for men (Kessler et al., 2008; Welte, Barnes, Tidwell, & Hoffman, 2008). Pathological gamblers report that they practice their preferred gambling method for an average of 13.0 years (Maccallum & Blaszczynski, 2003), but problems with gambling only persist for 3.6–9.4 years on average (Kessler et al., 2008; Maccallum & Blaszczynski, 2003).

*Associated Features*

Pathological gambling occurs at higher rates among men; adolescents and young adults; those who are divorced, separated, or widowed; and non-Hispanic African Americans (Kessler et al., 2008; Petry, Stinson, & Grant, 2005; Shaffer et al., 1999; Welte et al., 2008). Family and twin studies have suggested that gambling problems are transmitted across generations. For instance, 23% of pathological gamblers report that one or both parents are problem gamblers (Black & Moyer, 1998), and adolescents who report that their parents have problems with gambling display significantly higher levels of gambling (and other problems such as drinking, smoking, drug use, and over-eating) (Jacobs et al., 1989). Twin studies have demonstrated that these effects are not merely due to shared environment, as the risk of pathological gambling has been shown to be higher among monozygotic twins than among dizygotic twins, in men with problem gambling (Slutske et al., 2000).

## Harm to Others
### PYROMANIA
*Defining Features and Subtypes*

Pyromania refers to a persistent pattern of behavior in which a person deliberately and purposely sets fires (APA, 2000). As in the case of other ICDs, the person often experiences tension or affective arousal before the behavior and a sense of relief or pleasure following the behavior. Fire-setting motivated by criminal activity (i.e., arson, insurance fraud), political beliefs, or vengeance for a perceived wrong is not considered to be pyromania. Also excluded from the diagnosis of pyromania are instances of fire-setting in response to command hallucinations or in the context of conduct disorder or antisocial personality disorder. People diagnosed with pyromania often have a fascination or preoccupation with fire and fire-related objects and activities (e.g., matches, fire alarms), which leads many such people to regularly watch neighborhood fires they did not start or even to seek employment with the fire department (Lejoyeux, McLoughlin, & Ades, 2006). There are no accepted subtypes of pyromania. Some have proposed a classification system for pyromania based on the motives of the behavior (Prins, Tennent, & Trick, 1985); however, this system conflicts with the DSM-IV-TR requirement that pyromania must not be motivated by criminal or financial factors (APA, 2000).

*Prevalence*

The prevalence of pyromania in the general population is not known. Indeed, in the section on prevalence, the DSM-IV-TR states only that "pyromania is apparently rare" (APA, 2000, p. 670). There are no available data on pyromania from epidemiological studies, and studies carried out in clinical and forensic adult samples (e.g., those charged with arson) report rates ranging from 0% to 39% depending on the sample assessed (Grant et al., 2005; Koson & Dvoskin, 1982; Lewis & Yarnell, 1951). In addition to differences in sample selection, the definition used for pyromania (if not the formal diagnosis) likely contributes to this wide range of reported rates. For instance, Kolko and Kazdin (1988) reported that in a child and adolescent sample, 52.4% of their sample reported recurrent fire-setting, but only 9.1% led to serious enough consequences that fire fighters were called. Therefore, rates will vary widely depending on how one defines the behavior.

*Onset and Course*

The average age of onset for pyromania is 18.1 years (Grant & Kim, 2007), although fire-setting behavior

has been reported in children and young adolescents (Kolko & Kazdin, 1988). Studies of clinical samples diagnosed with pyromania reveal that fire-setting episodes occur approximately once every 6 weeks (Grant & Kim, 2007). The course or duration of pyromania is not known, although rates of recidivism for fire-setting have been reported to range between 4.5% and 28%.

### Associated Features

As with prevalence, little is known about the associated features of pyromania. It has been suggested that pyromania occurs significantly more frequently among males than females (Lejoyeux et al., 2006), and that even when compared to clinical and forensic samples, those who engage in fire-setting are characterized by a history of more aggressive and antisocial behavior (Coid, Wilkins, & Coid, 1999; Kolko & Kazdin, 1991). Moreover, aggressive fire-setting also has been reported as a risk factor for future covert antisocial behavior, violence, and social problems (Del Bove, Caprara, Pastorelli, & Paciello, 2008).

### KLEPTOMANIA

### Defining Features and Subtypes

The defining feature of kleptomania is the recurrent failure to resist the urge to steal, even though the items are not needed for personal use or monetary value (APA, 2000). It is this lack of need for the stolen items that distinguishes kleptomania from nonpathological stealing or shoplifting. Consistent with other ICDs, this behavior is preceded by increased tension, followed by a tension release or feeling of pleasure, and is not performed due to financial need, vengeance, or in the context of another psychiatric disorder (e.g., not in response to command hallucinations or in the context of a manic episode). Most people with kleptomania report specific triggers for their urges to steal (e.g., stress), and the majority (68%) report intense shame or guilt following their behavior, suggesting that kleptomania is distressing (Grant & Kim, 2002a; Grant & Potenza, 2008).

### Prevalence

The prevalence of kleptomania is not currently known. Most researchers who study this behavior suggest that it is relatively rare, occurring in less than 1% of the general population (Goldman, 1991; Grant, 2006).

### Onset and Course

The average age of onset of kleptomania appears to be during late adolescence and early adulthood (Grant & Kim, 2002a; McElroy, Hudson, Pope, &

Keck, 1991), although onset has been reported after age 70 (McNeilly & Burke, 1998). People with kleptomania report an average duration of the disorder of 16–20 years and indicate that they steal an average of one or two times per week (Grant, 2004; Grant, Odlaug, & Wozniak, 2007; McElroy, Hudson, et al., 1991). Most of those diagnosed with kleptomania interviewed in research studies report that their stealing has resulted in arrest or incarceration at some point (e.g., Grant, Correia, & Brennan-Krohn, 2006); however, two-thirds of those arrested reported that their stealing persisted following the arrest(s) (McElroy, Pope, Hudson, Keck, & White, 1991).

### Associated Features

Kleptomania occurs more frequently among women than men by a ratio of up to 3:1 (e.g., McElroy, Hudson, et al., 1991). No consistent age or racial/ethnic differences have been observed among people diagnosed with kleptomania. Although there is no evidence for a family or genetic basis for kleptomania itself, people diagnosed with kleptomania do report a higher rate of mental disorders among their first-degree relatives, especially other impulse-control problems like alcohol and substance use, as well as mood disorders (Dannon, Lowengrub, Iancu, & Kotler, 2004; Grant & Kim, 2002a).

### INTERMITTENT EXPLOSIVE DISORDER

### Defining Features and Subtypes

The defining feature of intermittent explosive disorder (IED) is the occurrence of repeated episodes of assault and property destruction that are grossly out of proportion to the precipitating triggers or events (APA, 2000). A diagnosis of IED also requires that these impulsive aggressive episodes are not better accounted for by another disorder, such as bipolar disorder, psychotic disorder, or conduct disorder. The key features of IED are that the aggressive behavior is both repetitive and unplanned. The anger and impulsive aggression that occurs in IED typically is brief (<30 minutes in duration) (Coccaro, 2003) and most often involves interpersonal violence (approximately 70% of the time) or threats of violence (approximately 15%–20% of the time) (Kessler et al., 2006)

Research on IED has been hampered by the fact that it was not included in the DSM until DSM-III (APA, 1980), and also because the criteria changed in both DSM-III-R (APA, 1987) and DSM-IV (APA, 1994). To help advance the scientific study of IED, research criteria for IED have been proposed that provide more specific criteria than those appearing

in the current version of the DSM (APA, 2000). These research criteria also have undergone slight changes and were first presented as the research criteria for IED, Revised (IED-R) (Coccaro, Kavoussi, Berman, & Lish, 1998) and subsequently as the integrated research criteria for IED (IED-IR) (Coccaro, Schmidt, Samuels, & Nestadt, 2004; McCloskey, Berman, Noblett, & Coccaro, 2006). These integrated research criteria specify that diagnosing IED requires either verbal or physical aggression twice weekly, on average, for a period of 1 month or three episodes of physical assault or property destruction over 1 year (Coccaro & Danehy, 2006). They also state explicitly that the behavior cannot be premeditated and is not performed for tangible benefit (e.g., money, vengeance).

*Prevalence*

Prevalence estimates for IED differ slightly depending on which criteria are used. Using the DSM-IV criteria and requiring three lifetime IED episodes and one in the past 12 months yields an estimate of 7.3% for lifetime IED and 3.9% for the past 12 months (Kessler et al., 2006). When the more stringent criteria (i.e., three attacks in a 12-month period) are used, the prevalence estimates drop slightly to 5.4% lifetime and 2.7% for the past 12 months (Kessler et al., 2006). Rates of IED are approximately the same among clinical samples, with prior studies suggesting that 6.9% of psychiatric outpatients meet DSM-IV criteria for lifetime IED and 6.4% for current IED (e.g., Grant et al., 2005).

*Onset and Course*

Intermittent explosive disorder has an average age of onset of 14.8–18.3 years (Coccaro et al., 2004; Kessler et al., 2006). When present, IED persists for an average of 6.2–11.8 years (Kessler et al., 2006); however, the impulsive aggressive behaviors associated with IED reportedly occur throughout the lifespan, peaking in the fourth decade and decreasing over time from age 50 and beyond (Coccaro, Posternak, & Zimmerman, 2005; Coccaro et al., 2004). The average number of aggressive episodes in which a person with IED engages throughout his or her lifetime varies significantly depending on how IED is defined and ranges from 56 episodes for narrowly defined IED to seven episodes when a broader definition is used (Kessler et al., 2006).

*Associated Features*

More men than women are diagnosed with IED by a ratio of up to 3:1 (Coccaro, 2003); however, this difference appears to only be present when a broad definition of IED is used (i.e., requiring less frequent impulsive aggressive episodes) (Kessler et al., 2006). Those with lower levels of education and income are at increased risk of IED (Coccaro et al., 2005; Kessler et al., 2006), and these differences help to explain the relation sometimes observed between racial/ethnic minority status and IED (Coccaro et al., 2005). There appears to be familial transmission of IED, as approximately one-third of first-degree relatives of those with IED also have this disorder (McElroy, Soutullo, Beckman, Taylor, & Keck, 1998), and this increased likelihood of IED within families appears to be independent of comorbid diagnoses (see Coccaro, 2003).

## Conceptualizing Impulse-Control Disorders and Self-Harm

### Are These Behaviors "Mental Disorders?"

All of the behaviors reviewed in the previous section are clearly problematic, given that they result in harm to oneself or to others; however, should a failure to control one's behavioral impulses be considered a mental disorder? The answer to this question is not straightforward, given that no consensus yet exists about how the concept of mental disorder is best defined. The DSM-IV-TR defines a mental disorder as "a clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and that is associated with present distress (e.g., a painful symptom) or disability (i.e., impairment in one or more important areas of functioning) or with a significantly increased risk of suffering, death, pain, disability, or important loss of freedom" (APA, 2000, p. xxxi). By this definition, behaviors that are harmful to the self, such as NSSI and trichotillomania would seem to clearly qualify as mental disorders. But what about behaviors characterized by harm to others, such as fire-setting (i.e., pyromania) or anger attacks (i.e., IED)? Questions about whether behaviors that involve harming others should be classified as mental disorders have been raised for many years, as captured in the frequent distinction that is raised between "the mad" versus "the bad" (Tucker, 1999). The approach of the DSM has been to not classify isolated acts of violence or self-harm as mental disorders, but instead to include only deliberate, repetitive, and unplanned aggressive behaviors that are grossly out of proportion to precipitating triggers.

Beyond the DSM-IV-TR, scholars have proposed definitions for what constitutes a mental disorder. One of the most widely discussed conceptualizations

in the literature is the Harmful Dysfunction model proposed by Wakefield (1992, 1997). This model of mental disorders proposes that mental disorders require the presence of behaviors that have negative consequences for the individual as defined by sociocultural standards (i.e., are harmful) and also by the failure of some internal mechanism to perform the function for which it was designed (i.e., are dysfunctional). This model makes sense intuitively; however, several concerns have been raised, such as the fact that the natural function of most behaviors is not clearly known, thus making it difficult to ascertain when a dysfunction has occurred (e.g., Houts, 2001; McNally, 2001). So, although an interesting and useful approach, the Harmful Dysfunction model leaves many questions unanswered and does not help to clearly define and classify most of the mental disorders currently included in the DSM-IV-TR.

An alternative approach to conceptualizing mental disorders has been proposed by McHugh (1992), who suggests that it is wise to consider several different perspectives on what it means to have a mental disorder. Such an approach suggests that no single definition or model exists for what it means to have a mental disorder, thus acknowledging the heterogeneity of disorders and the multiple influences on each disorder (i.e., not all disorders are caused solely by dysfunction of some internal mechanism). McHugh proposes four perspectives from which to view mental disorders. A *disease perspective* uses categorical logic (i.e., either you have it or you do not), and suggests that mental disorders are caused by some identifiable biological abnormality. Disorders best conceptualized from this perspective include schizophrenia, autism, and bipolar disorder. A *behavior perspective* uses the logic of teleology (i.e., consideration of the purpose or function of behavior), and suggests that mental disorders can occur when goal-directed behaviors that we all display are performed in excess (e.g., eating, drinking, aggression) or when our behavior is driven by abnormal goals (e.g., drug use). The final two perspectives described by McHugh (1992) are the *dimensional perspective*, which suggests mental disorders can represent an extreme position on a continuum of some common traits (e.g., personality disorders), and a *life-story perspective*, which suggests that past events in one's life can lead to the experience of subjective distress (e.g., post-traumatic stress disorder).

The disorders described in this chapter fit most closely with the *behavior perspective* of mental disorders described earlier. Each of these ICDs and self-harm behaviors involve performing a behavior in the service of achieving some purposeful goal, such as the relief of aversive arousal/tension, or the experience of pleasure or gratification, but they are considered pathological because they do so using behavior that is harmful to the self or others. Other mental disorders characterized by excessive engagement in otherwise normative behaviors, such as disorders of eating (e.g., anorexia, bulimia), drinking (e.g., alcohol use disorders), and drug use (i.e., substance use disorders) also are best conceptualized from this perspective. In fact, this may help to explain why ICDs, self-harm behaviors, and other behavior disorders, such as those related to eating, drinking, and drug use, have high rates of comorbidity (Beautrais et al., 1996; Hilt et al., 2008; Kessler et al., 1999). It may be that these behaviors all serve very similar functions (e.g., escape from aversive arousal, experience of pleasure or gratification) and etiological pathways (e.g., similar genetic/neurobiological influences) and differ only in the form of the behavior selected to achieve that function. Although one could conceptualize these disorders as sharing this commonality, some authors have proposed that there are important differences among these ICDs and self-harm behaviors, with some defined by their impulsiveness, others by their compulsiveness, and yet others by their addictive nature.

### Clarifying the Nature of ICDs: Impulsiveness, Compulsiveness, and Addiction

The notion of an ICD spectrum in general and the placement of specific disorders on this spectrum in specific cases have been challenged over the years. One reason for this is that the disorders currently appearing on the ICD spectrum differ markedly in the form of the key behavior involved (e.g., firesetting, stealing, hair-pulling, gambling). These differences have led some researchers and clinicians to suggest that several disorders currently classified on the ICD spectrum are not best conceptualized as representing problems with impulse-control, but would be more appropriately placed on another spectrum, such as that of compulsive disorders, addictive disorders, or even affective disorders. In this section, we briefly describe and attempt to synthesize these different perspectives.

In considering how the ICD spectrum should be defined and composed, it is most important to have a clear understanding of what it means to be impulsive. Although impulsiveness is a commonly used

term, it is one for which there is a surprising lack of clarity and consistency in the definitions used by researchers and clinicians. Recent studies suggest that there are distinct dimensions of impulsiveness, such as *behavioral disinhibition*, *risky decision-making*, and *delay discounting* (Janis & Nock, 2009; Moeller, Barratt, Dougherty, Schmitz, & Swann, 2001; White et al., 1994). Behavioral disinhibition, sometimes referred to as behavioral impulsiveness, refers to a failure to inhibit an initiated response (e.g., failure to stop oneself from acting on an urge). Risky decision-making, sometimes referred to as cognitive impulsiveness, refers to making decisions that discount risk and increase the likelihood of negative consequences (e.g., choosing the riskiest of several alternatives). Delay discounting refers to a preference for smaller immediate rewards over larger later rewards (e.g., such as choosing to receive a small amount of money now rather than a larger amount of money later). Although risky decision-making and delay discounting are characteristic of some of the ICDs, it is the first dimension of behavioral disinhibition that is the central feature of each of the ICDs reviewed here. The differences in the form of the ICDs notwithstanding, they all involve a repeated failure to inhibit the urge to engage in a behavior that is harmful to oneself or to others and thus are appropriately classified together on the ICD spectrum.

Given that ICDs are characterized by a failure of behavioral inhibition, this raises the question of whether there also is consistency in the nature of the impulses experienced across different ICDs. As described in the preceding section, the behaviors performed in each ICD most commonly serve two functions: they lead to escape from, or decrease of, aversive arousal/tension (i.e., negative reinforcement); and they lead to a feeling of pleasure or gratification (i.e., positive reinforcement). Both of these processes appear among the DSM-IV-TR criteria for ICDs and have been implicated in the occurrence of self-harm (e.g., Nock & Prinstein, 2004, 2005) and therefore are considered central to these disorders. However, problems controlling behavioral impulses expected to help escape aversive affective or cognitive states, or to generate pleasurable states, also are characteristic of anxiety disorders and addictive disorders, respectively. This has led to debates about how best to conceptualize and classify ICDs and these related disorders.

Compulsions are "repetitive behaviors … or mental acts … the goal of which is to prevent or reduce anxiety or distress, not to provide pleasure or gratification" (APA, 2000, p. 457). The specific function that these behaviors play in reducing anxiety and distress has led some to argue that trichotillomania (Swedo, 1993; Swedo & Rapoport, 1991), pathological gambling (Decaria & Hollander, 1993), kleptomania (Dannon, 2002), and perhaps ICDs in general (McElroy, Phillips, & Keck, 1994) would be best conceptualized as obsessive-compulsive spectrum disorders. This argument has received further support from studies reporting common biological mechanisms between ICDs (e.g., trichotillomania) and obsessive-compulsive disorders (du Toit et al., 2001). However, ICDs are distinct from anxiety-related compulsions in that the former often are performed to obtain pleasure or gratification, which argues against placing ICDs and self-harm on the obsessive-compulsive spectrum.

Addiction has been defined as "compulsive drug use despite negative consequences" (Hyman, 2005, p. 1414) (although here the word "compulsive" means that a person is compelled to act on his or her urges). Addictive behaviors are most often performed in an effort to elevate one's mood. Similarly, kleptomania, pyromania, pathological gambling, and trichotillomania are characterized by attempts to obtain pleasure or gratification as a result of performing the behavior (APA, 2000). In addition, like ICDs and self-harm, addictive behaviors often are performed to decrease aversive states (e.g., drug-use in order to decrease the aversive symptoms of withdrawal). These similarities have led some to argue that ICDs and self-harm should be conceptualized as addictive disorders (Franklin et al., 2006; Grant & Potenza, 2006). Although there is clear overlap among addiction and ICDs/self-harm, they are distinct in that the former is driven primarily via dysregulation of the reward pathway and is characterized by the presence of tolerance and withdrawal, which do not appear to play a large role in ICDs or self-harm.

Finally, some researchers have proposed that disorders traditionally classified as compulsive or addictive behaviors should instead be classified within the ICD spectrum. For example, although currently conceptualized as compulsive disorders (APA, 1994), pedophilia and other forms of paraphilia have been described as ego syntonic and overlapping with ICDs (Barth & Kinder, 1987; Black, Kehrberg, Flumerfelt, & Schlosser, 1997). Some have highlighted the common co-occurrence of ICDs, self-harm, eating disorders, and substance use disorders, and have proposed that individuals who engage in one impulsive behavior are likely to engage in others (i.e., "multi-impulsive" patients) (Lacey & Evans, 1986).

We believe that the ICD spectrum, as currently defined and composed, should be retained, and as the structure of this chapter would suggest, we advocate adding self-harm behaviors to this spectrum. If any further change were made to this spectrum, we would propose expanding this spectrum to include disorders of eating, drinking, and drug use, given the many similarities across these different disorders. On one hand, such a move would be a clear break from the current DSM-IV-TR approach of classifying behaviors based on their topography rather than their etiology or function. On the other hand, however, the ICD spectrum as currently constituted already includes behaviors that are quite heterogeneous, and so this would not represent such a drastic change. Regardless of how these different disorders are classified in the DSM-5 (and beyond), an important focus for future research is to further examine the common etiologies of these disorders, and to elucidate the factors that determine which of these disorders develop among those characterized by problems with impulse-control.

## Influences on Impulse-Control Disorders and Self-Harm

Impulse control disorders and self-harm are multi-determined behaviors that are influenced by a wide range of factors, including genetic, neurobiological, social, developmental, and psychological factors. In this section, we summarize what is known about the influences of each of these factors on ICDs and self-harm behaviors. Given that the vast majority of research in these areas has focused on self-harm (and on suicide in particular), we provide greater coverage of findings in this area, but highlight similarities and differences with analogous findings on ICDs.

### *Genetic and Neurobiological Factors*
#### GENETIC FACTORS
Studies consistently have found that ICDs and self-harm occur at higher rates among the family members of those engaging in these behaviors than in the general population, as noted in the first section of this chapter. Evidence from twin and adoption studies suggests that a genetically heritable component is present in these disorders. For instance, studies of suicide among twins have revealed higher rates of concordance between monozygotic than dizygotic twins; and adoption studies have revealed higher concordance among biological compared to adoptive relatives (Baldessarini & Hennen, 2004; Brent & Mann, 2005, 2006). Importantly, the familial trans-

mission of suicide remains even after controlling for the presence of psychiatric disorders (Brent & Mann, 2005; Egeland & Sussex, 1985). Of course, it is unlikely that there is "a gene for" self-harm or ICDs, but instead that interactions between genetic and environmental factors contribute to biological and psychological processes that then have an impact on these ultimate outcomes of interest (Kendler, 2005; Moffitt, 2005; Moffitt, Caspi, & Rutter, 2006).

Although the exact mechanisms through which genetic factors might lead to self-harm and ICDs are not currently known, recent family studies have provided some leads about the key neurobiological and psychological processes involved. Although first-degree relatives of those who die by suicide are at increased risk for both suicide ideation and attempts, the risk of suicide ideation is reduced to a nonsignificant level when the presence of psychiatric disorders is controlled, whereas the risk of suicide attempts remains (Brent & Mann, 2005). This suggests that the familial transmission of suicide ideation is explained by the transmission of psychiatric disorders, but there is some tendency beyond this that must be passed on that increases the risk of acting on suicidal thoughts. This liability may be best conceptualized as behavioral disinhibition or a tendency to engage in impulsive aggression. This is consistent with the finding that there is a higher occurrence of suicidal behavior in the first-degree relatives of those who die by suicide characterized by impulsive aggression relative to those who do not (Brent, Bridge, Johnson, & Connolly, 1996; Brent & Mann, 2005), and also by recent findings indicating that a specific polymorphism of the serotonin transporter gene is associated with the subsequent experience of suicidality (Caspi et al., 2003). Research conducted over the past decade also has revealed evidence of familial transmission of ICDs such as trichotillomania (King, Scahill, et al., 1995), pathological gambling (Winters & Rich, 1998), and kleptomania (Grant & Kim, 2002a), further supporting the idea of familial transmission of behavioral disinhibition.

#### NEUROBIOLOGICAL FACTORS
Building nicely on the genetic studies mentioned earlier, research on the neurobiology of ICDs and self-harm has focused largely on potential problems in the serotonergic system of people with these disorders. Serotonin is an inhibitory neurotransmitter in the brain that plays an important role in the regulation of mood and behavior, and it has been shown to be particularly associated with the occurrence of impulsive and aggressive behavior. Low levels of

serotonin and its primary metabolite (5-hydroxyindole acetic acid; 5-HIAA) have been found in the brainstems and cerebrospinal fluid of those who die by suicide (Asberg, Nordstrom, & Traskman-Bendz, 1986; Mann, Arango, Marzuk, Theccanat, & Reis, 1989) and also have been shown to predict suicide attempts and death (Cooper, Kelly, & King, 1992; Nordstrom et al., 1994). Serotonin abnormalities, such as low serotonin binding (e.g., New et al., 2002) and low levels of serotonin metabolite 5-HIAA (e.g., Virkkunen, Nuutila, Goodwin, & Linnoila, 1987) also have been found in patients with ICDs. Because serotonin has been implicated in the occurrence of many different mental disorders (and more general bodily functions, such as sleeping, eating, and others), it is important to identify *how* serotonergic dysfunction might lead to ICDs and self-harm in particular. Addressing this issue, Mann and colleagues recently have shown in a very illuminating series of studies that people who die by suicide have serotonergic dysfunction (i.e., fewer presynaptic serotonin transporter sites and upregulated postsynaptic serotonin receptors) in a specific brain region (i.e., ventromedial prefrontal cortex) that is associated with behavioral inhibition (see Mann, 2003; Mann, Brent, & Arango, 2001). Studies of serotonergic dysfunction in pathological gambling also have revealed decreased levels of platelet monoamine oxidase B (e.g., Blanco, Orensanz-Munoz, Blanco-Jerez, & Saiz-Ruiz, 1996), which has been associated with sensation-seeking and impulsiveness (Weyler, Hsu, & Breakefield, 1990). These findings have begun to elucidate the specific mechanisms through which genetic and neurobiological factors may lead to problems with impulse-control that are involved not only in suicidal behavior, but in ICDs and self-harm more broadly (Grant, Brewer, & Potenza, 2006).

The majority of research on the neurobiology of ICDs and self-harm has focused on dysfunction of the serotonergic system, given the links between this system and impulsive aggression. However, some interesting findings have been reported involving other aspects of neurobiological functioning, such as those involved in the experience of stress, depression, and reward processing. For instance, postmortem studies have revealed increased noradrenaline levels and decreased α-adrenergic receptor binding in the prefrontal cortex of the brains of people who have died by suicide (Arango, Ernsberger, Sved, & Mann, 1993; Mann, 2003). However, given that increased noradrenaline levels are associated with the experience of stress and depression (Heim & Nemeroff, 2001), it is not clear whether these findings are specific to suicide and other forms of ICDs and self-harm. In addition, the experience of strong urges to engage in ICDs and self-harm and the reported experience of pleasure after such behaviors has led researchers to examine the role of the dopaminergic and endogenous opioid systems in the occurrence of such behaviors (Blum et al., 2000; Grant, Brewer, et al., 2006).

### Social and Developmental Factors

The development of ICDs and self-harm also is influenced by factors in a person's social environment. These influences include both distal factors that occur early in life, as well as more proximal factors present in the immediate environment. The distal factor most often associated with the development of ICDs and self-harm is the occurrence of early childhood maltreatment. Studies have consistently revealed evidence of an association between early childhood maltreatment and the occurrence of subsequent suicidal behavior (Joiner et al., 2007; Nock & Kessler, 2006), NSSI (Glassman, Weierich, Hooley, Deliberto, & Nock, 2007; Yates, 2004), and ICDs, such as trichotillomania (Boughn & Holdom, 2003; Lochner et al., 2002), pathological gambling (Petry & Steinberg, 2005; Scherrer et al., 2007), and pyromania (Root, MacKay, Henderson, Del Bove, & Warling, 2008). This association may be explained in part by the shared genetic and neurobiological characteristics of parent and offspring. That is, parents who are impulsive and aggressive by nature are more likely to have impulsive and aggressive children, and incidentally to act in an abusive way toward their offspring. However, evidence from studies of nonhuman primates reveals that early rearing experiences, such as being raised in a deprived social environment, contribute independently to the development of impulsive, aggressive, and self-injurious behavior via serotonergic dysfunction (Higley & Linnoila, 1997; Kraemer, Schmidt, & Ebert, 1997). Most recently, an exciting line of research has shown that not only do genetic factors and early environment independently influence the development of pathological behaviors, but that they interact to increase the likelihood of such outcomes (Caspi et al., 2003; Kaufman et al., 2004).

Proximal influences on the development of ICDs and self-harm include the experience of significant life stressors beyond childhood (e.g., Welte et al., 2008), social learning via interactions with peers (e.g., Prinstein, Boergers, & Spirito, 2001) or media (Whitlock, Purington, & Gershkovich, 2009), and access to the means required in the case of suicidal

behavior (Miller & Hemenway, 2008). The experience of stressful events in one's environment appears to be a general risk factor for the occurrence of ICDs and self-harm, as studies of virtually all of these disorders have reported that social stressors are a proximal risk factor in each case (Flessner et al., 2008; Hawton & Harriss, 2006). In contrast, it is likely that social learning processes influence which ICD or self-harm behavior a person will perform. For instance, several recent studies have shown that media reporting of suicide deaths can influence the occurrence of subsequent suicidal behaviors (Gould, 2001), increasing media attention to NSSI may be contributing to increases in the prevalence of this behavior (Whitlock et al., 2009), and interactive media such as the Internet can provide a means of spreading information about engaging in NSSI across peers (Whitlock, Powers, & Eckenrode, 2006). Moreover, research on health risk behaviors more generally has shown that people's (adolescents in most of this research) engagement in behaviors such as self-harm, aggression, alcohol/drug use, and related behaviors is significantly associated with the perception that one's close friends also are engaging in these behaviors (Brent, Perper, Mortiz, & Allman, 1993; Vitaro, Tremblay, Kerr, Pagani, & Bukowski, 1997). Stated more simply, people are more likely to begin and continue engaging in a specific abnormal behavior (e.g., stealing, starting fires, self-injuring) if those around them are also doing so. Once initiated, it is likely that other intrapersonal/psychological factors help to explain whether and to what extent the behavior persists over time.

### Psychological Factors

The psychological factors that lead to engagement in ICDs and self-harm emerge from the interaction of genetic/neurobiological and social/environmental factors. These psychological factors can be conceptualized and studied in myriad ways, and a full discussion of such factors could fill an entire volume (see Grant & Kim, 2003b; Hollander & Stein, 2006; Nock, 2009). Here, we provide a brief summary of the psychological factors most often associated with engagement in ICDs and self-harm.

Each of the ICDs and self-harm behaviors reviewed in this chapter represents problems in controlling behavioral impulses to engage in harmful behavior, and so perhaps not surprisingly, the psychological factors most often linked to these disorders are deficits in executive functions and high negative arousal. Executive functions refer to capacities for managing specific cognitive (e.g., attention,

planning, decision-making) and behavioral (e.g., response initiation, maintenance, and inhibition) processes (Lezak, 1995). Studies using brain-damaged patients and neuroimaging approaches suggest that the prefrontal cortex is the brain area most closely underlying such functions (e.g., Bechara & Van Der Linden, 2005). Integrating nicely with the findings on genetic (e.g., importance of serotonin transporter gene), neurobiological (e.g., serotonergic abnormalities in the prefrontal cortex), and environmental (e.g., maltreatment) factors reviewed earlier, studies on ICDs and self-harm have consistently revealed deficits in behavioral inhibition (Carlton & Manowitz, 1992; Grant, Correia, et al., 2006), decision-making (e.g., Best, Williams, & Coccaro, 2002; Cavedini, Riboldi, Keller, D'Annucci, & Bellodi, 2002), and problem-solving (e.g., Marazziti et al., 2008). Taken together, these findings provide an increasingly clear picture of the processes underlying problems with failure to inhibit the impulse to engage in maladaptive behaviors.

Studies of ICDs and self-harm also have consistently revealed problems with high negative arousal that may increase the likelihood of acting on behavioral impulses. This high arousal has been studied in the form of high emotion reactivity (Nock, Wedig, Holmberg, & Hooley, 2008), high levels of stress (Welte et al., 2008), elevated rates of psychological distress (Grant & Kim, 2002a), higher physiological arousal (Nock & Mendes, 2008), and high levels of neuroticism (Ashton, Marshall, Hassanyeh, & Marsh, 1994; Fernandez-Aranda et al., 2008). As mentioned in the first section of this chapter, each ICD and self-harm behavior is preceded most often by increased negative arousal, and the behavior is performed in an effort to decrease or escape from this arousal—highlighting the importance of this psychological factor in the occurrence of these disorders.

An important goal for future research on the psychological factors associated with ICDs and self-harm is to advance the understanding of what factors determine which particular ICD or self-harm behavior a person engages in and why. For instance, why does one person with poor impulse-control and high negative arousal decide to hurt himself or herself, whereas another person with this profile decides to set fires or steal items from a store? A wide range of psychological, genetic, neurobiological, and environmental factors likely contribute to such determinations, and gaining better clarity on this issue is important not only for improving our understanding of these disorders, but also for

enhancing our ability to effectively assess and treat these problems.

## Assessment and Intervention
### Assessment

As in most areas of psychopathology, the assessment of ICDs and self-harm should incorporate the use of multiple measurement methods, including interviews, rating scales, and performance-based tests. The assessment methods used in any specific case will differ depending on whether the focus is on screening, diagnosis, or monitoring over the course of treatment. In each of these domains, many more assessment measures are available for suicidal behaviors (see Brown, 2000 for extensive reviews; Goldston, 2000; Nock, Wedig, Janis, & Deliberto, 2008) than for NSSI (Nock, Wedig, Janis, et al., 2008) and ICDs (Grant, 2008); however, these latter areas have received increased attention in recent years, and a number of excellent assessment tools currently are available for scientific and clinical use.

The first focus of assessment typically is to determine who in a population is most at risk for the outcomes of interest. As such, a range of assessment measures has been developed to enable scientists and clinicians to screen for ICDs and self-harm and their risk factors. For instance, the Columbia Suicide Screen (D. Shaffer et al., 2004) is a screening questionnaire designed to identify middle school and high school students at risk for suicide. Importantly, a related line of research has suggested that, despite common perceptions, asking teens questions about suicide does not increase their distress or likelihood of experiencing suicidal thoughts (Gould et al., 2005). Screening measures also are available for ICDs, such as the clinician-administered Minnesota Impulse Disorders Interview (Grant, 2008), which serves as an efficient method of screening for the presence of each of the ICDs reviewed in this chapter.

The next focus of assessment is making a determination about whether those who screen positive meet criteria for an ICD or are actually experiencing self-harm thoughts or behaviors. Unfortunately, ICDs and self-harm behaviors are not included in most used structured or semi-structured diagnostic interviews, such as the Structured Clinical Interview for DSM-IV (First, Spitzer, Gibbon, & Williams, 2002). However, specialized measures exist for in-depth assessment once the potential presence of an ICD or self-harm has been detected, such as the Self-Injurious Thoughts and Behaviors Interview (Nock, Holmberg, Photos, & Michel, 2007), Trichotillomania Diagnostic Interview (Rothbaum

& Ninan, 1994), and Structured Clinical Interview for Pathological Gambling (Grant, Steinberg, Kim, Rounsaville, & Potenza, 2004).

Once the presence of ICDs and self-harm are determined, monitoring of these disorders over time becomes especially important, given the potential harm to self and others involved in these problems and due to their persistence (as described earlier). Scientists and clinicians should conduct ongoing monitoring and risk assessment, following the currently available guidelines for such practices provided by professional organizations (American Academy of Child and Adolescent Psychiatry, 2001; APA, 2003) or individual experts in the field (Brown, 2000; Jacobs, Brewer, & Klein-Benheim, 1999).

In each phase of assessment, it is important to bear in mind several special issues that commonly arise in the measurement of ICDs and self-harm. First, given that ICDs and self-harm typically are comorbid with each other (e.g., Grant & Kim, 2003a) and with other DSM-IV-TR disorders (e.g., Christenson et al., 1994; Kessler et al., 2008), careful differential diagnosis is especially important. Second, because of the sensitive, embarrassing, and in some cases illegal nature of some ICDs and self-harm, many people fail to report such behaviors unless asked directly, and some still deny them on initial interview. For this reason, it is important to use a multi-method assessment approach, and to assess for the presence of these disorders more than once, in order to increase the likelihood of detecting such behaviors. Third, people with ICDs and self-harm often experience shame or guilt as a result of these disorders, and so the presence of such feelings should be assessed and, if present, they should be addressed as part of the intervention provided.

### Intervention

Recent research has revealed both good and bad news about the treatment of ICDs and self-harm. The good news is that the percentage of people in the general population who receive treatment for mental disorders and self-harm has increased significantly over the past decade (Kessler, Berglund, Borges, et al., 2005). The bad news is that, despite this increase, the rates of these outcomes have not changed (Kessler, Demler, et al., 2005). Although this latter finding suggests that the treatments administered in many community settings may not be particularly effective, it is notable that several new psychological and pharmacological treatments have proven efficacious in decreasing the rates of ICDs and self-harm.

## PSYCHOLOGICAL TREATMENT

Cognitive therapy (CT), which was initially developed to treat depression, has been adapted for a range of behavior problems, including self-harm and ICDs. Brown and colleagues (2005) recently modified CT specifically for suicide attempters and, through a randomized clinical trial, found that adult suicide attempters receiving CT, relative to treatment as usual, reported significantly lower reattempt rates and severity of depression throughout the 18-month follow-up period. This modified CT aimed to identify proximal thoughts and core beliefs that are activated before attempting suicide and to improve impulse control, problem solving and coping skills, degree of hopelessness, availability of social support, and compliance with treatment services (Brown et al., 2005; Henriques, Beck, & Brown, 2003). Cognitive therapy has also been developed and tested among small samples for pathological gambling (see Lopez Viets & Miller, 1997) and among adults for anger disorders (see Deffenbacher, 2003).

Cognitive-behavioral therapy (CBT), which is similar to CT but includes a more substantial focus on behavior change, also has been proven effective in the treatment of ICDs and self-harm. For instance, dialectical behavior therapy (DBT), a version of CBT that targets suicidal and nonsuicidal self-injurious behaviors (Linehan, 1993a, 1993b), has proven especially effective in the treatment of self-harm (Linehan, Armstrong, Suarez, Allmon, & Heard, 1991; Linehan et al., 2006). By validating the patient while simultaneously modifying his or her behavior, DBT focuses directly on reducing life-threatening behaviors (e.g., suicide attempts, NSSI), treatment-interfering behaviors (e.g., not returning clinician's phone calls), and quality-of-life interfering behaviors (e.g., homelessness), as well as on increasing behavioral skills. Dialectical behavior therapy clinicians use change strategies to improve mindfulness (i.e., nonjudgmental focus on present thoughts and feelings), distress tolerance, emotion regulation, and interpersonal effectiveness. These goals are achieved through multiple modes of service delivery (e.g., individual therapy, in-group skills training, telephone consultation, therapist consultation meetings). Cognitive-behavioral therapy techniques and behavioral approaches have also been supported as efficacious means of treating trichotillomania (Franklin et al., 2006), kleptomania (Durst, Katz, Teitelbaum, Zislin, & Dannon, 2001; Gauthier & Pellerin, 1982), pathological gambling (Petry & Roll, 2001; Sylvain, Ladouceur, & Boisvert, 1997), pyromania (Bumpass, Fagelman, & Brix, 1983; McGrath, Marshall, & Prior, 1979), and IET (Edmondson & Conger, 1996).

Other psychological treatment strategies also have aimed to reduce disorders of self-harm and impulse control. For example, periodically contacting depressed or suicidal patients (e.g., through telephone calls, letters) discharged from a hospital emergency center has reduced the likelihood of reattempt relative to a group of discharged patients who did not receive any contact (Motto & Bostrom, 2001; Welu, 1977). Other interventions, such as the use of support groups (e.g., Gamblers Anonymous for pathological gambling) also have shown promise in the treatment of ICDs, although attrition rates are fairly high (Stewart & Brown, 1988). Future research must identify more effective treatments for these behavior problems, develop a clearer understanding of the mechanisms through which these treatments have their effects, and work to ensure that the most effective treatments possible are available to clinicians and patients in the community.

## PHARMACOLOGICAL TREATMENT

### Antidepressants

Some studies have reported positive results for antidepressant treatment of ICDs and self-harm. For instance, increased rates of antidepressant use in nationally representative (Gibbons, Hur, Bhaumik, & Mann, 2005) and adolescent (Olfson, Shaffer, Marcus, & Greenberg, 2003) samples have been associated with reduced rates of suicide. Selective serotonin reuptake inhibitors (SSRIs) in particular also have been shown to be effective in treating NSSI among severely to profoundly mentally retarded populations (Bodfish & Madison, 1993; Markowitz, 1992) and in adolescent populations when the treatment has been used in combination with CBT (Goodyer et al., 2007). Although the use of SSRIs in treating certain ICDs has not been as widely studied, SSRIs have been recommended as effective treatments for pathological gambling (Hollander et al., 1998; Kim, Grant, Adson, Shin, & Zaninelli, 2002) and IED (i.e., impulsive aggression; Coccaro & Kavoussi, 1997), based on what is known about serotonergic dysfunction contributing to ICDs. Results on the effectiveness of SSRIs for treating trichotillomania and kleptomania have been more controversial—with some studies demonstrating their efficacy (Dannon, 2002; Swedo & Rapoport, 1991) and other studies revealing no effects (Christenson, Mackenzie, Mitchell, et al., 1991). It has been suggested that SSRIs are more effective in treating ICDs when in combination with therapy (e.g., Lepkifker et al., 1999) and mood-stabilizing drugs

(Burnstein, 1992; Coccaro & Danehy, 2006) than when SSRIs are the only treatment implemented.

Despite reports of the effectiveness of antidepressants in the treatment of ICDs and self-harm, concerns about potential adverse effects of SSRIs have led to controversy. Some adverse effects (e.g., increased skin picking; Denys, van Megen, & Westenberg, 2003) have been reported when SSRIs have been used to treat NSSI. Similarly, studies on SSRI treatment of trichotillomania and kleptomania have reported relapse of symptoms (Bayle, Caci, Millet, Richa, & Olie, 2003; Stein & Hollander, 1992). The use of SSRI treatment for suicidal behaviors has been persistently debated. Several experimental studies have reported that those receiving SSRIs actually have a higher rate of suicidal thoughts and attempts than do those receiving placebo (e.g., Whittington et al., 2004). However, other studies report no such increase (e.g., Gibbons et al., 2005). It is likely that further study over the next several years will be required to resolve this debate.

### Mood Stabilizers
Mood stabilizing anticonvulsants have been shown to significantly reduce suicide risk (Goodwin et al., 2003). Anticonvulsants have been shown to be effective in treating other forms of self-harm, such as NSSI (Cordas, Tavares, Calderoni, Stump, & Ribeiro, 2006). Mood stabilizers (Pallanti, Quercioli, Sood, & Hollander, 2002; Parks et al., 2005) alone have been recommended for some ICDs, but they should be used cautiously due to potential adverse effects (e.g., reduction in mood; Coccaro & Danehy, 2006; Cowdry & Gardner, 1988).

### Antipsychotics
There have been mixed findings regarding the effectiveness of antipsychotic medication for ICDs and self-harm. Although some types of antipsychotic medications have been reported to reduce risk in suicide (e.g., clozapine) (Ernst & Goldberg, 2004), it has been suggested that neuroleptics could increase suicide risk in some cases due to subsequent akathisia (increased psychomotor agitation) and akinesia (apathy, difficulty initiating usual activities) (Drake & Ehrlich, 1985; Shaw, Mann, Weiden, Sinsheimer, & Brunn, 1986). Antipsychotics also have been reported to effectively reduce NSSI (Sandman, 2009), aggression (Schur et al., 2003), and trichotillomania (Stein, Harvey, Seedat, & Hollander, 2006); however, due to potential adverse effects, antipsychotics are not recommended as the first pharmacological treatment option for ICDs, nor are they recommended to be administered in large doses (Stein et al., 2006).

### Opioid Antagonists
Opioid antagonists are another promising form of pharmacological treatment for ICDs and self-harm. Multiple studies, albeit consisting of small sample sizes, have demonstrated that opioid antagonists reduce NSSI (Sandman, Barron, & Colman, 1990; Symons, Thompson, & Rodriguez, 2004). Similar effects have been reported regarding ICDs (e.g., pathological gambling, kleptomania) (Grant & Kim, 2002b; Kim & Grant, 2001).

## Prevention
Prevention programs for ICDs and self-harm have received much less scientific and clinical attention; however, some effective programs have been identified. Suicide prevention programs have been studied much more extensively than other ICDs and self-harm behaviors. In a systematic review of suicide prevention programs, primary care physician education programs and means restriction (e.g., increasing firearm restriction) were found to be the most effective in reducing suicide rates (Mann et al., 2005). Although substitution methods may emerge, means restriction could induce a transition from the use of more lethal means, such as firearms—which account for more than 50% of suicides in the United States—to less lethal means (Gould, Greenberg, Velting, & Shaffer, 2003). Other methods of suicide prevention, such as general public education, school-based awareness programs for youth, and media intervention efforts, lack sufficient research or have been found to be less effective (Gould et al., 2003; Mann et al., 2005). School-based awareness programs have demonstrated zero to negative effects (D. Shaffer, Garland, Vieland, & Underwood, 1991), whereas skills training (e.g., problem solving, coping) has produced more promising positive results (e.g., E. A. Thompson, Eggert, Randell, & Pike, 2001). Guidelines for reporting suicide in the media have been established to avoid a potential contagion effect (Gould et al., 2003; Mann et al., 2005), but the effectiveness of such guidelines is not currently known. Whitlock and Knox (2009) have suggested that since NSSI is a risk factor for suicide, NSSI prevention programs that resemble those for suicide may be useful in reducing rates of NSSI, although this also remains an open empirical question.

Prevention programs for ICDs have received the least amount of attention—a possible result of their low prevalence. Policy makers may exhaust valuable

time and resources trying to prevent disorders that occur much less frequently than other behaviors, such as suicide. Although prevention programs for each of these disorders may exist, none have been systematically evaluated. Future prevention efforts could target behaviors that are often associated with ICDs. For example, prevention strategies that target violence may be helpful in reducing rates of ICDs (e.g., IED).

## Conclusion

Disorders of impulse control and self-harm are characterized by a persistent inability to inhibit urges to engage in harmful behavior, to the point that such behavior causes significant distress and impairment. Disorders on the impulse control spectrum are somewhat heterogeneous, in the form of behaviors characterizing each disorder and in their prevalence, sex distribution, and course. Yet, these disorders also show several important commonalities beyond their defining features. They most often are preceded by aversive arousal that dissipates after the behavior and are followed by gratification or pleasure; they all typically have an onset during adolescence; and they appear to share genetic/neurobiological, environmental, and psychological influences that contribute to problems with heightened arousal and poor executive functioning. Most prior research in this area has focused on suicidal behaviors, but other disorders on this spectrum have received increased attention in recent years. The dangerous, sensitive, and often illegal aspects of disorders on this spectrum introduce problems for their assessment and treatment; however, significant advances have been made in this area, and currently a range of evidence-based approaches to assessment, intervention, and prevention are available to clinicians, researchers, and the public. Nevertheless, there is clearly much more work that must be done to increase understanding and decrease the prevalence and impact of these disorders.

## Future Directions

As highlighted in this chapter, there is still much we do not know about the epidemiology, etiology, assessment, and treatment of ICDs and self-harm, and so research is needed on multiple fronts, each of which was mentioned earlier and so will not be reiterated here. We believe several additional and as yet unanswered questions are especially pressing and should guide future research in this area. First: Is persistent engagement in moderate-to-severe self-harm behaviors a mental disorder, and if so, should such disorders be placed on the impulse control spectrum? Compelling arguments have been made regarding why self-harm should be classified in DSM-5 (Muehlenkamp, 2005; Oquendo, Baca-Garcia, Mann, & Giner, 2008), and doing so would have significant implications for research, assessment, and treatment. We believe that, if such a classification is made, such behaviors should appear on the impulse control spectrum, given the similarities outlined in this chapter. Second, and related to the previous point: Given the commonalities and comorbidities among disorders characterized by behavioral dyscontrol, including ICDs, self-harm, eating disorders, alcohol and drug use disorders, and some anxiety disorders, should all of these disorders be placed on the same spectrum (or overlapping or intersecting spectra)? Doing so would result in a significant reorganization of existing DSM disorders, as well as a change from classifying behaviors based primarily on topography to classifying behaviors based more on the processes that produce and maintain these behaviors. Third, as research efforts continue to reveal the etiologic pathways that lead to each of these disorders, as well as uncover effective methods for assessing and treating these disorders, it will be important to consider commonalities and differences among different disorders and to map them onto common traits in order to more efficiently advance work in each area. Despite the many similarities between ICDs and self-harm, research on these two classes of behaviors rarely intersects. Greater communication among researchers and cross-fertilization of ideas and findings from these different areas of research are likely to lead to more rapid advances in each domain. Finally, surprisingly little is known about effective methods for assessing, treating, and preventing each of the disorders reviewed in this chapter. Therefore, it is especially important that researchers and clinicians focus intensively on developing more effective and efficient methods for assessing, predicting, and preventing these dangerous behaviors.

# The Spectrum of Personality Disorders

Susan C. South, Thomas F. Oltmanns, *and* Robert F. Krueger

### Abstract

The concept of personality disorder has existed throughout the history of psychology and psychiatry. The ten current personality disorders (PDs) listed in the DSM-IV are conceived of as distinct syndromes. Nevertheless, DSM-IV PDs overlap extensively with each other, with normal personality traits, and with Axis I psychopathology. Thus, many investigators suggest that, in DSM-5, the classification system for PDs should be revised to better reflect the closeness of the links between personality and psychopathology, perhaps by linking both constructs within broader spectrums of psychopathological variation. The most common and well-accepted suggestion is that the categorical diagnoses of DSM-IV should be replaced with a dimensional model of pathological personality traits, and the links between personality traits and more syndromal forms of psychopathology (Axis I disorders) should also be explicitly articulated. In this chapter, we review current research on how PDs are linked with broad spectrums of personality and psychopathology. Specifically, we examine
(1) evidence relevant to the etiology and course of PDs, (2) how these disorders can best be assessed, and (3) evidence regarding the most effective practices in the treatment of PDs, with the aim of articulating how etiology, course, assessment, and treatment of PDs might be conceptualized in a spectrum-based classification system.

**Key Words:** Assessment, etiology, personality disorders, spectrum, treatment

The current *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (American Psychiatric Association [APA], 2000) identifies ten categorical disorders of personality, coded on Axis II, which are presumed to begin relatively early in life, follow a chronic and debilitating course, and result in significant personal, social, and occupational impairment or distress. The personality disorders (PDs) show considerable overlap with both "normal-range" personality traits and other forms of psychopathology (coded on Axis I). This has led some to suggest that PDs be reconceptualized as elements within broader spectrums of mental illness. From this vantage point, personality traits provide the underlying structures for understanding the full range of human variation, including the pathological range.

Both episodic (DSM-IV Axis I) psychopathologies, and relatively more enduring forms of psychopathology (DSM-IV Axis II) can then be understood as manifestations within spectrums organized by underlying personality-based risk for diagnosable mental disorders. Personality disorders are enduring, extreme manifestations of personality, and episodic mental disorders occur when persons with vulnerable personalities encounter circumstances that are beyond their ability to cope (e.g., a person with a propensity toward negative affect undergoes a significantly stressful life transition, resulting in a depressive episode). Indeed, this "spectrum perspective" is likely to have some impact on the organization and structure of the DSM, which is currently undergoing revision, with the publication of DSM-5 scheduled for 2013.

In this chapter, we review current research on where PDs fall within spectrums of personality and psychopathology. Specifically, we examine evidence relevant to the etiology and course of PDs, how these disorders can best be assessed by current techniques, and evidence regarding best practices in the treatment of PDs.

## Conceptual Overview of Personality Disorders

With regard to the DSM, PDs have existed as discrete forms of mental illness since the first edition (APA, 1952). Conceptualizations of personality pathology arose from myriad clinical and theoretical formulations, from being viewed as *formes frustes* of more acute, debilitating pathology (e.g., schizotypal PD and schizophrenia) to Freudian notions of poor ego development (e.g., narcissistic PD; Frances & Widiger, 1986; Livesley, 2001). The first and second editions of the DSM listed descriptions of each main type of personality disorder (12 in the first edition, ten in the second), and a categorical diagnosis was made by use of these brief (one- to two-paragraph) descriptions. In the third edition of the DSM, the PDs were separated from more putatively acute disorders of mental functioning (e.g., major depressive disorder, schizophrenia) and placed on Axis II (APA, 1980); it was hoped that by placing the PDs on their own axis, clinicians would feel less of a pull between assigning *either* a more acute, transient condition, *or* a chronic, relatively stable character defect. Even more importantly, each of the disorders was now defined by a polythetic set of criteria, a certain number of which were required to meet a diagnosis.

Over the course of the four editions of the DSM, several disorders have been added (e.g., schizotypal, narcissistic, avoidant, and dependent in DSM-III), others have been removed (e.g., cyclothymic). Many have been present consistently since DSM-I (e.g., antisocial, paranoid, schizoid), although with various revisions to specific definitions and criteria (Coolidge & Segal, 1998). The current DSM-IV-TR (APA, 2000) includes ten PDs grouped into three, somewhat arbitrary (Sheets & Craighead, 2007), descriptive clusters: paranoid, schizoid, and schizotypal in Cluster A (odd-eccentric); antisocial, borderline, histrionic, and narcissistic in Cluster B (dramatic-erratic); and avoidant, dependent, and obsessive-compulsive in Cluster C (anxious-fearful).

All ten PD diagnoses are a collection of symptoms from one of four areas: affect, cognition, behavior, and interpersonal relations. A diagnosis is met if an individual meets enough criteria (e.g., four of seven paranoid symptoms) by demonstrating that symptom and by meeting the general provision of impairment or distress. As with any DSM disorder, it is presumed that each class or category of PD is at least somewhat unique in etiology, course, and treatment correlates (Widiger & Mullins-Sweatt, 2007). The PDs, therefore, are presumed to be nontrivially distinct from each other, from other forms of psychopathology (e.g., major depressive disorder, schizophrenia), and from general models of normal personality structure. We know from abundant research, however, that the ten PDs are highly comorbid with each other (Bornstein, 1998; Lilienfeld, Waldman, & Israel, 1994; Livesley, 2003) and with Axis I psychopathology (Dolan-Sewell, Krueger, & Shea, 2001), and they show high correlations with measures of normative personality traits (Costa & Widiger, 2002). The current diagnostic classification system for the PDs has been criticized on numerous other grounds, including poor reliability, poor convergent and discriminant validity, and inadequate coverage (Clark, Livesley, & Morey, 1997; First et al., 2002; Livesley, 2003; Millon, 2002; Widiger & Trull, 2007).

These criticisms have led to two interrelated lines of research. First, it has been suggested that the current conceptualization of PD should be revised, with a change from the current "yes/no" categorical system of diagnosis to a system whereby personality pathology is assessed on some type of dimensional scale (Widiger & Trull, 2007). Evidence in favor of a dimensional system includes better reliability and stability of personality assessment, the lack of a discrete boundary between normal and abnormal personal functioning, and empirical evidence that personality structure is similar across clinical and nonclinical samples (Clark & Watson, 1999; Livesley, 2003; Livesley, Jang, & Vernon, 1998; O'Connor, 2002). Second, researchers have investigated the different forms of interplay between PDs, normal personality, and psychopathology. Although there is mixed evidence for the various forms of relationships, the greatest support seems to be in favor of "spectrum" models that explain covariance of these constructs in terms of higher-order factors. A spectrum model would, in fact, pull together both dimensional conceptions of personality pathology and the ways in which personality traits form the basis for personality dysfunction and acute forms of psychopathology. We review evidence for both lines of research here.

### Dimensional Conceptualizations of Personality Disorders

It was only with the third edition of the DSM that thresholds were delineated to identify the presence versus absence of a disorder per se (APA, 1980). This revision of PD diagnoses certainly helped with the ability to operationalize PDs in structured interviews and to thereby study their reliability and validity (e.g., Stangl et al., 1985). Categorical diagnoses have many benefits, including ease of conceptualization and communication among health professionals. Unfortunately, attempts to delineate discrete categories of pathology with clearly identified cut-points have instead resulted in inadequate coverage, as seen by the high prevalence of PDNOS (not otherwise specified); arbitrary thresholds (e.g., Is someone with five symptoms of borderline personality disorder truly different from someone with six symptoms? (see Asnaani, Chelminski, Young, & Zimmerman, 2007); and heterogeneity among individuals with the same diagnosis (there are 151 ways to earn a diagnosis of borderline PD; Skodol et al., 2002b; Widiger & Trull, 2007).

Given the numerous difficulties with a categorical model of PDs, there is now strong interest in moving toward a dimensional conceptualization of personality pathology (Trull & Durrett, 2005; Widiger & Simonsen, 2005; Widiger, Simonsen, Krueger, Livesley, & Verheul, 2006; Widiger & Trull, 2007). This push is based, at least in part, on the attempt to integrate research on PDs with basic science research on personality traits. Even though the current PDs originated in the clinical experiences of psychiatrists or psychoanalytically trained clinicians, with little input from normative personality trait research (Ball, 2001; Livesley, 2001; Millon et al., 1996), there appears to be a great deal of overlap between normal personality traits and abnormal personality traits (Markon, Krueger, & Watson, 2005).

One of the most prolific areas of research into dimensional conceptualizations of PDs has involved using one of the most popular models of normal personality, the Five Factor Model (FFM), to describe personality pathology. The FFM grew out of the lexical tradition of factor analytic models of trait theory, and includes the broad dimensions of extraversion, neuroticism, conscientiousness, agreeableness, and openness, each of which can be further divided into six separate facets (McCrae & Costa, 2008). Extensive empirical research supports the construct validity of the FFM. Factor analytic studies consistently find a similar underlying structure of the FFM (McCrae & Costa, 2008), behavior

genetic research supports the genetic basis of the five factors (Bouchard & Loehlin, 2001), and the five factors appear to be universally found across different races and cultures (Allik, 2005; Yamagata et al., 2006). Thus, the FFM appears to be appropriate to build a bridge between current PD diagnoses and normal personality traits.

Numerous studies have shown that DSM-defined PDs can be adequately represented with the FFM traits (Widiger & Costa, 2002), including the underlying facet dimensions (Axelrod, Widiger, Trull, & Corbitt, 1997; Dyce & O'Connor, 1998; Morey et al., 2002). For instance, the FFM description of borderline PD consists of high levels of many of the facets of neuroticism, plus low facets of agreeableness (i.e., trust, compliance; Mullins-Sweatt & Widiger, 2006). Meta-analysis of multiple independent samples has confirmed that the ten DSM-IV-TR PDs are related to the five higher-order factors in predictable and meaningful ways, with most lying in a quadrant formed by high neuroticism and low agreeableness (Samuel & Widiger, 2008; Saulsman & Page, 2004). Using ratings of hypothetical PD patients created by expert clinicians, Lynam and Widiger (2001) developed FFM prototypes of the PDs that largely accounted for covariation among PD symptoms.

The FFM does not stand alone as the only possible dimensional conceptualization of PDs. More than 18 different dimensional systems of classification have been proposed as alternatives to the current DSM classification (Widiger & Simonsen, 2005), and several of these dimensional systems have been operationalized with standardized assessment instruments. These systems differ in how they dimensionalize personality pathology. The Millon Clinical Multiaxial Inventory (MCMI, Millon, 1983; MCMI-II, Millon, 1987; MCMI-III, Millon, Millon, & Davis, 1994) uses the DSM PD constructs but presents scores dimensionally. In comparison, instruments like the Dimensional Assessment of Personality Pathology-Basic Questionnaire (DAPP-BQ; Livesley & Jackson, 2002) and the Schedule for Nonadaptive and Adaptive Personality (SNAP; Clark, 1993) were developed through structural modeling of personality traits thought to cover the range of personality pathology. The resulting factor structures of these different systems are not perfectly overlapping; for instance, the DAPP-BQ has four higher-order factors of emotional dysregulation, dissocial behaviour, inhibitedness, and compulsivity (Livesley et al., 1998), whereas the SNAP has three higher-order domains of positive affectivity, negative

affectivity, and constraint (Clark, 1993). However, the SNAP and DAPP-BQ show a great deal of convergence at the specific trait level (Clark, Livesley, Schroeder, & Irish, 2002). In fact, a common hierarchical structure consistently appears across different measures of pathological personality, with four main factors emerging: extraversion (stimulus-seeking, exhibitionism, assertiveness, sociability, and detachment), antagonism (mistrust, aggression, suspiciousness, altruism, compliance, and submissiveness), constraint (dutifulness, achievement, ambitiousness, responsibility, and self-discipline), and emotional dysregulation (self-harm, dependency, alienation, depressiveness, and vulnerability) (Widiger & Simonsen, 2005).

A remaining issue pertains to "diagnosing" a PD using a dimensional model. One suggestion uses a four-step process within the FFM: (1) a comprehensive description using the 30 FFM facets; (2) identification of social and occupational impairments; (3) determination of the level of clinically significant impairment; and (4) matching the individual's FFM profile to diagnostic "prototypes" (Widiger, Costa, & McCrae, 2002; Widiger & Mullins-Sweatt, 2009; Widiger & Trull, 2007). Such a system would represent a paradigm shift, as it goes against the grain of the categorical system of psychiatric nomenclature; however, a dimensional system represents an opportunity to provide valid and reliable descriptions of personality pathology that are much richer in description than the current PD diagnoses. Numerous other advantages also accrue from a dimensional approach. We turn now to discuss how a dimensional approach can be helpful in handling the co-occurrence of putatively separable syndromes, a phenomenon traditionally known as comorbidity.

## Comorbidity

One strong argument against the current categorical system of classification for personality pathology is the extreme comorbidity both within Axis II PDs, and between Axis I and Axis II disorders. The diagnosis of just one PD in an individual is rare; more common is the assignment of multiple PDs (Grant, Stinson, Dawson, Chou, & Ruan, 2005b; Zimmerman, Rothschild, & Chelminski, 2005), or the catch-all label of *personality disorder not otherwise specified* (PD-NOS; Verheul, Bartak, & Widiger, 2007; Verheul & Widiger, 2004). As much research attests, considerable overlap also exists between Axis I and Axis II psychopathology (Oldham et al., 1995). Dolan-Sewell and colleagues (2001) reported that between 66% and 97% of PD patients also

meet criteria for an Axis I disorder; in addition, between 13% and 81% of patients with a syndrome disorder can also be diagnosed with a PD. Certain patterns of comorbidity are more likely to be found, both in population-based and clinical samples. For instance, mood and anxiety disorders are often found in patients with PDs, particularly avoidant and dependent PD (Grant et al., 2005a). Substance use disorders are most commonly found in common with Cluster B PDs (Ball, 2005a; Compton, Conway, Stinson, Colliver, & Grant, 2005; Trull, Waudby, & Sher, 2004).

Currently, four models are used to explain Axis I–II connections (see Clark, Watson, & Mineka, 1994; Krueger & Tackett, 2003; Tackett, 2006; Watson, Clark, & Harkness, 1994; Widiger & Smith, 1999). These four models are known as the Vulnerability Model, the Complication/Scar Model, the Pathoplasty Model, and the Spectrum Model. The Predisposition or Vulnerability Model proposes that a PD acts as risk factor for the development of an Axis I clinical disorder. According to the Scar Model, the presence of an Axis I disorder "scars" an individual's preexisting personality, leading to the development of a PD. If an individual has both an Axis I and Axis II disorder that are etiologically distinct, the Pathoplasty Model suggests that the Axis II disorder will affect the course, severity, or treatment response to the Axis I disorder. Finally, the Spectrum Model states that that Axis I and Axis II disorders are comorbid because specific disorders can be well-conceptualized as being within the same psychopathology spectrums.

These models are not necessarily incompatible, and evidence supports a number of accounts of the ways in which Axis I and II disorders may be related. For instance, reports from the Children in the Community Study find support both for the influence of childhood MDD on the development of subsequent Axis II pathology (Kasen et al., 2001) and for adolescent PD symptoms as a risk factor for the development of later anxiety disorders (Johnson, Cohen, Kasen, & Brook, 2006b), eating disorders (Johnson, Cohen, Kasen, & Brook, 2006a), or unipolar depression (Johnson, Cohen, Kasen, & Brook, 2005a). Longitudinal studies have also found evidence for the influence of Axis I disorders in adolescence on presence of PDs (Rey, Morris-Yates, Singh, Andrews, & Stewart, 1995) and higher PD dimensional scores in young adulthood (Lewinsohn, Rohde, Seeley, & Klein, 1997). The general point is that Axis I and II disorders are related, as opposed to being entirely distinct. These relations need to be

modeled and conceptualized in working toward a richer understanding of how personality phenomena are connected with the development of symptoms and syndromes that are more episodic.

## Etiology and Development

Biological and genetic factors play important roles in personality pathology. The relevant literature ranges from comprehensive theories linking neurobiological substrates to specific forms of personality dysfunction, to behavior and molecular genetic research on specific PD diagnoses and latent factors underlying personality disorder traits. Cultural and psychosocial factors also play a role in the etiology and development of personality pathology, and longitudinal studies provide evidence of certain childhood predictors of adolescent and adult PDs. We turn now to review these literatures.

### Biological and Genetic Basis of Personality Disorders

For decades, it was assumed that PDs were largely a result of psychosocial and environmental factors. The field of behavior genetics, which came to prominence in the latter half of the 20th century, changed many peoples' thinking by conclusively demonstrating a genetic basis to most forms of psychopathology, including PDs (e.g., Kendler et al., 2008).

The behavior genetic literature relies heavily on studies of twins. With advances in genotyping technology, however, many researchers are now moving toward molecular genetic studies of personality pathology. Unfortunately, molecular genetic work on personality has been stymied by poor replicability and small effect sizes (Krueger & Johnson, 2008). This situation is not unique to behavioral phenotypes and has also been observed with other disease phenotypes (e.g., Tuma, 2009).

With regard to the twin literature, there has been a wide range of estimates of genetic and environmental influences on the DSM PDs, varying by population sampled and the method of PD assessment used (see Livesley & Jang, 2008, for a recent review). Using a structured interview for the DSM-IV PDs, Torgersen and colleagues (2000) reported heritabilities ranging from 28% to 79%. Other research using structured interview assessments of PDs, found heritabilities at the lower end of the estimates that Torgersen and colleagues (2000) found for the cluster A and cluster C disorders (Kendler et al., 2006; Reichborn-Kjennerud et al., 2007).

Given the mixed results for DSM conceptualizations of PDs, researchers have turned to examine behavior genetic models of dimensional personality traits. As reviewed earlier, extensive overlap occurs between normal and pathological personality traits, to the point at which PD prototype descriptions have been created from normal models of personality (i.e., the FFM). The major dimensions of the FFM have consistently been shown to have heritabilities ranging from .4–.6 (Bouchard & Loehlin, 2001). And, indeed dimensional conceptualizations of pathological personality traits tend to have more consistent estimates in this range, for both more narrow, lower-order traits (Livesley, Jang, Jackson, & Vernon, 1993), as well as higher-order traits (Jang, Livesley, & Vernon, 1998). These data also support a hierarchical conceptualization of personality pathology, inasmuch as there is evidence for genetic influence on the higher-order broader factors (e.g., emotional dysregulation), as well as genetic influences specific to the lower-order traits, beyond influences on the higher-order factors (Livesley, Jang, & Vernon, 1998).

### Psychosocial and Cultural Factors

Although PDs and pathological traits are moderately heritable, environmental factors also influence the development of PDs. Childhood risk variables that have been linked to the diagnosis of PD include low socioeconomic status in the family of origin, single-parent family, parental death, and childhood physical health problems (Cohen, 2008). Findings from several longitudinal studies have also uncovered other predictors of PD development, including childhood verbal, physical, and sexual abuse as well as other forms of family stress and trauma (see Clark, 2005, for a recent review).

In general, the psychosocial risk factors for adult personality psychopathology fall into one of three categories: maladaptive experiences in the family of origin; traumatic experiences, including childhood abuse; and social and interpersonal stressors (Pars, 2001). Problematic parenting behaviors evidenced by age 16 in offspring have been linked to elevated risk for offspring PDs (particularly antisocial, avoidant, borderline, histrionic, paranoid, and schizotypal) at age 22 and age 33 (Johnson, Cohen, Chen, Kasen, & Brook, 2006). Maladaptive parenting (e.g., harsh punishment, low amount of time spent with child, low affection, loud arguments with spouse) has also been significantly associated with PDs during adolescence and late adulthood (Johnson, Cohen, Kasen, Smailes, & Brook, 2001a).

One of the most researched psychosocial predictors of adult personality pathology is childhood

abuse (Fossati, Madeddu, & Maffei, 1999; Grover et al., 2007). Childhood verbal abuse has been linked with presence of paranoid, narcissistic, borderline, and obsessive-compulsive PDs, and elevated symptom levels of borderline, narcissistic, paranoid, schizoid, schizotypal PDs (Johnson et al., 2001b), whereas Cluster A and Cluster B PDs were associated with physical and sexual abuse in adolescence and young adulthood (Cohen, Brown, & Smailes, 2001). Certainly the PD most strongly tied to child neglect and abuse is borderline PD (Zanarini, 2000). Data from the Collaborative Longitudinal PDs Study (CLPS) indicates that child maltreatment is in fact highly prevalent across all ten PDs; 34% of persons with a PD reported childhood sexual abuse, and 82% reported some type of childhood neglect (Battle et al., 2004). Borderline PD was the disorder most clearly linked with childhood maltreatment; obsessive-compulsive PD was also associated with sexual abuse, and individuals with antisocial PD showed elevated rates of verbal and sexual abuse.

With regard to cultural factors, given that the diagnosis of PD is dependent on dysfunction related to cultural norms—"an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture" (APA, 2000, p. 685)—it is possible that PDs may look different depending on the population studied. In general, the few studies to examine structural equivalence of PD pathology finds invariance across different cultures (Pukrop et al., 2001; Van Kampen, 2002; Zheng et al., 2002). Rigozzi et al. (2009) compared the structure of the International Personality Disorders Examination Screening Questionnaire (Loranger et al. 1994) in four French-speaking African subsamples and a subsample from Switzerland. They found that both a two-factor and four-factor solution replicated across the two cultures; further, the four-factor solution was similar to the four factors identified by Livesley (1998).

### Longitudinal Course and Related Impairment

The DSM (APA, 2000) definition of PDs includes the provision that these disorders are "stable and of long duration," "inflexible and pervasive," and usually present by adolescence. Reports from the Children in the Community Study (CIC), which has collected data on more than 800 individuals beginning in childhood, have shown that mean levels of PD symptoms are highest in adolescence; a decline occurs from age 9 to age 27, but general

symptoms are relatively stable across all assessment ages (Cohen, Crawford, Johnson, & Kasen, 2005). The authors suggest that declines in PD symptoms over adolescence may represent a normative improvement in the types of maladaptive behaviors underlying PDs (e.g., impulsivity, rule breaking), whereas the most impaired individuals show increasingly deviant behavior beginning in adulthood. In the CLPS study, participants with diagnosable PDs tend to vary even from month to month on meeting threshold criteria and show high rates of remission, although they were more stable than individuals meeting a major depressive disorder diagnosis (Skodol et al., 2005). Dimensional conceptualizations of PDs were more stable over time, with some symptom dimensions (e.g., affective instability in borderline PD) showing greater stability than others (e.g., self-injury). Zanarini and colleagues (2005) also found relatively high rates of remission for borderline PD (73.5% over the 6-year study), suggesting that the road to health is slower for borderline PD patients than for patients with major mood disorders, but noting that recurrence is much rarer. Thus, across these three studies using community and clinical samples, evidence demonstrates a notable decline in PDs from adolescence into early adulthood.

One of the most consistent findings from these longitudinal studies is the greater stability found for dimensional conceptualizations of PDs versus categorical diagnosis. That is, the correlational stability of PD symptom counts over time is higher (Shea et al., 2002) than the stability of PD diagnoses per se (see McDavid & Pilkonis, 1996, for a review). This is further support for a reconceptualization of personality pathology, and another reason why researchers have turned to normal models of personality, particularly the FFM, as an alternative to current PD categories (i.e., such models provide constructs with greater temporal stability). A recent meta-analysis of longitudinal studies of the FFM found relatively good consistency of the traits, with stability coefficients increasing from .31 in childhood to .54 during older adolescence/young adulthood, with a high point of .74 in the 50–70 year age range (Roberts & DelVecchio, 2000). Utilizing data from the CLPS study, Warner and colleagues (2004) examined whether the stability of PD symptoms was attributable to the stability of normal personality traits (i.e., FFM dimensions) underlying the disorders. For three of the four PDs (schizotypal, borderline, and avoidant), FFM traits predicted change in the disorders over time, but change in the disorders did not predict change in the FFM factors. These results

were consistent with the view that the same personality dimensions underlie both normal and pathological personality. Thus, PDs may in fact represent both biologically based temperaments and chronic and maladaptive behaviors that result as a function of interactions with the world (Clark, 2005).

Personality disorders are relatively common disorders that are related to personal distress and/or associated impairments that are not directly tied to a diagnostic criterion. Strong evidence now suggests that PDs impair functioning in multiple domains of life (Chen et al., 2006; Grant et al., 2004; Skodol et al., 2002; Skodol, Johnson, Cohen, Sneed, & Crawford, 2007), including strained family relationships (Johnson, Chen, & Cohen, 2004), poorly functioning marital relationships (South, Turkheimer, & Oltmanns, 2008), a greater likelihood of Axis I disorders (Johnson et al., 1999), and higher risk for violence and criminal behavior (Johnson et al., 2000). Using the Children in the Community sample, Chen et al. (2006) found that personality disorder diagnosis at age 22, particularly a Cluster B disorder, was associated with lower quality of life (i.e., a composite of physical health, psychological well-being, social relationships, role function, and contextual domain) at age 33, even after controlling for co-occurring Axis I disorders, demographics, and physical illness. In particular, the diagnosis of PDNOS appears to be strongly related to concurrent and future problems, including interpersonal difficulties, comorbid Axis I pathology, poor educational achievement, suicide attempts, and physical aggression (Johnson et al., 2005b).

## Assessment

Several important issues must be considered with regard to the assessment of PDs, regardless of whether these problems are viewed in terms of the DSM-IV categorical definitions or in terms of a dimensional approach to personality pathology. These include the choice of measurement tools (e.g., interviews versus questionnaires) and the selection of a source of relevant information (e.g., the self versus other people who know the person well).

### General Considerations

Disordered views of the self and others prevent many people with PDs from seeking help. When they do enter treatment, they may not describe their problems in a way that allows the therapist to recognize accurately the nature of their problems. Consider the example of paranoid personality disorder. Because they believe that all faults lie with others and not with the self, most paranoid individuals do not complain that they are unnecessarily suspicious, lacking in trust, or hypervigilant. Instead, they typically present with problems that reflect hostile and adversarial relationships with others. People who are narcissistic do not see themselves as being grandiose or entitled, but rather trace their problems to the failure of other people to appreciate their importance. People who meet the criteria for antisocial personality disorder often put a positive spin on their pathological personality traits and describe themselves as being adventuresome or fun-loving. Viewed from the perspective of the self, personality problems can easily be misconstrued or minimized.

An extended, comprehensive assessment process also requires a willingness to engage in an exchange of personal information that may be difficult for people with PDs to tolerate. Given their hypersensitivity to threat, direct confrontation may cause a paranoid person to become more guarded and less trusting of the therapist or to terminate therapy prematurely. People with antisocial personality disorder may view the process as an opportunity for manipulation and deception. Therefore, in discussing the information that is collected during the assessment process, the therapist must walk a fine line, balancing acceptance with objectivity.

The concept of social dysfunction plays an important role in the definition of PDs, as well as in their assessment. Subjective distress and social impairment provide a large part of the justification for defining these problems as mental disorders. If the personality characteristics identified in DSM-IV criterion sets typically interfere with a person's ability to get along with other people and perform social roles, they become more than just a collection of eccentric traits or peculiar habits. They can then be viewed as a form of harmful dysfunction (Kendell, 2002; Wakefield, 1999). In fact, most of the clusters of pathological personality traits that are described on Axis II do lead to impaired social functioning or occupational impairment (Oltmanns, Melley, Turkheimer, 2002; Skodol et al., 2007).

Unfortunately, the assessment of impairment in psychosocial functioning presents a difficult challenge for a number of reasons. One is that the criteria for social impairment have not been clearly defined (Ro & Clark, 2009). In some cases, specific criteria seem necessarily to imply interpersonal difficulties. For example, one criterion for obsessive-compulsive PD is: "excessively devoted to work and productivity to the exclusion of leisure activities and friendships." Other items require additional data gathering to

indicate whether the feature in question, if present, actually causes a problem in the person's life (e.g., "shows rigidity and stubbornness"). Patients who are being treated in a clinical setting necessarily seem to suffer from distress or social impairment, but the assessment of these problems may be more difficult with regard to people who are not seeking treatment.

Questions about the impact of PD features also require the demonstration of self-knowledge. If a person does acknowledge the presence of a certain characteristic such as rigidity, he or she still might deny that it has any detrimental influence on daily activities. Should we accept that statement at face value? Are there other sources of information that might be consulted? The vast majority of studies that have examined psychosocial functioning and PDs have relied exclusively on self-report questionnaires to measure impairment. One example is the Social Functioning Questionnaire, an eight-item measure of general social functioning, e.g., "I have difficulties in getting and keeping close relationships" (Tyrer, 1993). The correlation between the SFQ and the Beck Depression Inventory in one study of 577 college students was .63 (Oltmanns et al., 2002). Clearly, mood has an important impact on subjective responses regarding psychosocial functioning.

Developmental issues also create challenges for the assessment of PDs, particularly with regard to the formal diagnostic categories defined in DSM-IV. One involves an assumption about age of onset for PDs (Tackett, Balsis, Oltmanns, & Krueger, 2009). According to DSM-IV, to assign a PD diagnosis "its onset can be traced back at least to adolescence or early adulthood." The manual does not allow for the possibility of a late-onset PD (Widiger & Seidlitz, 2002). How is that information collected for an older adult? If a 60-year-old person currently exhibits a sufficient number of features to qualify for a specific PD diagnosis, the clinician would need to establish that these symptoms were also evident many years ago. Should we rely on the person's recollections of long-past experiences to verify the diagnosis, recognizing that autobiographical memories are often flawed? The most practical solution is to focus on the person's recent experience, recognizing that it is difficult to create a completely accurate portrait of past experience.

Another important developmental issue involves the possibility of age bias in the DSM-IV diagnostic criteria (Balsis, Gleason, Woods, & Oltmanns, 2007; Balsis, Woods, Gleason, & Oltmanns, 2007). Some older adults with significant personality pathology may remain undiagnosed and untreated because the features listed in the manual were not chosen with the social context and physical condition of older adults in mind. For example, one criterion for avoidant personality disorder is met if the person "avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection." This criterion would be of little value in the consideration of people who are retired from their jobs. Formal psychometric assessments conducted with people from various age groups have demonstrated that a substantial proportion of the DSM-IV criteria may be inappropriate for use with older adults (Agronin & Maletta, 2000). It remains to be determined whether alternative descriptors can be identified that would be more useful in identifying constructs related to personality pathology in older adults (Tackett et al., 2009).

### Assessment Instruments

The most widely recognized approach to the assessment of PDs, in both research and clinical practice, involves the use of interviews. Many different semistructured interviews have been developed for the diagnosis of PDs (Zimmerman, 1994). Examples include the Structured Interview for DSM-IV Personality (SIDP-IV; Pfohl, Blum, & Zimmerman, 1997) and the Personality Disorders Interview (PDI-IV; Widiger, Mangine, Corbitt, Ellis, & Thomas, 1995). Each of the interview schedules provides a list of opening questions on topics related to the diagnostic features, as well as suggested follow-up probes to be used whenever the person admits problems in a particular area. Clark and Harrison (2001) have described in detail the advantages and potential weaknesses of these instruments. Most efforts to evaluate empirically the utility of semistructured interviews have focused on the issue of reliability. Inter-rater reliability estimates in a joint interview format are higher (average $\kappa > .60$) than either short-interval test–retest or the long-interval test–retest. Reliability increases when PDs are computed using dimensional scores rather than categorical scores (Zimmerman & Coryell, 1989; Pilkonis, Heape, Proietti, & Clark, 1995). Less attention has been paid to the validity of diagnostic interviews in the assessment of PDs. Convergent validity (different interviews compared to each other or an interview compared to a self-report questionnaire) has been shown to be relatively poor (Clark, Livesley, & Morey, 1997). Clinicians should therefore consider the results of diagnostic interviews with some caution.

These instruments are considered to be the "gold standard" with regard to the diagnosis of PDs, but they depend largely on the ability or willingness of the person to recognize the nature of his or her problems.

Another popular approach to the assessment of PDs involves the administration of self-report questionnaires. Several different instruments are available. Some focus on symptoms of specific PDs, others focus on personality traits that are related to personality pathology. A final option is to collect information regarding interpersonal difficulties that follow as a consequence of PDs. Rather than focusing on diagnostic scales, with an emphasis on somewhat arbitrary thresholds and a categorical view regarding the presence or absence of specific PDs, some self-report instruments place greater emphasis on personality dimensions. Some of these focus exclusively on normal personality traits. One popular alternative of this type is the NEO-PI-R, a questionnaire that provides scores based on the FFM of personality (Costa & McCrea, 1989). Using this type of measure for the assessment of traits that are related to PDs, one might expect patterns of scores that have been shown to be associated with each of the different disorders (Lynam & Widiger, 2001; Miller, Pilkonis, & Clifton, 2005). For example, a person with antisocial personality disorder would be expected to produce scores that are high on some facets of neuroticism, such as angry hostility and impulsiveness, high on certain facets of extraversion, such as excitement seeking, low on certain facets of agreeableness, such as tendermindedness and straightforwardness, and low on certain facets of conscientiousness, such as self-discipline and dutifulness. A person who is pathologically dependent would also be expected to produce a high score on neuroticism (especially anxiousness and self-consciousness), as well as high scores on agreeableness (especially trust, compliance, and modesty). Many leading investigators favor this approach to the assessment of pathological personality characteristics (Samuel & Widiger, 2008; Widiger & Mullins-Sweatt, 2009).

The Schedule for Nonadaptive and Adaptive Personality (SNAP) is a factor analytically derived, self-report instrument that is designed to measure trait dimensions that are important in the domain of PDs (Clark, 1990; 1993; Simms & Clark, 2006). The instrument includes both obvious and more subtle items, which are intended to tap the high and low ends of all of the trait dimensions. The core of the SNAP is composed of 15 scales, including 12 trait scales associated with relatively specific forms of personality pathology and three more general "temperament"

scales (negative temperament, positive temperament, and disinhibition). For example, the specific trait scales most related to paranoia include mistrust, aggression, and detachment. The SNAP also includes five validity scales that can be used to identify subjects who have responded carelessly or defensively. They are also sensitive to various other response sets that might contribute to an invalid profile. In addition to the 15 trait scales, the SNAP can also be used to derive scores on 13 diagnostic scales, which correspond to each of the specific PD categories included in DSM-IV. The combination of validity scales, trait scales, and diagnostic scales makes the SNAP an especially useful instrument to be used in an assessment aimed at the identification of personality problems related to paranoia.

The fact that semistructured interviews and self-report questionnaires have traditionally been used in the assessment of PDs should not imply that they are the best sources of information. Like everyone else, people with PDs are frequently unable to view themselves realistically and are unaware of the effects of their behavior on others (Oltmanns, Turkheimer, & Strauss, 1998; Westen & Schedler, 1999). Because realistic, accurate information about a client's behavior may not be obtained from the client's own report, it is often useful to collect information from other sources. Family members, friends, and other acquaintances may provide an important perspective. Studies that have examined the relation between self-report data and informant report data regarding personality pathology have found that the two sources often disagree (Klonsky, Oltmanns, & Turkheimer, 2002; Oltmanns & Turkheimer, 2009; Thomas, Turkheimer, & Oltmanns, 2003).

Comparisons between self- and peer reports reveal an interesting paradox regarding PDs. Take paranoia as an example. People who are viewed by their peers as being paranoid do not see themselves as being suspicious or lacking in trust. Rather, they described themselves as being angry and hostile (Clifton, Turkheimer, & Oltmanns, 2004). Research has shown that those who had thought of themselves as being paranoid were often regarded by others as cold and unfeeling. Although it has not yet been determined how the two very different types of information should be used, it is fair to state that patient and informant evaluation represent two different assessment approaches to personality that produce two different portrayals of a client's PD. Perhaps utilizing information from both sources may help a clinician gain a more comprehensive picture of a client's personality disorder than if the

clinician were to rely solely on one source of information.

## Treatment for Personality Disorders

A variety of different therapies have been proposed and developed for the PDs. These treatments vary in their goals, strategies, techniques, and objectives. Many of the assumptions of treatment for PDs were based on putative distinctions from Axis I clinical disorders. Because PDs were thought to begin at an earlier age and remain chronically stable through the life course, many assumed they would be more difficult to treat than clinical disorders. Conversely, it was also assumed that treatment would necessarily be in the form of psychotherapy, not pharmacotherapy. These assumptions have now been challenged (see e.g., Krueger, 2005, for a review). For instance, clinical lore suggested that people with PDs were less motivated for treatment because these disorders are egosyntonic; recent research disputes this stereotype, finding that people with PDs are more motivated for treatment than patients without PD pathology (van Beek & Verheul, 2008).

It is often difficult to decide what measures will be used to qualify a treatment as "efficacious," because the criteria for PDs vary widely both within a diagnosis and between diagnoses of different PDs. Some interventions focus on specific behaviors associated with PDs (see Piper & Joyce, 2001, for a review). Dialectical behavior therapy (DBT), for instance, was originally designed to treat parasuidical behaviors and grew to encompass borderline PD (Linehan & Dexter-Mazza, 2008). Another complexity and limitation of intervention studies is the myriad outcome measures: Should treatment success be defined by absence of the PD diagnosis, symptom severity, general psychosocial functioning, or some other measure? According to these and other treatment outcome indicators, research now supports the efficacy of different manualized treatments for PDs. Most focus on one disorder (borderline), however, and the mechanism of action in most of these treatments is still uncertain. We focus here on manualized treatments supported by randomized clinical trials that are targeted at one or more of the ten DSM-IV PDs.

### *The Efficacy of Psychotherapy for Personality Disorders*

Contrary to the clinical lore that PDs are chronic syndromes not amenable to therapeutic intervention, research seems to be converging on the effectiveness of psychotherapy for the treatment of PDs (see Verheul & Herbrink, 2007, for a recent review). In a meta-analysis of the efficacy of therapeutic intervention for PDs, Perry, Banon, and Ianni (1999) found 15 studies that examined the outcome of short- or long-term psychotherapy for persons with PDs. They reported effect sizes of 1.11 and 1.29 for self-report and observer-rated outcome measures, respectively, of psychotherapy on PDs. Three of the fifteen studies included in the meta-analysis were randomized controlled treatment trials, and the average effect size for these three studies was .75. Further, the authors indicated that psychotherapy resulted in a recovery rate seven times greater than the natural recovery rate for borderline PD.

The different forms of psychotherapy that have been utilized for PDs can generally be grouped into four categories: psychodynamic/interpersonal, cognitive behavioral, supportive, and mixed (e.g., cognitive analytic therapy, a mixture of psychodynamic and cognitive behavioral; Ryle, 2001). These types of therapies can differ from other types grouped under the same general orientation. They also vary in duration, modality (group vs. individual vs. hospital-based), and focus. The forms that these interventions have taken when developed specifically for PD patients have, by and large, not been directed at any specific PD diagnosis per se. Certainly, borderline personality disorder is the most commonly studied disorder in the research literature, and DBT has become the industry standard for borderline PD. However, most PD treatments focus on the behaviors and skill deficits known to accompany one or more PDs (Piper & Joyce, 2001). These include relational patterns (Benjamin, 1993), maladaptive schemas (Beck et al., 1990), social skills deficits (Alden, 1989), or self-harming behaviors (Tyrer et al., 2003).

Several studies have examined the impact of one type of intervention for multiple PDs. Huband and colleagues (2007) examined the effectiveness of a social problem-solving therapy for PD patients in the community. Patients in the problem solving group ($N = 87$) attended psychoeducation sessions followed by 16 weekly group-based social problem-solving skills sessions. Compared to a waitlist control group, those in the intervention group had better problem-solving skills and lower overall anger expression. Abbass et al. (2008) investigated the efficacy and long-term effectiveness of intensive, short-term dynamic psychotherapy (ISTDP) for PDs. The goal of the ISTDP intervention was to develop awareness and expression of feelings and identify the psychic defenses that hinder exploration of early

trauma and broken attachments. The ISTDP group ($N = 14$) was compared to a waitlist control group ($N = 13$), who eventually received treatment as well. The most prevalent PDs in both groups were borderline and avoidant. The ISTDP group improved relative to the control group on multiple outcome measures at post-treatment, including ratings on the Brief Symptom Inventory and Inventory of Interpersonal Problems, clinician-rated global assessment of functioning, employment rate, and hours worked per week.

To determine whether different forms of psychotherapy may be more efficacious, Leichsenring and Leibing (2003) conducted a meta-analysis to compare psychodynamic and cognitive-behavioral therapy (CBT) for PDs. They found 14 psychodynamic studies and 11 studies of CBT that met inclusion criteria. Of the psychodynamic studies, three were randomized controlled designs, whereas four included randomized comparison of two types of treatment; five of the CBT studies used a randomized controlled design. The authors reported an overall effect size of 1.46 for psychodynamic therapies and 1.00 for CBT. Effect sizes remained significantly different from zero when including only self-report outcome measures or observational outcome measure. For psychodynamic studies, including only randomized controlled studies still resulted in a significant effect size, whereas the active therapy condition was more effective than control for three of the five randomized controlled cognitive therapy studies. The authors concluded that both psychodynamic and CBT are efficacious treatments for PDs, with no apparent differences in efficacy between the two forms of intervention. Of note, this review was unable to compare directly the efficacy of these two types of interventions in the treatment of specific PDs. Future research is certainly needed that compares specific forms of psychotherapeutic intervention for the ten different types of PDs, or the full range of abnormal trait constructs that may frame DSM-5.

To date, the PD treatment literature is limited in several respects. Certainly, there is a need for more randomized controlled treatment trials, as too many effectiveness studies rely on case-comparison methods. Many studies are also conducted without manualized therapy; future work should strive to follow a manual that is then made widely available for replication studies and for community therapists who wish to implement the intervention. It would also be easier to compare results across studies if there was greater unanimity in (a) assessment of impairment prior to and following treatment, (b) diagnostic tools for assessment of PDs, and (c) duration of follow-up period. Further, the research in this area should be extended to demonstrating that, in the long-run, psychotherapy for PDs is more cost-effective than no treatment at all (Bartak, Soeteman, Verheul, & Busschbach, 2007). In the era of managed health care, it is necessary to demonstrate that psychotherapy intervention will lower the disease-cost associated with PDs if it is to be widely implemented in community settings.

### Interventions for Borderline Personality Disorder

Borderline PD, because of its high costs in terms of treatment utilization (Bender, 2001; Zanarini, Frankenburg, Hennen, & Silk, 2004) and associated impairment, including suicide attempts (e.g. Oldham, 2006), has been the focus of most research into efficacious and effective PD interventions. The American Psychiatric Association's practice guideline recommends psychotherapy as the primary treatment modality for borderline PD, supplemented by pharmacotherapy if needed (APA, 2001). Dialectical behavior therapy (Linehan, 1993) has emerged as the standard treatment for borderline PD. Dialectical behavior therapy is a variation of CBT that also incorporates aspects of meditation and Eastern philosophy. Originally developed to treat women with suicidal and self-harming behaviors, it was extended to the treatment of patients with borderline PD. Randomized clinical trials have shown that DBT is more effective than treatment as usual (Linehan, Armstrong, Suarez, Allmon, & Heard, 1991) and therapy by community experts (Linehan et al., 2006). However, DBT was no more effect than community therapy at reducing the frequency of self-mutilating, suicidal, and impulsive behaviors (Linehan et al., 2006), one of the primary targets for intervention as stated in the goals of DBT. Verheul and colleagues (2003) found that borderline PD patients in a DBT treatment condition demonstrated less attrition from therapy than treatment as usual and a reduction in self-mutilating and impulsive behaviors, but not suicidal behaviors. Other limitations of DBT include questions about its generalizability to nonclinical populations and the long-term stability of treatment gains, in addition to the drawbacks of such a time- and resource-intensive intervention (Paris, 2008).

Cognitive-behavioral therapy has also received empirical support in the treatment of borderline PD (Binks, 2006). The treatment focus of CBT, for PDs

and other forms of psychopathology, is on maladaptive cognitive schemas which, in combination with affective, motivational, and social processes, determine behavior (Beck, Freeman, Davis, & Associates, 2004). For borderline PD in particular, CBT focuses on cognitive schemas of vulnerability and poor sense of self. Davidson and colleagues (2006) randomized 106 borderline PD patients to treatment as usual (TAU) or CBT plus TAU, with patients attending an average of 16 CBT sessions. Cognitive-behavioral therapy plus TAU resulted in fewer suicidal acts, a reduction in positive symptom distress index, and a decrease in dysfunctional core believes and state anxiety (Davidson, 2006). Blum et al. (2008) reported on the outcome of patients who completed the Systems Training for Emotional Predictability and Problem Solving (STEPPS) program, an adjunct to a patient's ongoing treatment. STEPPS is an outpatient, group-based treatment that includes cognitive-behavioral elements, skills training, and an educational component for primary mental health-care professionals and friends or family members of the patient. Patients in the STEPPS plus TAU group improved markedly over a comparison group of individuals receiving only TAU, according to several outcome measures (e.g., rating scale of borderline symptoms, global assessment of functioning, negative affectivity, Beck Depression Inventory, and social adjustment). Other CBT therapies that have shown improvement for borderline PD patients include a brief treatment (Weinberg, 2006) and schema-focused therapy, a hybrid of CBT and psychodynamic therapy (Giesen-Bloo, 2006).

Given that many PDs were initially identified by clinicians who were working in a psychodynamic conceptual framework, there has long been an interest in applying psychodynamic interventions to the treatment of PD patients. With the recent advent of manualized psychodynamic treatments, it has been possible to test the efficacy of this approach. One form of psychodynamic treatment, mentalization-based therapy (MBT), is incorporated into a partial hospital program and attempts to teach PD patients to observe and identify how their behaviors and the behaviors of others are linked to emotions and desires (Bateman, & Fonagy, 2006). Mentalization-based therapy has now been supported for the treatment of borderline PD (Bateman & Fonagy, 1999, 2001), although it has only been implemented in a hospital setting to this point. Another psychodynamically oriented therapy, transference-focused psychotherapy (TFP), uses the patient–therapist relationship to correct dysfunctional emotion regulation skills.

Clarkin and colleagues (2007) compared DBT, transference-focused psychotherapy, and a dynamic support treatment among 90 participants diagnosed with borderline PD. All three types of treatment were associated with improvement in multiple domains (e.g., suicidality, social adjustment, irritability, anger) over a 1-year time period. Of the three, TFP showed improvement in the greatest number of outcome variables.

### Pharmacotherapy for Personality Disorders

As with psychotherapeutic interventions, most of the pharmacotherapies for PDs have focused on borderline PD. It is quite common for borderline PD patients to take multiple medications concurrently (Zanarini et al. 2004). A variety of different classes of drugs have been used, including neuroleptics, selective serotonin reuptake inhibitors (SSRIs), and mood stabilizers (Paris, 2008; Zanarini, 2004). In general, these pharmacological agents are relatively efficacious at reducing overall psychopathology, as well as anger and impulsivity, in patients with borderline PD. The lack of effectiveness for mood stabilizers in reducing the emotional dysregulation seen in borderline PD patients (but see Zanarini & Frankenburg, 2003, for a possible exception) suggests that the type of affective instability in these patients is quite different from that seen in patients with bipolar disorder (Paris, 2008).

### Comorbid Personality Disorders and Axis I Disorders

Any discussion of treatment for PDs must also acknowledge the role that comorbidity plays in course and treatment of both Axis I and Axis II disorders. The rise in research on PDs following their move to Axis II in DSM-III (APA, 1980) exposed the high rates of comorbidity between PDs and Axis I clinical disorders; that is, the fact that one or more PDs are diagnosed in individuals with a clinical disorder at rates higher than would be expected by chance (see Verheul, Ball, & van den Brink, 1998). For instance, it is estimated that 20%–50% of inpatients and 50%–85% of outpatients with a current diagnosis of major depression also meet criteria for a PD (Corruble, Ginestet, & Guelfi, 1996). Comorbidity has many implications for the natural course, recovery, and treatment of psychopathology. Comorbid borderline PD and post-traumatic stress disorder (PTSD) is associated with increased risk for hospitalization and higher levels of dysfunction (Zlotnick et al., 2003). The presence of a PD diagnosis can also impair recovery and remission from

an Axis I disorders. Viinamaki and colleagues (2003) compared patients' comorbidity for Cluster C and major depression ($N$ = 30) with major depression-only patients ($N$ = 60) over a 24-month follow-up period. The comorbid group was more likely to have a diagnosis of major depression at follow-up and less likely to have recovered.

For many years, it was a widely heralded truism that PDs affect the treatment of Axis I clinical disorders (Pilkonis, 2001; Reich, 2003b). However, more recent research suggests that PDs may not be as detrimental to treatment for Axis I clinical syndromes as previously thought. The most studied Axis I disorders in terms of comorbid PD and effects on intervention are depression, anxiety, and substance abuse/dependence. The evidence regarding the impact of comorbid PD pathology on treatment for depression is mixed. Research shows that cognitive treatment for depression is less effective for individuals with comorbid PDs than for individuals without PD pathology (Fournier et al., 2008; Newton-Howes, Tryer, & Johnson, 2006; Reich, 2003a). Patients with comorbid depression and Cluster C PDs show less improvement in response to treatment (Hardy et al., 1995), delayed recovery (Patience, McGuire, Scott, & Freeman, 1995), and quicker time to relapse (Ilardi, Craighead, & Evans, 1997). However, two recent meta-analyses showed only mixed support, at best, for the negative effect of PDs on depression outcome (Kool et al., 2005; Mulder, 2002). Further, a recent study found no impact of personality traits commonly associated with PDs (e.g., neuroticism; Blom et al., 2007) on interpersonal psychotherapy (IPT) for depression, whereas another study found that both personality traits (e.g., harm avoidance) and diagnosed PDs adversely impacted IPT but not CBT for depression (Joyce et al., 2007).

The impact of PDs on treatment for anxiety disorders also appears mixed. Cluster C PDs are related to poor treatment outcome in those comorbid for obsessive-compulsive symptoms (Cavedini, Erzegovesi, Ronchi, & Bellodi, 1997). Research also shows that borderline PD appears to impact treatment for people with PTSD (Feeny, Zoellner, & Foa, 2002) or depression (Goodman, Hull, Clarkin, & Yeomans, 1998; Meyer, Pilkonis, Proietti, Heape, & Egan, 2001). However, Feeny et al. (2002) found that patients with comorbid chronic PTSD and borderline PD did not differ in psychopathology, PTSD severity, social functioning, or diagnostic status from chronic PTSD-only patients following CBT for chronic PTSD. Moreover, patients with comorbid borderline PD improved to the same degree as non-comorbid PTSD patients even when treated in community settings, as opposed to CBT experts (Hembree, Cahill, & Foa, 2004). Based on a review and synthesis of the available literature at that time, Dreessen and Arntz (1998) concluded "there is no robust negative impact of personality disorders" on treatment of Axis I anxiety disorders (p. 493).

Finally, the impact of PDs on intervention for substance abuse and dependence has also been widely investigated. Personality disorders, particularly antisocial and borderline PDs, are highly prevalent among individuals with a substance abuse diagnosis (Sher & Trull, 1994; Trull, Sher, Minks-Brown, Durbin, & Burr, 2000; Trull et al., 2004). The presence of a comorbid PD in addition to a substance abuse disorder is also associated with myriad negative outcomes, including more pronounced abuse, greater psychiatric dysfunction, greater susceptibility to relapse, and increased risk for suicide and hospitalization (for a review, see Ball, 2005). One recent study found that individuals with comorbid substance use disorders and antisocial PD had higher levels of substance use symptom severity and related dysfunction (e.g., legal problems, family conflicts) than individuals with a substance use disorder and no comorbid antisocial PD (Westermeyer & Thuras, 2005). However, empirical research negates clinical lore, which suggests that individuals with a dual diagnosis of substance use and antisocial personality disorder have poorer outcomes (Brooner, Kidorf, King, & Stoller, 1998; Cacciola, Rutherford, Alterman, McKay, & Snider, 1996). In fact, patients with a diagnosis of alcohol abuse comorbid with antisocial PD responded to an abstinence-focused cognitive behavioral treatment as well as alcohol abuse-only patients (Longabaugh et al., 1994). A modified version of DBT has also been found to be efficacious in the treatment of patients with borderline PD comorbid with substance use disorder (Linehan et al., 1999).

Thus, although support exists for the negative effect of a PD diagnosis on the treatment for Axis I clinical disorders, there is also evidence failing to support this effect. It may be that the level of severity of personality pathology, as represented by number of diagnosable PDs, is a better indicator of treatment outcome than presence of a PD per se (Ogrodniczuk, Piper, Joyce, & McCallum, 2001). There is also evidence that, although patients with comorbid depression and PD pathology do not respond well to psychotherapy, they do respond to pharmacotherapy (Fournier et al., 2008; Newton-Howes et al., 2006).

## Conclusion
### *Future Directions: Expanded Research Agenda for Complex Cases*

Therapy for PDs is a challenging area of research, given the complex and multifaceted nature of these conditions. These are inherently heterogeneous disorders that may require flexible therapies that can be adapted to the myriad symptom presentations and related dysfunctions of persons with PDs. Much is still unknown about whether there is one "best" type of psychotherapy for any or all PDs. Some types of therapy have largely focused on one PD (e.g., DBT for borderline), whereas several PDs (e.g., Cluster C PDs) have been largely neglected in the research literature. If any one type of psychotherapy is to be refined and adapted for use with all PDs, it will be important to identify the core dysfunction that may lie at the heart of all PDs (Krueger, Skodol, Livesley, Shrout, & Huang, 2007); thus, a treatment that presumes to affect PDs in general might focus on the interpersonal difficulties that underlie all PDs.

Another option is to combine the principles and techniques of various treatments to form an integrated intervention best suited to the individual client. This may be the best option for adaptive treatments both across and within therapy patients. Certainly, different types of treatment may be necessary over the course of the disorder. Research shows that the symptoms of borderline PD that remit first are more acute symptoms (e.g., self-mutilation, quasi-psychotic thought), whereas temperament symptoms (e.g., chronic/major depression, intolerance of aloneness) are slower to remit over time (Zanarini et al., 2007). The success of treatments like DBT is their focus on abating the acute phase of borderline PD; future research may attempt to develop interventions on chronic symptoms that are more stable and enduring.

Adding one more layer of complexity to the treatment of PDs is the difficulty of comorbidity with Axis I clinical syndromes. Many controlled studies of the efficacy of psychotherapy for PDs exclude individuals with comorbid substance abuse problems. As noted, a great deal of comorbidity exists between Axis I and Axis II disorders (Dolan-Sewell et al., 2001), but only a handful of treatments that have been developed to focus on both at the same time. For instance, Ball (1998) developed dual-focus schema therapy (DFST), a manualized cognitive-behavioral intervention that focuses on relapse prevention and targeted interventions for maladaptive schemas and associated coping styles, specifically for substance-dependent patients with a comorbid PD. Whether using DFST or a combination of eclectic techniques, a therapist will need an overarching framework that provides guidelines for how to treat the complexities of cases with multiple Axis I and Axis II pathologies and related interpersonal and social difficulties. Livesley (2008) suggests a five-step process: safety, containment, control and regulation, exploration and change, and integration and synthesis. Thus, the therapist works with the patient to move from areas of crisis-management toward emotional regulation and finally a focus on establishing a stable and adaptive sense of self.

Reconceptualizing these entities in terms of dimensional spectrums of psychopathological variation may be helpful in clarifying these patterns. For example, a personality style with high neuroticism predisposes to a range of mood and anxiety (internalizing) disorders. Some presentations consistent with the idea of PD being present might then be understood as persons with unusually high levels of neuroticism, and hence, more severe personality pathology as well as more severe and more diverse internalizing problems. The magnitude of intervention needed to achieve symptom amelioration would then also be conceptualized dimensionally, as related to the overall extent of internalizing psychopathology. The question from this perspective is not, "What should we do when we treat a patient with a specific anxiety disorder and a specific PD?" Rather, the question is, "What kinds or intensities of intervention are appropriate for patients ranging in severity along an internalizing spectrum of problems?" For example, what intervention is appropriate for the mildly neurotic individual with a current depressive episode (lower in the spectrum)? How does this differ from the patient with extreme neuroticism, profound interpersonal difficulties likely attributable to neurotic worries (cf. avoidant PD in the current system), and various comorbid and often intense mood and anxiety symptoms that also wax and wane over time? Thinking more dimensionally about psychopathology opens up these novel possibilities for conceptualizing intervention strategies focused more on the complete history and current symptom picture, rather than trying to parse those phenomena in terms of categories of psychopathology that are known to have somewhat arbitrary and often overlapping boundaries.

V. Mark Durand

**Abstract**

Disorders of development include a range of disorders first evidenced in childhood. Although most disorders have their origins in childhood, a few fully express themselves before early adulthood. This chapter describes the nature, assessment, and treatment of the more common disorders that are revealed in a clinically significant way during a child's developing years. The disorders of development affect a range of functioning from single skills deficits to more pervasive problems that negatively impact a child's ability to function. Included is coverage of several disorders usually diagnosed first in infancy, childhood, or adolescence, including the neurodevelopmental disorders (e.g., attention-deficit/hyperactivity disorder, autism spectrum disorder, communication disorders, intellectual disability, and specific learning disorder) and the disruptive, impulse control, and conduct disorders (e.g., oppositional defiant disorder, conduct disorder). Recommendations for future research on the potential for advancing knowledge regarding spectrums within some of these disorders as well as recommendations for treatment are outlined.

**Key Words:** Attention-deficit/hyperactivity disorder, autism spectrum disorder, conduct disorder, specific learning disorder, oppositional defiant disorder

Almost all psychological disorders are disorders of development in the sense that they change over time. Most disorders originate in childhood, although the full presentation of the problem may not manifest itself until much later. This chapter reviews the more common disorders that are revealed in a clinically significant way during a child's developing years and are of concern to families and educators. The disorders of development affect a range of functioning from narrow skills deficits (e.g., specific learning disorder) to more pervasive problems that negatively impact a child's ability to function (e.g., autism spectrum disorder). This chapter includes coverage of several disorders usually diagnosed first in infancy, childhood, or adolescence. The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) introduced general categories of these disorders,

including the neurodevelopmental disorders (e.g., attention-deficit/hyperactivity disorder, autism spectrum disorder, communication disorders, intellectual disability and specific learning disorder) and the disruptive, impulse control, and conduct disorders (e.g., oppositional defiant disorder, conduct disorder) (American Psychiatric Association, 2013).

## Spectrum Disorders

The disorders described in this chapter represent a broad range of problems first evident in childhood. Some of the disorders discussed may be considered part of a spectrum of disorders—a group of disorders that are thought to be related through the sharing of risk genes or pathophysiological mechanisms (Hyman, 2007). For instance, some of what was previously considered "the pervasive developmental disorders" (e.g., autistic disorder, Asperger's

disorder, childhood disintegrative disorder) are now included together under the diagnosis of autism spectrum disorder (ASD) (Durand, 2014). This is an explicit recognition that these disorders share common social communication deficits and repetitive and restricted behaviors, and they may represent one underlying condition. There is considerable comorbidity among attention-deficit/hyperactivity disorder (ADHD), conduct disorder (CD), and oppositional defiant disorder (ODD), although any conclusion about their being part of a spectrum of disorders is premature (Shaffer, Leibenluft, Rohde, Sirovatka, & Regier, 2009). Where appropriate, research on comorbidity and the progress being made on identifying possible spectrum disorders is reviewed.

## Neurodevelopmental Disorders
### Attention-deficit/Hyperactivity Disorder

The primary characteristics of ADHD include a pattern of inattention and/or of hyperactivity and impulsivity. These deficits can significantly disrupt academic efforts, as well as social relationships. ADHD is one of the most common reasons children are referred for mental health services in the United States (Cuffe, Moore, & McKeown, 2009).

#### CLINICAL DESCRIPTION

The DSM-5 differentiates two types of symptoms for ADHD. The first includes problems of *inattention.* People may appear not to listen to others; they may lose necessary school assignments, books, or tools; and they may not pay enough attention to details and make careless mistakes. The second type of symptom includes *hyperactivity and impulsivity*, which includes fidgeting, having trouble sitting for any length of time, always being on the go, blurting out answers before questions have been completed, and having trouble waiting turns. Either the first (inattention) or the second (hyperactivity and impulsivity) domains of symptoms must be present for someone to be diagnosed with ADHD (Sibley, Waxmonsky, Robb, & Pelham, 2013).

Inattention, hyperactivity, and impulsivity often lead to other problems that appear secondary to ADHD. Academic performance tends to suffer, especially as the child progresses in school. The cause of this poor performance is not known. It could be a result of the problems with attention and impulsivity characteristic of ADHD, and in some children this can be made worse by factors such as concurrent learning disabilities, which are common in boys with ADHD (DuPaul & Volpe, 2009).

Children with ADHD are likely to be unpopular and rejected by their peers (McQuade et al., 2012). Here, the difficulty appears to be directly related to the behaviors symptomatic of ADHD. For example, one study found that young girls with ADHD in general were likely to be rejected by peers but that this likelihood was more pronounced in those with hyperactivity, impulsivity, and inattention when compared to girls who had only the inattentive type (Hinshaw, 2002). Evidence suggests that some children with ADHD (who are not also depressed) actually have an inflated sense of their own competence in areas such as social acceptance, physical appearance, and self-worth (McQuade et al., 2012).

#### EPIDEMIOLOGY

Attention-deficit/hyperactivity disorder is estimated to occur in 3%–7% of school-age children in the United States, and an international analysis of prevalence suggests that the disorder is found in about 5.2% of the child populations across all regions of the world (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007). This finding of comparable international rates of ADHD is important because debates continue about the validity of ADHD as a disorder. Previously, there were historic differences in the number of people diagnosed with this disorder, with children in the United States being more likely to receive the label of ADHD. Based on this difference, some argue that ADHD in children is simply a cultural construct (Timimi & Taylor, 2004). However, with improvements in diagnosis, countries that previously reported lower rates of ADHD are now finding similar numbers of these children being brought to the attention of helping professionals (Barkley, 2006c).

Prevalence estimates suggest gender differences, with boys three times more likely to be diagnosed with ADHD than girls, and this discrepancy increases among clinic referrals (Spencer, Biederman, & Mick, 2007). The reason for this gender difference is largely unknown. It may be that adults are more tolerant of hyperactivity among girls, who tend to be less active than boys with ADHD. Boys tend to be more aggressive, which will more likely result in attention by mental health professionals (Barkley, 2006c). Girls with ADHD, on the other hand, tend to display more internalizing behaviors—specifically, anxiety and depression (Barkley, 2006c).

Children with ADHD are first identified as different from their peers around age 3 or 4; their parents describe them as active, mischievous, slow

to toilet train, and oppositional (Jones, Daley, Hutchings, Bywater, & Eames, 2007). The symptoms of inattention, impulsivity, and hyperactivity become increasingly obvious during the school years. It is estimated that about half of the children with ADHD have ongoing difficulties through adulthood (McGough, 2005). Over time, children with ADHD seem to be less impulsive, although inattention persists. During adolescence, the impulsivity manifests itself in different areas; for example, they are at greater risk for obesity, teen pregnancy, and contracting sexually transmitted diseases. They are also more likely to have driving difficulties, such as crashes; to be cited for speeding; and to have their licenses suspended (Nigg, 2013). Although the manifestations of ADHD change as people age, many of their problems persist (Weyandt & DuPaul, 2006).

Evidence for a spectrum of disorders—including ADHD—awaits empirical evidence. Up to 80% of children with ADHD are diagnosed with one or more other disorders (Wilens et al., 2002). Common comorbid disorders in children include anxiety, depression, and disruptive behavior (Barkley, 2006a). Similarly, almost 90% of adults with ADHD are likely to have at least one other disorder, including disruptive behavior, depression, anxiety, and substance use disorders (McGough, 2005).

Several other DSM-5 disorders, also found in children, appear to overlap significantly with this disorder. Specifically, ODD, CD, and bipolar disorder all have characteristics seen in children with ADHD (Shaffer et al., 2009). The impulsivity and hyperactivity observed in children with ADHD can manifest themselves in some of these symptoms. It has been estimated that at least half of those with ADHD could also be diagnosed with ODD (Barkley, 2006b).

## ETIOLOGY

Attention-deficit/hyperactivity disorder is considered to be highly influenced by genetics, with a relatively small role played by environmental influences in the cause of the disorder when compared to many other psychological disorders (Nigg, 2012). The relatives of children with ADHD have been found to be more likely to have ADHD themselves than would be expected in the general population (Biederman et al., 1992). These families display an increase in psychopathology in general, including conduct disorder, mood disorders, anxiety disorders, and substance abuse (Faraone et al., 2000).

This research and the comorbidity in the children themselves suggest that some shared genetic deficits may contribute to the problems experienced by individuals with these disorders (Freitag et al., 2012).

More than one gene is probably responsible for ADHD (Bobb, Castellanos, Addington, & Rapoport, 2006), with attention focusing on genes associated with the neurochemical dopamine, although norepinephrine, serotonin, and γ-aminobutyric acid (GABA) are also implicated in the cause of ADHD. More specifically, there is strong evidence that ADHD is associated with the dopamine $D_4$ receptor gene, the dopamine transporter gene (DAT1), and the dopamine $D_5$ receptor gene. DAT1 is of particular interest because methylphenidate (Ritalin)—one of the most common medical treatments for ADHD—inhibits this gene and increases the amount of dopamine available (Contini et al., 2013).

Researchers are looking for endophenotypes, those basic deficits—such as specific attentional problems—characteristic of ADHD. Specific areas of current interest for ADHD are the brain's executive attention system, working memory functions, inattentiveness, and impulsivity. Research is now focused on tying specific genetic defects to these cognitive processes to make the link between genes and behavior (del Campo, Müller, & Sahakian, 2012; Rommelse et al., 2009).

The strong genetic influence in ADHD does not rule out any role for the environment (Sharp et al., 2003; Waldman & Gizer, 2006). In one of the first gene–environment interaction studies of ADHD, researchers found that children with a specific mutation involving the dopamine system (DAT1 genotype) were more likely to exhibit the symptoms of ADHD if their mothers smoked during pregnancy (Kahn, Khoury, Nichols, & Lanphear, 2003). Prenatal smoking seemed to interact with this genetic predisposition to increase the risk for hyperactive and impulsive behavior, although subsequent research shows mixed results (Ficks & Waldman, 2009).

Research on the neuroanatomy of ADHD suggests that the overall volume of the brain in those with this disorder is slightly smaller (3%–4%) than in children without this disorder. A number of areas in the brains of those with ADHD appear affected (Valera, Faraone, Murray, & Seidman, 2007), although a consistent finding is decreased volume of right caudate nucleus in ADHD (Soliva, 2011).

A variety of such toxins as lead, allergens, and food additives have been considered as possible

causes of ADHD over the years. Some work suggests that exposure to lead, for example, can increase the risk of developing symptoms of ADHD (Goodlad, Marcus, & Fulton, 2013). The theory that food additives such as artificial colors, flavorings, and preservatives are responsible for the symptoms of ADHD remains controversial. Initial studies suggested that these substances have little or no effect on the symptoms of ADHD (Barkley, 1990; Kavale & Forness, 1983). However, more recent work suggests that restricting these chemicals in a child's diet may have a positive impact on up to 33% of children with ADHD, although these positive results are strongest when data come from parent reports as opposed to those of teachers (Nigg, Lewis, Edinger, & Falk, 2012).

Negative responses by parents, teachers, and peers to the affected child's impulsivity and hyperactivity may contribute to feelings of low self-esteem among children who are also depressed (Barkley, 2006c). Years of constant reminders by teachers and parents to behave, sit quietly, and pay attention may contribute to a negative self-image in these children, which, in turn, can negatively affect their ability to make friends. Thus, the possible biological influences on impulsivity, hyperactivity, and attention, combined with attempts to control these children, may lead to rejection and consequent poor self-image. An integration of the biological and psychological influences on ADHD suggests that both need to be addressed when designing effective treatments (Rapport, 2001).

### ASSESSMENT AND TREATMENT

Evaluation of ADHD focuses on a number of areas, including an assessment of current social and academic concerns and differential diagnosis. Information from parents is important in assessing the child's behavior outside of school and how the family and school have collaborated on the problems (Weyandt & DuPaul, 2013). Findings from measures such as the ADHD rating scale-IV (DuPaul, Power, Anastopoulos, & Reid, 1998), the DSM-IV ADHD rating scale (Gomez, Harvey, Quick, Scharer, & Harris, 1999), the disruptive behavior rating scale (Barkley & Murphy, 1998), or the Conners Parent Rating Scale (Conners, Sitarenios, Parker, & Epstein, 1998) provide more objective assessment of functioning that can be used to assess norms and to monitor treatment.

In addition, assessment extends to the functioning of the family and community resources, since parental behavior training and school intervention are often recommended. The use of assessment tools varies considerably across professionals, in part because assessors come from different disciplinary backgrounds (e.g., counseling, clinical or school psychology) and they work in varied settings (e.g., school, clinic, or university settings) (Handler & DuPaul, 2005).

Treatment for ADHD has proceeded on two fronts: biological and psychosocial interventions. Typically, the goal of biological treatments is to reduce the child's impulsivity and hyperactivity and to improve attention skills. Psychosocial treatments generally focus on broader issues such as improving academic performance, decreasing disruptive behavior, and improving social skills.

Since the use of stimulant medication with children with ADHD was first described (W. Bradley, 1937), hundreds of studies have documented the effectiveness of this class of medication in reducing the core symptoms of the disorder. It is estimated that 3.5% children in the United States are being treated with these medications (Zuvekas & Vitiello, 2012). Drugs such as methylphenidate (Ritalin, Metadate, Concerta) and D-amphetamine (Dexedrine, Dextrostat) have proved helpful for more than 70% of cases in at least temporarily reducing hyperactivity and impulsivity and improving concentration on tasks (Connor, 2006). Adderall, which is a longer acting version of these psychostimulants, reduces the need for multiple doses for children during the day but has similar positive effects (Connor, 2006).

A newer drug—Strattera (or atomoxetine)—also appears effective for some children with ADHD, but it is a selective norepinephrine-reuptake inhibitor and therefore does not produce the same "highs" when used in larger doses—a recent concern due to the abuse of prescription drugs among teens. Research suggests that other drugs, such as one of the antidepressants (bupropion, imipramine) and a drug used for treating high blood pressure (clonidine), may have similar effects on people with ADHD (Spencer, 2006). All these drugs seem to improve compliance and decrease negative behaviors in many children, although their effects do not usually last once the drugs are discontinued.

Some portion of children with ADHD do not respond to medications, and most children who do respond show improvement in ability to focus their attention but do not show gains in the important areas of academics and social skills (Smith, Barkley, & Shapiro, 2006). In addition, the medications often result in negative side effects, such as insomnia,

drowsiness, irritability, and potential cardiovascular problems (Kornfield et al., 2013). Because of these findings, researchers have applied various behavioral interventions to help these children at home and in school. In general, the programs set such goals as increasing the amount of time the child remains seated, improving academic performance, or engaging in appropriate play with peers. Other programs incorporate parent training to teach families how to respond constructively to their child's behaviors and how to structure the child's day to help prevent difficulties (Power et al., 2012). Social skills training for these children, which includes teaching them how to interact appropriately with their peers, also seems to be an important treatment component (de Boo & Prins, 2007). For adults with ADHD, cognitive-behavioral intervention for the distractibility and organizational skills problems appears quite helpful. Most clinicians typically recommend a combination of approaches designed to individualize treatments for those with ADHD, targeting both short-term management issues (decreasing hyperactivity and impulsivity) and long-term concerns (preventing and reversing academic decline and improving social skills).

To determine whether a combined approach to treatment is the most effective, a large-scale study initiated by the National Institute of Mental Health was conducted by six teams of researchers (Jensen et al., 2001). The Multimodal Treatment of Attention-Deficit Hyperactivity Disorder (MTA) study included 579 children who were randomly assigned to one of four groups. One group of the children received routine care without medication or specific behavioral interventions (community care). The three treatment groups consisted of medication management (usually methylphenidate), intensive behavioral treatment, and a combination of the two treatments. The study lasted 14 months. Initial reports from the study suggested that the combination of behavioral treatments and medication, and medication alone, were superior to behavioral treatment alone and community intervention for ADHD symptoms. For problems that went beyond the specific symptoms of ADHD, such as social skills, academics, parent–child relations, oppositional behavior, and anxiety or depression, results suggested slight advantages of combination over single treatments (medication management, behavioral treatment) and community care.

Some controversy surrounds the interpretation of these findings—specifically, whether the combination of behavioral and medical treatments is superior to medication alone (Biederman, Spencer, Wilens, & Greene, 2001; Pelham Jr., 1999). One of the concerns surrounding the study was that, although medication continued to be dispensed, the behavioral treatment was faded over time, which may account for the observed differences. And there is growing evidence that behavioral interventions alone can significantly improve ADHD symptoms (Fabiano et al., 2009). Overall, research suggests that many individuals can benefit from a combination of therapies (Shaw et al., 2012).

### Specific Learning Disorder

This section describes learning disorders in reading, mathematics, and written expression—all characterized by performance that is substantially below what would be expected given the person's age, intelligence quotient (IQ) score, and education. Also briefly reviewed are disorders related to communication.

### Clinical Description

According to DSM-5 criteria, a specific learning disorder is defined as a substantial discrepancy between a person's academic achievement and what would be expected for someone of the same age—referred to by some as "unexpected underachievement" (J. M. Fletcher, Lyon, Fuchs, & Barnes, 2007; Scanlon, 2013). DSM-IV-TR listed specific disorders in reading, mathematics, and written expression as separate disorders, but because of the significant overlap in these disabilities they are now combined to assist clinicians in taking a broader view of the individual's learning styles (Scanlon, 2013). A specific learning disorder is usually defined as a discrepancy of more than 2 standard deviations between achievement and IQ (American Psychiatric Association, 2013). In addition, this disability cannot be caused by a sensory difficulty, such as trouble with sight or hearing, and should not be the result of poor or absent instruction. Finally, the difficulties should be sufficient to interfere with the students' academic achievement and to disrupt their daily activities. As with other disorders, clinicians rate the disorder on levels of severity.

### Epidemiology

Estimates of the prevalence of learning disorders range from 5% to 10% (Swanson, Harris, & Graham, 2013). It is currently believed that nearly 6 million children in the United States are diagnosed as having a specific learning disorder (Altarac & Saroha, 2007). There do appear to be

racial differences in the diagnosis of learning disorders, with approximately 1% of White children and 2.6% of Black children receiving services for problems with learning in 2001 (R. Bradley, Danielson, & Hallahan, 2002). This research suggests that the differences were related to the economic status of the child but not ethnic background.

Difficulties with reading are the most common of the learning disorders and occur in some form in 4%–10% of the general population (R. Tannock, 2005b). Mathematics difficulties appear in approximately 1% of the population (R. Tannock, 2005a), but there is limited information about the prevalence of disorder of written expression among children and adults. Early studies suggested that boys were more likely to have a reading disorder than girls, although more contemporary research indicates that boys and girls may be equally affected by this disorder (Feinstein & Phillips, 2006). Students with learning disorders are more likely to drop out of school (Vogel & Reder, 1998), more likely to be unemployed (Shapiro & Lentz, 1991), and more likely to have suicidal thoughts and attempt suicide (Daniel et al., 2006).

A group of disorders loosely identified as *communication disorders* seems closely related to learning disorders (American Psychiatric Association, 2013). These disorders can appear deceptively benign, yet their presence early in life can cause wide-ranging problems later. For a brief overview of these disorders, which include childhood-onset fluency disorder (previously called stuttering) and language disorder (which combines DSM-IV-TR expressive and mixed receptive-expressive language disorders), see Table 25.1.

### Etiology

Theories about the causes of learning disorders include genetic, neurobiological, and environmental factors. The genetic research in this area is

**Table 25.1  Communication disorders**

**Childhood-Onset Fluency Disorder**

| Clinical description | Statistics | Etiology | Treatment |
|---|---|---|---|
| A disturbance in speech fluency that includes a number of problems with speech, such as repeating syllables or words, prolonging certain sounds, making obvious pauses, or substituting words to replace ones that are difficult to articulate. | Occurs twice as often among boys as among girls. Begins most often in children by the age of 6, and 98% of cases occur before the age of 10 (Maguire, Yeh, & Ito, 2012). Approximately 80% of children who stutter before they enter school will no longer stutter after they have been in school a year or so (Kroll & Beitchman, 2005). | Rather than anxiety causing childhood-onset fluency disorder, this problem makes people socially anxious (Ezrati-Vinacour & Levin, 2004). Multiple brain pathways appear to be involved, and genetic influences may be a factor (Maguire et al., 2012). | Parents are counseled about how to talk to their children. *Regulated-breathing method* is a promising behavioral treatment in which the person is instructed to stop speaking when a stuttering episode occurs and then to take a deep breath (exhale, then inhale) before proceeding (Onslow, Jones, O'Brian, Packman, & Menzies, 2012). Altered auditory feedback (electronically changing speech feedback to people who stutter) can improve speech, as can using forms of self-monitoring, in which people modify their own speech for the words they stutter (Onslow et al., 2012). |

**Language Disorder**

| Clinical description | Statistics | Etiology | Treatment |
|---|---|---|---|
| Limited speech in *all* situations. *Expressive language* (what is said) is significantly below *receptive language* (what is understood); the latter is usually average. | Occurs in 10% to 15% of children younger than 3 years of age (C. J. Johnson & Beitchman, 2005) and is almost five times as likely to affect boys as girls (Whitehurst et al., 1988). | An unfounded psychological explanation is that the children's parents may not speak to them enough. A biological theory is that middle ear infection is a contributory cause. | May be self-correcting and may not require special intervention (Whitehurst et al., 1988). |

particularly complex. It is clear that learning disorders run in families, and sophisticated family and twin studies bear this out (e.g., Christopher et al., 2013). Yet analyses of the genes involved suggest that many effects are not specific—meaning that different genes are not responsible for reading disorders and mathematics disorders. Instead, there are genes that affect learning, and these may contribute to problems across domains (reading, mathematics, writing) (Plomin & Kovas, 2005).

Children (and adults) often have very different problems associated with reading. Reading disorders are sometimes broken into problems with word recognition (difficulty decoding single words—sometimes called *dyslexia*), fluency (problems being able to read words and sentences smoothly and automatically), and comprehension (difficulty getting meaning from what is read) (J. M. Fletcher, Lyon, Fuchs, & Barnes, 2007). Most research to date focuses on problems with word recognition, and there is evidence that some develop these problems primarily through biological processes, while others develop problems as a result of environmental factors (Shaywitz, Mody, & Shaywitz, 2006). Genes located on chromosomes 2, 6, 15, and 18 have all been repeatedly linked to these difficulties (Cope et al., 2012; Zou et al., 2012). At the same time, environmental influences such as the home reading habits of families can significantly affect outcomes—especially with skills such as word recognition—suggesting that reading to children at risk for reading disorders can lessen the impact of the genetic influence (Petrill, Deater-Deckard, Thompson, DeThorne, & Schatschneider, 2006).

Research suggests structural, as well as functional, differences in the brains of people with learning disabilities. Specifically, three areas of the left hemisphere appear to be involved in problems with dyslexia (word recognition): Broca's area (which affects articulation and word analysis), an area in the left parietotemporal area (which affects word analysis), and an area in the left occipitotemporal area (which affects recognizing word form) (Shaywitz et al., 2006). A different area in the left hemisphere—the intraparietal sulcus—seems to be critical for the development of a sense of numbers and is implicated in mathematics disorder (J. M. Fletcher et al., 2007). In contrast, there is no current evidence for specific deficits responsible for disorders of written expression.

Disorders of reading have been diagnosed more often in English-speaking countries. Although some have thought that this may simply be a difference in diagnostic practices, biological research now suggests it may involve the relative complexity of the written word in English. Researchers tested individuals who displayed reading disorders and who spoke English, French, or Italian (Paulesu et al., 2001). Although those who spoke Italian did better on tests of reading, brain imaging (positron emission tomography) while all subjects were reading indicated each experienced the same reduced activity in the left temporal lobe. It was hypothesized that the complexity of reading English may account for these cultural differences.

Psychological and motivational factors that have been reinforced by others seem to play an important role in the eventual outcome of people with learning disorders. Factors such as socioeconomic status, cultural expectations, parental interactions and expectations, and child management practices, together with existing neurological deficits and the types of support provided in the school, seem to determine outcome (J. M. Fletcher et al., 2007).

### Assessment and Treatment

Assessment for learning disorders is a complex process that involves ruling out medical explanations for learning difficulties and determining the nature of the specific learning problem(s). Typically, professionals conduct informal observations of the student in school settings and review academic work. Following medical screening, more focused assessments are conducted to assess general intellectual capabilities and specific deficit areas. There is some controversy over using the discrepancy between IQ and achievement as part of the process of identifying children with learning disorders. Part of the criticism involves the delay between when learning problems occur and when they finally result in a large enough difference between IQ scores and achievement scores—which may not be measurable until later in a child's academic life. An alternative approach—called "response to intervention" —is now being used by many clinicians. It involves identifying a child as having a learning disorder when the response to a known effective intervention (for example, an early reading program) is significantly inferior to the performance by peers (Sadler & Sugai, 2009; VanDerHeyden & Harvey, in press). This provides an early warning system and focuses on providing effective instruction.

Treatment of learning disorders primarily requires educational intervention. Biological treatment is usually restricted to those individuals who may also have comorbid ADHD. Educational efforts can be

broadly categorized into (a) specific skills instruction, including instruction on vocabulary, finding the main idea, and finding facts in readings; and (b) strategy instruction, which includes efforts to improve cognitive skills through decision making and critical thinking (J. M. Fletcher et al., 2007).

One of the approaches that has received considerable research support is *direct instruction* (Carnine, Silbert, Kame'enui, & Tarver, 2004). The components that make up this program include systematic instruction, using highly scripted lesson plans, placing students together in small groups based on their progress, and teaching for mastery (teaching students until they understand all concepts). In addition, children are constantly assessed and plans are modified based on progress or lack of progress. Direct instruction and a number of related training programs appear to significantly improve academic skills in children with learning disorders (Kame'enui, Fien, & Korgesaar, 2013).

One study used functional magnetic resonance imaging scanning to compare how children with and without reading disorders processed simple tasks (Temple et al., 2003). The children with reading difficulties were then exposed to 8 weeks of intensive training on a computer program that helped them work on their auditory and language processing skills. Not only did the children improve their reading skills, but their brains started functioning in a way similar to the brains of their peers who were good readers. This and similar studies (Molfese, 2012) mirror results seen with other disorders—namely, that behavioral interventions can result in functional changes in the brain.

### Autism Spectrum Disorder

Autism spectrum disorder (ASD) is a neurodevelopmental disorder that, at its core, affects how one perceives and socializes with others (Durand, 2014). DSM-5 took most of the disorders previously included under the umbrella term "pervasive developmental disorders" (i.e., autistic disorder, Asperger disorder, and childhood disintegrative disorder) and combined them into this one single category (American Psychiatric Association, 2013). Rett disorder (a known genetic disorder affecting mostly females) was removed as a separate disorder but individuals will receive a diagnosis of ASD with the qualifier "associated with Rett syndrome" or "associated with MeCP2 mutation" (the gene involved in Rett syndrome). As occurred throughout DSM-5, the designation of "not otherwise specified" was also deleted.

### Clinical Description

Two major characteristics of ASD are expressed in DSM-5: (1) impairments in social communication and social interaction, and (2) restricted, repetitive patterns of behavior, interests, or activities (American Psychiatric Association, 2013). In addition, there is recognition that the impairments are present in early childhood and that they limit daily functioning. It is the degree of impairment in each of these characteristics that presumably distinguishes individuals previously diagnosed with the separate disorders of autistic disorder, Asperger's disorder, and pervasive developmental disorder—not otherwise specified.

To accommodate the range of difficulties in the two symptom clusters (social/communication interaction and restricted, repetitive patterns of behavior, interests, or activities), DSM-5 introduced three levels of severity: Level 1— "Requiring support," Level 2— "Requiring substantial support," and "Level 3— "Requiring very substantial support." Separate ratings are provided for social/communication interaction and for restricted interests and repetitive behaviors. This focus on levels of support is similar to the American Association on Intellectual and Developmental Disabilities categorization of intellectual disability based on the level of support or assistance people need: intermittent, limited, extensive, or pervasive, rather than on an IQ score (Thompson et al., 2009). Each level of support is described qualitatively and, as yet, has no quantitative equivalent. This subjectivity makes assigning the appropriate level of support needed somewhat problematic if the person with ASD does not perform at the extreme ends of these categories

One of the defining characteristics of people with ASD is that they do not develop the types of social relationships expected for their age (Durand, 2014). Research on the symptoms of ASD, including communication difficulties and social difficulties (which were listed independently as part of DSM-IV-TR), led to considerable overlap of these symptoms (Frazier et al., 2012; Gotham, Risi, Pickles, & Lord, 2007). DSM-5 combines these two areas into one general symptom cluster (social communication/interaction) (American Psychiatric Association, 2013). Difficulties with social communication and interaction are further defined by the inclusion of three aspects—problems with social reciprocity, nonverbal communication, and initiating and maintaining social relationships—all three of which must be present to be diagnosed with ASD.

For young children, the signs of social problems usually include a failure to engage in skills such as joint attention (Gillespie-Lynch et al., 2012; Schietecatte, Roeyers, & Warreyn, 2012; Wong & Kasari, 2012). When sitting with a parent in front of a favorite toy, young children will typically look back and forth between the parent and the toy, smiling, in an attempt to engage the parent with the toy. However, this skill in joint attention is noticeably absent or impaired in children with ASD.

In one study, scientists showed an adult man with ASD of the Asperger's type scenes from some movies and compared how he looked at social scenes with how a man without ASD did so (Klin, Jones, Schultz, Volkmar, & Cohen, 2002). The man with ASD scanned nonsocial aspects of the scene (an actor's mouth and jacket), while the man without ASD looked at the socially meaningful sections (looking from eye to eye of the people conversing). This research suggests that people with ASD may not be interested in important aspects of social situations, and this may interfere with their ability to develop meaningful relationships with others.

In addition to the social communication and interaction difficulties characteristic of persons with ASD, they also display behaviors that are relatively rigid and/or unusual ("restricted and repetitive patterns of behavior, interests, or activities") (Leekam, Prior, & Uljarevic, 2011). This can sometimes extend to compulsive-like preoccupations with certain topics or activities. DSM-5 defines this second aspect of ASD as including at least two of the following patterns of behaviors: (1) speech, motor movements, and/or use of objects that are overly stereotyped or repetitive; (2) disproportionate following of routines, repetitive patterns of verbal or nonverbal behavior, or extreme resistance to change; (3) extraordinarily strong fixations on objects or certain topics; and (4) unusual responses to sensory input, including the apparent absence of usual responses or hyperresponsiveness to things such as loud noises, textures, smells, lights, and so on (American Psychiatric Association, 2013).

### Epidemiology

Current estimates of the rates of ASD are based on the previous DSM-IV-TR and ICD-10 criteria (C. Lord & Bishop, 2010). ASD was once thought to be a rare disorder (e.g., 1 in 10,000 births), although more recent estimates of its occurrence show an increase in its prevalence. The Centers for Disease Control and Prevention reported that in 2008 1 in every 88 children in the United States

had been labeled with some form of autism, with 1 in 54 boys and 1 in 252 girls having the diagnosis (Centers for Disease Control and Prevention, 2012). The vast majority of the rise in the rates may be the result of changes that took place with DSM-IV-TR (Miller et al., 2013), as well as increased awareness on the part of professionals and the general public (Frombonne, Quirke, & Hagen, 2011). More specifically, the addition of Asperger's disorder and pervasive developmental disorder—not otherwise specified expanded the range of persons included under this label.

Gender differences are apparent in the more severe range of ASD, with the average reported male-to-female estimate being 4.4 to 1 (Frombonne et al., 2011). Estimates for the higher end of the spectrum remain unclear. Most people with ASD develop the associated symptoms before the age of 36 months (American Psychiatric Association, 2013).

People with ASD display a range of IQ scores. It is estimated that two out of every three individuals with ASD have intellectual disabilities (referred to previously as mental retardation and defined as an IQ score less than 70, comparable deficits in adaptive functioning, and present before the age of 18) (Dykens & Lense, 2011). IQ measures are used to determine prognosis: The higher children score on IQ tests, the less likely they are to need extensive support by family members or people in the helping professions. Conversely, young children with ASD who score poorly on IQ tests are more likely to be severely delayed in acquiring communication skills and to need a great deal of educational and social support as they grow older. Usually, language abilities and IQ scores are reliable predictors of how children with ASD will fare later in life: The better the language skills and IQ test performance, the better the prognosis (Klin, 2011).

### Etiology

It is now abundantly clear that ASD has a genetic component (Rutter, 2011). What is also evident is that the genetics of ASD is highly complex (Addington & Rapoport, 2012; Caglayan, 2010; Klei et al., 2012). Numerous genes on a number of our chromosomes have already been implicated in some way in the presentation of ASD (Li, Zou, & Brown, 2012). Research is finding that in many cases mutations occur that either create extra copies of a gene on one chromosome or result in the deletion of genes (called *copy number variants*—CNVs) (Luo et al., 2012). What is also being discovered is that these types of mutations can be present in

a child even if the mother or father does not have these copy number variants. Mutations in genes can occur initially in one family member as a result of a mutation in a germ cell (egg or sperm) of one of the parents or in the fertilized egg after conception (called *de novo mutations*) and there is growing evidence that a portion of persons with ASD display these types of mutations (Kong et al., 2012; S. J. Sanders et al., 2012; Sebat et al., 2007). It is not clear why these changes in genetic material occur, but they may increase risk of ASD by 5 to 20 times (Neale et al., 2012). These de novo mutations help explain why this disorder can occur in families who do not have a familial history of ASD.

Research on ASD is looking at the role of insecticides, for example, on creating damage through a process called *oxidative stress* (a disruption in the normal process by which cells rid themselves of harmful free radicals) (Chauhan & Chauhan, 2006). Some work suggests that certain occurrences of the genetic mutations observed in groups of persons with ASD make them particularly susceptible to the damaging effects of these types of toxins (Shelton, Hertz-Picciotto, & Pessah, 2012). Other prenatal events are also possibly linked to ASD. For example, several studies suggest that prolonged episodes of maternal fever appear to increase the risk of the newborn having ASD (e.g., Atladóttir, Henriksen, Schendel, & Parner, 2012). On the other hand, there are mixed results when researchers study the possible influence of maternal influenza infection during pregnancy (Atladóttir et al., 2012; Zerbo et al., 2013). Research has also targeted the role of metabolic conditions during pregnancy such as diabetes, hypertension, and obesity in the development of ASD (Krakowiak et al., 2012). It appears that prenatal exposure to a range of conditions that compromise a pregnancy may increase the risk of ASD, with no one factor predominating (Gardener, Spiegelman, & Buka, 2011; Volk, Lurmann, Penfold, Hertz-Picciotto, & McConnell, 2013).

There appears to be an increased risk of having a child with ASD among older parents. One group of researchers in Israel, for example, found that fathers 40 years old and up were more than five times more likely to have a child with ASD than fathers under the age of 30 (Reichenberg et al., 2006). The same correlation does seem to hold up for maternal age and may be independent of parental age (Croen, Najjar, Fireman, & Grether, 2007; Durkin et al., 2008; Parner et al., 2012). Although how this association occurs is not fully understood, it is tempting to suggest that the role of de novo mutations is at least partly to blame. In other words, as the sperm of fathers and eggs of mothers age, they are more likely to be exposed to various toxins that can increase the risk of these types of genetic changes.

The study of ASD is a relatively young field and still awaits an integrative theory. It is likely, however, that further research will identify the biological mechanisms that may explain the social aversion experienced by many people with the disorder. Also to be outlined are the psychological and social factors that interact early with the biological influences, producing deficits in socialization and communication, as well as the characteristic unusual behaviors.

### Assessment and Treatment of Autism Spectrum Disorder

The most favorable treatment outcomes are achieved if intervention for the symptoms of ASD begins very early in life. As a result, there is increased interest in identifying children with ASD as early as possible (Al-Qabandi, Gorter, & Rosenbaum, 2011; Paul J. Frick, Barry, & Kamphaus, 2010). Several national consensus panels (including the American Academy of Neurology, the American Psychological Society, the American Academy of Child and Adolescent Psychiatry, and the American Academy of Pediatrics) recommend early screening, especially when there is parental concern or for all children between 18 and 24 months (Warren & Stone, 2011).

If ASD is suspected, assessment focuses on the diagnosis and implications for treatment. Several assessment devices reliably diagnose this disorder (e.g., Autism Diagnostic Observation Schedule [ADOS], Autism Diagnostic Interview—Revised [ADI-R]) (C. Lord et al., 2000). Given the range of problems posed by children with this disorder, a multidisciplinary team (including professionals in speech and language, physical therapy, education, and psychology) is often required.

Like the approach to individuals with intellectual disabilities, most efforts at treating people with ASD focus on enhancing their social, communication, and daily living skills, and on reducing problem behaviors, such as tantrums and self-injury (Durand, 2014). Early intensive behavioral intervention (EIBI) is generally recommended for very young children. Pioneered by Lovaas and his colleagues at University of California, Los Angeles, intensive behavioral treatment for communication and social skills problems involves 40 hours or more per week of intervention, which seemed to improve intellectual and educational functioning. Follow-up

suggests that these improvements are long lasting for a percentage of children (Lord et al., 2005; McEachin, Smith, & Lovaas, 1993), although subgroups of children who are most successful have yet to be identified (Matson & Smith, 2008). Variations of this approach that emphasize developmental considerations (e.g., Dawson et al., 2010) and naturalistic play settings (Strain & Bovey, 2011) have a growing evidence base, and some work suggests improvement in social brain function with these forms of early and intensive behavioral intervention (Dawson et al., 2012).

Although social deficits are among the more obvious problems experienced by people with ASD, they can also be the most difficult to teach. A number of approaches are now used to teach social skills (for example, how to carry on a conversation and ask questions of other people), including the use of peers who do not have ASD as trainers, and there is evidence that those with ASD can improve their socialization skills (Stichter, O'Connor, Herzog, Lierheimer, & McGhee, 2012; Thomeer et al., 2012).

People with ASD often do not acquire meaningful speech; they tend either to have limited speech or to use unusual speech, such as echolalia. For children with no or very limited speech, basic behavioral procedures of shaping and discrimination training are used to teach these nonspeaking children to imitate others verbally (Goldstein, 2002). Despite the success of some children in learning speech, other children do not respond to this training, and workers sometimes use alternatives to vocal speech, such as sign language, symbol systems, social narratives, and vocal output devices (Miranda & Iacono, 2009; Test, Richter, Knight, & Spooner, 2011).

Medical intervention has had little success on the core symptoms of social and language difficulties. A variety of pharmacological treatments are used to decrease agitation, and the major tranquilizers and serotonin-specific reuptake inhibitors seem helpful here (Volkmar, Klin, & Schultz, 2005). However, to date there are no medical interventions that have been demonstrated to correct the central problems of social communication deficits and restricted and repetitive behaviors (Carrasco, Volkmar, & Bloch, 2012; Siegel & Beaulieu, 2012).

### Intellectual Disability

Intellectual disability (ID) (previously referred to as mental retardation) is a disorder evident in childhood as significantly below-average intellectual and adaptive functioning (Goodman & Scott, 2012). People with ID experience difficulties with day-to-day activities to an extent that reflects both the severity of their cognitive deficits and the type and amount of assistance they receive. Perhaps more than any other group, people with ID have throughout history received treatment that can best be described as shameful (Scheerenberger, 1983). With notable exceptions, societies throughout the ages have devalued individuals whose intellectual abilities are deemed less than adequate.

### Clinical Description and Epidemiology

People with ID display a broad range of abilities and personalities. Some individuals who have mild or moderate impairments can, with proper preparation, carry out most day-to-day activities. Many can learn to use mass transportation, purchase groceries, and hold a variety of jobs. Those with more severe impairments may need help with eating, bathing, and dressing themselves, although with proper training and support they can achieve a degree of independence. These individuals experience impairments that affect most areas of functioning. Language and communication skills are often the most obvious. In contrast, people with more severe forms of ID may never learn to use speech as a form of communication, requiring alternatives such as sign language or special communication devices to express even their most basic needs.

Intellectual disorder was included on Axis II of DSM-IV-TR but is now a DSM-5 disorder (American Psychiatric Association, 2013), and the criteria are in three groups. First, a person must have *significantly subaverage intellectual functioning*, a determination made with one of several IQ tests, with a cutoff score set by DSM-5 of approximately 70. Roughly 2%–3% of the population score at 70 or below on these tests. The American Association on Intellectual and Developmental Disabilities (AAIDD), which has its own, similar definition of ID, has a cutoff score of approximately 70–75 (Schalock et al., 2010).

The second criterion of both the DSM-5 and the AAIDD definitions for IDs calls for *concurrent deficits or impairments in adaptive functioning*. Scores from an IQ test are not sufficient for a diagnosis of ID; a person must also have significant difficulty in at least two of the following areas: communication, self-care, home living, social and interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety. This aspect of the definition is important because it excludes people who can function quite well in society but who, for various reasons,

do poorly on IQ tests. For instance, someone whose primary language is not English may do poorly on an IQ test but may still function at a level comparable to peers. This person would not be considered to have ID even with a score of below 70 on the IQ test.

The final criterion for intellectual disabilities is the *age of onset.* The characteristic below-average intellectual and adaptive abilities must be evident before the person is 18. This cutoff is designed to identify affected individuals when the brain is developing and therefore when any problems should become evident. The age criterion rules out the diagnosis of ID for adults who suffer from brain trauma or forms of dementia that impair their abilities. The age of 18 is somewhat arbitrary, but it is the age at which most children leave school and when society considers a person an adult.

Perhaps the most controversial change in the AAIDD definition of ID is its description of different levels of this disorder, which are based on the level of support or assistance people need: *intermittent, limited, extensive*, or *pervasive* (Luckasson et al., 1992). The AAIDD system identifies the role of "needed supports" in determining level of functioning, whereas DSM-IV-TR implies that the ability of the person is the sole determining factor. The AAIDD system focuses on specific areas of assistance a person needs that can then be translated into training goals (Schalock et al., 2010).

Approximately 90% of people with ID fall under the label of mild ID (IQ of 50–70), and when you add individuals with moderate, severe, and profound ID (IQ below 50), the total population of people with this disorder represents 1%–3% of the general population (Emerson, 2012).

The course of ID is chronic; however, the prognosis for people with this disorder varies considerably. Given appropriate training and support, individuals with less severe forms can live relatively independent and productive lives. People with more severe impairments require more assistance to participate in work and community life.

Over the last century IQ scores have risen, a phenomenon known as the *Flynn effect* (Flynn, 1984). IQ tests are adjusted every decade or two to keep the average score around 100. For most people, these changes have no practical effect. However, for people hovering at the cutoff point for ID, this may mean the difference between receiving the diagnosis or not (V. M. Durand & K. Christodulu, 2006; Kanaya & Ceci, 2012). In one study, the number of people scoring just below 70 (the cutoff for mild

ID) tripled when they were administered one of the revised IQ tests (Kanaya, Scullin, & Ceci, 2003). These results emphasize the caution needed when interpreting who does or does not have ID.

### Etiology

There are literally hundreds of known causes of ID, including environmental (e.g., deprivation, abuse, and neglect), prenatal (e.g., exposure to disease or drugs while in utero), perinatal (e.g., difficulties during labor and delivery), and postnatal (e.g., infections and head injury).

Heavy use of alcohol among pregnant women can produce *fetal alcohol syndrome*, a condition that can lead to severe learning disabilities (Douzgou et al., 2012). Other prenatal factors that can produce ID include the pregnant woman's exposure to disease and chemicals, and poor nutrition for the fetus. In addition, lack of oxygen (anoxia) during birth, and malnutrition and head injuries during the developmental period can lead to severe cognitive impairments. Despite the rather large number of known causes of ID, nearly 75% of cases either cannot be attributed to any known cause or are thought to be the result of social and environmental influences (Rauch et al., 2012).

Almost 300 genes have been identified as having the potential to contribute to ID, and it is expected that there are many more (Rauch et al., 2012). A portion of the people with more severe ID have identifiable single-gene disorders, involving a *dominant gene* (expresses itself when paired with a normal gene), a *recessive gene* (expresses itself only when paired with another copy of itself), or an *X-linked gene* (present on the X or sex chromosome).

Only a few dominant genes result in ID. One example of a dominant gene disorder, *tuberous sclerosis*, is relatively rare, occurring in 1 of approximately every 30,000 births. About 60% of the people with this disorder have ID, and most have seizures (uncontrolled electrical discharges in the brain) and characteristic bumps on the skin that, during their adolescence, resemble acne (Tsai & Crino, 2012).

*Phenylketonuria* (PKU) affects 1 of every 14,000 newborns and is characterized by an inability to break down the chemical phenylalanine, found in normal human diets. Until the mid-1960s, the majority of people with this disorder had ID, seizures, and behavior problems resulting from high levels of this chemical. However, researchers developed a screening technique that identifies the existence of PKU; infants are now routinely tested at

birth, and any individuals identified with PKU can be successfully treated with a special diet that avoids the chemical phenylalanine. Because untreated maternal PKU can harm the developing fetus, there is concern now that women with PKU who are of childbearing age may not stick to their diets and inadvertently cause PKU-related ID in their children before birth (Hanley, 2008). *Lesch-Nyhan syndrome*, an X-linked disorder, is characterized by ID, signs of cerebral palsy (spasticity or tightening of the muscles), and self-injurious behavior, including finger and lip biting (Nyhan, 1978). Only males are affected, because a recessive gene on the X chromosome is responsible.

*Down syndrome*, the most common chromosomal form of ID, was first identified by the British physician Langdon Down in 1866. The disorder is caused by the presence of an extra 21st chromosome and is therefore sometimes referred to as *trisomy 21*. During cell division, two of the 21st chromosomes stick together (nondisjunction), creating one cell with one copy that dies and one cell with three copies that divide to create a person with Down syndrome. People with Down syndrome have characteristic facial features, including folds in the corners of their upwardly slanting eyes, a flat nose, and a small mouth with a flat roof that makes the tongue protrude somewhat. Nearly *all* adults with Down syndrome past the age of 40 show signs of dementia of the Alzheimer type, a degenerative brain disorder that causes impairments in memory and other cognitive disorders (Ness et al., 2012). This disorder among people with Down syndrome occurs earlier than usual (sometimes in their early 20s) and has led to the finding that at least one form of Alzheimer disease is attributable to a gene on the 21st chromosome.

The incidence of children born with Down syndrome is related to maternal age. A woman at age 20 has a 1 in 2,000 chance of having a child with Down syndrome; at the age of 35, this risk increases to 1 in 500; and at the age of 45, it increases again to 1 in 18 births (J. A. Evans & Hammerton, 1985; Hook, 1982). There are now sophisticated tests of maternal blood that can be used to detect Down syndrome as early as the first trimester of pregnancy (Wax, 2007). However, information about this chromosomal abnormality does not convey information about the eventual severity of the disorder. Despite this lack of information, some estimate that a prenatal diagnosis of Down syndrome leads to a choice for an elective abortion about 25% of the time (Bishop, Huether, Torfs, Lorey, & Deddens,

1997). Prenatal testing for Down syndrome cannot assist parents with information about the outcomes.

*Fragile X syndrome* is a second common chromosomally related cause of ID (King, Hodapp, & Dykens, 2005). This disorder is caused by an abnormality on the X chromosome, a mutation that makes the tip of the chromosome look as though it were hanging from a thread, giving it the appearance of fragility. As with Lesch-Nyhan syndrome, which also involves the X chromosome, fragile X primarily affects males because they do not have a second X chromosome with a normal gene to balance out the mutation. Unlike Lesch-Nyhan carriers, however, women who carry fragile X syndrome commonly display mild to severe learning disabilities (Santoro, Bray, & Warren, 2012). Men with the disorder display moderate to severe levels of ID and have higher rates of hyperactivity, short attention spans, gaze avoidance, and perseverative speech. In addition, such physical characteristics as large ears, testicles, and head circumference are common. Estimates are that 1 of every 1,000 males and 1 of every 3,000 females are born with fragile X syndrome (King et al., 2005).

Up to 75% of the cases of ID fall in the mild range and are not associated with any obvious genetic or physical disorders. People with these characteristics are thought to have cognitive impairments that result from a combination of psychosocial and biological influences, although the specific mechanisms that lead to this type of ID are not yet understood (Hammel et al., 2008). The cultural influences that may contribute to this condition include abuse, neglect, and social deprivation.

### Assessment and Treatment of Intellectual Disabilities

Conducting a thorough assessment is essential to providing effective services for individuals with ID (V. M. Durand & K. V. Christodulu, 2006). Reliable and valid assessment protocols incorporate multiple methods and multiple sources in order to obtain the information needed to make an accurate diagnosis of ID. Areas of assessment include the assessment of cognitive, adaptive, and social-emotional behaviors. Commonly administered intelligence tests used with individuals who are sufficiently verbal include the Wechsler Intelligence Scales (e.g., Wechsler Preschool and Primary Scale of Intelligence—III; Wechsler Intelligence Scale for Children—IV; Wechsler Intelligence Scale for Adults—IV [Wechsler, 2002, 2003, 2008]; and the Stanford-Binet Intelligence Scales [Roid, 2003]).

A variety of intelligence tests are available for individuals with more limited communication skills. The Kaufman Assessment Battery for Children, Second Edition (K-ABC-II) (Kaufman, 2004) is applicable for children from ages 2 ½ to 12 ½ but requires that the child has some receptive language ability. The Leiter International Performance Scales—Revised is a completely nonverbal test (appropriate for individuals ages 2–21) and may be best for those with very limited skills (Leiter, 2002). The Mullen Scales of Early Learning (MSEL) is designed for very young children (ages 1–42 months) and assesses skill in areas including gross motor, visual reception, fine motor, receptive language, and expressive language (Mullen, 1997).

In addition to measuring cognitive development, it is also necessary to administer a measure of adaptive functioning to determine the presence of ID. Adaptive functioning refers to how effectively individuals cope with common life demands and how well they meet the standards of personal independence expected of someone in their age group, sociocultural background, and community setting. The Vineland Adaptive Behavior Scales (Sparrow, Balla, & Cicchetti, 1984) and the Adaptive Behavior Scales—Revised (Lambert, Leland, & Nihira, 1992) are tests available to assess adaptive abilities in children. These scales typically provide a clinical cutoff score that is a composite of performance in a number of adaptive skill domains. Additional instruments, such as measures of academic achievement, are often administered when conducting a comprehensive battery in the assessment of children to formulate a diagnosis of ID (V. M. Durand & K. V. Christodulu, 2006).

Individuals with ID have a higher prevalence of comorbid disorders and behavior problems than do the general population (Borthwick-Duffy, 1994; Matson & Barrett, 1993). Assessment procedures for specific emotional and behavioral problems are generally placed into the following categories: interviews, behavior rating scales, self-report measures, and direct observation procedures (American Association on Mental Retardation, 2000; C. R. Johnson, 1998).

Direct biological treatment of ID is currently not a viable option. Generally, the treatment of individuals with ID parallels that of people with ASD, attempting to teach them the skills they need to become more productive and independent. For individuals with mild ID, intervention is similar to that for people with specific learning disorder. Specific learning deficits are identified and

addressed to help the student improve such skills as reading and writing. At the same time, these individuals often need additional support to live in the community. For people with more severe disabilities, the general goals are the same; however, the level of assistance they need is often more extensive. Advances in electronic and educational technologies greatly enhance learning, even for people with profound ID.

People with ID can acquire skills through the many behavioral innovations first introduced in the early 1960s to teach such basic self-care as dressing, bathing, feeding, and toileting to people with even the most severe disabilities (V. M. Durand & K. V. Christodulu, 2006). Communication training is a core goal for people with ID. The goals of communication training differ, depending on the existing skills. For people with mild levels of ID, the goals may be relatively minor (for example, improving articulation) or more extensive (for example, organizing a conversation) (Sigafoos, Arthur-Kelly, & Butterfield, 2006). Some have communication skills that are already adequate for day-to-day needs.

For individuals with the most severe disabilities, this type of training can be particularly challenging, because they may have multiple physical or cognitive deficits that make spoken communication difficult or impossible. Alternative systems of communication may be easier for these individuals, including the teaching of sign language and *augmentative communication strategies.* Augmentative strategies may use picture books, teaching the person to make a request by pointing to a picture—for instance, pointing to a picture of a cup to request a drink (Light & McNaughton, 2012). A variety of computer-assisted devices as well as tablet computers can be programmed so that the individual presses a button to produce complete spoken sentences (for example, "Would you come here? I need your help"). People with limited communication skills can be taught to use these devices, which helps them reduce the frustration of not being able to relate their feelings and experiences to other people.

A significant portion of people with ID can be physically or verbally aggressive, or they may hurt themselves. Fortunately, our knowledge of the origins of these behaviors has increased over the past several decades, along with our ability to respond to these behaviors in a positive, constructive way (Durand, 2012). As a result of this expansion of knowledge, work on interventions with persons exhibiting severe challenging behavior has increased in a multitude of areas, such as environmental/curricular

changes (Dunlap, Kern-Dunlap, Clarke, & Robbins, 1991; I. M. Evans & Meyer, 1985; Meyer & Evans, 1989) and teaching specific alternative skills (Durand, 2012). Outcome data on these approaches suggest that significant improvements can be obtained at home, at school, and in the community.

In addition to ensuring that people with ID are taught specific skills, caretakers focus on the important task of supporting them in their communities. "Supported employment" involves helping an individual find and participate satisfactorily in a competitive job (Hall, Butterworth, Winsor, Gilmore, & Metzel, 2007). Research has shown not only that people with ID can be placed in meaningful jobs but also that, despite the costs associated with supported employment, it can be cost-effective (Sandys, 2007).

There is general agreement about *what* should be taught to people with ID. The controversy in recent years has been over *where* this teaching should take place. Should people with ID, especially the severe forms, be taught in specially designed separate classrooms or workshops, or should they attend their neighborhood public schools and work at local businesses? Increasingly, teaching strategies to help these students learn are being used in regular classrooms and in preparing them to work at jobs in the community (Frankel & Gold, 2007).

## Disruptive, Impulse Control, and Conduct Disorders
### Conduct Disorder

Conduct disorder is a DSM-5 diagnosis for children who violate the basic rights of others or who engage in behaviors that violate society's norms. These children chronically engage in multiple and serious behavior problems (e.g., lying, cheating, truancy, theft, arson, etc.).

### CLINICAL DESCRIPTION

A diagnosis of CD requires the presence of three or more criteria from the following general categories: aggression to people and animals, destruction of property, deceitfulness or theft, and serious violation of rules (American Psychiatric Association, 2013). Clinicians can rate the severity of the disorder as mild (few if any conduct problems in excess of those required to make the diagnosis, and conduct problems cause only minor harm to others), moderate (number of conduct problems and effect on others intermediate between "mild" and "severe"), or severe (many conduct problems in excess of those required to make the diagnosis, or conduct problems cause considerable harm to others). In

addition, DSM-5 provides for the designation of two subtypes; *childhood-onset type* (the onset of at least one criterion characteristic of CD prior to age 10 years) or *adolescent-onset type* (the absence of any criteria characteristic of CD prior to age 10 years). New to DSM-5 is also an additional subtype called "with a callous-unemotional presentation" (Barry, Golmaryami, Rivera-Hudson, & Frick, 2012). This designation is an indication that the young person presents in a way that suggests personality characteristics similar to an adult with psychopathy.

The DSM-5 criteria for CD focus almost entirely on observable behaviors (for example, "has used a weapon that can cause serious physical harm to others"). Underlying personality traits (for example, being self-centered or manipulative), which are also often an important aspect in this disorder, are not part of the diagnosis, in part to improve the reliability of the diagnosis.

### EPIDEMIOLOGY

One population-based longitudinal study found that the presence of CD among children aged 4½ –5 years was 6.6%, with 2.5% exhibiting problems in the moderate to severe range (Kim-Cohen et al., 2005). Many children with CD—most often diagnosed in boys (Eme, 2007)—become juvenile offenders and tend to become involved with drugs (P. J. Frick, 2012). For many of these children, rule violations, such as staying out late at night or truancy from school, begin at an early age (before 13 years of age).

Early identification of this lifelong pattern of antisocial behavior is important because young children who display antisocial behavior are likely to continue these behaviors as they grow older (Soderstrom, Sjodin, Carlstedt, & Forsman, 2004). Data from long-term follow-up research indicate that many adults with antisocial personality disorder or psychopathy met the criteria for CD as children (Robins, 1978; Salekin, 2006); the likelihood increases if the child has both CD and ADHD (Lynam, 1996). In many cases, the types of norm violations that an adult would engage in—irresponsibility regarding work or family—appear as younger versions in CD: truant from school, running away from home.

### ETIOLOGY

Research on the influences affecting CD in children is evolving. It is clear that genetic factors are important in the development of these disruptive behaviors, although there are relatively few

well-conducted studies in this area. In part, this may be due to the apparent heterogeneity of symptoms of the disorder. One study, for example, found that symptoms such as breaking and entering and truancy showed limited evidence for heritability, while destruction of property, lying, stealing without confrontation, use of weapons, and fighting showed moderate heritability (Gelhorn et al., 2005). The same study found bullying, cruelty to animals, breaking and entering, truancy, and running away showed the effects of substantial shared environment (Gelhorn et al., 2005). Newer research confirms different developmental pathways for children with conduct disorder with influential factors, such as age of onset of the antisocial behavior, the presence/absence of significant levels of callous-unemotional traits, and the presence/absence of problems with anger regulation (Pardini & Frick, 2013).

Familial research has its origins in Patterson's influential work, which suggested that aggression in such children may escalate, partly as a result of their interactions with their parents (Granic & Patterson, 2006; Patterson, 1982). This research finds that the parents often give in to the problem behaviors displayed by their children. This "coercive family process" combines with other factors, such as parental depression, poor monitoring of their child's activities, and less parental involvement, to help maintain the aggressive behaviors (Chronis et al., 2007; Patterson, DeBaryshe, & Ramsey, 1989).

Biological influences appear to interact with environmental experiences such as early childhood adversity (Kendler, Aggen, & Patrick, 2013). In a family that may already be under stress because of divorce or substance abuse (Hetherington, Stanley-Hagan, & Anderson, 1989; Patterson et al., 1989), there may be an interaction style that encourages antisocial behavior on the part of the child (Wootton, Frick, Shelton, & Silverthorn, 1997). The child's disruptive and impulsive behavior—partly caused by the child's difficult temperament and impulsivity (Chronis et al., 2007; Kochanska, Aksan, & Joy, 2007)—alienates other children who might be good role models and attracts others who encourage disruptive behavior (Vuchinich, Bank, & Patterson, 1992). These behaviors may also result in the child dropping out of school and a poor occupational history in adulthood (Caspi, Elder Jr., & Bem, 1987).

ASSESSMENT AND TREATMENT

A comprehensive evaluation is conducted with children with serious behavioral concerns and includes information about the behavior problems, family concerns, school concerns, and differential diagnosis with overlapping disorders such as ADHD, learning disorders, and ODD (Barry et al., 2012). Assessing the seriousness of behavior problems, especially in younger children, can be complicated by the tolerance thresholds of parents and teachers (Renk, 2008). The Child Behavior Checklist (CBCL) in its various forms for parents, teachers, and for self-report (Achenbach, 1991, 1991a, 1991b, 1991c), for example, is the most thoroughly researched assessment tool and provides norm-based information that is essential for decision making.

The most common treatment strategy for children involves parent training (Patterson, 1982; M. R. Sanders, 1992). Parents are taught to recognize behavior problems early and how to use praise and privileges to reduce problem behavior and encourage prosocial behaviors. Treatment studies typically show that these types of programs can significantly improve the behaviors of many children who display antisocial behaviors (Cornforth, Fairchild, & Thompson, 2012). A number of factors, however, put families at risk either for not succeeding in treatment or for dropping out early; these include cases with a high degree of family dysfunction, socioeconomic disadvantage, high family stress, a parent's history of antisocial behavior, and severe CD on the part of the child (Dumas & Wahler, 1983; Kazdin, Mazurick, & Bass, 1993). Psychosocial intervention often extends to the school, and both approaches have significant empirical bases (Brown et al., 2008).

### Oppositional Defiant Disorder

Children with ODD display uncooperative, defiant, and hostile behavior toward authority figures, although to a lesser degree when compared to children with CD. These types of problems are among most common causes of clinic referrals for children (Nock, Kazdin, Hiripi, & Kessler, 2006). Considerable heterogeneity exists in the behaviors that comprise ODD and CD, and research continues in order to identify distinguishing features to improve models that disentangle multiple pathways for these disorders (Pardini & Frick, 2013; Rowe, Costello, Angold, Copeland, & Maughan, 2010).

Assessment mirrors the process and tools used for CD and includes a comprehensive evaluation formed after collecting information about the behavior problems, family concerns, school concerns, and differential diagnosis with overlapping disorders such as ADHD, learning disorders, and mood and anxiety disorders, as well as CD

(Biederman, Ball, Monuteaux, Kaiser, & Faraone, 2008). Treatment also includes a heavy emphasis on psychosocial interventions that are home and school based—also paralleling treatment for CD. Research on these treatments suggests that they produce moderate to large effect sizes for behavior problems (Brown et al., 2008; Eyberg, Nelson, & Boggs, 2008; McMahon, Kotler, Steele, Elkin, & Roberts, 2008).

### *Intermittent Explosive Disorder*

Youth with *intermittent explosive disorder* have episodes in which they act on aggressive impulses that result in serious assaults or destruction of property (Coccaro, 2012). Although it is unfortunately common among the general population to observe aggressive outbursts, when you rule out the influence of other disorders (for example, antisocial personality disorder, borderline personality disorder, a psychotic disorder, and Alzheimer disease) or substance use, this disorder is not often diagnosed. The lifetime prevalence of this disorder using a more narrow definition as used in DSM-5 yields a lifetime prevalence rate of 5.4% in the United States (Coccaro, 2012).

This diagnosis is controversial and has been debated throughout the development of the DSM. One concern, among others, is that by validating a general category that covers aggressive behavior it may be used as a legal defense—insanity—for all violent crimes (Coccaro & McCloskey, 2010).

Research is at the beginning stages for intermittent explosive disorder and focuses on the influence of neurotransmitters such as serotonin and norepinephrine and testosterone levels, along with their interaction with psychosocial influences (stress, disrupted family life, and parenting styles). These and other influences are being examined to explain the origins of this disorder (Muresanu, Stan, & Buzoianu, 2012). Cognitive-behavioral interventions (for example, helping the person identify and avoid "triggers" for aggressive outbursts) and approaches modeled after drug treatments appear the most effective for these individuals, although few controlled studies yet exist (McCloskey, Noblett, Deffenbacher, Gollan, & Coccaro, 2008).

### Conclusion

Taken together, the developmental disorders result in significant obstacles to providing many children with appropriate educational, social, and vocational opportunities. Fortunately, the rapid acquisition of knowledge regarding most of the developmental disorders offers great promise toward a greater understanding of the nature of these disorders, as well as toward improving treatments. Integrative approaches—combining biological, cognitive, and social factors—to both research on etiology and treatment provide a more optimistic view of these problems of childhood, holding out hope for these children, their families, and society.

### *Future Directions*

The following questions represent just a handful of remaining issues that have the potential to further the research agenda for the major developmental disorders:

• There is a significant amount of treatment research for ADHD, and a growing amount that combines both medical and behavioral approaches. Given the practical limitations of both approaches (e.g., side effects of medication, time and skills required for behavioral approaches), there is a current need for "scale-up" research in this area. This research would evaluate if these interventions are effective when they are implemented under conditions that would be typical if an educational setting or typical family were to implement them (i.e., without special support from a research team).

• Additional research on the nature of the disruptive behavior disorders (ODD and CD) is needed to address the spectrum of problems that are so troublesome for both families and educational settings. More information on the biological and psychosocial origins of these problems would aid future treatment efforts.

• The profound social deficits characteristic of the autism spectrum disorder continue to challenge current treatment efforts. An integrative theory of these disorders remains to be developed and could provide clues as to the underlying processes contributing to these social problems, which could guide improvements in current intervention efforts.

• Genetic research on the range of difficulties contributing to ID needs to be greatly expanded. This information will be invaluable in efforts to prevent the problems that lead to such profound cognitive impairments and interfere with independent functioning.

### Abstract

This chapter provides an overview on cognitive disorders in adults from a neuropsychological perspective. It begins with a critical review of existing taxonomies for these disorders, especially those contained in the DSM-IV, and continues with a summary of neuropsychological terminology used in the chapter and the effects of focal brain lesions. A number of medical and neurological disorders are described, and their cognitive correlates are reviewed using data from clinical case studies and epidemiologic research. The conditions summarized include a brief consideration of medical disorders that do not involve primary central nervous system pathology, followed by extensive review of brain insults (trauma, infections, exposures) and primary neurological disorders (dementias, cerebrovascular disease, motor system disorders, structural lesions, epilepsy, autoimmune disorders). A concluding section describes current issues in understanding cognitive disorders and likely future approaches to research on them.

**Key Words:** Brain trauma, cognitive disorders, cognitive impairment, dementia, encephalopathy, neurocognition, neuropsychological assessment, subcortical dementia

This chapter reviews the behavioral manifestations of cognitive disorders in adults. The framework for the chapter and the contents of the discussion derive directly from a neuropsychological perspective. The chapter begins by considering what cognitive disorders are, how they are defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) (American Psychiatric Association [APA], 1994), other possible taxonomies for defining and categorizing these disorders, and approaches to understanding the behavioral characteristics of them. The chapter then proceeds with descriptions of the behavioral characteristics of cognitive disorders in adulthood, including a brief consideration of medical diseases and an extensive review of external brain insults and primary neurological disorders. It ends by considering future directions in understanding these disorders and diseases.

## What Are Cognitive Disorders?
### *The Universe of Disorders Affecting Cognition in Adults*

For a neuropsychologist, writing a chapter on cognitive disorders is an exercise in focus and containment. Highly specific pathognomonic patterns of cognitive characteristics are associated with many diseases, disorders, and syndromes. More generalized, nonspecific findings are also seen across a number of disorders. Such characteristics and findings constitute the field of clinical neuropsychology. In general, the types of disorders and diseases with prominent cognitive manifestations include adult manifestations of conditions that occur or originate in childhood (developmental disorders), disorders that are generally classified as "psychiatric," exposures to exogenous drugs and chemicals, neurological diseases, and medical conditions. All of these

categories of illness can also contribute to the occurrence of reversible acute or chronic confusional states characterized by generalized and shifting cognitive symptoms.

## ADULT MANIFESTATIONS OF DEVELOPMENTAL CONDITIONS

These can arise from disorders of learning or attention, including learning disabilities (LD; e.g., disorders of reading, writing, arithmetic; nonverbal LDs) and attention-deficit hyperactivity disorder (ADHD, inattentive or hyperactive types). Extremes in intelligence quotient (IQ) dating from childhood also significantly affect cognitive function in adulthood (e.g., mental retardation, borderline IQ, superior IQ). These patterns of "native ability" or premorbid function are important because they persist and affect the patterns and types of cognitive changes that accompany the occurrence of central nervous system (CNS) insults and disorders in adulthood.

Before or after birth, children may also develop acute or chronic illnesses that affect CNS function, with manifestations extending to or even appearing in adulthood. There are too many of these to list exhaustively, but a few examples will be given along with their importance to lifelong patterns of cognitive abilities. Congenital disorders can affect cognition in a manner similar to that seen with LD and ADHD. For example, cerebral palsy and hydrocephalus are often associated with highly individual and specific cognitive anomalies. Some children are born with severe atrophy of the brain or a hemisphere of the brain, or unusual formations of the blood vessels in the brain (arteriovenous malformations or AVMs) that may have longstanding implications for cognitive function. Examples of important neuropsychiatric disorders with cognitive sequelae that are or can be longstanding include autism, schizophrenia, depression, post-traumatic stress disorder (PTSD), and personality disorders. Inherited and/or spontaneous medical disorders can also be associated with longstanding cognitive stigmata. Examples include thyroid diseases and other endocrine disorders, diabetes, heart disease, neoplasms outside of the CNS, respiratory illnesses affecting oxygenation of the brain, and renal failure. Epilepsy is a common chronic condition of childhood that can be associated with significant cognitive findings and changes, depending upon the etiology, type, and severity of the seizure disorder. Primary neurological insults and illnesses also occur in childhood or even in prenatal life, including traumatic brain injuries (TBIs), exposures to toxic chemicals such as metals or solvents, brain tumors, infections like meningitis, strokes, or even the childhood onset of diseases usually occurring in adulthood such as multiple sclerosis (MS) or Huntington disease (HD). The cognitive manifestations of disorders that can develop in both childhood and adulthood are an important area of concern because they are often distinctive at different developmental stages and have differing implications for future function. For example, neurological insults and diseases in childhood often produce a much more generalized pattern of cognitive changes than the more focal patterns in adults that will be described in this chapter. Interestingly, children often recover cognitive function better than do adults following brain insults, due to the plasticity of the developing brain.

Finally, it is important to consider late-appearing effects of childhood-onset conditions and CNS insults. Chronic medication use can affect brain function later in life; an example of this phenomenon involves drugs for epilepsy. Radiation treatment for cancers can also affect the brain on a permanent or even delayed basis. For example, leukemia was once treated with high doses of radiation that, in some patients, was associated with development of brain lesions in middle age. Even childhood lead exposure can manifest itself in behavior later in life. For example, the author saw an adult patient whose hyperthyroidism caused release of lead that had been stored in her bones during childhood, resulting in behavioral changes (Goldman, Kalis, White, & Hu, 1994).

## NEUROPSYCHIATRIC AND PSYCHIATRIC DISORDERS

Many disorders that fall into the psychiatric domain are associated with anomalies of brain structure and of neurotransmitter function. These abnormalities are well documented for schizophrenic-spectrum diseases and for major affective disorders (Seidman, Cassens, Williams, & Pepple, 1992; Harvey & Keefe, 2009; Langenecker, Jin Lee, & Bieliauskas, 2009). Given the findings, these conditions might better be designated as "neuropsychiatric." The cognitive correlates of many other disorders that fall within the psychiatric domain have also been described. Examples include anxiety disorders and PTSD, personality disorders, and motivational states such as malingering and factitious disorders. Although not the primary focus of this chapter, the cognitive correlates of these disorders in individual patients must be considered when evaluating the impact of primary neurological and medical diseases on cognition.

**MEDICAL AND NEUROLOGICAL DISORDERS AND CENTRAL NERVOUS SYSTEM INSULTS**

Neurological diseases and disorders, and CNS insults from exogenous agents are the focus of this chapter. Primary neurological and neurodegenerative diseases with major cognitive sequelae include cerebrovascular disease, primary progressive dementia, MS, Parkinson disease (PD), brain tumors, and many other conditions. Central nervous system insults affecting cognition can arise from TBIs, chemical exposures of many types (medications, substances of abuse, industrial chemicals), and infection. Non-neurological medical diseases can affect cognition through both primary and secondary mechanisms. Conditions within this category include non-CNS neoplasms, immunological disorders, systemic infections, metabolic diseases, and symptom-based disorders such as fibromyalgia and chronic fatigue syndrome.

## How Should Cognitive Disorders be Classified or Diagnosed?

**DSM-IV TAXONOMY FOR COGNITIVE DISORDERS**

The DSM-IV (APA, 1994) divides cognitive disorders into four categories as follows:

1. *Delirium* refers to acute confusional states associated with general medical conditions, substance-induced encephalopathies, multiple etiologies, and "not otherwise specified" etiologies.

2. *Dementia*, the second "cognitive disorder" included in the DSM-IV, is characterized as being remarkable for deficits in multiple cognitive domains, including "memory," attributable to "the direct physiological effects of a medical condition," the persisting effects of exposures to substances, or multiple etiologies. The manual lists four basic categories of dementia related to neuropathologically based "medical disorders:" Alzheimer disease (AD; further categorized as early vs. late onset), vascular dementia, human immunodeficiency virus (HIV), and "other" (traumatic brain injury, PD, HD, Pick disease, Creutzfeldt-Jacob disease, normal pressure hydrocephalus, hypothyroidism, vitamin $B_{12}$ deficiency, intracranial radiation, substance-induced persisting dementias). Other categories of dementia relate to other general medical conditions, substance-induced persisting dementia (caused by exposure to substances of abuse, medications, or chemical toxicants), multiple etiologies, and etiology not otherwise specified.

3. *Amnestic disorders*, the third category of DSM-IV cognitive disorder, refer to conditions in which the patient cannot learn new information or is unable to remember previously learned information or events. The amnesias included in this category are due to general medical conditions or exposure to a substance, and are explicitly not diagnosable as delirium or dementia. They can be transient (less than 1 month in duration) or chronic (lasting more than 1 month). Examples of the medical conditions listed as possible etiologic bases for these amnesias include trauma, surgery, strokes, and brain infections that produce pathology in brain structures that subserve the functions mediating learning and memory. The category also includes *substance-induced persisting amnestic disorder*, which can be classified a secondary to alcohol, certain medications, and other or unknown substances (which include chemical toxicants).

4. *Cognitive disorder not otherwise specified (NOS)* is the fourth category. This diagnosis includes mild neurocognitive disorders identified through quantified assessment in patients who also have objective evidence of a systemic medical condition or CNS dysfunction. Postconcussional disorder with memory or attentional deficits is also included in this category.

The DSM-IV diagnostic system for cognitive disorders has several critical problems. First, it omits many disorders with prominent cognitive symptomatology (e.g., MS, progressive supranuclear palsy, epilepsy, lupus, and focal stroke, to name just a few). Second, the descriptions of the cognitive deficits accompanying each category overlap excessively, are vague, and are not as specific or complete as the state of knowledge about cognitive disorders allows. Especially notable is the frequent reference to "memory impairment," without specifying the type of memory problem and with the apparent assumption that memory problems are more or less universal in the progressive neurological disorders, an assumption that would be disputed by many clinicians and scientists who study these disorders (Bondi et al., 2009; Knopman et al., 2001). Finally, there is no consistent organizing principle underlying the diagnoses applied. Rather, the grouping of diagnoses includes at least three dimensions: acute versus chronic (acute event vs. persisting dementia), reversibility (delirium vs. dementia), and etiology (substances, genetics).

It is possible to consider classifying cognitive disorders in a more systematic fashion. For example, one classification principle could be based on the cognitive and behavioral manifestations of each disorder, organizing them by either observed types of behavioral and self-reported symptoms or by the typical domain- and process-specific patterns seen on neuropsychological assessment. For example, they could be classified as disorders most prominently involving language changes, memory dysfunction, visuospatial deficits, inattention, impairments in working memory/executive function, or diffuse dysfunction. Another possibility would be to organize them with regard to reversibility and progression (e.g., reversible confusional states, acute encephalopathies, static encephalopathies, progressive dementias).

Probably the most efficient organizational strategy for classifying cognitive disorders—and the one that forms the basis of this chapter—is to use etiology. Using this approach, cognitive disorders in adults can be divided into those emanating from medical disorders producing primary or secondary aberrations in brain function. Examples include metabolic, endocrine, respiratory, and other system-based medical conditions, as well as symptom-based disorders of unknown etiology such as fibromyalgia. A second group of cognitive disorders results from external insults to the brain. These can include open- and closed-head trauma, infections of the brain (e.g., HIV, herpes, meningitis, prion diseases), chemical exposures (medications, substances of abuse, industrial chemicals, environmental toxicants), radiation, and even the absence of critical elements (e.g., malnutrition). Finally, primary neurological, neurovascular, and neurodegenerative disorders also lead to disorders of cognition. These conditions include primary progressive dementias, stroke, vascular dementia, brain tumor, immune and autoimmune disorders of the CNS, motor system diseases, MS, epilepsy, and hydrocephalus, among many others.

## What Evidence Is Used to Describe the Typical Behavioral Characteristics of Cognitive Disorders in Adults?

The cognitive impairments and dysfunctions associated with the conditions described in this chapter have been studied and defined in a variety of ways, including self-reported symptoms, deficits inferred by clinicians or family members based on patient behavior, and neuropsychological test performance.

The latter evidence has received the greatest weight and attention in the literature on cognitive disorders. Neuropsychological tests provide a quantified means of assessing domain-specific cognitive functions and specific kinds of cognitive processes, are standardized with regard to test administration and scoring (so that data from different sites provided by different examiners can be reliably compared), have normative values that allow inference of degree of impairment when comparing patients or groups of patients to referents with similar backgrounds (especially age, gender, education), and have been extensively validated with regard to the information that they provide about the functioning of specific brain structures and systems over many years of research in neuropsychology and cognitive neuroscience. In addition, the reliability, validity, and specificity of neuropsychological tests have been extensively studied and reported (Strauss, Sherman, & Spreen, 2006). This chapter describes findings from research using clinical case series methodology, as well as epidemiologic methods.

### NEUROPSYCHOLOGICAL DOMAINS AND PROCESSES

Neuropsychological function is usually classified into domains, with specific tests generally assigned to one or more of these domains, depending upon the skills being assessed or the task demands of the test. A listing of the generally accepted domains follows, with examples of tests for each domain. For detailed descriptions of the tests and cognitive processing demands associated with each of these domains, the reader is referred to volumes by Lezak et al. (2004) and Strauss et al. (2006).

*Attention*

This domain refers to the capacity to monitor and process incoming stimuli; it is generally assessed by tasks such as the Continuous Performance Test (Rosvold, Mirsky, Sarason, Bransome, & Beck, 1956), which requires acknowledging a critical stimulus in a series of stimuli; Digit Span forward, which requires repeating back a series of numbers after they have been read by the examiner (Wechsler, 1997a); or Visual Span forward, requiring the correct replication of a series of blocks or boxes tapped by the examiner (Wechsler, 1997a).

*Executive Function*

This domain can be difficult to define, and there is some disagreement about what is included in it. However, it generally refers to the ability to develop

strategies for solving novel problems or completing tasks, abstraction and reasoning, and capacity to inhibit responding to distracting stimuli. It is assessed by tasks such as the Similarities Test (correctly identifying the concept that makes two objects or concepts similar) (Wechsler, 1997b); Digit Span Backward (correct reversal of a string of numbers read aloud by the examiner) (Wechsler, 1997a); and the Stroop Task (ability to correctly identify the color of the ink in which color words are presented, with the ink a different color from the word) (Stroop, 1935). Another example is the Wisconsin Card Sorting Test (correctly inferring the implicit rules for categorizing visual stimuli and maintaining and switching sorting rules in response to examiner feedback) (Berg, 1948).

### Working Memory

This domain refers to the ability to hold and process information in completing tasks. The Letter-Number Sequencing Test from the Wechsler scales (Wechsler, 1997b) is an example of a working memory test. For this task, the patient hears a sequence of letters and numbers in random order and then must repeat them back in the correct numerical and alphabetical order.

### Language Skills

This domain encompasses basic linguistic processing, including naming, fluency, repetition of words and sounds, language comprehension, writing, and reading. Tests that assess this domain include the Boston Naming Test (correct identification of the name of an object depicted in a drawing) (Goodglass & Kaplan, 2000) and the Boston Diagnostic Aphasic Examination (includes many tests probing aspects of language) (Goodglass, Kaplan, & Barresi, 2000).

### Visuospatial Abilities

Visuospatial processing includes mentally organizing visual percepts and visual constructions. An example of a nonmotor visuospatial task is the Hooper Visual Organization Test (Hooper, 1983), which requires correctly naming objects that have been depicted in cut-up form. Visual construction tasks include replications of drawings of visual designs using blocks that have sides that are red, white, or half red-half white (Block Design) (Wechsler, 1997b), drawing various objects to command (Boston Visuospatial Quantitative Battery) (Goodglass et al., 2000), or puzzle assembly (Object Assembly) (Wechsler et al., 1997b).

### Learning and Memory

This complex domain includes the capacity to learn new material (encoding), store the material (retention), and recall it at will (retrieval). Types of tests that assess anterograde memory include story passages that must be learned and recalled on immediate and delayed recall (Wechsler Memory Scale Logical Memory) and visual designs that must be replicated from immediate and delayed recall (Wechsler Memory Scale Visual Reproduction) (Wechsler, 1997a). Memory for information that the patient has known for a long time (retrograde memory) can also be assessed. Tasks assessing this type of memory function include Albert's Famous Faces (Albert, Butters, & Levin, 1979), in which the examinee views famous faces from various decades and must identify the person depicted; there are also retrograde memory tests that are developed to test the individual's memory of her or his own life. Procedural memory refers to the ability to learn a new skill, such as reading writing that looks like it would in a mirror (mirror reading).

### General Intellectual Function/Academic Skills

Neuropsychologists often use tests to estimate an examinee's cognitive ability level prior to a brain insult or development of a neurological disorder. For adults, these tests (called "hold tests") can be used to estimate premorbid verbal or visuospatial abilities. Such tests include single-word reading tasks such as the Wide Range Achievement Test Reading subtest (Wilkinson, 1993), vocabulary tests in which the examinee must define words, or tests requiring recall of information learned in school or through life experience (Wechsler Scales Information subtest) (Wechsler, 1997b). Premorbid visuospatial abilities can often be estimated in adults using the Wechsler Picture Completion subtest (identifying the missing detail in a picture) (Wechsler, 1997b) or the Arithmetic subtest of the Wide Range Achievement Test (Wilkinson, 1993).

### Fine Manual Motor Skills

Motor abilities are generally assessed using techniques involving the hands, in which the examinee taps a tapping device with the index finger or inserts pegs into a pegboard. Outcomes are usually total correct responses or time to completion for each hand and both hands together (pegboards). These tests are not cognitive measures but can be used to assess motor contributions to test performance on visuospatial tasks that have a motor component and to gain clues about focal or lateralized brain damage.

### Focal Cognitive Impairments

Structure–function relationships underlie a great deal of the inference process used in interpreting neuropsychological assessment results. A very general rendering of the domain-specific impairments associated with some major brain structures will be provided here. This section should be referred to in the descriptions of disease-associated cognitive deficits detailed later whenever *focal cognitive impairment* is mentioned.

Damage to the frontal lobes or that involves brain systems with frontal lobe components often results in deficits in the domains of attention, executive function, and working memory, sometimes also affecting learning and retrieval of newly learned information (but not true retention of it over time). Because the frontal lobes are richly connected to other parts of the brain, secondary frontal lobe dysfunction may be evident following damage to other brain areas, in which the domain-specific deficits just described are seen but are milder than those following primary insults to or disease of the frontal lobes.

Lesions affecting the lateral aspects of the temporal lobe on the dominant side of the brain (usually the left in right-handers) can result in language impairment, especially of naming ability. Mesial temporal lobe damage (hippocampal system) results in memory deficits for learning and retention of verbal (dominant hemisphere) or nonverbal information (nondominant hemisphere, usually the right hemisphere in right-handers).

The parietal lobes are involved in the processing of visuospatial information. Damage to them, especially the nondominant parietal lobe, may result in inability to organize visuospatial material. Inattention to one side of space can follow damage to the contralateral parietal lobe. Deficits in reading and arithmetic can also be seen following lesions in specific areas of the parietal lobes.

The occipital lobes also process visual information; dysfunction localized to these lobes can be manifested by profound inability to place objects in space.

The basal ganglia, which include structures that are important in motor function and are affected in disorders like PD, mediate visuospatial functions as well.

The cerebellum, also involved in motor function, appears to play a role in cognitive function, particularly visuospatial organization.

The white matter, which constitutes a large part of the brain under the gray matter, is important to cognitive function as well. Intact function of the myelin sheaths in the white matter allows effective information processing and transfer of information from one part of the brain to the other. White matter lesions can affect visuospatial processing, fine manual motor skills, retrieval of information from memory stores, and skills associated with the functioning of the frontal lobes.

Neuropsychology and behavioral neurology are rooted in studies of individuals with focal cerebral lesions, who demonstrate the kinds of deficits summarized earlier. These case study descriptions of individuals and case series provided the basis for research in cognitive neuropsychology, cognitive neuroscience, and clinical neuropsychological assessment. Clinical experience is also a key component of clinician-based inference concerning sites of brain damage in patients and associated neurological disorders (Filley, 2001; Luria, 1966; Mesulam, 2000; White, 1992).

Epidemiological evidence using case–control designs or exposure–outcome methodologies in populations of patients (population based case–control studies, exposure–outcome studies) are the basis for many of the conclusions about cognitive dysfunction associated with the specific disorders summarized in this chapter. Such studies are more objective and allow quantification of effect sizes and other parameters related to the severity of the specific cognitive deficits associated with the disorders described.

Often the evidence cited in a section describing a disease will include both case-based clinical inferences and epidemiological data. The two sources of information have very different advantages and disadvantages. Epidemiological studies can make it difficult to identify qualitative data or "pathognomonic signs" that indicate dysfunction associated with a disease or brain structure. They are, however, a very efficient means of identifying dose–effect relationships between degree of exposure to an agent and outcome (e.g., titers for infections, amount of tumor tissue, dosage of exposure to a drug). They are also better at identifying degree of deficit associated with different stages of a disease or degree of disease severity than clinical methodology. In fact, using epidemiological designs, it is much easier to confirm subtle dysfunction associated with brain disorders or insults. Clinical inference of dysfunction requires much greater impairment (scores 1–2 standard deviations below expectation on a test) than epidemiological methodology. Using case–control or exposure–outcome designs, it is possible to identify very subtle cognitive dysfunction that would

not qualify as a clinical "impairment" or "deficit": group differences or dose–effect relationships can be found within the normal range of test performance. Identifying such dysfunction can provide valuable clues about cognitive changes in the earliest stages of an illness and provide markers for evidence of progression or type of dysfunction when patients develop clinically relevant impairments in cognition.

In the following sections of this chapter, reports on the types of cognitive dysfunction seen in neurodegenerative diseases and following exogenous brain insults and structural brain lesions will include epidemiological evidence, reports from clinicians on findings from cases, and the author's 30-plus years of experience in assessing thousands of patients with cognitive disorders in university hospital and Veterans Administration Hospital settings.

## Medical Disorders

Medical disorders that are not neurodegenerative disorders and do not result from exogenous insults to the brain or structural brain lesions can be associated with cognitive dysfunction and deficits due to both primary and secondary effects on the brain or neurotransmitter systems. An example of primary effects is hypoxia from respiratory failure. Secondary effects can be associated with confusional states or delirium. For reviews of the impairments associated with medical diseases through these kinds of mechanisms, the reader is referred elsewhere (Brands & Kessel, 2009; Bruce, Aloia, & Ancoli-Israel, 2009; Lezak et al., 2004).

## Brain Insults
### Trauma

Head trauma is the most common form of brain injury. It ranges from mild TBI, defined in various ways, to severe TBI, with a wide variety in cognitive deficits apparent in both the acute stages and following medical recovery. Factors that determine the type and severity of cognitive dysfunction following TBI include severity of the brain injury, degree of deficit immediately following the injury, age, repeated brain injury, polytrauma involving other parts of the body, and preinjury alcohol abuse (Dikmen, Machamer, & Temkin, 2009; Hannay, Howieson, Loring, Fischer, & Lezak, 2004). Severity of injury has been defined in a number of ways, including score on the Glasgow Coma Scale, which quantifies quality of eye opening, motor, and verbal responsivity (see Dikman et al., 2009 for details on scale and scores) and length of post-traumatic amnesia (PTA) or time during which the patient is unable

to retain new information following the traumatic event (see Hannay et al., 2004 for severity estimates). Head injuries are often classified as penetrating head injuries, in which an object enters the brain; closed-head injuries, in which the brain sustains damage from primary contact to the head, as well as secondary injuries resulting from downstream neural processes initiated by the primary injury; and concussion, which can occur in the absence of a direct blow to the head but results from acceleration injuries such as those than can occur in whiplash. The primary brain injuries related to brain trauma include contusions at the site of the injury and on the opposite side of the brain (*contrecoups* injury), diffuse axonal injury resulting from acceleration/deceleration, and hematomas (Hannay et al., 2004). These kinds of injuries are important because long-lasting, even permanent residual impairments may be evident in patients with a history of TBI.

Cognitive impairment following TBI can be focal in nature (i.e., related to the site or sites of the brain injury) or diffuse, representing dysfunction from multiple brain sites. In their excellent review of the cognitive and behavioral consequences of TBI, Hannay and colleagues summarized the deficits associated with mild, moderate, and severe trauma. Mild TBI may result in subtle cognitive impairments that are not obvious to the observer, including attentional impairment and verbal retrieval problems accompanied by emotional distress and fatigue. Patients who have sustained moderate TBI may be able to work and live independently but may nevertheless demonstrate frontal lobe damage in their diminished capacity for or interest in planning and organizing, loss of spontaneity, impulsivity, and apathy. Focal cognitive deficits may also be apparent (see the section "Focal Cognitive Impairments" for a description of focal structural cognitive dysfunction). Severe TBI can be quite devastating, with permanent, severe effects in multiple cognitive domains that can include attention, short-term memory, working memory, and/or visuospatial abilities. The executive dysfunction associated with severe TBI can be especially devastating, affecting self-determination, awareness, and self-regulatory behavior (Hannay et al., 2004). This author has seen patients with histories of severe TBI and comas lasting months whose scores on tests of intelligence are normal but who cannot work because they are so apathetic and unable to organize and mobilize themselves. They can also have significant problems on tests assessing the ability to generate hypotheses, reason, develop strategies to solve problems or carry out tasks efficiently, and complete

tasks when there is any kind of distraction. The behavioral and emotional correlates associated with these cognitive impairments and TBI-induced neuropathology can be severe (see Prigatano & Maier, 2009; Hannay et al., 2004).

## Infections

Although many types of infections can affect the brain, three of the most common or cognitively interesting are described here.

### HUMAN IMMUNODEFICIENCY VIRUS

Human immunodeficiency virus (HIV) primarily affects the immune system but can be neurovirulent, crossing the blood–brain barrier early in the disease (Davis et al., 1992). Brain structures that are particularly vulnerable to the neuropathological effects of HIV include the gray and white matter of the frontal lobes and the caudate nucleus and putamen. It is believed that approximately 30%–50% of HIV-infected individuals are cognitively impaired, although a substantial portion of these people may not show related deficits in their ability to carry out activities of daily living (Grant, Sacktor, & McArthur, 2005). Three levels of cognitive impairment have been defined for HIV, all of which exclude impairments related to delirium or other neurocognitive disorders. Asymptomatic cognitive impairment is defined as scores 1 standard deviation below the mean on standard neuropsychological tests assessing two or more domains of function without effects on activities of daily living; mild neurocognitive disorder is indicated by scores at least 1 standard deviation below the mean on tests assessing two or more domains accompanied by at least mild deficiencies in daily functioning; HIV-acquired dementia is characterized by marked impairment in at least two ability domains with scores at least 2 standard deviations below normal and marked impairment in daily functioning (Antinori et al., 2007). Woods and colleagues summarized domain-specific cognitive dysfunction. They emphasized deficits in attention, especially selective attention; working memory; executive function (planning and self-monitoring); learning and memory at the level of encoding and retrieval; prospective memory ("remembering to remember"); verbal fluency; and information processing speed. Visuospatial deficits were said to be probable but require further investigation (Woods et al., 2009).

### PRION DISEASES

Four diseases caused by prion infections are known, two of which are very rare and hereditary and one of which (kuru) was caused by cannibalism. The most common prion disease is subacute spongiform encephalopathy (SSE), often called Creutzfeldt-Jakob disease (CJD), although Victor and Ropper (2001) dispute this terminology. Two forms of SSE have been described: CJD, which generally occurs in the sixth decade of life, and "mad cow disease" or "new variant CJD," which occurs in people who are much younger. Subacute spongiform encephalopathy is characterized by changes in cognition and behavior, with visual and gait abnormalities. Myoclonic jerks are typically seen (Victor & Ropper, 2001). The dementia is rapidly progressive and involves multiple cognitive domains. In this author's experience, SSE can be distinguished from other neurodegenerative disorders by the rapidity of the cognitive decline and the co-occurrence of fasciculations.

### HERPES ENCEPHALITIS

Brain infection from herpes simplex type 1 has been described as the most common form of acute encephalitis. The acute symptoms include fever, seizures, confusion, stupor, and coma, with characteristic hemorrhagic lesions in the temporal and medial orbital frontal lobes (Victor and Ropper, 2001). The cognitive sequelae can be quite severe, including a dense amnesia, language deficits, and severe problems with self-regulatory behavior, planning, and reasoning.

## Chemicals

In its chapter on substance-related disorders, the DSM-IV (APA, 1994) describes the effects of a large number of substances along several dimensions (dependence, abuse, intoxication, withdrawal, intoxication delirium, withdrawal delirium, amnestic disorder, psychotic disorders, mood disorders, sexual dysfunction, and sleep disorders). The drugs listed include several substances of abuse (alcohol, cannabis, cocaine, hallucinogens, nicotine, phencyclidine) as well as medications that may also be abused (opioids, amphetamines, inhalants, sedatives/hypnotics/anxiolytics) and categories for polysubstance abuse and other substances. Of this list of drugs, we will briefly describe the cognitive deficits associated with alcohol use only; the reader is referred to the DSM-IV and elsewhere (Gonzalez, Vassileva, & Cobb Scott, 2009) for a detailed description of the cognitive impairments associated with acute and chronic use of cannabis, cocaine, benzodiazepines, methamphetamine, ecstasy, and opiates. Glue sniffing is associated with a specific neurobehavioral syndrome and results from exposure to toluene, an industrial chemical described later.

Prescribed medications that are not typically abused may also affect cognition through primary or secondary mechanisms. The reader is referred to the *Physician's Desk Reference* (PDR) and product material descriptions for details on these pharmaceuticals. We will follow our discussion on the cognitive effects of alcohol with a summary on the effects of industrial chemicals.

## ALCOHOL

Because it is a neurotoxic chemical, alcohol has acute effects on brain function and cognition that are readily apparent to the most casual observer of people in bars and at parties who are partaking of the drug. However, for social drinkers, these effects appear to be temporary, at least as assessed by neuropsychological test measures (Rourke & Grant, 2009). Patients who meet DSM-IV criteria for alcohol dependence or alcohol-induced persisting amnestic disorder (APA, 1994), however, often exhibit cognitive deficits and cognitive dysfunction. Rourke and Grant summarized the literature on rates of cognitive disorders among alcoholics as follows. Among alcoholics, 10% meet criteria for alcohol-induced persisting amnestic disorder or alcohol-induced persisting dementia. Of the 90% of alcoholics who do not meet criteria for these two disorders, about 50% show no cognitive impairments after 2–3 weeks' abstinence. Of the remaining 50% with neuropsychological impairments evident 3 weeks after they stop drinking, 70%–90% show mild cognitive deficits that improve after several months or years of abstinence, whereas 10%–30% maintain mild cognitive dysfunction after a year of abstinence. The mild deficits seen in alcoholics who have recently stopped drinking include impairments in tests of attention (especially on tasks with high processing demands), abstraction and problems solving, visuospatial skills both with and without motor components, and learning and memory at the levels of learning, encoding, and possibly retrieval. These problems are often seen in the context of normal IQ and verbal skills. Patients with these mild cognitive problems tend to have prominent white and gray matter pathology in the frontal lobes. Rourke and Grant emphasize that the cognitive deficits seen in alcoholics may vary somewhat and are affected by a number of other factors, including age, genetic and developmental factors, hepatic dysfunction, history of head injury, nutritional deprivation, hypoxemia from cigarette smoking, sleep disturbances, seizures, repeated alcohol withdrawal, and antisocial personality disorder (Rourke & Grant, 2009).

Wernicke-Korsakoff encephalopathy (WK) is a distinctive disorder that begins with a set of acute symptoms that include confusion, abnormal eye movements, and ataxic gait secondary to thiamine deficiency (the Wernicke phase). As the acute confusional state abates, a dense amnesia is apparent in which the patient is profoundly impaired in ability to learn and retain new information and has trouble remembering information from the past. The domain-specific deficits associated with the mild form of cognitive deficits of alcoholism are also present (Rourke & Grant, 2009).

Dementia associated with alcoholism is characterized by impairments in learning and memory accompanied by frontal lobe dysfunction (deficits in planning, abstraction, reasoning, attention) (Hannay et al., 2004). The neuropathology appears to disproportionately involve white matter (Filley, 2001) and may reflect progressive brain atrophy (Rourke & Loberg, 1996).

## INDUSTRIAL CHEMICALS

The effects of exposure to industrial chemicals in adulthood have been described for many substances (White & Janulewicz, 2009; White, Feldman, & Proctor, 1992a; Feldman, 1999; White, Feldman, & Travers, 1990). Chemicals that have been investigated most extensively include metals (lead, arsenic, mercury, thallium, aluminum, tin, manganese), solvents (trichloroethylene, tetrachloroethylene, 1,1,1-trichloroethane, toluene, xylene, n-hexane, Stoddard solvent, styrene), pesticides (e.g., organophosphates, carbamates), persistent organic pollutants (polychlorinated biphenyl), and gases (carbon dioxide, sarin, soman).

Because each chemical can exert specific and differing focal effects on brain structure and function, it is difficult to generalize about the cognitive effects of these substances. For example, toluene exposure has been studied rather intensively due to chronic abuse by glue sniffers. This chemical preferentially affects the white matter and cerebellum (Rosenberg et al., 1988; Filley, Rosenberg, & Heaton, 1990), with impairments in frontal lobe functions and visuospatial abilities, whereas solvents such as tetrachloroethylene (perchloroethylene, dry cleaning fluid) appear to especially affect frontal/limbic systems, with particular effects on reasoning and memory (White, 2001). Similarly, lead appears to affect frontotemporal lobe function, resulting in memory impairments and problems with sustained attention, whereas methylmercury is known to preferentially affect the motor strip, the visual cortex and the

cerebellum, resulting in visuospatial and visual-motor deficits. Although most chemicals have the greatest effect on cognition and behavior at the time of exposure, with some recovery following absence of exposure, some chemicals, such as mercury and carbon dioxide, can have delayed effects on the brain and behavior.

However, adult exposure to industrial chemicals generally affects some combination of the domains of attention, executive function, working memory, visuospatial and visual-motor skills, anterograde memory, or retrograde memory, with sparing of basic language skills, such as naming. A classification system for diagnosing neurotoxic disorders from solvents developed by Baker and White (World Health Organization, 1985) characterized the conditions of exposure (acute vs. chronic) and permanency of outcomes (brief intoxication vs. chronic residual brain disorder) in terms of severity (mild, moderate, severe). This system has been applied to the diagnosis of encephalopathy following exposure to many types of industrial chemicals (White et al., 1992a).

## Neurological Disorders
### Primary Progressive Dementias
The primary progressive dementias are disorders that are notable for progressive cognitive and behavioral decline due to a degenerative neuropathological process.

#### ALZHEIMER DISEASE
Alzheimer disease is thought to be the most common form of dementia. Neuropathologically, it is characterized by the presence of neurofibrillary plaques and tangles in the brain, accompanied by neuronal atrophy and loss of synapses (Alzheimer, 1907). Medial temporal lobe structures, such as the hippocampus, are the first brain structures to be affected, followed by the association areas of the frontal, temporal, and parietal lobes (Braak & Braak, 1991), with relative sparing of the white matter and primary sensory and motor areas (Bondi, Salmon, & Kaszniak, 2009). These neuropathological changes are accompanied by acetylcholine depletion (Whitehouse et al., 1982). The greatest risk factor for the development of AD is advancing age, with dramatic increases in the incidence and prevalence of the disease through the 80s and 90s. Family history of AD in a first-degree relative is associated with about a four-fold increase in the risk for other family members (van Duijn, Stijnen, & Hofman, 1991), although the genetics of the disorder are quite complicated and several genes have been identified

as causative. The apolipoprotein E (ApoE) 4 allele on chromosome 19 has been repeatedly found to be more common in AD patients than in controls (Corder et al., 1993). Alzheimer disease may be more common in women and in people with lower occupational and educational attainments (Bondi et al., 2009) and is seen more frequently in persons with histories of head injury, especially those who carry the ApoE 4 allele (Mayeux et al., 1995).

The neuropathological progression of AD—from medial limbic structures to association areas in the frontal, temporal and parietal lobes—is associated with the cognitive changes expected, given the structure–function relationships subserved by these brain areas. The most remarkable initial cognitive finding in AD is a decline in anterograde memory function seen especially at the level of retention of newly learned information: Patients forget both information and events very quickly. They also have trouble learning new information and begin to forget information that they have known in the past (retrograde memory loss). In this author's experience, the retrograde memory loss appears to work backward, with forgetting of information from more recent decades followed eventually by loss of memories from youth and childhood. In addition, patients with AD begin to lose semantic memory relatively early in the course of the disease, with inability to name common objects or find words, accompanied by errors in the semantic and phonemic quality of speech. Problems with executive function—problem solving, inhibiting distractions, and working memory—also begin relatively early, as do deficits in visuospatial skills. As the disorder progresses, deficits in all domains of function co-occur, and the patient becomes profoundly cognitively impaired. Table 26.1 summarizes the cognitive deficits seen in AD and in vascular dementia, the other most common form of dementia in the elderly. Alzheimer disease is often used as the hallmark disorder representing a cortical dementia, which is characterized neuropathologically by lesions in gray matter and functionally by widespread cognitive deficits. In contrast, disorders that are characterized as subcortical dementias are notable for pathology deep in the brain, below the gray matter, and for functional deficits in attention and executive function, visuospatial skills, manual motor speed and dexterity, and capacity to learn new information and retrieve it from memory stores, with relative sparing of language skills (Albert et al., 1979). Table 26.4 (below) summarizes several neurodegenerative diseases along the cortical/subcortical continuum.

**Table 26.1 Alzheimer disease (AD) vs. cerebrovascular dementia (CVD)**

| | AD | CVD |
|---|---|---|
| Attention | Intact digits forward; problems with anything complex | Slowed reaction time, errors |
| Executive/working memory | Impaired | Impaired |
| Motor | Mild impairment | Moderate impairment |
| Language | Naming deficit with phonemic and semantic errors; reading intact until late stages | Word retrieval problems* |
| Visuospatial | Moderate impairment | Moderate impairment |
| Anterograde Memory | Severely impaired learning and retention | Impaired learning and retrieval; recognition/retention relatively intact** |
| Mood/Personality | Paranoia may occur; loss of "personhood" as disease progresses | Anxiety/depression may appear very early; fatigue common |
| Retrograde Memory | Remote > recent; loss works backward | May see retrieval problems across decades; retrograde memory sometimes worse than anterograde on tests |

Summary of findings in early to moderate stages of the two disorders
*Unless there is focal ischemia in speech areas, when naming and other language deficits may be present
**Unless there is involvement of structures mediating memory retention

Because cognitive decline is the hallmark symptom of AD, research has focused on the identification of cognitive changes in the elderly that indicate the earliest functional evidence of disease onset. Initially, this work focused largely on changes in memory but has expanded to include progressive declines in other cognitive domains as well, with complex and competing taxonomies for types of decline. The term *mild cognitive impairment* has been applied to these taxonomies and may represent the prodrome of AD or other neurological disorders.

OTHER PRIMARY PROGRESSIVE DEMENTIAS

Other primary progressive disorders have been described that are often difficult to distinguish from AD in living patients but have distinct neuropathological features. Often termed the frontotemporal or frontal lobe dementias (FTD), these disorders include Pick disease (Pick, 1898, 1906), progressive subcortical gliosis (Neumann & Cohn, 1967), and dementia of the frontal lobe type (Neary et al., 1986). The underlying neuropathology is found in the frontal and/or temporal lobes, without the presence of the neurofibrillary plaques and tangles found in AD and with gyral atrophy confined to the rostral temporal and frontal lobes (without the characteristic parietal involvement see in AD) (Moss, Albert, & Kemper, 1992).

These disorders are often misdiagnosed as AD, with the correct diagnosis discovered at autopsy. Research attempts to differentiate AD from FTD using neuropsychological data from patients whose brains were later biopsied have been summarized by Bondi et al. (2009, pp. 175–178). Taken together, these studies indicate that patients with FTD show poorer executive skills in the context of better retained short-term memory and visuospatial abilities than AD patients.

A condition called *primary progressive aphasia* (Mesulam, 1982), which is characterized by rapid loss of meaningful fluent speech, has also been described. This appears to be a clinical diagnosis that, on autopsy, has been shown to accompany several types of neuropathological degeneration, including that of AD and FLD.

*Cerebrovascular Disorders*

Conditions that affect the cerebrovascular system of the brain are also extremely common and occur at about the same rates as AD—and at higher rates in some countries (Fratiglioni, De Ronchi, & Agüero-Torres, 1999). These conditions can be caused by

occlusion of blood vessels in the brain or hemorrhage. They include common disorders such as ischemic stroke, transient ischemic attack (TIA), cognitive syndromes related to vascular dysfunction diagnosed as or related to vascular dementia (vascular cognitive impairment, vascular dementia, white matter disease), and rarer pathological conditions (AVMs, cerebral aneurysms, and cerebral autosomal dominant angiopathy with subcortical infarcts and leukoencephalopathy [CADASIL]). Each disorder will be described briefly in terms of its pathology, followed by a description of associated cognitive dysfunction. In cerebrovascular disorders, focal cognitive deficits confined to very specific functions are often apparent, as are aphasic disorders and specific constellations of symptoms related to pathology in certain tissue classes. These focal cognitive impairments have been described earlier as related to specific parts of the brain (see the section "Focal Cognitive Impairments") and will be discussed briefly as appropriate.

### ISCHEMIC STROKE

Strokes are diagnosed following the rapid onset of neurological deficits that cannot be explained on the basis of convulsions. Ischemic stroke occurs when blood vessels are blocked, causing cell death. Embolism (occlusion of a blood vessel by an abnormal particle in the blood) and thrombosis (blood clots) can cause vessel blockages (Victor & Ropper, 2001). Stroke is a very common cause of death worldwide, with only heart disease more frequently occurring as a cause of death (Paul, Srikanth, & Thrift, 2007). The cognitive sequelae of stroke are dependent upon the site of the stroke and the brain functions mediated by the structures at the stroke site.

Cognitive effects of stroke can be primary; that is, as the result of pathology in specific brain structures. For example, patients with strokes in the third convolution of the frontal lobe on the side of the brain dominant for language (Broca's area) may exhibit expressive aphasia. However, secondary cognitive effects of stroke also occur, as when a stroke occurs in a brain pathway connecting two brain regions, with cognitive deficits related to the functional attributes of the disconnected brain region. An example of the latter from the author's experience is a stroke in the thalamus disrupting connections to the right parietal area, resulting in a syndrome in which the patient neglected the left side of space. Many strokes disrupt pathways to the frontal areas of the brain (which are the most richly connected to other brain structures), resulting in secondary frontal lobe dysfunction. The latter can

be seen especially clearly on tasks assessing executive function (working memory, novel problem solving, complex attention, inhibiting distractions) and is generally less extreme than that seen in patients with primary frontal pathology. It should be noted that patients with multiple strokes may exhibit more than one focal neurological syndrome and that strokes can occur in the context of other neurological or cerebrovascular disorders.

### TRANSIENT ISCHEMIC ATTACK

Transient ischemic attacks are currently defined as brief episodes (less than 1 hour) of neurological deficit following presumed ischemia in the brain or eye when there is no imaging or other evidence of brain infarction (Albers et al., 2002). The occurrence of TIAs in many patients is associated with clinical stroke in the period immediately following (Wu et al., 2007).

In the acute phase of a TIA, the patient may exhibit focal cognitive deficits, of the type described earlier for ischemic stroke, that quickly resolve. For example, the patient may be quite aphasic for a few minutes, with inability to produce coherent words or sentences, unable to produce low-frequency words for a period after that, and then fully able to speak. Following resolution, neurological deficit of this type often disappears. However, many patients have multiple TIAs, and there is evidence that half of patients with histories of TIAs show deficits or dysfunction on neuropsychological testing, although these may not constitute focal neurobehavioral syndromes (Bakker et al., 2003).

### VASCULAR DEMENTIA

Vascular dementia is diagnosed in patients who have cognitive deficits, and who have greater pathology than would be seen with single focal stroke or TIA. Often, these patients have a combination of clinical strokes and microinfarcts without obvious clinical symptomatology. At one time, it was believed that vascular dementia was characterized by a sudden onset of focal neurological deficit with step-wise progression. However, only 40% of patients diagnosed with vascular disease have focal neurological signs or a diagnosis of stroke (Bowler, 2002). It has been suggested that there may be two types of vascular dementia. The first is seen in patients with clinical infarction(s), sudden onset, and focal neuropsychological deficits. The second appears after a critical mass of subcortical small vessel pathology has occurred, develops slowly, and the clinical course is remarkable for slow progression and deficits in

cognitive abilities associated with frontal-subcortical systems (Brown, Lazar, & Delano-Wood, 2009). Tatemichi (1990) pointed out that vascular dementia may develop for several reasons, including the critical location of a stroke or strokes, volume of cerebral injury resulting from infarction, numbers of strokes occurring, and co-occurrence of stroke with AD.

The neuropsychological deficits seen in patients with vascular dementia most commonly include reduced fine manual motor speed and coordination, executive dysfunction, and impaired visuospatial skills. Deficits in memory function are generally limited to slowed encoding or problems retrieving newly learned information (unless a focal stroke has occurred in medial temporal areas), and language dysfunction is most often manifested in word-finding or word retrieval deficit rather than frank aphasia (unless infarcts have occurred in primary language areas). Changes in mood may also occur, especially symptoms of agitated depression in patients who have not previously experienced depressive disorders.

Vascular dementia is included in the DSM-IV as a diagnostic entity (APA, 1994, p. 146). However, the diagnostic criteria include memory impairment, focal neurological signs, and specific neuropsychological syndromes that do not occur in many patients, especially those who have not had clinical strokes.

The differential diagnosis of vascular dementia and AD can be complex because there is some overlap in the cognitive profiles of the two disorders and also because some patients have both disorders. However, a few neuropsychological signs, based on the author's experience, provide clues for this differential diagnostic dilemma and are presented in Table 26.1. In vascular dementia, mental control skills (e.g., spelling *world* backward) are often more impaired than short-term memory (e.g., three-word recall on the Mini-Mental Status Examination).

### Vascular Cognitive Impairment
Vascular cognitive impairment (VCI) refers to the early, subtle manifestations of vascular dementia, and is similar in concept to the mild cognitive impairment discussed earlier in relation to AD. It is thought to reflect dysfunction in the white matter (Brown et al., 2009).

### White Matter Disease/White Matter Lesions
White matter (WM) pathology is thought to be a major determinant of the cognitive and behavioral changes seen in vascular dementia (Brown et al.,

2009; Filley, 2001). Because loss of white matter volume is a feature of "normal aging" (Filley, 2001), assessment of the pathological consequences of changes in the WM is complex. Overall, however, lesions in the WM associated with vascular dementia are, in our experience, clearly associated with the motor, visuospatial, and executive dysfunction found in patients with magnetic resonance imaging (MRI) lesions in the WM, history of TIAs or TIA-like episodes, and risk factors for stroke or microvascular pathology (e.g., hypertension, cardiac disease, diabetes).

### ARTERIOVENOUS MALFORMATIONS
Arteriovenous malformations are malformations of the blood vessels, in which they appear as tangles of veins and arteries without a capillary bed (Arteriovenous Malformation Study Group, 1999; Stapf et al., 2001). In many patients, AVMs are asymptomatic until they rupture, resulting in brain hemorrhage, or cause seizures. Neuropsychological deficits have been identified in patients with AVMs compared to controls, although the literature on this issue is confusing because it has generally failed to differentiate the cognitive findings in AVM patients with and without history of hemorrhage (see Brown et al., 2009, for a review). Arteriovenous malformations are treatable with surgery. In this author's experience, patients with AVMs and no history of seizures or hemorrhage are unlikely to show cognitive deficit, whereas those with ruptured AVMs often show focal and more general cognitive deficits related to the site of the AVM in the patient's brain.

### Dural Arteriovenous Fistulas
Dural arteriovenous fistulas are a form of vascular malformation similar to AVMs, but located in the dura (AVMs can be located anywhere in the brain or dura). However, a dementia syndrome has been described associated with the occurrence of these lesions (Hurst et al., 1998; Matsuda, Waragai, Shinotoh, Takahashi, Tagaki, & Hattori, 1999; Tanaka, Morooka, Nakagawa, & Shimizu, 1999).

### CEREBRAL ANEURYSMS
Bulges in the walls of brain arteries, cerebral aneurysms (CAs) have weak walls and are highly susceptible to rupture, causing subarachnoid hemorrhages. They occur most commonly in the circle of Willis; the associated cognitive deficits depend upon the site of the rupture and tend to be focal in nature. For example, patients with rupture of the anterior cerebral artery often experience short-term memory deficits. Cerebral aneurysm ruptures are reportedly

the fourth most common cause of stroke (5%–10%) (Adams & Davis, 2004).

Cerebral autosomal dominant angiopathy with subcortical infarcts and leukoencephalopathy is an autosomal dominant disorder considered by some to be a variant of vascular dementia (Filley, 2001, pp 151–154), although the associated neurological and behavioral features are somewhat different from those described earlier for vascular dementia. First described in 1955, in two sisters (van Bogaert, 1955), data from several large cohorts show that the disorder is associated with several different mutations on chromosome 19q12 (Tournier-Lasserve et al., 1993). Other diagnoses found in patients or families of patients with CADASIL include mood disorders, stroke, dementia, and migraine (Filley, 2001). Imaging and neuropathological studies indicate that, early in the disorder, distinct lesions occur in the white matter and merge as the disease progresses into a generalized leukoencephalopathy (Harris & Filley, 2001). Although gray matter lesions occur in some cases, the dementia associated with the disorder appears to be explained by the white matter pathology (Hedera & Freidland, 1997). This disorder is remarkable for its behavioral manifestations, which can be seen in the absence of overt neurological deficit. Frequently, the initial symptoms involve mood and neuropsychiatric symptoms (Filley et al, 1999; Harris & Filley, 2001), with later cognitive decline. The cognitive dysfunction is notable for abulia, perseveration, impaired vigilance, and poor memory retrieval in the context of spared language (Filley, 2001).

## Diseases of the Motor System

Many diseases involve brain systems that mediate motor movement. In this section, we focus on parkinsonian disorders and those with related pathology and similar symptomatology, and on HD.

### PARKINSON DISEASE, PARKINSONISM, AND RELATED DISORDERS

These disorders, which involve motor movement and arise from neuropathology in the basal ganglia and deep motor neurons, and/or the presence of Lewy bodies in brain structures, are considered together because they are similar in their clinical features and underlying pathology. Table 26.2 summarizes the severity of domain-specific neuropsychological deficits observed clinically in the parkinsonian and related disorders, and Table 26.3 provides details concerning the types of cognitive processing problems that are apparent within each neuropsychological domain for each disorder. The cognitive disorders associated with these diseases tend to be subcortical in nature or to involve a mixture of symptoms that are both subcortical and cortical. These distinctions are summarized in Table 26.4, which compares several parkinsonian disorders on the cortical/subcortical dimension.

### Parkinson Disease and Parkinsonism

The term *parkinsonism* refers to a constellation of motor signs and symptoms that include muscular rigidity, disequilibrium, masked face, problems initiating movement, slowed movement, postural abnormalities, gait disturbance, and motor impairments in speech. This group of symptoms is evident in parkinsonian disorders arising from a variety of brain insults and events, as well as in idiopathic PD.

**Table 26.2 Severity of domain-specific dysfunction: Parkinsonian syndromes**

|         | Attention | Executive | Visuospatial | Motor |
|---------|-----------|-----------|--------------|-------|
| PD      | +         | +         | ++           | ++    |
| PSP     | +         | ++        | +++          | +++   |
| CBGD    | +         | ++        | ++           | +++   |
| DLBD    | ++        | +++       | +            | +     |
| PD+AD   | +         | ++        | ++           | ++    |
| PD+DFLT | ++        | +++       | ++           | ++    |

PD, Parkinson disease; PSP, progressive supranuclear palsy; CBGD, cortical basal-ganglionic degeneration; DLBD, diffuse Lewy body disease; PD+AD, Parkinson disease and Alzheimer disease; PD+DFLT, Parkinson disease and frontal lobe dementia

**Table 26.3 Domain-specific deficits in parkinsonian syndromes: Qualitative**

| | Naming/Language | Anterograde Memory | Comments |
|---|---|---|---|
| PD | Naming generally intact; can see retrieval deficits; right onset cases may have more problems | Impaired learning, retrieval; visuospatial <verbal; intact recognition | Micrographia; hypophonia; depression, fatigue |
| PSP | Intact lexicon; affected by motor problems | Like PD | Extreme expressive problems; ocular deficit; echolalia possible; extreme cognitive and behavioral rigidity |
| CBGD | Mild to moderate naming deficit; semantic paraphasias | Like PD | Light drawings; wandering hand; affect/personality varies |
| DLBD | Naming varies; often retrieval deficit | Impaired learning, retrieval | Diffuse multifocal disorder |
| Extrapyramidal onset AD | Impaired naming w/semantic paraphasias, phonemic paraphasias | Impaired learning, retrieval, retention | Visual hallucinations w/PD sx and memory loss |

PD, Parkinson disease; PSP, progressive supranuclear palsy; CBGD, cortical basal-ganglionic degeneration; DLBD, diffuse Lewy body disease; AD, Alzheimer disease

Parkinsonism or parkinsonian syndromes can result from medications (e.g., tardive dyskinesia following use of antipsychotic medications like Haldol), exposure to chemical toxicants (MTPT, solvents, manganese), viral infections, trauma (e.g., dementia pugilistica in boxers), and strokes or lacunes in the basal ganglia and associated brain structures. Sometimes the course of the disorder is different. For example, patients with toxicant- or stroke-induced parkinsonism may progress extremely slowly or not at all in terms of symptoms and disability once their clinical picture has emerged.

Parkinson disease is a common neurodegenerative disorder associated with aging, although cases can occur before age 40 and even in childhood. Its clinical presentation includes the parkinsonian symptoms just described, accompanied by pill-rolling tremor when the patient is at rest, small handwriting (micrographia), soft stuttering speech, and neuro-ophthalmologic abnormalities. Steps are typically small in size, all movements are slowed, there is stiffness in muscle tone when moving a limb (cogwheel rigidity), and the patient may report depression (McPherson & Cummings, 2009; White, Au, Durso, & Moss, 1992d). Parkinson disease appears to have a genetic component, and certain genes are seen more often in the families of patients with PD, but the exact genetic determinants of the disease are not well understood. The stage of the disease is often described in terms developed by Hoehn and Yahr (1967). In the first stage, patients exhibit motor symptoms only on one side of the body, whereas in Stage 2 symptoms occur bilaterally but there is no gait disorder. In stage 3, mild gait disturbance is accompanied by mild to moderate disability. Stage 5 is characterized by confinement to wheelchair or bed (White et al., 1992d). The depletion of the neurotransmitter dopamine in PD has led to use of dopaminergic medications for treatment. In fact, PD can frequently be distinguished from parkinsonism because symptomatology in patients with PD typically improves with these medications, whereas it does not in patients whose parkinsonian symptoms arise from other causes. In addition, PD patients usually show tremor, which is not seen in other forms of parkinsonism.

**Table 26.4 Cortical vs. subcortical dementia**

| PD | Subcortical |
|---|---|
| PSP | Subcortical |
| CBGD | Both |
| DLBD | Both |
| Extrapyramidal-onset AD | Cortical |

PD, Parkinson disease; PSP, progressive supranuclear palsy; CBGD, cortical basal-ganglionic degeneration; DLBD, diffuse Lewy body disease; AD, Alzheimer disease

Terminology for cognitive dysfunction in PD is disputed and confusing. Patients with PD and parkinsonism typically show dysfunction in multiple domains when undergoing neuropsychological testing. This constellation of neuropsychological deficits is seen most prominently in slowed fine manual motor speed accompanied by incoordination (White et al., 1996), and impairment in tasks assessing visuospatial skills, inhibiting distractions and perseverations, developing strategies for carrying out a task, solving novel problems in a flexible manner, or holding information in short-term memory storage and manipulating it. On verbal memory tasks, patients typically have more difficulty learning and retrieving information that is not logically organized (word lists, word pairs) than on organized verbal learning tasks like recalling stories. Learning and retrieval of visual designs is typically particularly difficult. Multiple-choice recognition paradigms generally demonstrate better learning of information than when patients are asked to spontaneously recall information. Speech is often soft and sometimes stuttering or poorly paced, but the linguistic (semantic) aspects of speech are generally well retained (e.g., knowing the names of objects). Word-list generation is generally difficult for patients with PD and parkinsonism. Handwriting is typically small (micrographia). In unilateral parkinsonism or stage 1 PD, the cognitive profile sometimes appears to reflect the functioning of the contralateral hemisphere: For example, patients with right-sided onset of motor symptoms may have more trouble than others with verbal tasks, whereas left-onset patients may have disproportionate visuospatial dysfunction. Parkinson disease–associated neuropsychological findings are sometimes referred to as a *subcortical dementia* (see Table 26.4) or simply the neuropsychological profile accompanying PD or parkinsonism (White et al. 1992d).

The term "Parkinson disease dementia" (PDD) has been applied to patients with especially marked presentations of this just-described cognitive profile. Said to affect about 40% of PD patients (Emre, 2003), this syndrome was summarized by McPherson and Cummings (2009) as being characterized by especially severe deficits in executive and visuospatial function, accompanied by anterograde memory impairment that is more severe than in patients with PD without dementia but not as severe as seen in AD. This manifestation of cognitive decline in PD fits the DSM-IV description of dementia associated with a medical condition (PD) well.

Some PD and parkinsonism patients have concurrent AD. Our experience suggests that, in these cases, the cognitive profile of AD tends to predominate, although visuospatial and motor deficits are more prominent than those typically seen in AD. Patients with AD whose clinical course begins with an extrapyramidal motor onset are sometimes seen. In these patients, the correct diagnosis becomes apparent over time, the patient does not respond to dopaminergic medications, and the clinical course of AD predominates.

*Lewy body disease*

Lewy body disease (LBD) is neuropathologically related to the widespread occurrence of Lewy bodies in the brain. Lewy bodies are also present in both PD and AD, so that LBD can sometimes be difficult to differentiate from the other two disorders. It is remarkable for parkinsonian symptoms, visual hallucinations, and uneven alertness (McKeith et al., 2005). Impairments in attention and executive functions, as well as in visuospatial skills, are prominent, although confrontation naming and recognition memory are intact (see Table 26.3).

*Progressive Supranuclear Palsy*

Progressive supranuclear palsy (PSP) is characterized at onset by a tendency to fall and by a "doll's eye" gaze abnormality in which the patient loses volitional control of upward and downward gaze, as well as lateral eye movement. (Full eye movement can be obtained if the patient fixes on a target.) Tremor is unusual. Limbs are stiff and spastic, neck is stiff, and masked facies is common. Dysphagia and slurred speech are typical. The patient loses control of the voluntary musculature, eventually progressing to a "locked-in" state, with loss of voluntary speech despite consciousness and ability to process incoming information. The disease typically occurs in the sixth to seventh decade, with death following in 5–10 years (McPherson & Cummings, 2009). Neuropathologically, the disease is remarkable for loss of neurons in deep nuclei and loss of cholinergic neurons, along with characteristic neurofibrillary tangles that differ from those seen in AD (Victor & Ropper, 2001).

Progressive supranuclear palsy is the disorder from which the concept of subcortical dementia (Albert et al., 1974) was developed. The cognitive deficits associated with PSP are similar to those seen in PD, although the motor and visuospatial deficits tend to be much more remarkable. Speech is slurred, and echolalia may be seen, with anarthria in the later stages—however, naming appears to be intact but can be hard to evaluate given motor and retrieval deficits.

Learning of new information is possible but may be slowed, and verbal information is learned much more easily than visuospatial information; using recognition paradigms for assessment of memory functions shows better learning and retention than using recall paradigms. Mood is often depressed and anxious, characterized by sadness and isolation (see Tables 26.2, 26.3, 26.4).

### Cortical Basal-ganglionic Degeneration

Cortical basal-ganglionic degeneration (CBDG) is a slowly progressive disorder with underlying neuropathology in the basal ganglia and cerebral cortex. It was first described by Rebiez and colleagues in a report on three cases in 1968 (Rebiez et al., 1968). This syndrome is remarkable for onset of various motor symptoms that appear most prominently on one side of the body and a distinctive syndrome in which the patient loses control of an arm or hand, so that it flies upward. Motor features of the disorder include rigidity, loss of kinesis, dystonia, myoclonus, and postural instability. Neuropathologically, the disease is marked by degeneration of the substantia nigra and motor nuclei, accompanied by posterior (parietal) cortical degeneration. The cognitive manifestations are quite interesting, because the patient may show lateralized brain dysfunction (especially in the early stages, when prominent lateralized motor symptomatology is present), and the dementia associated with the disorder includes elements of frontal-subcortical dysfunction that are similar to those seen in PD, accompanied by elements resembling Alzheimer dementia. Consistent with PD, patients show impaired visual-motor and visuospatial function and short-term memory deficits at the levels of encoding and retrieving new information, although they are able to retain substantial amounts of the information they learned, as demonstrated when their recall is tested using multiple-choice recognition probes. Like patients with AD, they often have trouble with naming objects or pictures of objects (confrontation naming) and make semantic paraphasias (substituting an incorrect word for the target word) in speech or on naming tasks. Like patients with both PD and AD, they demonstrate executive dysfunction (Mimura, White, & Albert, 1997). They differ from these other patient groups in that their drawings are frequently very light.

### Cerebellar Disorders

Spontaneous or inherited cases of atrophy of the cerebellum and nearby structures occur, as do cerebellar lesions in MS and following brain insults, such as exposure to chemical toxicants (especially solvents and ethanol) (White et al., 1992a). The cognitive sequelae of cerebellar disease can involve many domains due to the connections of the cerebellum to other parts of the brain (Schmahmann, 1991). The classic cognitive dysfunction apparent with many types of cerebellar lesions and disease are described in the section "Focal Cognitive Impairments" on focal structural lesion effects.

### HUNTINGTON DISEASE

Like PD, HD is a disorder neuropathologically involving the basal ganglia. However, neuronal degeneration in HD involves the head of the caudate nucleus and the putamen, and it cannot be effectively treated with dopaminergic medications. The disease is named after George Huntington, who first described the disorder in 1882. Long known to be inherited as an autosomal dominant trait, the chromosomal locus of the HD gene was identified in 1983 (Gusella et al., 1983), and the mutation itself described in 1993 (Huntington's Disease Collaborative Research Group, 1993). The genetics of HD are interesting in that the gene is characterized by a trinucleotide repeat (CAG). The number of CAG repeats occurring on the gene in a particular individual at risk for HD determines whether he or she will develop the disease (>36 repeats), and predicts the age at onset of HD symptomatology (larger number of repeats is associated with earlier age of onset, with typical onset in middle age) and speed of progression of the disease itself. Huntington disease is characterized by motor dysfunction remarkable for involuntary movements and impaired capacity for voluntary motor activity, a "frontal-subcortical" dementia with many features overlapping with the dementias seen in parkinsonian syndromes, and affective symptoms that include depression, apathy, and irritability (Brandt, 2009).

The cognitive dysfunction that develops in patients with HD is notable for relative sparing of ability to name objects and other aspects of language (except word-list generation) in the context of impaired attention, executive function, and visuospatial and visual-motor skills. The impairment in learning and memory includes diminished ability to learn word pairs and visuospatial information, with retrieval of newly learned information being especially problematic (White, Vasterling, Koroshetz, & Myers, 1992c; Brandt, 2009), although there is some disagreement about whether forgetting of newly learned information

occurs over delays (deficit in retention) (Brandt, 2009). This author's experience and the limited research on the progression of cognitive change in HD suggest that it is slow (White et al., 1992c).

Because the onset of HD is often in middle age (or even later), and because there is a genetic test that allows identification of individuals who will develop the disease, it has been possible to study prodromal cognitive change in HD prior to onset of the neurological symptoms. Brandt (2009) has reviewed this literature, which is complex, concluding that persons close to diagnosis may show cognitive changes, although those far from diagnosis do not (Brandt, Shpritz, Codori, Margolis, & Rosenblatt, 2002).

## Structural Lesions
### BRAIN TUMORS
Brain tumors account for significant morbidity in cancer patients, about 25% of whom experience a primary tumor or metastatic tumor in the brain. Only stroke exceeds tumor as cause of death from intracranial disease (Victor & Ropper, 2001, p. 676). Primary brain tumors include the infiltrative gliomas (the most common form of brain tumor), meningiomas (which are not in the brain itself), and CNS lymphoma. Metastatic tumors also occur secondary to cancers in other physiological systems and structures. In addition, paraneoplastic disorders occur in which disease occurring in other parts of the body (especially cancers) have focal or generalized effects on brain structures. The cause of paraneoplasm is unclear but may be related to autoimmune mechanisms. For example, cerebellar degeneration can be seen following tumors in other parts of the body (Victor & Ropper, 2001, p. 724).

The cognitive sequelae of brain tumors can be focal and/or generalized. The location of the tumor may be important, causing focal cognitive deficits of the type described earlier (see the section "Focal Cognitive Impairments"). However, due to edema and vascular effects of some tumors, cognitive effects may be more generalized and include confusion. It has been hypothesized that rate of growth determines how generalized the cognitive consequences of brain tumor will be, with fast-growing tumors having the greatest pressure effects (Gleason & Meyers, 2002; Hom & Reitan, 1984; Meyers, 2000; Hannay et al., 2004). Despite the possibility of generalized as well as focal effects of tumors on cognition, Luria (1966) agreed with the clinical experience of this author that focal effects of tumors are usually apparent (especially if they are noninfiltrative).

### HYDROCEPHALUS
Adult presentations of hydrocephalus include hydrocephalus ex vacuo, in which the individual presents with enlarged ventricles due to normal aging or the presence of a degenerative dementia such as Alzheimer disease (Filley, 2001), and the cognitive problems seen relate to the aging process or another disorder. Acute hydrocephalus can also occur in adults, which may be related to hemorrhages due to various types of vascular lesions (Victor & Ropper, 2001, p.662). Normal-pressure hydrocephalus (NPH) is a condition that is diagnosed following a triad of symptoms that include cognitive dysfunction, gait disturbance, and sphincter incontinence (Adams et al., 1965). Although sometimes linked to occurrence of TBI, multiple white matter strokes, or infections, NPH is generally idiopathic in etiology. Cognitive deficits are generally secondary to frontal lobe dysfunction and, in the author's experience, may include impairment in judgment and reasoning, perseverations, inattention, and executive dysfunction (see also Filley, 2001, Ch. 14).

### CALLOSAL DISCONNECTIONS
Disruption of the corpus callosum, a bundle of fibers that connect the two hemispheres of the brain, can be seen following surgical resection of the corpus callosum (a treatment for epilepsy) and due to callosal agenesis that may be congenital or acquired. The major cognitive consequences of callosal disruption arise from ineffective transfer of signals from one side of the brain to the other. This can result in slowed or poor integration of information in carrying out tasks. In the author's experience, this may also lead to rather dramatic symptoms involving motor function, known as "alien hand" syndrome. The patient's two hands may "fight" or work in an uncoordinated manner when putting block designs or puzzles together or in which the patient's hand does not follow the patient's intent (e.g., refuses to let go of a chair or other object when the patient tries to move away from it).

## Epilepsy
Like the parkinsonian syndromes and primary progressive dementias, the term "epilepsy" covers a wide variety of symptoms and results from multiple underlying causes. Buchtel and Selwa define epilepsy as a disorder that "results from hyperexcitability in neuronal circuits, resulting from structural, genetic, or fundamental neuronal function" (Buchtel & Selwa, 2009, p. 267). When neuronal circuits

become "hyperexicted," electrical activity in the brain generates a seizure, which can be characterized by motor movements, sensory changes, cognitive dysfunction, change in consciousness, loss of consciousness, and amnesia for the event. The event itself is referred to as the *ictal* phase. Behavioral changes can also be observed in the *preictal* phase just before a seizure (an aura) and interictally, when the patient is not having seizures. Single seizures have a number of causes, including fever, alcohol withdrawal, overdose of a medication, or chemical exposure, but epilepsy is diagnosed when seizures are recurrent and the patient demonstrates abnormalities on electroencephalogram (EEG). *Symptomatic epilepsy* refers to a seizure disorder (with recurrent ictal events) that has a clear etiology such as trauma, stroke, infection, or chemical or pharmaceutical exposure in the brain. The term *idiopathic epilepsy* is used when there is no clear etiology to the seizure disorder.

Ictal events are termed *partial seizures* when they emanate from a particular area of the brain, and further classified as complex partial seizures if the patient loses consciousness or is unable to remember the seizure. *Generalized seizures* occur as a result of abnormal electrical activity involving the brain as a whole. For an exhaustive listing of seizure subtypes, see Buchtel and Selwa (2009, p. 278) or the link that they cite at http://www.ilae-epilepsy.org.

Patients with epilepsy often show cognitive dysfunction on neuropsychological assessment when they are not having seizures and EEGs are normal on the day of testing. In patients with partial and complex partial seizures, the evidence of cognitive dysfunction is often focal or lateralized (see the section "Focal Cognitive Impairments" on the domain-specific evidence of focal cognitive impairment). For example, a patient with a seizure focus in the frontal lobes might have deficits in attention and executive function. Cognitive dysfunction is less focal in patients with generalized epilepsy. The most common form of partial epilepsy is temporal lobe epilepsy. If the seizure focus is in the dominant temporal lobe (usually the left side of the brain), this form of epilepsy is associated with naming difficulties (with lateral temporal foci) and problems with verbal memory (mesial temporal involvement). Patients with nondominant temporal lobe foci are more likely to have problems with visual memory and visual constructions. Temporal lobe epilepsy (TLE) has been studied extensively with regard to interictal personality syndromes that are thought to typify nondominant and dominant TLE (Greenberg & Seidman, 1992; Schomer et al., 2000).

## Autoimmune Disorders

Some disorders that occur through inflammatory autoimmune mechanisms exert significant direct effects on brain structures and functions, resulting in cognitive changes. Two of these disorders—MS and systemic lupus erythematosus (SLE)—will be described here. For a more exhaustive review of some relatively rare forms of autoimmune/inflammatory disorders affecting the CNS and their cognitive sequelae, the reader is referred to Filley (2001, Ch. 8).

### MULTIPLE SCLEROSIS

The cognitive, behavioral and symptomatic presentations of MS have been studied quite extensively, perhaps due in part to the difficulty in definitively diagnosing MS prior to the availability of clinical MRI methodology, which provides direct evidence of MS lesions in the CNS. Positive imaging findings accompanied by laboratory findings of abnormalities in the cerebrospinal fluid (elevated immunoglobulin G index, evidence of oligoclonal bands) are now critical to the diagnosis of this disorder. Current clinical criteria for MS diagnosis include the occurrence of two or more episodes of MS symptoms accompanied by evidence of at least two separate CNS lesions (McDonald et al., 2001). Multiple sclerosis symptoms include visual changes (visual field cuts, blindness, diplopia), motor dysfunction, slurred speech (dysarthria), and paresthesias. Patients frequently report fatigue as a very early symptom (White, Nyenhuis, & Sax, 1992b; Thornton & DeFreitas, 2009). Neuropathologically, MS is most notable for plaques in the white matter that occur preferentially around the ventricles, corpus callosum, cerebellum, brainstem, optic nerves, and spinal cord (Noseworthy, Lucchinetti, Rodriguez, & Weinshenker, 2000; Victor & Ropper, 2001). The disease is known to have a genetic basis and is considered very likely to occur because of environmental exposures interacting with genetic vulnerability. The types of precipitating exposures have not been well defined, although viruses and exposures to certain neurotoxic chemicals have been considered. The disease is much more common in women and in people who live in the extreme northern and southern portions of the globe.

A taxonomy for types of MS has been developed based on the course of the illness, occurrence of acute symptoms, and progression. The most aggressive and rarest form of MS, malignant MS, is associated with rapid progression and death, whereas benign MS is remarkable for few and mild symptomatic episodes

even over a long period of time. Relapsing-remitting MS is the most common form of the disease in the initial stages and is remarkable for the occurrence of symptomatic episodes interspersed with symptom-free intervals. However, this form often develops into secondary progressive MS as the disease progresses, at which time symptoms are always present and worsening. Primary progressive MS is diagnosed when the patient shows progressive decline without symptom-free interludes from the beginning (Thornton & DeFreitas, 2009). These differing clinical courses of MS are important because they appear to be related to the cognitive sequelae of the disease, as well as to prognosis and course.

The neuropsychological test performance characteristics of patients with MS have been studied in several meta-analytic investigations combining multiple studies (Wishart & Sharpe, 1997; Thornton & Raz, 1997; Zakzanis, 2000; Henry & Beatty, 2006; Prakash, Snook, Lewis, Motl, & Kramer, 2008). Thornton and DeFreitas (2009) provide an excellent tabulation of these findings, with a summary of the research on frequency of "cognitive impairment" (performance at least 2 standard deviations below average) (Nocentini et al., 2006; Rao, Leo, Bernardin, & Unverzagt, 1991). These findings and our own clinical experience (White et al., 1992b) and the experience of others (Filley, 2001) suggest that MS patients can differ quite markedly in the cognitive deficits/dysfunction that they show. This may be related to site of lesions, lesion load, intensity and duration of progression of the disease, and other factors. However, some cognitive findings are quite commonly encountered as subtle or severe findings on neuropsychological tests. Slowed information processing and deficits in working memory are typical, as are deficits in manual motor speed and dexterity and on visuospatial tasks (including those that do not require motor manipulations). Word-list generation is often diminished. Effects are also seen on memory tasks and sometimes naming tests because of problems retrieving information from memory storage, including newly learned information and facts that a person has learned over a lifetime. On formal testing, ability to learn and recall visuospatial information may be more affected than learning of verbal information. This general pattern of deficits is similar to that seen in frontal/subcortical dementia (Filley, 2001). Cognitive deficits may be especially severe and even appear to be generalized during an MS exacerbation, in patients with a long course, or in patients who have significant cerebral atrophy associated with the disease. Partial or apparently complete recovery from cognitive dysfunction/deficits often occurs following recovering from an acute episode of MS symptomatology, and it is important that testing done during exacerbations or periods of acute illness be repeated to get an accurate idea of how well the patient can function in daily life during asymptomatic intervals (White et al., 1992b).

### SYSTEMIC LUPUS ERYTHEMATOSIS

Systemic lupus erythematosus can affect multiple body systems, and the CNS is involved in up to two-thirds (West, 1994) or 70% of cases (Johnson & Richardson, 1968), a condition known as lupus cerebritis. The cognitive and neurological manifestations of CNS lupus have been attributed to widespread microinfarcts in the cortex and cerebellum (Victor & Ropper, 2001, Ch. 34) and white matter disease pathology (Filley, 2001). The cognitive dysfunction associated with SLE varies in severity but, based on our clinical experience, most prominently involves attention and executive dysfunction, visuospatial deficits, and problems in retrieving newly learned information in the context of intact language skills such as naming.

## Conclusion

As this chapter clearly shows, the cognitive deficits associated with a vast array of brain disorders have been described in both the clinical literature and through epidemiological and neurocognitive research methodology. Patterns of domain-specific dysfunction and cognitive processing deficits or dysfunction have been identified for damage to individual brain structures and brain systems. Focal dysfunction from damage to these structures and systems can occur with stroke, brain tumors, and other structural lesions; following brain insults such as infections or trauma; and during the neurodegeneration that occurs in disorders like AD, parkinsonian syndromes, and MS, especially in the early stages. Some of the patterns of dysfunction that can be seen in these neurological conditions have been described as cortical or subcortical dementias. This distinction provides clues about the neuropsychological domains that are affected in a disorder, although the specific cognitive processing deficits and pathognomonic signs accompanying cortical and subcortical dementias vary among the disorders. The patterns of cognitive dysfunction and deficit that accompany neurological disorders and insults allow the neuropsychologist or behavioral neurologist assessing patients to differentially diagnosis likely brain structures affected in patients who

suffer from CNS disease using behavioral findings, especially in combination with history and imaging results.

The patterns of focal and disorder-specific cognitive dysfunction described in this chapter are far more detailed than those listed in the DSM-IV under cognitive disorders. In some cases, there is outright disagreement between the DSM and the neuropsychological and neurobehavioral literature. This is especially true in the domain of memory, which is described by the DSM as being affected in virtually all disorders. For some of these disorders, the neuropsychological literature might support a deficit in learning, although not in memory when "memory" is defined as the capacity to retain information over time. Furthermore, the clinical and research evidence from neuropsychological approaches to CNS disorders addresses more domains of functional cognitive processing deficits with greater specificity than does the DSM, providing a clearer picture of the cognitive profiles expected with different diseases.

Cognitive dysfunction can also be generalized, occurring in most or all neuropsychological domains, in patients with neurological disorders. This occurs especially when the brain damage is widespread and in the later stages of neurodegenerative disorders, when atrophy and collapse of brain structures occur. Generalized cognitive dysfunction of this type is termed *dementia* and can be distinguished from delirium. In dementia, the dysfunction is permanent, with little fluctuation or relentless progression, whereas patients with delirium frequently show great variability in dysfunction and may recover completely from it once the cause is addressed. This distinction is in accord with DSM definitions.

### Future Directions

The fields of cognitive neuropsychology and cognitive neuroscience have exploded in recent decades, examining the cognitive and behavioral effects of CNS diseases and pathology with regard to the cognitive determinants of domain-specific processing deficits, brain systems approaches to understanding CNS disorders, functional and structural brain imaging evidence concerning the structural and systems-based determinants of cognitive deficits, and nosology of subtypes of disorders. Many questions remain:

• Would it be possible to develop a DSM for cognitive disorders associated with neurological diseases that succinctly defines them in a manner similar to the DSM approach?

• What will we learn about the determinants of cognitive dysfunction, using imaging techniques in which the brain is visualized while patients and controls carry out cognitive tasks? Will the structural determinants of similar patterns of dysfunction that occur over several disorders become more apparent? Will the differences between these disorders also become clearer?

• Brain banks have increased in number, in which pathological tissue can be examined and compared to cognitive dysfunction that has been assessed during the lifetime of individuals. What will this tell us about the relationships between neuropathology and cognition?

• What role does genetics play in cognitive disorders? Do certain genes affect the expression of patterns of native abilities with which individuals are born (i.e., life-long tendencies for attentional dysfunction, problems with verbal expression or comprehension, or deficits in visuospatial or visual-motor function)? What genes play a role in the development of certain neurodegenerative disorders or vulnerability to brain insults? What are the interactions between genes that drive native ability patterns and those that cause or predispose individuals to CNS disorders and damage (gene–gene interactions)? Are there gene–environment or gene–environment–gene interactions that are important in the development of certain disorders?

• Finally, the behavioral evidence strongly suggests that there are subtypes of certain diseases. For example, patients with AD often present with different patterns of cognitive deficit, especially early in the disorder. Alzheimer disease caused by autosomal dominant inheritance has long been thought to differ from "spontaneous cases," which we now know are often associated with inherited differences in the ApoE allele. Similarly, brain bank data suggest that the pathological findings in patients who have been diagnosed with AD vary widely, as do the relationships between degree of measured pathology and severity of cognitive dysfunction seen in the patient during his or her lifetime. How will the combination of behavioral findings, genetic information, imaging, and neuropathological evidence drive new understandings of the definitions of cognitive disorders?

# Specialty Areas and Trends in Practice

# Clinical Psychology Interventions in Primary Care

Leonard J. Haas

## Abstract

This chapter reviews the need for clinical psychology services that are integrated into the primary health-care environment and covers in depth the issues that an effective primary care clinical psychologist must understand to function effectively in primary care. These are understanding the primary medical care environment, recognizing the unique characteristics of primary medical care patients who seek psychological services, and the key treatment tactics and strategies necessary for effective work in a primary care environment. Recommendations are illustrated with numerous case examples adapted from the experiences of a veteran primary care clinical psychologist.

**Key Words:** Boundaries, brief treatment, medication, patient perspectives on psychological treatment, physician–psychologist collaboration, problem-focused psychotherapy, somatic complaints, teamwork, therapeutic partnerships, underserved populations

The role of the clinical psychologist in primary care, and the need for such a role, can best be appreciated by considering the following facts:

• Most citizens in the United States (and arguably, in most other countries) obtain their health care in the primary medical care setting. In the United States, primary care is usually offered in outpatient clinics staffed by family physicians, general internists, pediatrics, obstetrician-gynecologists, or some combination of these specialties (Beardsley, Gardocki, Larson, & Hidalgo, 1988; Flocke, Frank, & Wenger, 2001; Green, Fryer, Yawn, Lanier, & Dovey, 2001; Katon et al., 1990; Kroenke et al., 1994; Mojtabai & Olfson, 2008). Not surprisingly, the primary care setting is also the one in which most psychosocial and psychiatric problems are first presented. Most individuals in need of mental health services will turn to their primary care physician as their first and sometimes only source of help (Cauce et al., 2002) and, indeed, most researchers suggest that

half or more of common mental disorders are treated exclusively in the primary care sector (Bea & Tesar, 2002). The prevalence of these disorders is substantial. Conservative estimates suggest that 18.5% of U.S. adults meet criteria for a mental health problem that significantly affects their functioning or well-being (Narrow, Rae, Robins, & Regier, 2002).

• The distinction between physical and mental health problems is increasingly problematic: The medical conditions seen in primary care frequently involve chronic diseases related to patients' behaviors, attitudes, relationships, and social environments, including physical inactivity, poor diet, obesity, smoking, and poor adherence to recommended medical regimens (Smedley & Syme, 2000; World Health Organization, 2003). For a variety of reasons, psychologically distressed patients experience increased physical symptomatology (Katon et al., 1990; Kroenke et al., 1994); patients with these "biopsychosocial" problems use medical resources at up to twice the

baseline utilization rates (deGruy, 1996). In some cases, such as with somatization disorder, the increased utilization is extraordinary—up to nine times the national norm (Smith, 1994). There are also additional substantial numbers of patients with conditions such as hypertension, diabetes, functional gastrointestinal disorders, or low back pain who could benefit from clinical health psychology interventions (Trask et al., 2002) either because they need help making changes in their health behavior or they are distressed and stressed by having the illness.

• Primary care physicians have difficulty detecting and/or addressing these mental health or psychosocial issues effectively (Andersen & Harthorn, 1989; Christensen, Fetters, & Green, 2005; Kolbasovsky, Reich, Romano, & Jaramillo, 2005; Yeung et al., 2004). In cases of chronic diseases, which require self-management, primary care physicians have difficulty effectively addressing patients' motivations, behavior, and relationships, and particularly their seemingly irrational failures to adhere to medical recommendations (Katon et al., 2001). In cases of psychiatric disorders, those primary care clinicians who detect psychiatric issues frequently have difficulty informing the patient of their diagnosis: patients reject mental diagnoses since they strongly resist the idea that "this is all in my head" or "I have a mental illness" (Freidin, Goldman, & Cecil, 1980). Studies of time use in primary care visits (Deveugele, Derese, van den Brink-Muinen, Bensing, & De Maeseneer, 2002) suggest that when the physician considers the problem psychological but the patient does not, visits last longer.

• When the doctor and patient do agree that a psychological problem is the source of the patient's complaints, the primary care physician's preference is usually to offer a prescription, and less commonly a referral to a mental health specialist. Neither of these approaches is terribly effective: The nonadherence rate for psychiatric medications prescribed in such settings approaches 50%, and the percentage of patients who resist mental health referrals may be even higher (Forrest, Shadmi, Nutting, & Starfield, 2007; Gonzalez, Williams, Noel, & Lee, 2005).

• If referrals to mental health specialists were acted upon, problems of access would immediately become obvious. Specialty mental health care in the United States (as in most societies where it exists) has much more limited capacity than does primary care and, as a result, barriers to access are common: less flexibility in scheduling and access, and usually higher costs for patients. Ironically, patients who surmount these obstacles still drop out of treatment prematurely, at rates of 30%–60% (Johansson & Eklund, 2006; McFarland & Klein, 2005). Because the "patient capacity" of a traditional psychotherapist is approximately 300 patients per year, it is obvious that any sort of reasonable referral rate would quickly overwhelm the available resources (of note, the typical primary care physician carries a "panel" of 3,000–4,000 active patients).

This state of affairs has resulted in the emergence of a subspecialty of clinical psychology focused on providing psychological services within the primary care environment, collaborating closely with primary care clinicians, and providing rapid-access consultation to these physicians. First conceptualized as biopsychosocial (Engel, 1980) as an approach to health, psychological practice in primary care settings has been called *integrated care* (McDaniel & Campbell, 1997), *collaborative care* (O'Donohue, 2004), or simply primary care psychology (Haas & DeGruy, 2004). Regardless of its name (and indeed some clinical health psychology and behavioral medicine practices are conceptually overlapping), psychological treatment provided in the primary care setting offers a number of benefits to patients (and, arguably, to the health-care system as a whole). Psychologists' presence in primary care has been shown to increase primary care physicians' awareness of and ability to respond to psychosocial aspects of their patients' problems (Craven & Bland, 2006). Anecdotally, the availability of primary care psychologists also reduces barriers to obtaining psychological treatment and may facilitate treatment at earlier junctures in the development of disorders. Additionally, when psychologists and physicians provide collaborative primary care, patients' unhealthy behavior choices, distorted beliefs about illness, and difficulty adhering to medical regimens are more effectively treated.

Practice as a primary care clinical psychologist differs in many ways from the type of practice for which most psychologists were prepared. Consider, as an example, a fictional morning clinic session derived from the author's primary care clinic practice (the rapid, thorough chart completion in particular may differ in reality):

> ***8:30 a.m.***: *Initial visit for Sally Jones, aged 53, referred for smoking cessation. Getting an overview of her life circumstances, the psychologist learns that she is recently divorced after a 10-year marriage to a physically abusive*

man. She has never discussed the abuse with anyone other than her children, who were quite unsupportive of her and didn't believe that their father could have been abusive. Resisting the temptation to explore this aspect of her history further, the psychologist focuses on why her physician referred her. She acknowledges that her doctor has tried to get her to quit smoking several times, concerned about her family history of lung and heart disease and her frequent respiratory infections. Although she recognizes that she "should quit," Ms. Jones believes that "cigarettes are my friends," and relapses after short periods of abstinence. Much of the session is devoted to understanding her attraction to such "friends" (and, implicitly, husbands) who aren't good for her health, and she agrees to "sign on" for a few more such "interesting discussions."

**9:30 a.m.**: Followup visit for Rifqa Bordomi, a 32-year-old Somali woman who is having difficulty parenting her adolescent son; she emigrated to the United States to escape the violence of that nation's civil war, and she shows symptoms of post-traumatic stress disorder (PTSD). Despite these symptoms, her major concern is the upsetting changes she is seeing in her son, who is increasingly alienated from the family and Somali culture. The son, who is in the waiting room, is invited to join the session, and a productive, brief family therapy session ensues, and both agree to a least one follow-up session together.

**10:15 a.m.**: In the "break room" between scheduled patients, the psychologist encounters one of the clinic physician, Harriet Obsidian. Dr. Obsidian is a compassionate, skilled doctor with whom the psychologist has collaborated frequently. Today, she is frustrated and distressed by how tired and sad she becomes when working with a particular patient, and she asks if perhaps she should transfer care of this woman, a patient who has multiple unexplained physical ailments. They have a productive discussion on the relationship between this patient and the physician's hypochondriac, querulous mother, which helps the physician recognize her uncharacteristically intense response to the patient.

**10:30 a.m.**: Eliot Turgid is scheduled for a consultation visit; Mr. Turgid is a married 46-year-old man who seems unresponsive to the selective serotonin reuptake inhibitor (SSRI) that was prescribed for him. Since a consultation was requested, the psychologist asks a nearby medical assistant to find the man's physician, who is able to join them briefly for the visit. Because of the patient's history and the fact that SSRI medication "makes me angry all the time," the psychologist suspects that that the most appropriate diagnosis for this man may be bipolar disorder type II, and speculates with the

patient and physician whether a mood stabilizer might be more appropriate for such a condition than an SSRI. The physician concurs, decides to prescribe valproic acid, and moves on to the next patient. The psychologist must then help the patient cope with this new diagnosis of a "serious mental illness" (in the patient's words), and to understand the nature of the disorder and its treatment, as well as engage him in follow-up treatment. In this case, the patient opts for an online support group, but agrees to keep the option open to return.

**11:30 a.m.**: Follow-up visit with Jimmy Karp, a 28-year-old electrician. Mr. Karp believes he's "crazy," but his only evidence for this is that his physician referred him to a psychologist (for stress-induced headaches, as it turns out). After a productive discussion of what health psychology has to offer for his condition, he agreed to treatment, but only if it does not involve a psychiatric diagnosis. Since his medical diagnosis is "atypical tension headache," the psychologist is able to code the visits as a Health & Behavior intervention. This set of codes does not require a psychiatric diagnosis, and after this was explained to the patient, he was amenable to treatment. The present session reviews the patient's progress in applying progressive muscle relaxation and deep breathing techniques, and in charting possible triggers of his headaches.

**11:45 a.m.**: The psychologist is paged to an exam room in which Dr. Obsidian is seeing a patient with asthma who is resistant to quitting smoking; a 10-minute discussion of what the patient understands the doctor to be recommending, and why, reduces the patient's resistance somewhat. When the psychologist suggests that the doctor and patient try an "experiment" to reduce smoking to "only those cigarettes you really enjoy," and agrees to meet with them for a follow-up visit, both agree to the plan.

**12:15 p.m.**: The reception desk asks if the psychologist could fit in a few minutes to see a young mother of three whose husband has been deployed for military service; she had brought her youngest in for a "well-baby exam" but the medical assistant noted how distraught she seemed. The psychologist meets with her for a few minutes, legitimizes her distress, and assesses her support system. She reports that she has several close family members living nearby, and feels she can cope reasonably well; she just feels temporarily overwhelmed for unknown reasons. A quick review of her circumstances reveals that she has been getting very little sleep over the past 2 weeks, and that a neighbor's husband who is also deployed was just severely wounded. The psychologist acknowledges the sources of her distress, gives her some suggestions for improved sleep hygiene,

*and information about a deployed families support group that is available online, and explains how she can make an appointment if she feels it is necessary.*

*12:30 p.m.: The psychologist finishes his notes and charts, which are entered in an electronic health record shared with the physicians in the clinic. He reviews his upcoming patient appointments and notes from the chart that his first afternoon visit is with a patient who has just been discharged from the intensive care unit; he makes a mental note to inquire about this, completes the charting, makes a few follow-up phone calls, and walks to a nearby café for a late (and brief) lunch at 1:00 p.m.*

Of course, almost all psychologists must practice flexibly, since patients' needs vary. However, I suggest that encounters such as those illustrated here are both common in primary care settings and unique to psychological primary care practice, for several reasons:

• Standard 50-minute appointment times are often unworkable; flexible scheduling related to specific goals is necessary.

• The demands on the psychologist's skills change dramatically and frequently, at unpredictable times. A patient who is struggling with impulse control and shame issues related to compulsive shopping may have accumulated sufficient credit card debt that this has become the biggest stressor for her; she may need help with debt management before the underlying issues can be addressed. Other patients may simply need information, such as the patient who was convinced she had bipolar affective disorder because of pronounced irritability; she was enormously relieved after a brief visit in which her symptoms and family history were reviewed, and the conclusion reached that her irritability stemmed from sleep disturbance and job stress.

• The patient's social network by definition includes another important professional relationship—that with their primary care physician (and sometimes others including pharmacist, medical assistant, nutritionist, nurse practitioner, and physician assistant), and part of primary care psychology treatment often involves helping to resolve impasses in those important relationships.

• The patient population spans an enormous range, including patients who might typically be seen by psychotherapists; patients who are chronically mentally ill, who might be seen in intensive outpatient settings; patients similar to those seen in behavioral medicine clinics and pain clinics; those who would typically be treated in substance abuse clinics; those in crisis who would typically first be in contact with crisis intervention specialists; those in need of information, who might be seen by health educators; and those who would ordinarily not be seen by any sort of mental health or psychoeducation specialist.

• Medication is almost always at issue in primary care; patients are either currently taking prescribed drugs, considering whether to take them, failing to take them, or unhappy with them and desirous of being prescribed a "better" medication.

• Problems are multisystemic—organic, behavioral, cultural, interpersonal, familial, legal, educational, vocational, residential, or some combination of these—and patients' most pressing concerns are not always those the psychologist most wants to address (Haas, Houchins, & Leiser, 2003).

Primary care practice offers clinical psychologists the opportunity to serve patients on the "front lines," and to offer psychological treatment for an enormous range of problems. In addition, primary care psychologists serve a translational role; they may help patients and physicians resolve difficulties in jointly managing patients' illnesses, they may help physicians understand the application of psychological principles to patient care, and they may help patients understand the links between mind, body, and behavior. In exchange for these opportunities, primary care clinical psychologists may sacrifice some degree of professional autonomy. For example, the record-keeping system, clinic schedule, billing practices, choice of support staff, and fee schedule may be arranged by nonpsychologist administrators. Ideally, the needs of the psychologist will be considered in a well-functioning primary care clinic, but they will certainly not be paramount.

To have the desired impact on the medical care system and the population of patients which it serves, the primary care clinical psychologist must understand the primary medical care environment, must recognize the unique characteristics of the patient population, and must be able to effectively apply a wide range of psychological treatment methods tailored to the needs of the patient and the constraints of the environment. Each of these topics is addressed in greater depth in the remainder of this chapter.

## Understanding the Primary Care Environment

The primary care physician is what most patients would call their "regular doctor." More specifically,

primary medical care has been defined by the Institute of Medicine (2003) as "integrated, accessible health-care services [provided] by clinicians who are accountable for addressing a large majority of personal health-care needs, developing a sustained partnership with patients, and practicing in the context of family and community" (p. 7).

There are four federally designated medical specialties in primary care: internal medicine, family practice, pediatrics, and obstetrics-gynecology. In addition, physician assistants (and less frequently, nurse practitioners) serve as patients' primary care providers. Of the 850,000 U.S. physicians, one-third are in the primary care specialties (Pasco & Smart, 2003). The typical primary care physician sees perhaps 16–30 patients per day, in visits of under 15 minutes in length (Balkrishnan, et al., 2002). Although primary care physicians often consider themselves generalists rather than specialists, almost all are credentialed in a medical specialty, which means that they have had 3–4 years of residency training after obtaining their medical degrees and have passed a specialty board certification exam (Haas & DeGruy, 2004).

Primary care has been called the de facto mental health system in the United States (Schurman, Kramer, & Mitchell, 1985). For psychiatric conditions, most primary care physicians' first choice of treatment is medication, most notably SSRI antidepressants. Primary care physicians write most of the prescriptions for psychoactive medications in the United States, by some estimates, up to 80% of such prescriptions (Beardsley et al., 1988). Despite criticism of primary care doctors' skill in prescribing for psychiatric conditions, the evidence comparing them to specialists (mainly psychiatrists), suggests that their skills are equivalent (Mojtabai & Olfson, 2008; van Rijswijk, Borghuis, van de Lisdonk, Zitman, & van Weel, 2007). In addition, some primary care physicians (primarily in the specialties of family medicine and pediatrics) also offer counseling, although this has become less common as reimbursement has decreased (Himelhoch & Ehrenreich, 2007).

Efforts to categorize the types of problems addressed in primary care have demonstrated that the majority of primary care patients have multiple problems (Flocke et al., 2001; Kroenke et al., 1994). Research that attempts to cluster primary care problems suggests that two highly prevalent clusters involve pain-related problems and chronic disease management (Stange, Zyanski, Jaen, & Callahan, 1998; Weiss, 1999), and further suggests that the primary care foci can be conceptualized in groups of problems centered on lifecycle-related issues (birth of child, retirement, death of spouse, etc.), risky behavior (uncontrolled hypertension, excessive drinking, smoking), caloric balance (obesity and more rarely, anorexia), pain, and a large proportion of "medically unexplained" (usually categorized as somatoform) symptoms. Although many symptoms can be related to psychological disorders, most primary care clinicians do not consider themselves to be providers of mental health care, and prefer to either refer such problems or disregard them in favor of "competing opportunities" (Stange, Woolf, & Gjeltema, 2002) to provide help they feel competent to offer. This is perhaps an unintended consequence of dichotomizing patients' problems into "mental" and "physical," since doing so helps primary care doctors think of themselves as "not psychological providers."

The presence of a clinical psychologist in the primary care setting allows physicians to address patients' psychological issues more effectively. However, this tells only half the story. The complementary issue is that patients with psychological disorders often have unmet medical needs or masked medical problems (Grace & Christensen, 2007). Two-thirds of primary care patients with a psychiatric diagnosis have a significant physical illness (Spitzer et al., 1995; Spitzer et al., 1994). Thus, the second benefit to patients seen in integrated primary care settings is that their psychologists are exposed to more information about the patients' overall health, and are thus more able to detect conditions that should be addressed medically.

> *Example: A patient referred for treatment of depression was evaluated by the primary care psychologist, who inquired carefully about the specific nature of the patient's sleep disturbance and found that the patient was likely suffering from untreated sleep apnea. Discussion with the patient's physician and appropriate testing showed this to be the case, and the patient's mood improved as the sleep apnea was treated.*

Nonetheless, the more frequent issue addressed by the primary care clinical psychologist is that of psychological symptoms being expressed somatically (Kroenke, 1992). As noted earlier, pain complaints comprise an enormous proportion of primary care visits, and recent evidence suggests the close association of pain and depression (Freedland, Carney, & Skala, 2004). The amplification of cardiac risk posed by untreated depression (and conversely the improved recovery rates shown when cardiac patients are treated for depression) is significant—and often

overlooked when no psychologists are involved (Bogner & de Vries, 2008; Wells et al., 1989). Part of the translational role that the psychologist plays is to treat these conditions without forcing patients to adopt psychological concepts first.

> *Example: A 45-year-old woman was referred for anxiety treatment, despite the fact that she insisted that her symptoms were the result of poorly treated cardiac arrhythmias; she was successfully engaged in treatment and helped with her symptoms by framing the issue as stress caused by her fears about her heart; a variety of cognitive-behavioral techniques aimed at "calming her nervous system so as not to trigger an arrhythmia" were used successfully without resolving the question of whether or not she had an anxiety disorder.*

Rich as they are in opportunities for improved patient care, primary care environments are deficient in one key element: time in which to capitalize on these opportunities.

The duration of the average primary care visit in the United States has diminished from the standard "office visit" of 20 minutes to slightly under 13 minutes over the past few decades (Deveugele et al., 2002; Mechanic, McAlpine, & Rosenthal, 2001). An indirect illustration of this change is the fact that the second (and final) edition of a text on psychotherapy in medical contexts entitled *The Twenty-Minute Hour* (Castelnuovo-Tedesco, 1986) was published the same year as the first edition of a similar book on counseling for primary care physicians entitled *The Fifteen-Minute Hour* (Stuart & Leiberman, 1986) that is now in its third edition (Stuart & Leiberman, 2002). This is true as much for psychologists as it is for physicians.

> *For example, a 30-year-old mother of three young children who is seeing the primary care psychologist for treatment of PTSD arrives 30 minutes late to her session; she has been scheduled for 50 minutes, but since the psychologist has a full schedule that day, only 15 minutes of remaining time is available. Not only is transportation difficult for this young woman, but the delay was caused by her accomplishing one of the goals she and the psychologist had been discussing—resolving the conflict between the need to immunize her children and her anxious fears that she would thereby subject them to the risk of an adverse reaction. She and the psychologist were able to have a 10-minute worthwhile session focused on the changes in her thinking about the immunization, as well as noting several relatively less anxious periods during the previous 2 weeks and clarifying what led to their occurrence (the remaining few minutes were spent scheduling a follow-up visit and discussing what information to provide to the primary care physician).*

During primary care office visits, patients typically present multiple complaints, averaging three per visit, but sometimes as many as 12 (Flocke et al., 2001; Haas, Houchins, & Leiser, 2003). The pressure of time often leads the physician to interrupt patients after (or during) the description of the first complaint, redirect the conversation to biomedical rather than socioemotional areas, and leave patients with unexpressed needs, unanswered questions, and confusion about their responsibilities for follow-up (Bell, Kravitz, Thom, Krupat, & Azari, 2002; Kravitz & Callahan, 2000; Kroenke, 2003).

Primary health care is rife with obstacles to effective communication in addition to time pressure. Significant numbers of patients can be characterized as having "low health literacy," or difficulty understanding medical instructions and recommendations (Baker et al., 1996; Rudd, 2007; Wolf, Gazmararian, & Baker, 2007). In addition, patients often have explanatory models or perspectives on their illnesses that are discrepant with those of the physician (Lang, Floyd, & Beine, 2000; Lang, Floyd, Beine, & Buck, 2002). For example, one compelling study showed that as many as two-thirds of general (nonurgent) primary care patients were afraid that their symptoms indicated a serious illness (Jackson & Kroenke, 2001). Half of these patients left their visits still concerned about this, even though their physicians diagnosed them as having mild or benign conditions. For a surprisingly large number of "presenting problems"—even complaints as simple as "cough"—patients entertain a wide and often discrepant set of possible diagnoses that can differ widely from those considered by their physicians (Bergh, 1998). At an even more basic level of communication, there are discrepancies between doctor and patient regarding such apparently straightforward aspects of the visit as whether or not a prescription was given (Lapane, Dube, Schneider, & Quilliam, 2007).

## Understanding the Primary Care Patient

Although many patients may be typical of those seen in specialty mental health care, the majority of primary care patients have characteristics that make them unique. These characteristics often have significant impact on the patient's reaction to seeing a primary care psychologist, and on their response to psychological treatment. As noted earlier, it is axiomatic

that the primary care patient "has" a primary care physician, and it is almost axiomatic that the patient has been prescribed medication for the presenting condition. In addition:

• *Primary care patients often have multiple comorbid psychological and medical problems.* Primary care patients often have both medical and psychological conditions, and often more than one of each. As noted earlier, the primary care psychologist must be familiar and comfortable with addressing the reality of patients' medical conditions, particularly when the biomedical and psychosocial conditions affect each other.

With respect to psychopathology, problems may be even less clearly defined. For psychologists coming to primary care from specialty mental health settings or academic treatment settings, it may be startling to learn how multifaceted and interrelated patients' psychological disorders can be. For example, the initial research into the effectiveness of screening primary care patients for psychopathology (Spitzer et al., 1994) found that nearly one-third of the respondents had three or more mental diagnoses. In the World Health Organization primary care study, seven of the eight specific psychiatric diagnoses studied had comorbidity rates of 50% or higher, the sole exception being alcohol abuse (Ormel, et al., 1994). The extensive co-occurrence of depression and anxiety in the primary care patient has been well documented (Parkerson, Broadhead, & Tse, 1996; Sartorius, Ustun, Lecrubier, & Wittchen, 1996), as has the overlap of anxiety and panic disorder (Kroenke, Spitzer, Williams, Monahan, & Lowe, 2007; Simon, Gureje, & Fullerton, 2001), depression and panic disorder (Ronalds et al., 2002), and Axis I and Axis II problems (Sansone, Whitecar, Meier, & Murry, 2001). Relevant to this latter point, a significant prevalence of Axis II disorders, particularly borderline personality disorder, has been found in primary care populations—again much of it unrecognized and untreated by physicians (Gross et al., 2002).

*Examples: A woman diagnosed (and well-treated for) schizophrenia who also has asthma and smokes (the referral problem was smoking cessation); a political refugee who has been tortured (the referral problem was gastrointestinal pain); a university faculty member suffering PTSD from the vicious academic politics that have resulted in the loss of a significant position (the referral problem was depression and alcohol abuse); a newly diagnosed diabetic patient who responds to the* diagnosis by binge drinking (the referral problem was "poor decision making"); a young woman with nightmares who is helped to connect the onset of her symptoms to her decision to accept a marriage proposal (the referral problem was "panic attacks").

• *Primary care patients frequently come from marginalized, vulnerable, or traumatized populations.* Primary care patients as a population tend to be older, less educated, poorer, and members of underserved or marginalized groups (Wells et al., 1989; U.S. Dept. of Health and Human Services, 2001) and frequently have fewer resources and more common risk factors for disease and disability—what deGruy (1996) has termed "psychosocial vulnerabilities." The prevalence of abuse and trauma histories in primary care populations is significant and related to both overall levels of health, as well as both "somatic preoccupation" (Sansone, Wiederman, & Sansone, 2001) and depression (Walker & Townsend, 1998). Abuse histories, in particular, are prevalent in primary care populations, especially among women, although the presenting concerns in these patients are often fibromyalgia, chronic fatigue syndrome, and sexual disorders, particularly dyspareunia. It is noteworthy that pain plays a significant role in five of the 11 clusters of complaints identified by Stange and colleagues (Stange et al., 1998). Further, recent work has elucidated the relationship between what may be termed "subclinical trauma" or "adverse childhood experiences" and later difficulty practicing effective self-care among hypertensive, diabetic, and pain patients (Dong et al., 2004).

*Example: The patient is a 53-year-old domestic violence victim who is struggling to establish a trustworthy social network, and who also suffers hypertension and joint pain. The primary care psychologist's treatment plan involves attempts to combine the goals of socializing and exercise by encouraging exercise classes, and resolving the self-blame, fear and anger resulting from the abuse. The patient, on the other hand, wants most to figure out how to get her teenage son to apply for a job so he'll contribute to the household and lower her resentment over the expenses he generates. It is only after this issue is addressed with at least partial success that she is ready to turn to the issue of protecting herself effectively and expanding her social network.*

• *Primary care patients often believe that their problems are not "mental."* Patients may be unfamiliar with, hesitant about, or even resistant to

psychological approaches to their problems. Primary care patients typically do not view their emotional disorders as something apart from their general health and a considerable number (up to half by some early estimates) will refuse referral to a mental health professional (Forrest et al., 2007). The stigma of mental illness and resistance to getting help in treating it are still common cultural features in the United States (Cole & Rajum, 1996). For example, Kessler and colleagues (Kessler et al., 2001) found that approximately 60% of adults with serious mental illness were not receiving regular treatment, the majority because they felt that they did not have a psychiatric problem. The most commonly reported reason that these seriously mentally ill individuals gave for failing to seek treatment (72%) and treatment dropout (58%) was "wanting to solve the problem on their own" (p. 201).

Patients (and sometimes doctors) have a primitive understanding of the meaning of a psychological referral. It is often difficult for the physician to explain to patients how psychological treatment will help them; it is also difficult and frequently not directly addressed that a referral does not mean the patient is insane, does not require that the patient must spend years of talking about their childhood, and does not mean that the physician is abandoning the patient (although it is sometimes the case that physicians refer patients they would rather not continue to see).

> Example: A despondent 34-year-old man whose clinical picture included irritability, sleep disturbance, anhedonia, and suicidal thinking refused medication and referral to a mental health specialist when his physician recommended it; in fact, he left the physician's practice. When he was later seen by the primary care psychologist, at the insistence of his wife, he was questioned about whether his prominent depressive symptoms has been addressed by his previous primary care doctor. He responded that his previous doctor had told him he was depressed, but he didn't believe the diagnosis; he felt that the physician was just trying to minimize his complaints and get rid of him quickly, and was particularly skeptical because "the doctor didn't even examine me." It was only after the psychologist successfully explained the methods by which depression is diagnosed, and why direct physical examination does not help to rule out the common medical conditions can cause depressive symptoms that the man became engaged in treatment.

• *Primary care patients often need community support or education more than (or more urgently*

*than) psychotherapy.* The primary care psychologist must think beyond individual psychotherapy to such nontherapy interventions as psychoeducational classes and support groups (Caudill, Schnable, Zuttermeister, Benson, & Friedman, 1991; Lorig, Mazonson, & Holman, 1993) and such self-help materials as books (Kemper, Lorig, & Mettler, 1993) and videotapes to provide timely, cost-effective help. The effective primary care psychologist must also have an extensive awareness of community resources such as 12-step programs, self-help groups, and community education classes (Kates & Craven, 1998), and should be open to the possibility of helping to develop programs in coordination with community agencies (Schroeder, 1997)—and perhaps even help patients to understand and coordinate their benefits.

Sometimes disparaged as "social work," or avoided in preference to psychotherapeutic exploration, such linkage and advocacy efforts for patients can often be the demonstration of caring that a patient needs, and they rarely result in "boundary" issues with patients.

• *Primary care patients often neglect basic aspects of self-care, such as diet, sleep, social support, and exercise.* Unawareness of the role that healthy sleep, diet, relationships, exercise, and stress management play in maintaining health is a component of the link between psychosocial vulnerability and poor health (Dong et al., 2004). The primary care clinical psychologist must be comfortable or become comfortable with the rapidly expanding knowledge base of clinical health psychology in order to best serve the primary care population. The reciprocal effects of sleep disruption and psychological stress, obesity, hypertension, and perhaps even diabetic control and pain control are only now being better appreciated (Czajkowski, Casey, & Jones, 2004).

> For example, a frustrated family physician referred a "noncompliant diabetic" to the primary care psychologist practicing in his clinic, requesting a consultation about behavior change; since the physician was able to simply have the patient walk down the hall after the medical visit to engage in a brief initial psychological session, it was easy to engage her. Empathic discussion of her illness and her life situation revealed that her noncompliance stemmed from her preoccupation with taking care of her toddler granddaughter, whose mother was a drug addict and currently in jail. Believing that every available moment and dollar should be spent on her

*granddaughter, the patient was neglecting her own health. One session of cognitive restructuring, focused on the need for better self-care in order to provider better grandparenting, served to help her resume her regimen. This change was reinforced by informing the physician of the discussion, so that ensuing changes in the diabetic regimen could be framed in the same manner, and suggestions for care-giving that were less burdensome to the patient could also be provided.*

• *Primary care patients often expect psychological treatment to be similar to primary medical care: continuous, episodic, and brief*. Expectations of continuous, problem-focused, episodic care are in keeping with the model of practice in primary care, but may be somewhat foreign to the typical graduate of an American Psychological Association (APA)-accredited training program, who was likely trained to "complete a course of treatment" and then "discharge" the patient. Patients (and perhaps even psychologists) should not be blamed for resolving a focal problem within a few sessions and needing treatment at a later date, perhaps months or years later, for a new concern. Although it is certainly worth an inquiry about reasons for the absence (or for the return), the primary care psychologist should not overinterpret episodic appearances for care. Instead, he or she should make it easy for patients to return for additional treatment if necessary, by such means as complimenting them for proactively seeking helping before even more distress or disability occurs.

• *Primary care patients often expect "directive" care*. A considerable number of patients follow through on psychology referrals only because "the doctor told me to"; the primary care psychologist cannot take for granted that the patient understands or accepts the premises under which most psychological treatment is conducted, particularly the emphasis on the patient's responsibility for self-defined treatment goals and the need to focus on thoughts and feelings, as well as behaviors. Those patients who do engage in psychological treatment may expect brief, practical, directive, and pharmaceutical-based treatment that is "finished" within a session or two.

Most psychologists would be rather wary of setting goals for their patients, and rightly so; however, the idea of giving patients a "menu" of possible goals of treatment that can be accomplished relatively quickly may be suitable and ethical. In addition to focusing on rapid symptom resolution, the effective primary care

psychologist must be able to rapidly "engage" patients. At times, it is necessary to briefly explain psychotherapy and counseling to patients unfamiliar with it; another sometimes uncomfortable role for many psychologists is "selling" psychological treatment: It may be necessary to raise patients' motivation for participating (without promising unrealistic outcomes). It is also noteworthy how uncomfortable nondirective approaches can make many primary care patients; jointly interviewing a new patient with a trainee freshly arrived from a "traditional" counseling psychology program, the author (uncharacteristically) allowed long periods of silence during the initial visit, which prompted the patient to ask: "Is it always this quiet in here?" The "engagement" phase of treatment is crucial but not sufficient to guarantee effective service, and the substrate of a good therapeutic partnership— caring, attentive listening—is essential as well (Adler, 1997; Sobel, 2008). Agenda setting is also a crucial skill (Haas et al., 2003; Mauksch, Hillenburg, & Robins, 2001), since the primary care psychologist may be under greater time pressure and be faced with a wider range of concerns than the specialty mental health psychologist. Primary care patients may have difficulty organizing their visits and respond poorly to unstructured visits. Skills at helping patients to increase their awareness of symptomatic and especially of symptom-free periods is of critical importance in such cases (Fisher, Lichtenstein, Haire-Joshu, Morgan, & Rehberg, 1993). Ideally, the primary care psychologist should have the ability to focus on interventions that have fairly rapid effects (e.g., within a matter of days); this often involves helping the patient to appreciate the importance of small behavior changes.

• *Primary care patients may have difficulty with their physicians, and may need help negotiating that relationship (or they may try to get the primary care psychologist to ally with them against the doctor).* "Difficult patients" are present in every primary care practice, by some estimates comprising 15% of primary care physicians' caseload (Haas, Leiser, Magill, & Sanyer, 2005). This is particularly an issue with patients who complain of pain. Naïve psychologists can be manipulated into allying with a patient against an "insensitive" physician who refuses to provide effective pain-killers (e.g., narcotics) to the suffering patient. The common currency of medical settings is physical complaints, so it is not surprising that somatic symptoms and

pain complaints, as well as "inadequate treatment" and "unsympathetic providers" form themes that constantly recur in work with primary care patients. Patients who present with somatization disorders and back pain, fibromyalgia and chronic fatigue syndrome, irritable bowel syndrome and other functional gastrointestinal disorders—all common somatic expressions of distress in primary care settings—must be helped to shift the focus of sessions to adaptive coping, symptom reduction, and efforts to improve quality of life and away from complaints about the failures of medical care (Bradley, Alarcon, Cianfrini, & McKendree-Smith, 2004). These are frequently considered "medically unexplained" (e.g., frustrating, bothersome, annoying) symptoms by physicians, and patients often get the message that the doctor doesn't like them. As one patient put it: "My doctor thinks I'm not sick enough to spend time on," or as another patient reported "My doctor told me he hates patients like me" (later discussion with the physician revealed that he was trying to communicate that he wanted to be helpful and felt inadequate to help her).

> *Other examples: A 57-year-old patient with diabetes and chronic pain is convinced that her doctor will stop seeing her if she engages in treatment with the psychologist; another patient isn't taking the medication that her doctor prescribed because of unpleasant side effects, but the doctor is "so nice" that the patient is too embarrassed to "confess" and has begun skipping follow-up appointments with her physician; a third is a 28-year-old woman with bipolar disorder whose agenda is to enlist the psychologist in an effort to get her physician to switch her from a mood stabilizer to a stimulant medication, since she is convinced she has attention-deficit hyperactivity disorder (ADHD).*

## Psychological Treatment Skills

The primary care psychologist must have a number of skills in addition to the specialized knowledge and attitudes touched upon here. The skill set can be summarized as follows:

• *The primary care psychologist should be able to skillfully address shame and stigma issues.* One key issue that the primary care clinical psychologist must address early in working with a primary care patient is the issue of stigma. Although psychological disorders and their treatment are more accepted and understood in the United States than in many other developed nations, there is still considerable potential for shame and

stigmatization of the primary care psychologists' patients, even in the most cosmopolitan U.S. city. As one Pacific Islander patient in an urban primary care clinic put it when seeing the psychologist for an initial visit, "This is for white people." Another patient, certain that sitting in a waiting room with a variety of patients still marked her as a "head case," insisted that she be able to phone the psychologist from the parking lot so that she would be able to get right into the office without being forced to sit in the waiting room. Especially since time is short, stigma must be addressed early in the treatment of the primary care patient.

Another and equally challenging issue is the guilt experienced by patients who have concluded (from popularized psychosomatic theorizing, TV shows, or "new age" therapists) that they have "created their symptoms" and are sick either because they are unconsciously producing the condition or have failed to use their mental powers to overcome the symptoms. The effective primary care psychologist must first tease out these explanatory frameworks, then help the patient to take appropriate responsibility for his or her condition. It can be helpful to distinguish for patients the difference between responsibility for *causing* the condition and responsibility for taking the necessary self-management steps to *treat* it.

Conversely, the behaviorally trained psychologist must recognize the biological realities of organic pathology and not insist that everything can be modified or cognitively restructured. Somatoform disorders represent yet another condition common in primary care, and are likely to trigger humiliation in patients who get the message "it's all in your head" (Lazare, 1987). A sensitive yet effective method of "stress reduction" treatment, which does not require argument with the patient about the "reality" of his or her symptoms, is most effective (Servan-Schreiber, Tabas, Kolb, & Haas, 2004).

• *The primary care psychologist should be able to skillfully integrate multiple perspectives on medication use.* Regardless of psychologists' opinions on the role of medication in psychological treatment, involvement in primary care will mean involvement in a drug-saturated environment. Prescriptions are expected by most patients and are offered with regularity by most primary care physicians. The effective primary care psychologist must have a working knowledge of common medications, since patients don't always know whether they're taking a generic or branded

medication, or what class of medication they have been prescribed (Small, 2004).

Two additional medication-related issues are easily overlooked: Nonpsychoactive medications may affect mental and behavioral functioning, and discontinuation of certain medications can have significant psychological effects (Gunning, 2004). Medication interactions, and the effects of drug or alcohol use on medication effects, are also issues that the psychologist should be able to assess, since patients are often more willing to disclose to psychologists than to their physicians. For example, a patient who liked and trusted his primary care doctor nonetheless kept from him the fact that the patient was drinking substantial amounts of alcohol, a fact he revealed to the primary care psychologist at the second session, and reluctantly allowed the psychologist to share with the physician. An early and comprehensive "medication history" may be important in setting the stage for effective psychological treatment. Even in integrated settings with electronic health records, which in theory make sure reconciliation easy, there are times when sequential prescriptions can cancel each other out. For example, a primary care patient being treated for depression (among other issues) was prescribed both modafinil (a wakefulness-producing medication with stimulant-like properties) and alprazolam (a benzodiazepine antianxiety agent with sedating properties); the net effect for this patient was drowsy days and sleepless nights, which she and her doctor attributed to treatment-resistant depression, for which she was prescribed increasingly high doses of antidepressants. The primary care psychologist's tactful questioning of the need for all these prescriptions led to a more rational regimen.

The psychologist who is skeptical of medication must be careful not to undermine the patients' (sometimes shaky) motivation to follow through with medication prescriptions. Direct and frank discussion with both physician and patient, in order not to unwittingly sabotage the patient–physician relationship and treatment plan, is crucial. For a number of psychological disorders, the combination of medication and psychotherapy is superior to either alone (Nathan, Gorman, & Salkind, 1999). Thus, even in cases in which the physician has not prescribed for the patient, either doctor or patient may ask the psychologist for recommendations about medications or dosage when a particular agent is being considered.

The primary care psychologist must be skilled at managing expectations and clarifying his or her role in such situations. This is especially true when the primary care psychologist may in fact have more familiarity with the effects of certain psychotropic medications than does the primary care physician; it is also an issue when he or she recognizes treatable psychopathology that the physician is not addressing and could usefully prescribe for. Unless he or she practices in a state that has granted prescriptive authority to psychologists, this information must be phrased carefully in question form, or as an observation about what the literature suggests, so that the psychologist's scope of practice is not exceeded (Haas & Malouf, 2005). Examples of "translational" and tactful approaches that are factual include: "I have read that—is useful in conditions like this; has that been your experience?," or "I saw a patient not long ago who was on—for symptoms similar to what this patient is experiencing, and he seemed to benefit from that medication."

• *The primary care psychologist should be able to skillfully use directive and prescriptive techniques.* Not only should the psychologist be able to help the patient set priorities for brief solution-focused behaviorally specific outcomes, it is frequently also the case that patients need help in changing their health-related behaviors. Adherence to long-term treatment and self-management of chronic disease is a well-known problem in primary care and behavioral medicine (World Health Organization, 2003); it is less well researched but certainly prevalent in psychological treatment. Useful advances in psychological approaches to these issues have been made by Prochaska and colleagues (Prochaska, 2005) and Rollnick (Rollnick, Mason, & Butler, 1999) among others. More recently, cognitive social psychologists have contributed usefully to self-regulation approaches (Baumeister & Vohs, 2004) than can help tailor behavior change programs to the patient's specific environment.

> For example, a primary care patient with anxiety symptoms was also found to have disrupted and insufficient sleep. The primary care psychologist was able to negotiate a 1-week "experiment" with altered sleep hygiene and an "emergency" supply of alprazolam, with the result of the experiment being symptom reduction, increased energy, and no need to use the backup prescription. This change required the psychologist to overcome the patient's reluctance to risk another week of

*disrupted sleep (the patient wanted to rely on sedatives), and to do this in a way that was not authoritarian but was persuasive.*

• *The primary care psychologist should have good teamwork skills.* The therapeutic frame often must be expanded to include the patient-therapist-family-physician network. As Drotar (1995) has described, developing effective collaboration is often time-consuming and requires sacrificing some of psychologists' hard-won independence. Yet, improved integration of psychological and primary care practice can be as simple for the psychologist as sending a copy of an intake report to a patient's family doctor. At the other extreme, efforts to integrate can be as far-reaching as full integration into primary care systems, with no difference in patients seen, time allocated, or problems addressed (Robinson & Strosahl, 2009). Primary care physicians expect confirmation regarding the patient having made the appointment, regarding the treatment plan, and regarding changes in the course of the problem. These communications should be concise and should focus in particular on a brief, comprehensible treatment plan. Patients should be informed about this, although most patients assume that their clinicians are in communication. It is also helpful to think about the frequency of treatment: A psychologist might see a psychotherapy patient four times in a month but the physician might evaluate the patient's progress once a month. Therefore, a monthly report might be reasonable unless you share a medical record. Unlike confidentiality in psychological practice, confidentiality in primary care is often taken to mean that all team members who are committed to professional expectations of confidentiality can share information. Typically, the specialists to whom a primary care physician refers a patient will send copies of the chart back to the referring doctor without asking the patient's permission. This practice would be quite unusual for a psychologist. Nonetheless, physicians usually want information about "their" patients. At the same time, psychologists' patients expect confidentiality, so clarity about what information will be shared is critical (Haas & Malouf, 2005).

The primary care psychologist should also take care not to under- or overestimate the physician's degree of knowledge about psychological treatment and psychopathology. It is not uncommon for the only exposure to formal teaching about mental/behavioral health issues to have been during medical school, and it may have consisted of a few lectures on psychiatry. At the other extreme, some physicians read the psychosocial literature, have attended workshops/CME events about mental and behavioral health treatment, have had psychotherapy themselves, and fully recognize the connection between the mind and the body.

A third aspect of teamwork is the often unspoken "ownership" of the patient. Competition regarding who "cares more about the patient" can develop, with destructive consequences if boundaries and communications are not clear. The psychologist must be careful not to triangulate the patient (or be triangulated by the patient) if there is disagreement about treatment plans. Collaborative relationships are the key. Primary care physicians become understandably defensive when their rates of recognition and methods of management of mental health problems are criticized, arguing in part that without adequate resources and with pressure to respond to other needs, they make rational decisions about the allocation of their time and effort (deGruy, 1996; Schwenk, 2002). In fact, the societal demands on primary care physicians to address an ever-broader range of health-related issues requires constant, sometimes painful tradeoffs. For example, estimates of the time required to successfully address recommended preventive medicine screening elements is 7–8 hours per patient (Balkrishnan et al., 2002), which means that one patient per day could be seen rather than the 25–30 patients that primary care physicians typically need to schedule. In addition, the rate of malpractice actions against primary care physicians, largely based on failure to diagnose life-threatening medical conditions, is also increasing. As Hamberger and colleagues (Hamberger, Ovide, & Weiner, 1999) note, doctors get sued for missing biomedical diagnoses, not psychosocial ones. The doctor who practices "defensive medicine" may thus spend time and effort to carefully rule out rare but dangerous conditions, with accordingly less attention paid to "softer" psychosocial issues.

• *The primary care psychologist should be able to skillfully intervene in doctor–patient or patient–health-care system conflicts.* At times (and perhaps more frequently in cases involving patients who use their medical symptoms as symbolic or interpersonal messages) the doctor–patient

relationship itself will be an issue. The patient may be affected more deeply than the physician, and may want to address the issue with the psychologist.

> For example, a patient who developed a "crush" on her doctor asked the psychologist if the doctor was married—this led to a useful discussion of her natural feelings of closeness to the doctor, and a productive exploration of the difference between devotion (which he was showing her since she was gravely ill) and romantic attraction. It helped that the psychologist and the physician worked closely enough together that they could discuss this issue.

Power issues are often present in medical care: For example, physicians may refuse to continue to treat patients who disagree with the treatment plan (or patients may fear that this will happen), and psychologists may hear complaints from patients about how their physicians dominate or intimidate them. Effectively balancing the competing demands of such a situation requires family therapy skills. It is noteworthy that more satisfactory relationships between patient and physician are predictive of improved health outcomes (Smedley & Syme, 2000). The patient may need help in resolving conflicts, especially if they are frightened that offending their doctor means loss of care. Although it is more common for patients to feel that their physicians do not care about them, it is also sometimes the case that physicians can become overinvolved with their patients; this can lead to insistent and even aggressive pressure on the patient to "get better".

The primary care psychologist should be able to take on somewhat of a consultant role with either patient or physician. Just as patients may need help with direct communication, physicians may need help in accurately assessing their communication and negotiation styles, or lack thereof (cf. Drotar, 1995). Accurate constructive feedback is a rare commodity in medical systems (Ende, 1983), and respectful colleagues who can help primary care physicians recognize their limits and perhaps expand them will be highly valued. Commonly, the primary care physician makes person-centered attributions about patients' behavior, and the psychologist can help to reframe these attributions to ones that are more productive.

• *The primary care psychologist should be able to skillfully manage his or her own boundaries and care for his or her own damaged ego.* Often, before an

effective working relationship has developed between the two clinicians, a frustrating patient will be sent to the psychologist. Certainly, such patients should be given all the help the psychologist can offer. It may also be necessary to help the patient recognize that his pathology may be difficult for his physician. In such cases, family therapy skills can be an asset, since the psychologist may be working to improve the physician–patient relationship, rather than to directly reduce the patient's distress. Regardless of the outcome of treatment, prompt and concise follow-up communication to the physician is appreciated. Pager messages, phone calls, and e-mails should be responded to quickly, as this is often a metacommunication of professional respect in medical settings. However, it is also important to recognize that the sense of urgency and time pressure inherent in these settings can be wearing. Professional support is essential; for some psychologists who practice exclusively in the primary care setting, the pressure to prove themselves to their medical colleagues can pose the risk of neglecting self-care strategies (Cole-Kelly & Hepworth, 1991). For example, the psychologist who never sets limits, seeing patients at home if they prefer, or on weekends, or at no charge if they claim indigence, needs peer support to develop better boundaries. As well, the psychologist must know very clearly the limits of his or her competence or capacity while remaining a generalist (Haas, 1993; Haas & Malouf, 2005). Ironically, a common way in which psychologists enhance their status among peers will detract from their effectiveness with primary care physicians—this being the display of theoretical sophistication. For example, explaining to a physician who is concerned about the patient's dependent "inner child" why such "pop psych" object relations theory adds unnecessary theoretical baggage to cognitive schema theory will bewilder and annoy most physicians. Differing approaches to treating medical conditions certainly exist (e.g., surgical vs. pharmaceutical treatment of cancer), although they are rarely as passionately held as are differing approaches in psychological treatment (e.g. behavioral vs. psychodynamic). The primary care physician is more likely to value practical, common-sense advice, and even suggestions for phrasing interventions (Stuart & Leiberman, 2002).

• *The primary care psychologist should have effective approaches to detecting and treating depression and substance abuse.* Most psychologists

would probably consider themselves skilled in depression treatment. However, since depression is the most prominent mental health problem in primary care, and since many primary care doctors are quite comfortable managing mood disorders, especially mild and moderate unipolar depression (Brody et al., 1994, 1995), patients referred by such physicians are frequently suffering from treatment-resistant depression, from Axis II problems co-occurring with the depression, dysthymia, or all of the above.

It is also common to be referred patients who were initially sent to a psychiatrist, even when the physician believes psychotherapy is indicated. Many primary care physicians do not realize how little psychotherapy psychiatrists actually provide (Kainz, 2002). Other common referrals include patients with somatoform disorders, borderline personality disorder, panic disorders, addiction problems, and dependent personality disorders (Haas et al., 2005; Kainz, 2002). An additional significant issue common in primary care settings is alcohol and drug abuse. Specialty mental health is typically distinct from addiction treatment, but this luxury is not available to the primary care psychologist, who must at least have a working knowledge of treatment approaches and community resources.

## Conclusion

Practicing in the primary care setting offers unique rewards and challenges to the clinical psychologist.

The physical location of the practice within or adjacent to a primary care clinic is often used as the defining characteristics of primary care clinical psychology, but primary care psychology is as much a point of view as it is a set of procedures or physical proximity to primary care physicians. In addition to endorsing the philosophy of primary care, the primary care psychology approach includes a special regard for generalism; an integrative, biopsychosocial orientation; an awareness that resources are limited and must be managed effectively; a perspective on psychopathology that searches for and builds on existing competencies; attentiveness to opportunities for educational and preventive interventions; and a population-based perspective.

Primary care needs psychology because alone it will never effectively address the enormous amount of untreated psychopathology, significant lifestyle and behavioral health problems, psychological impact of chronic illness, and the combined psychological impact of being ill and being a member of a vulnerable population. The pressured and overburdened primary medical care system cannot easily meet these needs, nor can the often-inaccessible specialty mental health system.

The psychologist who intends to make a meaningful difference in the quality of health care for the population as a whole must be involved in the primary care setting. Medicine is based on the *biomedical* model, but there is a need for a more inclusive *biopsychosocial* model if we are to fully understand the person who is the patient. Psychology, too, to the extent that it relies narrowly on the *psychosocial* model, would benefit from explicitly adopting the more comprehensive biopsychosocial framework. The primary care psychologist's knowledge and skill base draws heavily from clinical health psychology, behavioral medicine, developmental psychology, cognitive psychology, family psychology, systems theory, learning theory, and educational psychology, as well as from the philosophy of primary care. The bridging and translating role, although challenging, can yield enormous benefits—for the psychologist himself or herself, the patients, the physicians, and the health-care system. To the extent that primary care clinical psychology can bridge some of the disciplinary and philosophical barriers, it can help to improve both patients' health and the health-care system.

# Shifting Paradigms in Clinical Psychology: How Innovative Technologies Are Shaping Treatment Delivery

Linda A. Dimeff, Andrew P. Paves, Julie M. Skutch, *and* Eric A. Woodcock

### Abstract

The accelerated expanse, affordability, and advances in technology, along with the ubiquitous Web, will continue to radically transform how we prevent and treat behavioral problems and reduce human suffering. These technologies have the potential to break down barriers and close the gap between empirically supported treatments (ESTs) and those who need them. This chapter attempts to capture the current use of technology to strengthen and disseminate ESTs. We focus on those areas that have or are expected to have the greatest reach and impact in the years to come. Web- or computer-based technology, virtual reality, mobile technology, and social networking will all be highlighted. We present innovative ideas, the evidence base for existing applications (when available), and future directions. The omnipresence of technology in our daily lives perfectly positions it to be a powerful agent of change in the science and practice of clinical psychology.

**Key Words:** Computer-based training, computerized CBT, dissemination, empirically supported treatments, innovative technology, mobile technology, social networking treatments, Twitter, virtual reality

We are in the midst of a major paradigm shift. The accelerating expanse, affordability, and advances in technology, along with the omnipresence of the Web, will continue to radically transform how we prevent and treat behavioral problems and reduce human suffering. The swift moving currents of technology will impact and redefine how we gather information, how treatment will be provided, and our roles as treatment professionals. We need to look no further than the Web to recognize the unimaginable transformation that results from and through technology. The Web, just 5,000 days old, was originally conceptualized as "TV but only better" (Kelly, 2007). In this brief window of time, the Web has transformed many aspects of our lives: how we communicate, find information and conduct research, plan our time and trips, and pay our bills. We are immobilized when Internet access fails or when we are "out of range" of connectivity. Our work comes to a grinding halt, and we *feel* utterly disconnected. So intertwined are we with the Web that we can scarcely recall what life was like before its time.

Our enmeshed relationship with the Web is borne out by the statistics of its use: We collectively make 100 billion clicks per day accessing the more than 55 trillion links available on the Web, and we send two million e-mails and one million instant messages per second, resulting in total Web traffic running at 7 terabytes per second—the content equivalent of one-half of the holdings of the Library of Congress traversing the planet per second (Kelly, 2007). In less than 1,000 days, we have witnessed the explosive success of Web 2.0. We have found lost friends and new jobs on Facebook. And we have witnessed the rapid rise of Twitter—used for social and political purposes. Communications technology and innovation will continue to explode in dimension, reach, and impact.

The radical evolution of technology is but one factor accounting for the burgeoning of this new era in mental health services. The other important factor is the disturbing and seemingly intractable gap (Simon & Ludman, 2009) that continues to separate science from practice (Bebbington, Brugha, et al., 2000; Bebbington, Meltzer, et al., 2000; Kessler et al., 2003; Marks, 2004). We have developed, rigorously evaluated, and refined a number of powerful behavioral treatments for many Axis I and II problems over the past decades. In theory, clients now have treatment options when selecting an empirically supported therapy (EST) for many disorders. Yet, the likelihood that they will actually receive an EST is extremely low. In the United States, students working toward professional degrees in social work, psychology, and psychiatry seldom learn ESTs; when training is provided, it is cursory and insufficient to apply the treatment to adherence (Weissman et al., 2006). The prospects for learning do not improve after graduation, despite mandatory and ongoing continuing education (CE) as clinicians do not read textbooks or treatment manuals unless required to do so, and CE workshops seldom impact practice (Addis, 2002; Barlow, Levitt & Bufka, 1999; Davis et al., 1999). In contrast to the pharmaceutical industry, which spends millions annually on marketing their products, an analogous mechanism does not exist to promote the dissemination of behavioral and other efficacious psychosocial treatments.

The net effect of these factors is reflected in mental health treatment trends over the past two decades, where rates of psychotropic medication use continues to rise significantly while psychotherapy rates have held constant or have steadily declined (Olfson & Marcus, 2009; Olfson et al., 2002; Olfson, Marcus, Wan, & Geissler, 2004; Simon & Ludman, 2009). For example, the rate of antidepressant medication nearly doubled between 1996 and 2005, from 5.84% to 10.12%; however, the rate of those receiving psychotherapy in addition to psychotropic medications stayed constant (26.25% vs. 26.85%, respectively; Olfson & Marcus, 2009). Antidepressant medications now top the charts of the most common class of medications prescribed in the United States, surpassing hypertensive medications (Olfson & Marcus) despite the presence of three highly effective, short-term psychosocial treatments for depression (behavioral activation, cognitive therapy, and interpersonal psychotherapy; Cuijpers, van Straten, Anderson, & van Oppen, 2008).

Innovative applications of technology will provide the seismic force required to close the gap between research and practice. They are already being used to more efficiently and effectively deliver ESTs to a greater number of clients. Like the technology on which it is built, this area is expanding at a breathtaking pace. New research challenges arise in the process. How, for example, do we research application-based interventions when the technology morphs at a faster rate than our capacity to rigorously evaluate it? How "cutting edge" does the technology itself have to be when evaluating the efficacy of a technology-based intervention? For example, should investigators proposing high-impact and innovative clinical research involving technology be required to use empirically supported cutting edge technology? (We think, yes).

This chapter attempts to capture the transformation that is under way in how technology is already being used to strengthen behavioral ESTs and disseminate them. We focus on those areas that have or are expected to have the greatest reach and impact in the years to come. This chapter is divided into five sections. The first discusses the "dissemination problem" and how technology may be leveraged to close the gap between research and science. The second section examines the uses of computers and the Web to deliver treatments. This section spans the continuum from self-help to clinician-assist programs that structure and guide the treatment for novice clinicians. The third section explores the use of virtual reality (VR) in the treatment of anxiety disorders, as a method to offset the experience of pain through distraction during painful medical procedures, and to facilitate training in procedural learning in a fail-safe environment when hands-on practice is required. The fourth section examines one of the newest and fastest-moving areas of technology—mobile technologies in the prevention and treatment of behavioral problems. The fifth and final section reviews social networking, with a primary focus on Twitter, a micro-blog site that some believe may wield great powers, whereas others remain highly skeptical. We conclude with a discussion of the relevant issues that emerge from this paradigm shift.

## Leveraging Technology to Close the Gap Between Research and Practice

Despite considerable attention to the importance of bridging the sizeable gap between research and practice (e.g., APA Presidential Task Force on Evidence-Based Practice, 2006; Insel, 2009; New Freedom Commission, 2003), ESTs continue to be widely underutilized in routine clinical practice. Numerous dissemination barriers have been identified (Addis,

2002; Barlow et al., 1999; Dimeff et al., 2009; Fixsen, Naoom, Blase, Friedman, & Wallace, 2005; Shafran et al., 2009; Street, Niederehe, & Lebowitz, 2000). These include:

1. *System-based factors impede EST delivery.* One common barrier to clinicians delivering ESTs to their clients begins with the systems within which clinicians practice. Competent and highly motivated clinicians may be blocked from delivering an EST by clinic policy or insurance provider, often in an effort to contain costs (Dimeff & Koerner, 2007). Further, clients may live in rural or frontier areas, where there is simply limited access to mental health services entirely, let alone clinicians providing specific EST protocols (e.g., Cook & Hoas, 2007; Brems, Johnson, Warner, & Roberts, 2006).

2. *Therapists do not know ESTs.* Another barrier is the lack of effective training opportunities available to clinicians (e.g., Becker, Zayfert, & Anderson, 2004; Weissman et al., 2006), as well as clinician reluctance to read and rely on treatment manuals on their own (Addis, 2002). To illustrate, despite extensive research that overwhelmingly supports the efficacy of exposure procedures for anxiety disorders, very few clinicians are familiar with exposure procedures. In a sample of over 350 participants with generalized anxiety disorder, panic disorder, and social phobia, only 19% and 11% reported receiving behavioral therapy in 1991 and 1995–1996, respectively (Goisman, Warshaw, & Keller, 1999). Freiheit, Vye, Swan, and Cady (2004) surveyed licensed doctoral-level psychologists who regularly treated anxiety disorder patients about their use of a variety of exposure and nonexposure procedures in their treatment of obsessive-compulsive disorder (OCD), panic disorder, and social phobia. Although a majority of the participants (71%) identified as cognitive-behavioral in orientation, and 88% indicated that they used cognitive-behavioral therapy (CBT) to treat anxiety disorders, very few used the key change agent: exposure interventions (Freiheit et al., 2004). In the treatment of OCD, 67% frequently used cognitive restructuring and 41% frequently used relaxation training, whereas only 38% frequently used exposure and response prevention. Participants reported frequently treating social phobia via cognitive restructuring (69%), relaxation training (59%), and breathing retraining (47%), and relatively few participants frequently used self-directed in vivo exposure

(31%) or clinician-directed in vivo exposure (7%). Even fewer participants (12%) frequently used interoceptive exposure to treat panic disorder; indeed, 76% indicated that they never or rarely used interoceptive exposure to treat panic disorder.

In the area of post-traumatic stress disorder (PTSD), Becker et al. (2004) surveyed licensed doctoral-level psychologists about their use of exposure procedures to treat PTSD and found that the most commonly endorsed reason for not using exposure was limited training (60%). Only 28.5% of participants reported receiving any training in imaginal exposure for PTSD, only 27.1% had been trained in in vivo exposure for PTSD, and only 12.5% had been trained in exposure for other anxiety disorders. Overall, 47% of participants reported that they were "not at all" or only "slightly" familiar with imaginal exposure for PTSD and only 20% reported being "very familiar" and 72% of respondents reported feeling "not at all" comfortable using imaginal exposure to treat PTSD. In another study involving clinicians designated as PTSD specialists, fewer than 20% conducted repeated exposure to traumatic memories or trauma-related stimuli, and fewer than 10% did so routinely (Rosen et al., 2004).

3. *Knowing an EST is no guarantee that a clinician will actually provide it.* Among clinicians who are trained in specific ESTs, many do not regularly apply the treatments to their clients with the specific disorders. To illustrate, Becker et al. (2004) found that only about half of those who had received adequate training reported using imaginal exposure to treat PTSD, and less than one-third used it to treat at least half of their PTSD clients. Moreover, almost one-third of those trained never used imaginal exposure to treat PTSD. The reasons provided by participants included a preference for individualized treatment over manualized therapy (25%) and a concern that clients would decompensate (22%) if provided the EST, a belief not supported by the empirical literature (Foa, Zoellner, Feeny, Hembree, & Alvarez-Conrad, 2002; Nishith, Resick, & Griffin, 2002).

4. *Drift happens.* Another significant problem involves clinician "drift" from the treatment protocol over time (Waller, 2009). Drift can occur intentionally (e.g., clinician is not inclined to follow the protocol, believes a blended approach is more effective for his or her client, or simply prefers to vary the approach) or inadvertently (e.g., the clinician is shaped by the client through

the use of contingencies to do something other that the protocol; she may be punished by client when properly administering the EST protocol and reinforced for drifting; Schulte & Eifert, 2002. Either way, treatment potency and effect may be compromised (e.g., Bright, Baker, & Neimeyer, 1999; Miller, Yahne, Moyers, Martinez, & Pirritano, 2004; Waller, 2009).

One clear advantage of technology-based approaches over traditional face-to-face treatment is that they bypass clinician and system (i.e., clinic, insurance) barriers to delivery of ESTs to fidelity. This is particularly the case with the computer-based self-help interventions described in the section "Delivering Treatments Using Personal Computers and the Internet," and virtual reality interventions described in the third section, "Virtual Reality." Assuming the intervention is selected wisely, and sufficient motivation and capability exist to follow its steps and procedures, clients can expect to receive the full dose of the intervention and, with it, the intended positive outcomes.

## Delivering Treatments Using Personal Computers and the Internet

Since the groundswell in use of the Internet, innovative applications have been developed and launched to deliver evidence-based therapies over the Web. These tools vary widely, from pure self-help CBTs and clinician-guided self-help CBT to computer-assisted applications that guide treatment professionals in the delivery of efficacious CBTs. These approaches are new enough that naming conventions have not been codified. We use the most readily used of the term *computerized cognitive-behavioral therapy* (CCBT) to refer to these dynamic computer-based systems that deliver evidence-based CBTs directly to clients. (Other such terms include *computer-aided CBT* and *computer-assisted CBT.*) Computerized CBT refers to applications delivered via a personal computer, the Internet, interactive voice response systems (VRS), or mobile phones (National Institute for Health and Clinical Excellence, 2006). The distinguishing characteristic of CCBT compared to other technologies, such as video conference, standard phone contact, and e-mail, is the active engagement and interaction of the client in the CCBT environment (Marks, Shaw, & Parkin, 1998).

Computerized CBT was originally envisioned as an efficient, effective method of reaching the millions of untreated individuals who were suffering from behavioral problems and who were not already seeking and/or receiving adequate treatment (Marks et al., 2003). Computerized CBT was viewed as a first-line treatment for those with mild to moderate problems, one that could be accessed privately via the Internet or at one's primary health care provider. Nonresponders (i.e., those clients who did not achieve a sufficient clinical effect from the CCBT intervention) could then be "stepped up" to a higher level of care (Bower & Gilbody, 2005; Seekles, van Straten, Beekman, van Marwijk, & Cuijpers, 2009). More recently, the application of CCBT has been expanded for use by practitioners untrained in how to deliver a specific EST. Used in this way, clinician and client sit side by side and are mutually guided in treatment delivery by the CCBT (Craske et al., 2009). In this section, we will review the advantages of CCBT, highlight specific examples of different applications/types of CCBT for a variety of disorders, and discuss the research data to date.

### Advantages of Computerized Cognitive-Behavioral Therapy

The advantages of CCBT are primarily two-fold. First, they significantly expand the menu of self-help options for clients wishing to (primarily) direct their own care and treatment. Second, they facilitate the dissemination and implementation of efficacious CBTs delivered to a high degree of fidelity by a large number of treatment providers who would not otherwise offer ESTs.

#### EXPANDING THE MENU OF SELF-HELP OPTIONS

Seeking one's own solutions to complicated behavioral health problems and managing one's own treatment plan is something that people have always done. Indeed, regardless of topic, self-help books typically occupy more shelf space at bookstores and libraries than empirically derived treatment manuals. Primary and secondary prevention health promotion campaigns to reduce the risk of major killers—from heart disease and cancer to motor vehicle accidents—rely extensively on self-directed actions to reduce risks. Examples are everywhere. We modify what we eat, increase our exercise, wear seat belts and helmets, and don't drink and drive. We brush and floss twice daily. In short, the majority of people self-manage or direct their behavior in the service of their long-term goals for health and well-being.

Within clinical psychology, the self-help empirical literature is equally vast and extensive, with meta-analytic studies reporting small to medium effect sizes on major outcome variables across a spectrum of

disorders (Morgan & Jorm, 2008; van't Hoff, Cuijpers, & Stein, 2009; Ciujpers et al., 2009). To illustrate, a recent and exhaustive review of self-help treatments for subthreshold depression by Morgan and Jorm identified 38 diverse self-help treatments from St. John's wort (Pilkington, Boshnakova, & Richardson, 2006) and Korean ginseng (Kennedy & Scholey, 2003), to lavender (Akhondzadeh et al., 2003), lecithin (Benton & Donohoe, 2003), laughing (Berk, 2001; Newman & Stone, 1996), and light therapy (Golden et al., 2005; Tuunainen, Kripke, & Endo, 2004).

Self-help approaches, including self-help CCBT, offer a number of significant advantages over traditional face-to-face methods. First, they can be accessed around the clock and 365 days a year; their hours of operation are entirely client-determined. Services need not be temporarily delayed, postponed, or discontinued in the event of sickness, vacation, retirement, or clinic closure. Second, the direct and indirect costs to the client are significantly less than the cost of traditional methods. A number of CCBTs are free and freely accessed (e.g., http://www.psychologicalselfhelp.org, http://moodgym.anu.edu.au/welcome, http://www.beatingtheblues.co.uk/). Those that do require payment (e.g., www.myselfhelp.com) typically charge a nominal monthly subscription fee that is comparable to other monthly Internet subscriptions (e.g., Netflix, Audible books, etc.). Indirect costs associated with traditional methods are also saved, including transportation costs and loss of productivity while commuting and waiting. Third, self-help approaches require less motivation and commitment by the client before gaining access to treatment. In comparison to the extensive effort required to start traditional services (i.e., multiple calls to clinic, phone screen, initial paperwork, an initial session to assess "goodness of fit" between the clinician and client), self-help approaches are easily initiated. In the case of CCBT, gaining access often takes less than 5 minutes, the time it takes to create a user-name and password. The ease with which treatment can be sought has been identified as an important consideration, particularly in the treatment of depression (Harmen et al., 2001; Morey, Thacher, & Craighead, 2007). Finally, self-help approaches help eliminate the stigma that some individuals may associate with seeking out professional mental health services.

## Computerized Cognitive-Behavioral Therapy Across the Treatment Continuum

Computerized CBT spans a continuum of use, from pure self-help and guided self-help to CCBT-augmented therapy and use as a guide to treatment delivery (Craske et al., 2009). Differences in these approaches are discussed below.

### PURE SELF-HELP COMPUTERIZED COGNITIVE-BEHAVIORAL THERAPY

As a *pure-self help* application, users navigate their own course through the CCBT, with minimal or no involvement from others. In the majority of cases, the CCBT is accessed via the Internet by the client, with no other human involvement. In some cases, the extent of involvement may be directing the client to a computer in a primary care setting and showing them how to use it. A number of self-administered CCBTs have been developed and evaluated for a variety of behavioral problems, including depression (Clarke et al., 2002; Clarke et al., 2005; Spek et al., 2007), anxiety disorders (Andersson, Bergstrom, Carlbring, & Lindefors, 2005; Anderson, Jacobs, & Rothbaum, 2004; Carlbring et al., 2005; Farvolden, Denisoff, Selby, Bagby, & Rudy, 2005; Kenwright & Marks, 2004; Schneider, Mataix-Cols, Marks, & Bachofen, 2005), insomnia (Ström, Pettersson, & Andersson, 2004), and smoking cessation (Cobb, Graham, Bock, Papandonatos, & Abrams, 2005; Etter, 2005).

### GUIDED SELF-HELP COMPUTERIZED COGNITIVE-BEHAVIORAL THERAPY

Application of guided self-help CCBT typically involves pairing the CCBT with brief contact (by telephone, e-mail, instant message, or in person) with a clinician or coach. The extent of contact is often between 5 and 10 minutes, typically just before beginning the weekly CCBT module and/or upon session completion. Total coach/clinician time required for duration of the intervention is typically between 2 and 5 hours, significantly less than traditional face-to-face treatment. The functions of the guided approach are: (a) to increase motivation to use and complete the weekly CCBT session by "bookending" the session with scheduled (albeit brief) contact with the clinician or coach; (b) to ensure comprehension of content by providing clients with an opportunity to ask questions; (c) to assign and review homework; and (d) to overcome barriers to using the CCBT or completing the homework. Studies of guided self-help span depression (van Straten, Cuijpers, & Smits, 2008), social phobia (Andersson et al., 2006), panic disorder (Carlbring et al., 2006), pathological gambling (Carlbring & Smit, 2008), and obesity treatment (Micco et al., 2007). The evidence to date across multiple trials

overwhelmingly supports the importance of having a clinician or coach involved in administrating the CCBTs to facilitate user engagement and prevent dropout (Christensen, Griffiths, Korten, Brittliffe, & Groves, 2004; Clarke et al., 2002; Clarke et al., 2005; Kaltenthaler, Parry, Beverley, & Ferriter, 2008; Kaltenthaler, Sutcliffe, et al., 2008).

### COMPUTERIZED COGNITIVE-BEHAVIORAL THERAPY ENHANCED THERAPY

Computerized CBTs are also used to augment traditional face-to-face treatment. When used in this way, routine psychoeducation and other standardized EST content is "outsourced" to the CCBT, thus reducing treatment costs (to clinic, system, and/or payee) by reducing the extent of face-to-face treatment by as much as 50%. Studies examining the efficacy of CCBT-enhanced therapy have been conducted with social phobics (Andersson et al., 2006), PTSD patients (Litz, Engel, Bryant, & Papa, 2007), anxious children (Spence, Holmes, March, & Lipp, 2006), and anxious youth (Kendall, Hudson, Gosch, Flannery-Schroeder, & Suveg, 2008).

### COMPUTERIZED COGNITIVE-BEHAVIORAL THERAPY INTEGRATED WITHIN STEPPED CARE

Based on a public health model of care, the stepped care approach is characterized by different treatment steps arranged in order of increasing intensity, in which a specific level of care is not offered before it is needed or more intensely than is required and not later or at less intensely than is needed (Bower & Gilbody, 2005; Seekles et al., 2009). Clients start off with a low-intensity EST as the initial step, progress is monitored, and those who do not respond are then "stepped up" to a higher level of treatment. This process is continued until the therapeutic impact is achieved. When CCBTs are used in the context of stepped care, clients may start with the lowest level of care (pure self-help), then step up to guided CCBT, and then to traditional face-to-face treatment that may be enhanced by CCBT (MacGregor, Hayward, Peck, & Wilkes, 2009).

### COMPUTERIZED COGNITIVE-BEHAVIORAL FACILITATED THERAPY

The newcomer to the CCBT approaches, the facilitated therapy method involves simultaneously guiding the client and the clinician who is unfamiliar with a specific treatment protocol through its full administration. The one study of CCBT-facilitated treatment conducted to date took place within the context of a primary care clinic where nurses were administering ESTs for clients with anxiety disorders (Craske et al., 2009). Here, the client has the benefit of sitting side by side with a "live" treatment professional who can aid the client in implementing the content of the EST; however, the nurse need not have specialized training in the specific treatment protocol.

### *Does Computerized Cognitive-Behavioral Therapy Work? A Summary of Research to Date*

Marks and his colleagues recently concluded a systematic review of CCBTs that involved 97 applications from nine countries reported in 175 studies, 103 of which involved randomized controlled studies (RCTs) (Marks, Cavanagh, & Gega, 2007). They concluded that in comparison to waitlist (WL) controls or treatment as usual (TAU), CCBT is more effective, with small to medium effect sizes. Furthermore, in some, but not all studies comparing CCBT to traditional face-to-face treatment, CCBT performs comparably (Marks et al., 2007).

Kaltenthaler, Parry, et al. (2008) recently screened 445 references and reviewed 103 papers in their systematic review of CCBT for depression; of these, only three CCBTs were rigorously evaluated in RCTs: *Beating the Blues* (Proudfoot et al., 2004), *MoodGYM* (Christensen, Griffiths & Jorm, 2004), and *Overcoming Depression on the Internet* (*ODIN*; Clarke et al., 2002; Clarke et al., 2005). All studies compared CCBT to TAU; all included adults with mild to moderate depression. Participants across all four studies were predominantly female, ranging in age from 36 (SD = 9.4; Christensen et al., 2004) to 50 (SD = 10.8; Clarke et al., 2005). Computerized CBT was delivered alone or as part of an integrated package of care; control conditions included individual and group CBT, nondirective and primary care counseling, routine client management, and CBT therapy adjuncts, such as bibliotherapy. Results from their review provided "some evidence" to support the effectiveness of CCBT in the treatment of depression. Specifically, *Beating the Blues* was more effective than TAU for depression, *MoodGYM* and *BluePages* (a noninteractive website providing psychoeducational information on depression) were more effective in reducing depression compared to an attention control condition, and *ODIN* with staff reminders (guided) was more effective than TAU. Relatively high dropout rates were observed across all trials— 35% in *Beating the Blues*, 25.3% in *MoodGYM*, and 34% in *ODIN*.

Computerized CBTs have also been successfully implemented into large-sector systems, including four into a National Health Service self-help clinic in west London (Gega, Marks, & Mataix-Cols, 2004). These included: *COPE* for depression (Osgood-Hynes et al., 1998), *BTSteps* for OCD (Greist et al., 2002), *FearFighter* for panic and anxiety (Marks, Kenwright, McDonough, Whittaker, & Mataix-Cols, 2004), and *Balance* for generalized anxiety disorder (GAD) (Yates, 1996). *COPE* and *BTSteps* were both administered using interactive voice response (IVR) and a manual to guide clinician contacts with clients; *Balance* and *FearFighter* were initially delivered in the clinic (*FearFighter* was later placed on the Internet, where clients could access it from home). All CCBT participants first had a brief meeting with a clinician by phone (for those accessing CCBT at home) or in person (for those accessing CCBT in the office). Clinician contact with participants was limited to an initial brief screening and to provide brief advice if progress appeared slow. Results were very encouraging: CCBT participants improved significantly in distress and disability, and clinicians were able to manage four times more referrals by delegating routine treatment elements to the CCBT. In the United States, Kaiser Permanente Northwest has successfully implemented CCBTs in their system for the treatment of depression (Clarke et al., 2002). The early successes of CCBTs in public sector settings were among the factors that led to the 2006 landmark decision by the United Kingdom's National Institute for Health and Clinical Excellence (NICE) to approve the use of two CCBTs as part of their nationalized health care: *Beating the Blues* in the management of mild to moderate depression, and *FearFighter* (National Institute for Health and Clinical Excellence [NICE], 2006).

## Review of Specific Computerized Cognitive-Behavioral Therapies

We showcase a number of CCBTs in an effort to demonstrate the range and diversity of CCBTs, how they are investigated, and their outcomes. Content is organized into three sections to illustrate the broad categories of CCBT: *pure and guided self-help CCBT, CCBT-enhanced therapy,* and *CCBT-facilitated therapy*. Whenever possible, we arrange CCBTs for specific problems together within each section. Our review is not exhaustive. These CCBTs were selected for one or more of the following reasons: (a) they are seminal works, (b) they illustrate the continuum of uses of CCBT, (c) the CCBT itself is highly innovative, and (d) the research design is novel and/or the outcomes

are particularly important in considering future directions. Additionally, CCBTs involving the use of mobile technologies are reviewed within the mobile technologies section of this chapter.

### COMPUTERIZED COGNITIVE-BEHAVIORAL THERAPY FOR DEPRESSION
Beating the Blues *(guided self-help)*
Developed by U.K. researcher Judith Proudfoot and her colleagues, *Beating the Blues* was designed for use within a primary care setting and is now recognized by NICE as an efficacious, cost-effective treatment for mild to moderate depression (NICE, 2006). *Beating the Blues* consists of a 15-minute introductory video, and eight 1-hour interactive and customized computerized sessions (www.ultrasis.com). The CCBT was administered by a nurse at a primary care clinic who met briefly (no more than 5 minutes) with the participant at the start and at the conclusion of each session, for a maximum total of 10 minutes of face-to-face contact per CCBT session. The function of this contact was facilitative, intended solely to ensure that the participant was able to access the CCBT at the start and had completed each module (e.g., printed out the session summary, homework note, and the progress report at the end).

Clients with mild to moderate depression ($N = 274$) were randomly assigned to either the CCBT or TAU. Computerized CBT participants could also receive pharmacotherapy, practical assistance (e.g., case management services), and general support, as indicated by their physician, but no traditional face-to-face therapy. The TAU condition was structured to replicate naturalistic conditions of primary care settings, imposing few restrictions on the type or quality of services these participants could be provided, as deemed by their physician. Of the total sample, 35% dropped out of the study prior to completing the final assessment. In comparison to TAU, CCBT was efficacious in significantly reducing depressive symptoms and improving social and work adjustment. Importantly, no statistical interaction was found for drugs, severity of depression, or duration of preexisting depression, suggesting that *Beating the Blues* works for a broad spectrum of individuals with depression, with and without the use of antidepressant medications.

BluePages *and* MoodGYM *(minimal guided)*
Australian researcher Helen Christensen and colleagues (Christensen et al., 2004) developed and investigated two free Internet-delivered self-help programs (only one of which is a CCBT) designed

for individuals with depression who were not otherwise seeking professional treatment. *BluePages* is a non-interactive psychoeducation website providing evidence-based information about depression that addresses what it is, how to prevent, and how to treat depression (http://bluepages.anu.edu.au/). Content is written at an eighth-grade literacy level to ensure accessibility. Resources include an online virtual support group for people with depression, recommended books, and how to find further help in New Zealand and Australia. *MoodGYM* (http://moodgym.anu.edu.au/welcome) is an interactive CCBT based on CBT and interpersonal therapy (IPT) that contains five interactive modules (Feelings, Thoughts, Unwarping, De-Stress, Relationships) provided sequentially on a week-by-week basis, with all modules available for review in the final sixth week. Topic titles are humorous and add to this nonstigmatizing, engaging program (i.e., Bad Hair Day, Three Encounters of an Emotional Kind, My Scores on My Warpy Thoughts Test, and Life Whacks). Mood questionnaires with feedback based on normative data are provided throughout.

Participants were recruited via a questionnaire posted to 27,000 individuals, ages 17–52 years, living in Canberra, a major metropolis in Australia. Of these, 6,122 returned the survey, 752 met study criteria, and 525 were eventually consented and provided baseline data. Participants were randomized to one of three conditions: *BluePages* ($n$ = 166), *MoodGYM* ($n$ = 182), or an attention control condition ($n$ = 178) consisting of weekly contact with a lay interviewer to discuss lifestyle issues such as exercise, education, and health habits. To facilitate usage of both active interventions, participants assigned to *BluePages* and *MoodGYM* received weekly calls from an interviewer directing them to the website. *BluePages* participants visited the site an average of 4.5 (SD = 1.35) times and averaged 67.2 (SD = 24) hits; *MoodGYM* participants completed nearly half ($M$ = 14.8; SD = 9.7) of the 29 exercises. Overall, 79% of participants completed their intervention, and 83% of the intent-to-treat sample provided follow-up data. A statistically significant attrition rate between the active conditions was observed, with higher rates of study completion by *BluePages* participants. Interestingly, post-hoc analyses revealed that participants who scored the highest on psychological distress and high knowledge of psychological treatments were more likely to drop out. Overall findings support the feasibility and effectiveness of the Internet tools to reduce depressive symptoms (Christensen et al., 2004). Specifically, both active conditions were superior to control in reducing depressive symptom; *MoodGYM*, but not *BluePages*, was superior to the study control in improving dysfunctional thinking.

Overcoming Depression on the Internet (ODIN) Developed at Kaiser Permanente Center for Health Research, *ODIN* was developed as a pure self-help intervention for mild to moderate depression that can also be used in conjunction with traditional face-to-face therapy (Clarke et al., 2002). Based on cognitive therapy, *ODIN* is comprised of self-guided and semi-interactive skills training tutorials emphasizing cognitive restructuring techniques. Like a brief booklet, ODIN is organized into seven "chapters" or lessons, each with didactic information and interactive practice exercises. For example, in one chapter, *Thought Helper*, users first learn to identify their negative thoughts and generate positive counter statements. Next, users type their negative or irrational thoughts into a text box, click *search*, and ODIN provides several close matches from its backend database. Users then select those that appear to be the "best fit," click *submit*, then receive two to five possible counterthoughts for each dysfunctional thought selected. Built over a decade ago and at a time when video-streaming was no more than a distant fantasy, ODIN was largely text-based and lacked in rich visual media that is now industry standard.

Two RCTs of *ODIN* have been conducted to date. In the initial trial, clients identified as "depressed" ($N$ = 6,994) were recruited from 430,000 enrollees of Kaiser Permanente Northwest (KPNW; Clarke et al., 2002). Only 526 individuals (3.8% of the total target sample) registered for more information, and only 223 consented to participate. Participants were randomized to *ODIN* or to a no-access control condition. Following online consent and completion of an online assessment, ODIN participants were advanced to ODIN; control participants were advanced to the non-interactive KPNW website, where they could obtain information about a variety of health concerns, including depression, and could submit a question to an online nurse or pharmacist. All participants were free to receive nonexperimental usual care services for depression, including psychotropic medication and face-to-face therapy. Use of ODIN was disappointingly low (potentially due to the lack of rich interactions and media): the modal number of participants only used ODIN one time (41%), the median was two, the mean was 2.6 (SD = 3.5), with a range of 0–20 sessions. Assessments were conducted at enrollment and at 4, 8, 16, and

32 weeks after enrollment. Assessment completion rates ranged from 53% ($n = 148$) at Week 4 to 66% ($n = 196$) at Week 16. Importantly, the most depressed participants were significantly less likely to participate in the follow-up assessments procedure. No differences were observed between conditions on depressive symptoms, and no dose effect was found among experimental participants. Investigators hypothesized that the null findings were due to low rates of CCBT completion.

With this hypothesis in mind, investigators sought to correct this problem in the second study by focusing on increasing participant use of the Internet (Clarke et al., 2005). A pool of participants were again recruited using the same methods as described in the original study ($N = 6,030$). Of these, 200 depressed individuals provided consent. Participants were then randomized to one of three conditions: *ODIN* + phone call reminders ($n = 80$), *ODIN* + postcard reminders ($n = 75$), and TAU control condition ($n = 100$). Sixty-six percent ($n = 169$) of participants completed the 16-week assessment. *ODIN* participants in both intervention conditions significantly outperformed control participants in reporting greater reductions in depression, with more severely depressed participants showing the greatest gains over time. By the study's end, 20% of *ODIN* participants no longer met criteria for depression. Interestingly, no differences were observed between the two *ODIN* conditions, suggesting that the less-expensive postcard reminder was as robust as the more labor-intensive phone calls made by study staff.

## COMPUTERIZED COGNITIVE-BEHAVIORAL THERAPY FOR ANXIETY DISORDERS
### FearFighter
Developed by Stuart Toole and Isaac Marks, *FearFighter* (www.fearfighter.com) is based on 20 years of development and extensive testing in open clinical trials and RCTs. Designed to aid in the treatment of panic and other phobias, *FearFighter* has been demonstrated to reduce anxiety in individuals with comorbid depression and OCD. *FearFighter* is the only CCBT for anxiety approved by the National Institute of Clinical Excellence to date (NICE, 2006). *FearFighter* is delivered via the internet and is a ten-session exposure-based self-help treatment. Minimal human assistance is provided to users. Specifically, users receive approximately an hour of contact (either by phone or in person) with a nurse during the entire treatment, typically at the end of each CCBT session, for purposes of facilitating its use. Two RCTs have been conducted to date on

*FearFighter* by Marks and his colleagues (Marks et al., 2004; Schneider et al., 2005). Both involved the use of scheduled, brief clinician support for those receiving the CCBT, provided during weeks 1, 2, 4, 6, 8, and 10, and twice during the month-long follow-up. Clinician contact involved reviewing progress, gathering data on ratings of anxiety, and providing support and extra advice as needed. Clinician calls throughout the duration of the intervention were for 1 hour.

The first RCT ($N = 93$) involved outpatients with a phobia or panic disorder, who were randomized in a 2:2:1 ratio to the CCBT (based on exposure-based treatment strategies), traditional face-to-face exposure-based treatment, or to a placebo control computer-guided relaxation condition (Marks et al., 2004). Clinician support was administered to both the CCBT and control condition. All treatments were administered in a primary health care clinic. Dropout rates were significantly higher in both active treatment conditions compared to placebo (6%), with rates being nearly twice as high (43%) in CCBT than in traditional treatment (24%). Despite their higher dropout rate, both treatment conditions significantly outperformed control at post-treatment and at the 1-month follow-up. Mean effect sizes on the primary outcome measures were very large at post treatment and follow-up for CCBT (2.9 and 3.7, respectively) and traditional face-to-face treatment (3.5 and 3.5, respectively), whereas the control condition demonstrated medium effects (0.5 and 0.5, respectively).

Having demonstrated the efficacy of *FearFighter* (FF) when administered in a clinic setting, the second RCT sought to examine its effectiveness when provided off-site via the Internet (Schneider et al., 2005). Outpatients ($N = 68$) with a phobia or panic disorder were randomized in a 2:1 ratio to either *FearFighter* ($n = 45$) or to a minimal CBT without exposure (Managing Anxiety; $n = 23$). The Managing Anxiety (MA) program consisted of standard psychoeducation information about anxiety and panic and the importance of relaxation in controlling anxiety, as well as instruction in balancing worries with positive thoughts, diaphragmatic breathing, progressive muscle relaxation, and distracting. Both conditions were instructed to monitor behavior: FF participants compiled a daily diary of the self-exposures and MA participants completed homework sheets associated with the topics covered in the course. Both conditions received scheduled, brief clinician contacts, primarily by phone and, in two cases, by e-mail. The focus of these calls was again to reinforce their respective learning, answer questions, gather

ratings, and provide support. Participants in both conditions improved equally over the 10-week trial, although FF participants improved significantly more on five out of ten measures at the final 1-month follow-up.

Free from Anxiety (Fri fran oro in *Swedish*)
In Sweden, Andersson, Carlbring, and their colleagues have also conducted a number of RCTs on *Free from Anxiety*, a ten-module self-help CCBT delivered via the Internet. The first study ($N$ = 49) compared CCBT ($n$ = 25) to ten individual weekly sessions of CBT ($n$ = 24) for clients with panic disorder (PD; Carlbring et al., 2005). Both treatments consisted of standard CBT for PD, including psychoeducation, breathing retraining, interoceptive and in vivo exposure, and relapse prevention. Results found the CCBT equally effective as the traditional method. Composite within-group effect sizes were high in both groups and remained high at the 1-year follow-up (Cohen's d = 0.80 for CCBT and d = 0.93 for traditional face-to-face). Next, Carlbring et al. (2006) added brief weekly clinician contact to the CCBT and required subjects to send in their homework assignments before receiving the next treatment module. The brief calls were planned for no more than 10 minutes each and were for purposes of providing support. A total of 60 participants were randomized to either the multimodal treatment package or a WL control. Treatment participants averaged a total of 3.9 hours of clinician contact during the study's duration. Results revealed that, although all participants improved significantly with gains maintained at the 9-month follow-up, 77% of treated participants no longer met PD criteria at the end of treatment; all control participants continued to meet PD criteria.

Andersson and colleagues developed a multi-modal Web-based self-help CCBT site for treatment of social phobia, with nine modules spanning 186 Internet pages (Andersson et al., 2006). The treatment was based on CBT protocols as described by self-help books (Antony & Swinson, 2000; Butler, 2001; Kaver, 1999; Rapee, 1998). Each module included psychoeducational material and exercises, with the culmination of the course being client-written essays describing their experience with the CCBT and their outcome. Investigators randomized individuals with social phobia ($N$ = 64) to one of two conditions; the 9-week CCBT intervention ($n$ = 32) or WL control ($n$ = 32). Here, CCBT was combined with two live group sessions and minimal clinician contact. Results again demonstrated CCBT's

efficacy in that treated participants, but not controls, showed significant improvement on most outcome variables, and treatment gains were maintained at the 1-year follow-up. A second study for social phobia utilizing the same CCBT just described was conducted by Carlbring et al. (2007) that combined short weekly telephone calls, as they had in their earlier PD research, with a total duration of 95 minutes. Participants meeting diagnostic criteria for social phobia were randomized to either the treatment ($n$ = 29) or a WL control ($n$ = 28) condition. Compared to study controls, treated participants experienced significantly greater reductions in general and social anxiety, avoidance, and depression. Notably, adherence to treatment was high, with 93% completing treatment. Additionally, positive outcomes were maintained at the 1-year follow-up.

De-Stress
Litz et al. (2007) developed an 8-week clinician-assisted CCBT for PTSD and evaluated its efficacy on Department of Defense service members with PTSD resulting from 9/11 attacks on the Pentagon or combat in Iraq or Afghanistan. Participants ($N$ = 45) were assigned to either CCBT ($n$ = 24) or supportive counseling ($n$ = 21), also delivered via a Web application. In addition to the CCBT, experimental participants had an initial meeting with an individual clinician to generate a fear hierarchy. Additionally, clinicians provided training in two stress management strategies and initial training in simple cognitive reframing techniques. Clinicians also provided assistance in generating a final personalized stress hierarchy (via e-mail). Results from this study are somewhat compromised by high dropout and attrition rates in both conditions (five dropped before treatment and seven during treatment). Only 18 of the original 45 participants completed the 6-month follow-up assessment. Despite high attrition, *De-Stress* completers had significantly greater reductions in PTSD, depression, and anxiety at 6 months compared to controls. One-third of *De-Stress* completers (a quarter of the intent-to-treat sample) achieved high end-state functioning 6 months after treatment.

BRAVE for Children
Australian researchers Spence et al. (2006) examined the feasibility and efficacy of traditional treatment combined with Internet-delivered CCBT in clinically anxious children ($N$ = 72), ages 7–14. Participants were randomized to one of three conditions: standard clinic-based therapy ("CLINIC," $n$ = 22), clinic

plus CCBT ("CLIN-NET," $n = 27$), or a WL ($n = 23$) control. Both active conditions included the same treatment protocol over a 10-week period; the only difference was the mode of treatment delivery. Specifically, half the sessions for CCBT subjects were delivered via the Internet. The CCBT contained considerable use of animations, images, color, interactive elements, and self-assessment quizzes with immediate feedback. Each session contained approximately 20–30 Web pages and took around 1 hour to complete. Participants and their parents received an in-person tutorial on how to use the CCBT prior to the start of treatment, and CCBT compliance was monitored. Among completers at post treatment, 13 of 20 (65%) of CLINIC subjects, 14 of 25 (56%) of CLIN-NET participants, and three of 23 (13%) WL subjects no longer met criteria for their primary anxiety disorder, with both active conditions significantly outperforming WL. No difference was observed between the two active conditions. Importantly, treatment effects for both active conditions were consistent with other comparable treatment outcome studies of anxious children. At the 6-month follow-up, 78.9% of CLINIC subjects and 60.9% of CLIN-NET participants no longer met criteria for their primary anxiety diagnosis. By the 12-month follow-up, percentages of children free of their primary anxiety diagnosis increased in both conditions to 89.5% and 73.9%, respectively. Consistent with earlier findings, the differences between active conditions were not significant at either follow-up; however, both outperformed WL. Importantly, both active conditions earned high ratings of satisfaction from children and their parents, with no differences were observed between conditions, comparable rates of treatment retention, and comparable outcomes.

Extending their earlier work on BRAVE for children, March, Spence, and Donovan (2009) examined the efficacy of CCBT as a stand-alone intervention in the treatment of anxiety disorders in children. Clinically anxious children ($N = 73$), ages 7–12, were randomized to one of two conditions: CCBT via the Internet (NET; $n = 40$) or WL ($n = 33$). The 10-week intervention (BRAVE for Children-ONLINE) was adapted from the Internet course used in their prior research (Spence et al., 2006), in which each weekly module mirrored the clinic-provided traditional treatment and was designed to last approximately 60 minutes. In addition to the ten weekly modules, two bolster sessions were provided at 1 and 3 months post treatment to consolidate learning and emphasize relapse prevention

strategies. At post treatment, nine of the 30 NET participants (30%) and three of the 29 (10%) WL participants no longer met criteria for their primary anxiety disorder. The difference approached statistical significance. Five (16.7%) of the NET participants were fully free of any anxiety disorder, compared to one (3.4%) in the WL condition. NET participants however showed a significantly greater improvement in Clinician Severity Ratings and Children's Global Assessment Scale (Shaffer et al., 1983) over WL participants. The 6-month follow-up only involved reassessment of NET participants. The percentage of NET participants who no longer met diagnostic criteria for their primary disorder continued to increase, from 30% at post assessment to 75% at 6 months. Furthermore, 60.7% were free of all anxiety disorders at 6 months.

## COMPUTERIZED CBT-FACILITATED TREATMENT FOR EST-NAÏVE CLINICIANS

The final type of CCBT we review involves the use of technology to support or guide a novice clinician in administering an evidence-based treatment protocol to a client while maintaining a high level of fidelity (Craske et al., 2009). Currently primarily used in primary care settings in the treatment of anxiety and depression, the potential applications of such an approach, if effective, are considerable and could radically impact dissemination of evidence-based therapies and how we provide effective training. Rather than passive diffusion methods, such as attending a workshop or reading a textbook, trainees and professionals could receive in vivo, on-the-job training.

### Coordinated Anxiety Learning and Management (CALM): Tools for Living

Craske et al. (2009) have developed and begun investigating a CCBT that could be easily used in a variety of primary care contexts to support the delivery of CBT for anxiety disorders by novice clinicians. *CALM Tools for Living* singly addresses the four most common anxiety disorders that present in primary care settings: panic disorder, PTSD, GAD, and social anxiety disorder. One program (rather than four separate programs) navigates the clinician and client together through a treatment package for their primary anxiety disorder. CALM includes eight modules (i.e., self-monitoring, education, fear hierarchy, breathing retraining, cognitive restructuring, exposure to external cues, exposure to images, memories, sensations, and relapse prevention). Each module includes didactic text-based

content (session goals, summaries, educational information, review of prior learning), homework review, in-session practice of new skills, instructions for homework practice, and video demonstration of specific client-relevant CBT strategies. Each module concludes with a self-rating of understanding, quizzes, and clinician rating of client's demonstrated skills knowledge. Finally, customized print-outs of session materials are provided to the client, and ideographic examples described by the client are entered into CALM for retrieval and tracking at subsequent meetings. Clinician and client sit side by side while viewing the same monitor, where prompts are provided to the clinician in specific tasks. The program is intended to be completed in six to eight visits.

Research findings from an uncontrolled trial of CALM supported feasibility of this innovative approach through both the acceptance and use of CALM by clinicians and its effectiveness with clients (Craske et al., 2009). CALM was tested at 13 clinics across four sites and involved 13 clinicians who provided CALM to clients ($N$ = 261) in a primary care context. Although some suggestions for improvements were made (reduce amount of text, simplify language, eliminate redundancy), clinicians rated the program very highly across acceptability items. Study participants receiving CALM attended an average of 7.63 sessions (SD = 3.39; range = 1–19). Participants receiving at least one session of CALM reported high use of skills and strategies between their sessions. For example, participants reported using the breathing skills 6.5 times (SD = 3.6) and practiced in vivo exposure to feared stimuli 4.2 times (SD = 3.5) between the initial session when the strategy was introduced and the subsequent session. Assessment of self-reported levels of anxiety and depression, as well as outcome expectancies, indicated significant symptom reduction and clinical improvements that were not moderated by the presence or absence of psychotropic medication use.

### Comments

At present, a number of CCBTs have been developed for a myriad of behavioral disorders, although primarily to treat anxiety disorders and depression. The research to date is strong. Generally, CCBT is superior to no treatment and to TAU; in many cases, it is as effective as traditional face-to-face treatment. These positive findings have paved the way for its use in large public and nonprofit health-care systems, particularly when integrated within a broader stepped care approach. Computerized CBT

can be used in several different ways: as a "pure" self-help approach (requires no clinician involvement), a clinician-guided self-help approach (contact with clinician is made before and/or after engaging with the CCBT), to augment or enhance traditional treatment (psychoeducation is "outsourced" to CCBT), and to facilitate treatment delivery (Craske's CALM model).

Perhaps without intending to do so, CCBT can powerfully facilitate the dissemination of ESTs by reaching those individuals who may be unable or unwilling to seek out traditional psychotherapy. Additionally, CCBTs provide ESTs with fidelity; adhering to the treatment manual is implicit, as CCBTs do not inadvertently "drift" from the EST manual, dilute, or opt not to provide the EST. Computerized CBTs, however, are not without their limitations. Their primary challenge, particularly when used as a stand-alone option, is user-engagement. Just as psychotherapy may be the luxury of the rich or well-insured, CCBTs may be the luxury of the highly motivated, intelligent, and resourceful. Future research is still required to develop approaches that facilitate user engagement, and ultimately promote higher rates of CCBT use and completion. This research may be enhanced by applying empirically derived marketing and e-learning principles (Mayer, 2008).

Finally, CCBTs are unlikely to ever be sufficient for all clients with behavioral disorders. This may be particularly true for individuals with multiple, severe, and complex problems, such as those with borderline personality disorder (BPD). However, even in these cases, CCBTs can still be used to augment and facilitate the primary treatment.

### Virtual Reality

Virtual reality (VR) is among the earliest of technologies used in the treatment of psychological problems. Virtual reality immerses and engages the client in a 3-D computer-simulated world. The quality of immersion and activation of one's sense of "being in it" separates VR from other multimedia applications and devices, like television and computer games. Its earliest application was in the treatment of anxiety disorders, in which clients faced their fears virtually. Like situational or in vivo exposure, VR exposure therapy (VRET) for anxiety disorders was based on the same emotional-processing-of-fear model used in standard exposure therapy (Foa & Kozak, 1986), namely cue exposure and response prevention (Baker, Patterson, & Barlow, 2002; Peñate, Pitti, Bethencourt, de la Fuente, & Gracia, 2008). Use of VRET has

significantly increased in recent years as a treatment for PTSD in response to the President's Commission on Care for America's Returning Wounded Warrior (Dole & Shalala, 2007; Macedonia, 2009), which has further accelerated advances in technology, making VRET more affordable and more immersive. In addition to its use in the treatment of anxiety disorders, VR has also been successfully applied as a method of distraction to increase pain tolerance during painful medical procedures. Encouraging empirical support for its use as a pain analgesic during notoriously painful medical procedures, such as wound care with burn patients, makes it likely to have considerable reach and impact in the coming decade. In addition to these two well-researched areas of VR, other applications are beginning to emerge, including VR to aid in assessment of attention-deficit hyperactivity disorder (ADHD)-related deficits (Pollak et al., 2009) and to enhance street-crossing skills in the treatment of autism spectrum disorders (Goldsmith, 2009). In addition to these client-focused applications, VR has been used with considerable success as an effective method of training health professionals. We focus our review on those areas that currently have the greatest impact and evidence base to date, namely the application of VR in the treatment of anxiety disorders, as a method of distraction/pain analgesia, and as a training tool for new practitioners.

### The Role of Presence in Virtual Reality

Virtual reality's success is achieved through *immersion*, in which awareness of actual reality is suspended and temporarily replaced by an engrossing artificial environment. Successful immersion facilitates *presence*, the extent to which the client *responds* and *reacts* as if he or she is "there," present in the alternative world. For example, does the spider phobic become similarly anxious when "encountering" a virtual spider as in real life? Do riders of a virtual roller coaster swerve, duck their heads, and experience butterflies in their stomach when "moving" through the virtual landscape? Contributing further to presence is *continuity*, the extent to which the client's experience of the virtual world is not interrupted (Strickland, Hodges, North, & Weghorst, 1997). Immersion and activation of presence in VR have relied primarily on visual sensory immersion, typically achieved through use of a computer screen or a stereoscopic head-mounted display (HMD), both paired with a computer mouse, joystick, or keyboard for navigation and/or engagement in the virtual world. Activation of other senses beyond vision contribute to the extent of the client's immersion and can further facilitate presence. For example, tactile props, such as a furry toy to simulate spider hair, have been added in the VR treatment of spider phobia. More recently, the ability to activate a particular smell has been added to VR equipment, to further facilitate *presence,* thereby increasing the likelihood of the effectiveness of the VR experience (Rizzo et al., 2006).

### Virtual Reality Exposure Therapy in Treatment of Anxiety Disorders

Virtual reality exposure therapy research for treatment of anxiety disorders has flourished over the past decade, beginning with the pioneering single-case design work of North and North in their treatment of a flying phobia (North & North, 1994; North, North, & Coble, 1997). Virtual reality exposure therapy has been investigated for a number of disorders, often using well-controlled research designs. These include the treatment of acrophobia (Emmelkamp et al., 2002; Krijn et al., 2004; Rothbaum et al., 1995), claustrophobia (Botella, Baños, Villa, Perpiñá, & García-Palacios, 2000), flying phobia (Botella, Osma, Garcia-Palacios, Quero, & Baños, 2004; Maltby, Kirsch, Mayers, & Allen, 2002; Mühlberger, Herrmann, Wiedemann, Ellgring, & Pauli, 2001; Mühlberger, Wiedemann, & Pauli, 2003; Rothbaum, Hodges, Anderson, Price, & Smith, 2002; Rothbaum, Hodges, Smith, Hwan, & Price, 2000; Wiederhold, 1999), spider phobia (García-Palacios, Hoffman, Carlin, Furness, & Botella, 2002), agoraphobia (Botella, et al., 2004; Choi et al., 2005; North et al., 1996; Peñate et al., 2008; Vincelli et al., 2003); and PTSD (Rothbaum et al., 1999). More recently, VRET has been used to address high rates of PTSD among active-duty soldiers, veterans, and U.S. service members (Reger & Gahm, 2008), as it is estimated that as many as 20% of returnees from Iraq and 11% of returnees from Afghanistan suffer from PTSD (Dole & Shalala, 2007).

Findings from this extensive body of research overwhelmingly provide empirical support for VRET in the treatment of anxiety disorders. Specifically, controlled trials have consistently found VRET to be superior to WL and placebo control conditions and equivalent, if not slightly superior to traditional exposure therapy-based CBT at post test and at follow-up. A recent meta-analysis by (Powers & Emmelkamp, 2008) involving 13 VRET studies ($N$ = 397) found a large effect size for VRET compared to control conditions (Cohen's d = 1.11) (S.E. = 0.15, 95% CI: 0.82–1.39) across all primary and secondary outcome categories of analysis. As expected,

standard in vivo exposure therapy was not significantly more effective than VRET. In fact, results from this meta-analysis slightly favored VRET over standard in vivo therapy, with a small effect size favoring VRET over in vivo conditions on major outcome variables (Cohen's d = 0.35) (S.E. = 0.15, 95% CI: 0.05–0.65).

A number of unique aspects of VRET make it a compelling alternative to standard in vivo or situational exposure. First, in contrast to standard exposure, clinicians are easily able to create and control precise and clinically relevant factors associated with the feared stimulus (cue) and its surrounding environment. For example, in the case of spider phobia, the clinician can control the look and "feel" of the spider, the proximity of the spider to the client, and the environment in which the client encounters the spider to maximize activation of presence. Additionally, VRET allows for repeated, gradual, and systematic exposure to the feared stimulus (Garcia-Palacios, Hoffman, Carlin, Furness, & Botella, 2002). Second, VRET is often more convenient to administer than standard exposure procedures. Clinicians, for example, are not required to leave their offices, nor do they need to create and/or control extraneous conditions for the exposure, whether it is finding an alley that is similar to the alley a woman was raped in, borrowing a snake from a local pet shop to aid in the treatment of a snake phobia, or finding a tall building with easy roof access for the client fearful of heights. Finally, it allows for exposure to specific situations and triggers that would otherwise be impossible to find and/or adequately recreate. For example, clinicians treating PTSD in military personnel returning from Iraq or Afghanistan can tailor exact conditions to those associated with the traumatic event when using VR. Here, the user can drive a Humvee down a desert highway alone or in a convoy through Iraq-like city streets while hearing the explosions and human cries, as well as smell burning rubber (Gerardi, Rothbaum, Ressler, Heekin, & Rizzo, 2008).

VIRTUAL REALITY EXPOSURE THERAPY
ILLUSTRATED: THE FULL SPECTRUM VIRTUAL
IRAQ PTSD APPLICATION
The Institute of Creative Technologies at University of Southern California recently brought together two other premier VR labs in the United States (Virtually Better, Inc. and Virtual Reality Medical Center) to develop a sophisticated VRET for PTSD among military personnel in Iraq (see Rizzo et al., 2006 for a thorough review). The *Full Spectrum Virtual Iraq* environment includes several diverse

scenarios and is designed to be fully customized to the needs of the client. All scenarios can be adjusted for time of day, as well as weather and lighting conditions. Examples of the scenario settings include *city scenes* (a desolate city with low-populated streets, compromised old buildings, warehouses, factories, and a mosque and junk yard; and a highly populated city with bustling traffic, marketplaces, and monuments); *checkpoint* (includes a variety of moving vehicles that are arriving, stopping, and being inspected); *city building interiors* (users can navigate through the buildings; these buildings can be designed to be vacant or populated; characters populating the interior buildings can also be modified); *small rural village* (contains ramshackle structures, a village center, decaying garbage, and war-damaged vehicles); and a *desert military base* (includes tents, soldiers, and an array of military hardware). The VRET runs on two connected notebook computers: one used by the clinician to direct and control the exposure while the other drives the client's head-mounted device and orientation tracker. In addition to rich, complementary sounds matched to the visual animation, this VRET includes vibrations and a smell palette, both activated by specific triggers within the scene. Scents include burning rubber, cordite, garbage, body odor, smoke, diesel fuel, Iraqi spices, and gunpowder.

### Virtual Reality Pain Reduction
Researchers have recently applied VR to distract patients from painful burn treatment procedures, such as physical therapy and wound care (Hoffman, Doctor, Patterson, Carrougher, & Furness, 2000). Because pain perception involves a strong psychological component, burn patients often report reliving the original burn incident during wound care and other medical procedures (http://www.hitl.washington.edu/projects/vrpain/). Investigators hypothesized that VR may provide sufficient distraction to interrupt the patient's ability to attend to pain, and thus decrease the experience of pain (Hoffman et al., 2008).

Virtual reality's efficacy as an analgesic for burn patients has been investigated in several trials. Using a within-subjects controlled trial, seven patients (ages 9–32 years, with an average of 24% total body surface area burned) received both conditions (VR experimental condition and no distraction control) during each trial; condition order was randomized and counterbalanced (Hoffman, Patterson, Carrougher, & Sharar, 2001). All participants received no less than three trials; VR sessions were limited to 3 minutes

during physical therapy. Subjective pain ratings were significantly lower for participants receiving VR. Importantly, ratings of pain magnitude did not diminish with repeated use of VR. Later research applying a similar design with burn patients ($N$ = 11) during wound care produced similar findings (Hoffman et al., 2008). In contrast to earlier studies, participants received VR while wounds were debrided in the hydrotherapy tank and then dressed. Reports of pain were significantly less—from "severe" to "moderate" (7.6 and 5.1, respectively) during VR. Importantly, participants with the strongest illusion of "going inside" the virtual world had the greatest analgesic effect (from severe pain without VR to only mild pain with VR, 7.2 vs. 3.7, respectively). Reductions in pain have also been verified through functional magnetic resonance imaging (fMRI) research that shows significant reductions in activity in the five brain regions associated with pain (i.e., anterior cingulated cortex, primary and secondary somatosensory cortex, insula, and thalamus) during VR (Hoffman et al., 2004). Importantly, the positive analgesic effects of VR distraction do not appear to diminish with repeated exposure (Hoffman, Patterson, Carrougher, Nakamura, et al., 2001; Hoffman, Patterson Carrougher, & Sharar, 2001; Rutter, Dahlquist, & Weiss, 2009).

### ILLUSTRATION OF VIRTUAL REALITY IN TREATMENT OF BURN PATIENTS

SnowWorld, designed and created by Hunter Hoffman and his colleagues at the University of Washington, is the first immersive VR designed specifically for reducing pain via distraction. SnowWorld was built using Virtual World Development Software (www.virtools.com). Virtual reality is delivered using a HMD and headphones. (A water-friendly version of the head-mount has also been created and tested for use during the debriding process that occurs in specialized tubs in burn units.) Users of SnowWorld are transported into a visual world of snow-covered canyons filled with snowmen, penguins, swimming whales, and igloos. Users fly like fighter jets (controlled by a hand remote) through the seemingly vast world and launch snowballs at the snowmen, which explode on contact. Adding further dimension to the experience, *Graceland* (an upbeat, Grammy-award winning song by Paul Simon recorded in 1986 that is an eclectic mix of musical styles and that rose to the top of the charts in the U.K. and U.S.) plays in the background, providing the perfect accompaniment as the user experiences this imaginary virtual world.

### *Virtual Reality as a Method of Training Treatment Professionals*

Virtual reality has also been used extensively in medical and dental training as a means of developing requisite skills within a simulated fail-safe environment that resembles real-world conditions (Mantovani, Castelnuovo, Gaggioli, & Riva, 2004). Virtual reality has been applied to teaching physicians debridement of gunshot wounds (Delp, Loan, Basdogan, & Rosen, 1997), temporal bone dissection (Kuppersmith, Johnston, Moreau, Loftin, & Jenkins, 1997), arthroscopic knee surgery (Mabrey et al., 2000), orthopedic surgery (Tsai, Hsieh, & Jou, 2001), training and assessment of laparoscopic skills (Katsavelis et al., 2009; Gurusamy, Aggarwal, Palanivelu, & Davidson, 2009; Rolfsson et al., 2002), esophageal intubation (Kesavadas, Joshi, Mayrose, & Chugh, 2002), microsurgical excision of cerebral arteriovenous malformations (Ng et al., 2009), and interventional neuroradiology procedures (Chui et al., 2002). Virtual reality has also been used to teach bedside manner, basic patient communication and history taking, decision-making, and treatment planning (Dickerson et al., 2005; Fleetwood et al., 2000; Janda et al., 2004; Johnsen et al., 2005; Johnsen, Dickerson, Raij, Harrison, & Lok, 2006; McGee, Neill, Goldman, & Casey, 1998; Stevens et al., 2006).

Use of VR and virtual patients (VP) to train mental health treatment providers has significantly lagged behind medicine; however, some studies are beginning to emerge (Kenny, Rizzo, Parsons, Gratch, & Swartout, 2007). Yellowlees and Cook (2006) developed a VR system that simulates the experience of auditory and visual hallucinations in schizophrenic patients as a means of increasing clinician empathy. Beutler and Harwood (2004) have used VR to prepare new clinicians for work with their first clients through the use of a computer-generated client that responds verbally and with corresponding emotional facial expressions to a trainee clinician. Similarly, using advanced VR, Kenny and his colleagues have developed a language-capable virtual client ("Justin") with conduct disorder to train novice therapists in clinical interviewing skills with a resistant client. The clinician meets the 16 year-old Justin, a life-like 3-D teenager, in a virtual therapy room. The interview can be recorded for supervision purposes.

Controlled trials examining the efficacy of VR and VP in training of professionals are, at this time, sparse. Janda and colleagues (2004) randomized 39 students to traditional instruction or an enhanced

condition in which subjects practiced with a virtual client following the standard instruction. In comparison to those who received didactic instruction only, participants in the VR-enhanced condition asked more relevant questions, performed a more complete client history, and spent more time on client issues than did students who only received traditional instruction (Janda et al.). In an uncontrolled trial, Yellowlees and Cook (2006) found a significant training effect among medical students (*n* = 863) following use of the VR intervention in their understanding of visual hallucinations. By comparison, well-controlled trials within the field of medical research flourish and provide robust support for its efficacy as a supplemental method of training that provides the trainee with the benefits of hands-on training in a risk-free virtual environment (Gurusamy, Aggarwal, Palanivelu, & Davidson, 2008; Gurusamy et al., 2009).

### Comments

There is no question that VR is efficacious for a variety of purposes in clinical psychology. These include the treatment of anxiety disorders, as an analgesic via distraction for painful medical procedures, and as a fail-safe method of training health professionals in specific procedures that require hands-on practice. Despite its efficacy, the application and dissemination of VR in real-world settings has significantly lagged behind the data and its utility. This may change as the cost of VR (now well over $20,000 for a high-quality head-mount) goes down and as systems and networks adopt it as a primary strategy, as the Veteran's Administration did for the treatment of PTSD.

### Mobile Technologies

*Fortune* magazine-identified "guru" B.J. Fogg predicts that we are on the cusp of an "unstoppable revolution" (Reingold & Tkacyzk, 2008). Within 15 years, no other medium—from television and Web to word of mouth—will exert more influence on our behavior than our cell phones (Fogg & Eckles, 2007). His evidence? *We love our cell phones.* We dress them up, feel anxious when we can't find them, and spend more time with them than we do with our loved ones. *They are always with us,* often within range of an outstretched arm, whether we're working, flying, playing, or sleeping. Like magic wands, they are enchanting; they do almost everything imaginable and require little training. We can talk to a friend while rafting down the Colorado river, make reservations at a five-star restaurant for a dinner while walking to the office, take photographs and upload them to a website, transfer money from one bank account to another, and get driving instructions using a global positioning system (GPS). The possibilities seem endless.

How have mobile technologies emerged as the "hottest" media expected to significantly shape human behavior? Three factors are at play. First, in less than 10 years, mobile phones have become affordable, and are faster and more powerful than the first several generations of the desktop computer. Multifunctional "smart" phones are now relatively inexpensive, some costing as little as $50. Between 2005 and 2008, usage expanded by 65%, from 2.14 billion phones to 3.3 billion (Wikipedia, December 16, 2009b). Cellular coverage has also substantially increased over the years. In 2006, 80% of the world's population had cell phone coverage; by 2010, coverage will exceed 90% worldwide (GSM Association, 2006). Second, Apple succeeded in crossing a critical threshold by making it easy for anyone to download applications to their phone. Such third-party applications are now ubiquitous (Tedeschi, 2009). By May 2009, over 1 billion applications had been downloaded from Apple's App Store (Apple, 2009). As of this writing, over 75,000 iPhone applications were available in 77 countries, reaching tens of millions of iPhone users. Apple's commercial success has ignited its competition to move in similar directions (Borden, 2009). Third, the use and integration of mobile phone functionality has the potential to radically improve the quality and cost-effectiveness of health care at a time when health-care costs are significantly rising (Tanguy & Heywood, 2007). For example, the integration of many of its functions—from camera, text messaging, and the Internet, to special add-on hardware monitoring devices (e.g., insulin levels in the diabetic, oxygen absorption in the asthmatic)—will allow patients to directly transmit data about their condition from any location with cellular coverage to their physician for analysis and instruction, thus improving care and decreasing needless office and/or emergency room visits (Perez et al., 2006).

Although mobile technologies are a relative neophyte to research, recent studies have emerged testing the use of mobile technologies in changing a wide range of behavior. These include promoting sexual health and decreasing sexually transmitted diseases (STDs) in youth (Hoffman, 2009; Levine, McCright, Dobkin, Woodruff, & Klausner, 2008), promoting smoking cessation (Haug et al., 2008; Obermayer, Riley, Asif, & Jean-Mary, 2004; Riley,

Obermayer, & Jean-Mary, 2008; Rodgers et al., 2005; Whittaker et al., 2008), facilitating weight loss (Joo & Kim, 2007; Kubota, Fujita, & Hatano, 2004; Morak et al., 2008; Tanguy & Heywood, 2007), increasing physical activity (Damen, 2007; Hurling et al., 2007), providing dialectical behavior therapy (DBT) skills coaching in substance-dependent patients with BPD (Rizvi, Dimeff, & Skutch, 2009), and monitoring and facilitating treatment of chronic diseases, including severe asthma (Ryan, Cobern, Wheeler, Price, & Tarassenko, 2005), diabetes (Carroll, Marrero, & Downs, 2007; Quinn et al., 2008), medication compliance in HIV/AIDs patients (Puccio et al., 2006), and side effects for antiepileptic medication treatment (Frings et al., 2008). Additionally, hardware attachments for cell phones are being used to monitor, record, and transmit peak flow levels in patients with severe asthma (Ryan et al., 2005), test and transmit to their doctors the blood glucose levels of diabetic patients (Carroll, Marrero, & Downs, 2007), and monitor blood alcohol levels in concerned drinkers (Chmielewski, 2008). In this section, we will review current research highlighting multiple modes of intervention delivery via mobile phones, several applications that have been the primary focus of research to date, and finally, discuss the future of this burgeoning field of clinical intervention research.

Thus far, short-message service (SMS; aka "text messaging" or "texting") is the most commonly investigated mobile application in the area of behavior change. Fjeldsoe, Marshall, and Miller (2009) recently conducted a review of studies published to date investigating the use of SMS as part of a behavioral intervention. Of the original 33 papers identified, 14 evaluated the use of SMS to change behavior. The majority of these (*n* = 10) focused on clinical care of health behaviors (e.g., diabetes); the remaining four focused on preventive health behaviors (e.g., smoking cessation). Positive outcomes were observed in 13 studies, leading investigators to conclude that SMS can be a powerful means of facilitating behavior change. Several key benefits of SMS were identified, including wide population reach; interactive, tailored, and individualized messages; and instant delivery with asynchronous receipt.

The following section reviews mobile phone interventions conducted to date with relevance to clinical psychology. Because this area of research is still in its infancy, yet is expanding rapidly, we also include novel, cutting-edge applications of mobile technologies that are or are soon to be available as

products, but do not as yet have data to support their efficacy.

### Smoking Cessation

To date, three RCTs and four open trials have been conducted evaluating the efficacy of six different mobile technologies systems for smoking cessation. The majority of mobile phone interventions (MPIs) in these trials were applied to young adults (Haug et al., 2008; Obermayer et al., 2004; Riley et al., 2008; Rodgers et al., 2005; Whittaker et al., 2008). The researchers universally commented that MPIs are an ideal fit for this population: Young adults who do wish to quit smoking seldom access traditional smoking cessation services, yet they commonly use mobile phones and rely on them as their primary means of communication. Of the two MPIs for adults, one was designed and evaluated for the specific needs of adults smokers with HIV/AIDS (Vidrine, Arduino, & Gritz, 2006; Vidrine, Arduino, Lazey, & Gritz, 2006); only one program (Happy Ending) was developed and tested for uncomplicated adults (Brendryen & Kraft, 2008; Brendryen, Drozd, & Kraft, 2008). The MPIs for smoking cessation range dramatically, from simple use of the telephone for weekly counseling calls (Vidrine, Arduino, & Gritz, 2006; Virdine, Arduino, Lazey, et al., 2006) to well-integrated Web and text-messaging system that tailor interventions to the user in real-time and foster social support from friends to facilitate and maintain cessation (Obermayer et al., 2004; Riley et al., 2008). Only those studies using an RCT or with replication are summarized below.

#### YOUNG ADULT STUDIES

Obermayer et al. (2004) developed and pilot tested a program for college students that integrates an interactive website and cell phone technology to deliver a customized smoking cessation intervention. Students first complete an online assessment that provides the basis for a personalized intervention. Although most of the intervention involves text messages received during the day, users are encouraged to go to the website daily to view a graph that depicts their smoking during the preparation phase through the present or to view the supportive text messages they have received earlier. The website also contains educational modules, such as handling withdrawal, coping with urges, and managing weight gain. A particularly novel innovation involves the use of social support: Users can opt to provide password-protected access to support people who can view

their progress in quitting smoking and can leave a supportive message. Support persons receive a reminder e-mail prompting them to remember to leave a supportive message; tips are also provided on how to support the user who is attempting to give up smoking. Text interventions vary according to where the user is along the stages-of-change continuum (Prochaska & DiClemente, 1983, 1992), with messages increasing in frequency around the individual's quit date. Encouraging messages and tips to manage urges and other coping strategies are provided on the quit day. Users get no fewer than two texts per day, tailored to their progress; they can also communicate with the system should they desire additional assistance in managing a high-risk situation.

Obermeyer and colleagues have conducted two open trials to date, both with promising findings. In the first trial, college students ($N$ = 46) who smoked on a regular, daily basis and desired to quit were recruited to participate (Obermayer et al., 2004). Seven participants formally dropped out of the study, and eight were lost at follow-up. At the 6-week follow-up, 43% made at least one 24-hour attempt at quitting; 22% quit. (These analyses were based on the intent-to-treat sample; those without follow-up data were presumed to be smoking.) The second trial sought to replicate the initial study (Riley et al., 2008). Thirty-one college students who were daily smokers wishing to quit were recruited and received the intervention. In comparison to the first sample, these participants were significantly heavier smokers. Four participants were lost at follow-up. After 6 weeks, 45% reported abstinence (42% on the basis of a biochemical validation); those who continued smoking reported significant reductions in their use and dependence.

Rodgers et al.'s (2005) MPI involved a complex back-end database with 1,000 responses for delivery of personally relevant text messages depending on the user's stage of change. Users received five text messages daily leading up to their quit day. Three types of messages were provided: advice (what to expect when you are quitting, how to avoid weight gain, ways to improve nutrition), motivation and support (success stories, feedback on money saved from not smoking), and distraction (topics of general interest such as sports, trivia, and travel). Other features included: TXT Quizzes (facts about smoking with answers provided the next day), Quit Buddy (participants with similar characteristics and quit days were put in touch with each other), and TXT Crave (users could "pull" for advice in managing

a high-risk situation). A total of 1,705 young adult daily smokers (median age = 22) from New Zealand were randomized to the text MPI or control condition (received a text message every 2 weeks thanking them for their participation). All participants were invited to access other standard services (Quitline and nicotine replacement medication). In comparison to the control condition, MPI participants were significantly more likely to quit smoking, with nearly twice the rate of quitting. The MPI participants were also significantly more successful at not smoking at 6- and 12-week follow-ups. By the 26-week follow-up, however, no between-group differences were detected, due to increased rates of nonsmoking reported by controls. Investigators concluded that the MPI may be particularly helpful at facilitating smoking cessation.

### ADULT STUDIES

Brendryen and colleagues developed and evaluated *Happy Ending* (HE), an intensive multimedia 1-year smoking cessation program that uses the Internet and mobile phones to deliver SMSs, and provides interactive voice response, craving crisis help, and just-in-time phone assistance (Brendryen et al., 2008; Brendryen & Kraft, 2008). Happy Ending is fully automated, using a complex algorithm to deliver personalized and just-in-time responses. A two-arm RCT was conducted with daily smokers willing to quit on a prescribed day without the use of nicotine replacement therapy (NRT). Participants were either randomized to HE ($n$ = 144) or a control condition ($n$ = 146) consisting of a 44-page self-help booklet. The main outcome was repeated point abstinence (i.e., abstinence at all four time points). Happy Ending participants reported a clinically and statistically significant higher repeat point abstinence rates compared to controls (20% vs. 7%) and significantly higher levels of coping planning and precessation self-efficacy.

Vidrine et al. (2006a) examined the effectiveness of an 8-week MPI (telephone calls) for smoking cessation among individuals with HIV/AIDs. Proactive mobile phone counseling sessions were based on a CBT designed to increase coping and problem-solving strategies and build social support. Topics included preparing for and making a commitment to quit, withdrawal facts and effective coping, identifying triggers, and special health topics for HIV/AIDS-specific smokers. All participants received the Recommended Standard of Care (RSOC): physician advice, text-based self-help materials, and NRT. Participants were

randomized to RSOC only (*n* = 47) or RSOC plus MPI (*n* = 48). Eighty-one percent completed the 3-month follow-up, at which experimental participants were 3.6 times more likely to quit smoking compared to TAU participants (36.8% vs. 10.3%, respectively). Additionally, RSOC + MPI participants experienced greater reductions in anxiety and depression and increases in self-efficacy, compared to RSOC-only participants. Investigators also identified that MPI's efficacy was at least partially mediated by its ability to decrease symptoms of distress while increasing self-efficacy (Vidrine et al., 2006a, 2006b).

### *Obesity and Weight Loss Interventions*

Obesity has been described by the World Health Organization as a global epidemic (World Health Organisation, 1998). In 2000, the prevalence of obesity was 20% among U.S. adults, up 61% from 1991; 56% were overweight compared to 45% in 1991 (Mokdad et al., 2001). In their review of the successes and failures of public and behavioral health interventions to achieve weight loss, Tufano and Karras (2005) highlight a number of barriers that consistently appear in the literature. These include lack of treatment provider access to the latest, most efficacious interventions; lack of appropriate support services; and lack of motivation by treatment providers to work with heavy and obese patients (Frank, 1993). Tufano and Karras recommend leveraging robust mobile technologies to address the problem of obesity.

Hurling et al. (2007) evaluated the impact of a 9-week real-time assessment and personalized feedback delivered via the Internet and mobile phone on physical activity. Users began by completing an assessment to identify perceived barriers to physical activity, generate appropriate solutions, and identify the user's commitment to change. Users were then asked to record their exercise habits on a weekly basis and were then provided with constructive feedback relative to their own targets and the test group as a whole. A weekly scheduling tool for planning exercise was included. Users could opt to receive e-mail and/or mobile phone reminders. Through the use of an automated assessor, users received feedback on the rate of behavioral change (e.g., users are warned when their rate of change this week was significantly greater than in previous weeks, which may make it difficult to sustain in the weeks ahead). A text-based automated dialogue helped users identify perceived barriers and offers relevant solutions. Psychoeducational information with tips and suggestions, a library of

information on the degree of strenuousness of different activities, and charts displaying real-time output of their physical activity were also available via technology.

Participants (*N* = 77) were randomly assigned to the intervention condition (*n* = 47) or to a no-treatment control condition (*n* = 30). Participants in both conditions wore an accelerometer on their wrists to objectively measure physical activity. Those in the intervention condition received access to a suite of technology-based services, including: an Internet-based message board to directly communicate with experimental subjects, an online scheduler to facilitate weekly planning of physical activity, and periodic assessments to provide solutions about perceived barriers to physical activity, as well as e-mails and periodic text messages based on real-time assessments of physical activity from the accelerometer. In comparison to study controls, experimental participants engaged in significantly more physical activity weekly (averaging 2 hours and 18 minutes more than controls each week) and lost more body fat compared to controls (–2.18 vs. –.17 pounds, respectively).

Joo and Kim (2007) investigated the use of a multimedia 12-week weight reduction program comprised of behavior modification, exercise, and nutritional education. A total of 927 individuals from the community participated in the study. Weight assessments were obtained at a public health clinic at both baseline and follow-up. Following the baseline assessment, participants received a randomly generated (without repetition) weekly motivational and informational text message (e.g., "Be proud of yourself for exercising!," "Be aware of snack!," "Did you exercise today? Have a light meal and end the day with some stretching?"). Additionally, participants received a weekly informational brochure about exercise and diet via standard post. Of the original sample, data were available for 534 participants, and 433 (47%) completed the entire program. Statistically significant differences were observed pre to post intervention in reduction of weight, waist circumference, and body mass index scores. Over two-thirds of participants had a reduction in waist circumference between 5–7.5 cm.

Morak et al. (2008) recently piloted a Web-based therapy management system with mobile phone access to support obese patients (*N* = 25). Participants initially received a face-to-face consultation with a clinician, from which an individualized program was established. Participants met with their clinician once monthly during the 3-month study period.

In between meetings, participants monitored their weight and other relevant health variables as a means of increasing their awareness and motivation regarding their physical activity. Self-monitoring was intentionally utilized as an intervention/change strategy, and not for the sole purpose of assessment. Additionally, participants received reminder prompts via SMS to enter their data and weekly feedback on their weight. On average, participants received a total of 14 reminder texts. At the study's end, investigators found significant reductions in abdominal girth (2.4 cm), in body weight (2.4 kg), and body mass index (0.78 kg/m²). Eighty percent of the sample indicated that they found the text reminder prompts helpful, 85% found it helpful to receive weekly feedback about their weight trend, and 100% would recommend it to a friend. Interestingly, only 60% could imagine using their own cell phone, but 80% could imagine using their PC to access the program over the Internet.

### Lifestyle and Health Promotion Interventions

A highly innovative SMS intervention, *SEXINFO*, was recently developed and evaluated in a naturalistic setting in response to the growing rates of gonorrhea among inner city youth in San Francisco (Levine et al., 2008). With a primary goal of providing information and referrals to this at-risk population, researchers relied exclusively on the communication medium that most at-risk teens had in their possession: cell-phones. SEXIFNO was inspired by a similar program in London's Brook Centres' program (BBC News, 2004). Content for the SMS intervention was developed in an iterative process in which extensive end-user feedback was gathered via focus groups. Users were recruited through strategic placement of ads on city buses and Yahoo, and informational cards were distributed by outreach workers. In the first 25 weeks, 4,500 inquiries had been made and 2,500 led to provision of specific information. To gain access, users call a phone number, then type in SEXINFO. A list of codes is provided that users can then use to make selections for specific information or referrals. The top three messages accessed included: (1) "What 2 do if ur condom broke"; (2) "2 find out about STDs"; and (3) "If u think ur pregnant." (Additional information and access to text content is available at www.sexinfosf.org.)

*MyFoodPhone* (MFP) is the first-ever nutrition service that links individuals with their personal dietitian using a mobile phone. Its intent is to provide a fun and effective way of keeping a food journal,

receiving feedback, and ultimately staying motivated to continue a difficult lifestyle change (Tanguy & Heywood, 2007). The program consists of three steps: taking a picture of the food you eat; sending the photos to a personalized online food journal where users can, if they wish, add additional information to each photo; and receive coaching and feedback from a dietitian in the form of a video message. MyFoodPhone also includes a community support tool and a location where friends, family members, and others with a shared goal can provide support (e.g., share food journals to get motivating feedback or suggestions, share ideas about managing chronic health conditions, recipes, etc.).

Although, to our best knowledge, no empirical studies supporting its efficacy are available, the service is available through Sprint and has received considerable attention in the media (Munoz, 2005). MyFoodPhone designers and promoters highlight several key elements they believe contribute to its success: receiving personalized, video-recorded feedback from a dietitian; making the experience fun and engaging; and ensuring that all aspects of its use are convenient and easy (e.g., MFP is integrated into a phone service, so does not require the individual to carry around a separate device).

### Expanding the Use of Mobile Technologies: The DBT Field Coach 1.0

We are currently developing and evaluating a mobile phone application for use by clients with BPD who are receiving comprehensive DBT (Dimeff & Skutch, 2009; Rizvi et al., 2009). The primary purpose of the *DBT Field Coach* is to aid clients in using DBT skills in the context of their lives. Telephone consultation has always been a central treatment modality in standard outpatient DBT, intended to facilitate generalization of DBT skills to their natural environments—from the therapy room to the real world (Dimeff & Koerner, 2007). Rather than calling one's clinician *after* engaging in dysfunctional behavior, DBT encourages BPD clients to call for skills coaching should they have difficulty using their DBT skills. As an adjunct to standard treatment, the *Field Coach* can be used as an additional resource for clients, potentially before and/or instead of calling their primary clinician for coaching.

The hub of the *Field Coach* is the coaching device itself, which contains information about each DBT skill and instructions in their use. Upon activating the device, clients can choose to either be guided in a step-by-step fashion to select a specific skill to try, given the specific context (just as they might when

calling their individual clinician for skills coaching); alternatively, clients can also go straight to a specific skill for information, just as they might flip through their DBT skills notebook. In addition to this essential feature, the *Field Coach* includes a number of other applications to facilitate skills use and skills generalization: (a) Skill of the Day, a feature to receive a randomly generated DBT Skill each day, including what it is, how to use it, and an ongoing tally of daily attempts to practice the skill during the day; (b) Skills Diary Card Log, a feature that allows the client to monitor use of all DBT skills across the course of the day; data can be downloaded for later use by the DBT clinician; (c) Rainy Day Recordings, in which clients can upload video and audio messages from their DBT clinician and supportive friends and family members whom they can index and access when needed (e.g., when feeling discouraged, demoralized, hopeless, and other mood states that make it difficult to take the needed action); (d) 100 Reasons, a feature intended to enhance clients' motivation to engage in effective behaviors during particularly rocky times by displaying particularly salient images that capture their most important reasons (personalized for the user) to engage in effective (vs. dysfunctional) behavior (e.g., pictures of one's children, images of junkies that remind clients of what they do not want to become, etc.); and (e) Survival Tools, a feature that includes an assortment of files the client can access when they need to survive a crisis without making it worse (e.g., games and music to distract oneself from high-intensity urges; previously effective skills individual used with success in similar past situations).

### Just Around the Bend: Contextual Intelligence and Mobile Application Integration

We are at the tip of the iceberg in our understanding, design, and use of mobile technologies to treat behavioral problems. Thus far, interventions involve a single function or application running at a time (e.g., texting, taking a picture, sending a picture). Even the *Field Coach*, with its myriad of features and tools, barely scrapes the surface of what is possible. Just around the bend, new technology will make it possible for multiple applications to run concurrently in the background, and battery life will improve to support this functionality (Nokia, 2009). This advance will allow for the development of contextually intelligent programs—those that assess the relevance of new information based on

contextual factors (e.g., where a person is, who a person is calling or being called by, etc.). Use of such contextual intelligence, for example, could significantly expand the impact and reach of mobile technologies to facilitate behavior change. For example, the *DBT Field Coach 2.0* built using contextual intelligence could notice when users were nearing certain geographic high-risk hotspots using the GPS (and pre-identified GPS coordinates); *Field Coach* users could then receive a warning (e.g., "You are entering a high-risk area") and be asked if they need coaching. Images associated with their most cherished reasons for stopping a problem behavior could automatically appear on the screen. Similarly, incoming or outgoing calls and text messages could also include warnings, suggestions, and filters (built into the individual's contacts) based on preprogrammed information. For example, should a drug-using friend call, the phone could encourage the user to not pick up the call, but to instead use skills. The software could also be programmed to provide a special, prerecorded message for such callers (e.g., "I have stopped using drugs and am working hard to rebuild my life. Because of our history together, I cannot continue our friendship. Please do not call back. I wish you peace on your journey and all the best in life").

### Comments

Mobile phones have already captured our hearts and, for scientists and technologists, are now captivating our attention. Preliminary studies have demonstrated both the feasibility and efficacy of mobile technologies in producing behavior change. Even when only the most basic elements of mobile technologies are utilized (e.g., text messaging, camera), mobile phones can be used effectively for a variety of purposes, including behavior change. Data to date has supported their use in facilitating quitting smoking, weight loss, exercise, and reducing STDs. Our own feasibility research of the *DBT Field Coach 1.0* indicates that even patients with severe and complex behavioral problems, such as BPD with concurrent substance dependence, positively view the use of mobile technology—in this particular case—as a helpful tool to facilitate skills generalization during trying times. Emerging innovations that facilitate contextual intelligence by allowing multiple applications to run concurrently ("silently") in the background will revolutionize what is possible. Our own planning for *DBT Field Coach* 2.0 hints at these possibilities. Recognition of the potential for

future mobile technologies to radically promote behavior change provided the impetus for the National Institutes of Health to launch its first annual mobile health (m-Health) summit. Case studies for the summit are expected to examine how mobile technologies can be used to facilitate public health education, promote remote data collection and surveillance, facilitate diagnosis and health monitoring of patients in remote regions, and promoting healthy behavior change.

## Social Networking

Social network service or "social networking" is the latest technological newcomer to impact behavior change. Social networking refers to the use of online communities to locate, interact with, and exchange information with other users. Social networks typically link people by common interests, activities, or people they know in common. These online communities have the ability to strengthen and generalize the known positive effects of social support on behavioral change (Olsen & Kraft, 2009). The most popular social networks worldwide include Facebook, MySpace, Twitter, and LinkedIn, with over 300 million active users of Facebook (Wikipedia, 2009a), and over 55 million Tweets sent daily via Twitter worldwide (biz, 2010). Within the area of psychology, QuitNet (www.quitnet.com), an Internet-based community that combines CCBT with social networking to stop cigarette smoking and support maintenance of abstinence, may be the oldest and most successful of such applications. Launched by developer Nathan Cobb in 1995, QuitNet includes a number of features intended to aid smokers in stopping and maintaining their goals, including: numerous forums, chat rooms, expert and medical support, and "buddies" (individuals users identify, track, and receive alerts when they are online). Each day, over 3,000 support messages are posted; over 60,000 members use QuitNet each month (QuitNet, n.d.).

Clinical research using popular social networking sites is currently in an embryonic stage. Yet efforts to begin examining ways in which social networking sites can be leveraged as tools to promote behavior change are furiously under way, and some empirical investigation have begun (Olsen & Kraft, 2009). Indeed, the National Institute on Drug Abuse (NIDA, 2009) recently convened a special conference of addictions treatment outcome researchers and technology experts to examine how Twitter can be used to facilitate smoking cessation (NIDA, 2009).

## Twitter

Twitter, the popular social networking micro-blog, has rocketed in use since its introduction in 2006, and is beginning its emergence as a tool for changing chronic behaviors, such as cigarette smoking (NIDA, 2009). Simply, Twitter asks users, "What are you doing?" and provides 140 characters to respond. Users can subscribe to other users and become their "follower," allowing connection and increased social support. Many speculate that the brevity, along with its scope of reach (Comm, 2009; Israel, 2009; Morris, 2009), have made Twitter a powerful tool for political revolution (Grossman, 2009) and marketing (Comm), as well as an easy target for mockery (Stewart, 2009). With a monthly growth rate of 1,382% (McGiboney, 2009), over 6 million unique monthly visitors and 55 million visits per month (Kazeniac, 2009), Twitter is currently ranked third as the most used social network. Yet only 40% are retained (S. Hoffman, 2009).

Empirical data to date on the use of Twitter, either alone or with other more traditional tools as a treatment or intervention tool is lacking. However, its use in the context of behavioral change is being explored, and ideas for its application are proliferating quickly. For example, the Substance Abuse and Mental Health Services Administration (SAMHSA) has now begun using Twitter for its National Suicide Prevention Lifeline, to reach as many people as possible (Substance Abuse and Mental Health Services Administration [SAMHSA], 2009). SAMHSA is using TWITTER to provide didactic and prevention information.

Smoking cessation is another area in which Twitter is being used to reach large numbers of clients and to support behavior change. Prior to NIDA's efforts to investigate this application of Twitter, others had already begun to use the technology. The Moffitt Cancer Center Patient Smoking Cessation Program, a cancer center and research institute based in Florida, has added Twitter to its existing arsenal of online support. The Moffitt Center's Twitter account, Beaquitter, sends links to relevant, helpful articles, motivational statements, and tips and information (Smoking Cessation (beaquitter), 2009). Beaquitter also enhances social support by allowing the virtual connection of clients with the same behavioral goals. Many other similar Twitter accounts currently exist, some tied to larger online forums and groups, others not.

Although these are only two examples, use of the technology is widespread and growing at a rapid

rate, making Twitter an especially well-poised social networking tool to reach people and make an impact in the field of behavior change. Indeed, in Olsen and Kraft's (2009) initial qualitative analysis of interview data with a small sample ($N$ = 5) of social network users, they found that the personalized nature of Twitter coupled with the ease of staying connected to friends and family made the site very popular among participants. We expect a rapid increase in the uses of Twitter in the field of mental health to emerge, and with them a clearer empirical picture of its impact.

## Conclusion

We have witnessed an explosion of advances in technology over the past decade that has produced a paradigm shift in how we consider and deliver psychosocial treatments for behavioral problems. In a relatively brief period, the Web, in particular, has made possible a kind of connectedness and sharing of information that was inconceivable just a generation ago. Its advance has made it possible for motivated individuals throughout the world to receive evidence-based therapies for specific behavioral problems and disorders. Mobile phones and mobile technologies, already ubiquitous in our lives, are expected to play an even greater role in shaping and influencing our behavior. This advance will put the clinician, as well as therapy itself, in the palm of the client's hand (and in his or her pocket, purse, backpack) 24/7; wherever the mobile phone is, so goes the efficacious treatment. The reliability, predictability, cost-effectiveness, efficiency, and global reach of technology will significantly close the gap between research and practice; its use and advance will significantly impact the dissemination problem.

Already innovative technologies are used to deliver ESTs, augment and enhance face-to-face treatment, and facilitate the delivery of ESTs in cases in which the clinician knows little about the treatment. Recent advances in VR make it possible to produce exposure to multiple sensory stimuli that transport the individual to the sights, smells, and sensations of the battlefield or to provide a powerful analgesic during painful procedures. Mobile technologies are being used to promote a number of health behaviors. Our own work moves the potential of its use a step further, by providing in vivo coaching to promote skills generalization in severely disordered individuals with BPD. The integration of contextual intelligence will produce another quantum leap forward in the use of innovative technologies to impact human behavior. The exponential growth of technology makes it

difficult to fully envision what is around the corner, and the limitless ways in which technology will impact the practice and scope of clinical psychology in the years to come. Most likely, we are at the tip of the iceberg.

Several things are certain. First, technology will play an ever-increasing role in how treatment is delivered. This force will be driven by an increased effort to improve efficiency, cost-effectiveness, and to ensure that treatments known to work are delivered fully and to fidelity. Technology's reach will impact all areas of clinical psychology, from assessment to treatment to long-term maintenance of treatment gains. We predict that within 10 years, the provision of most psychological treatment in the world will be significantly aided by technology. Second, although new technological innovations will significantly improve the quality and reach of service delivery, they will not replace people. Clinicians will continue to play a crucial role, particularly in motivating clients to engage in treatment. This will be particularly true for clients with multiple, severe, and complex problems, such as those with BPD. Third, there is more in store. Just as the Web created a myriad of possibilities impossible to imagine before its arrival, other technologies unknown today will emerge tomorrow. They will interact with existing technologies and be used in ways wholly independent of our present-day devices.

This chapter sought to provide a window into the major applications of technology currently used to aid in the provision of psychosocial treatments for behavioral problems. We initially reviewed the innovative use of computers to provide, augment, and facilitate the delivery of ESTs. In this discussion of CCBT, we sought to describe several examples of CCBTs for different disorders and review their current evidence base. Next, we explored the use of VR to facilitate exposure in the treatment of anxiety disorders and as a pain analgesic for individuals undergoing highly painful medical procedures, such as wound care following severe burns. We then turned to the burgeoning area of mobile technology, an area still in its infancy. Although most of the work relevant to clinical psychology conducted to date uses the most primitive elements of mobile technology (e.g., text messaging) and involves changing health behaviors (e.g., smoking, dieting, exercise), we described other around-the-corner applications. This included a review of our own recent work involving mobile phones to provide in vivo coaching in DBT skills for clients with BPD and who are engaged in a DBT program. We also illustrated several specific ways in which contextual intelligence

may be used in the years to come. Finally, we reviewed the technology newcomer to psychology—use of social networking, and specifically the application of Twitter.

A final note: As the technology revolution continues to shape the new paradigm, new challenges to traditions emerge with great relevance to treatment developers, clinical outcome researchers, and those who rely on their research findings. First, how do we evaluate technology-based research proposals? Specifically, should proposals for technology-based treatment outcome research be required to earn exemplary critiques on both the scientific merit of the proposal *and* the innovation of the technology? Or, are traditional standards sufficient (i.e., the research is strong, investigators demonstrate a need for proposed trial, and area of research is innovative; however, the technology itself is not required to also be state-of-the art and built on empirically proven approaches). We strongly believe that the research is only as sound as the intervention it seeks to evaluate. In the case of technology-based research, innovation should be defined as both the *area* of technology (e.g., CCBT) and the extent to which the applied area of technology is innovative (e.g., the product itself is *also* innovative). It is not sufficient, in our view, for a research proposal to be built on dated technology, particularly when empirical research has demonstrated the new technology to be superior at changing behavior. Given the design and programming expense required to build highly engaging, interactive, and cutting-edge programs, it is imperative that grant proposal budget limits be expanded to allow investigators in this arena to build cutting-edge technology-based applications *and* conduct rigorous research. (Currently, budget amounts at the U.S. National Institutes of Health are sufficient to do one, but not both). Second, use of the commercial software industry standard in building technology-based tools and applications should be a requirement for public funding of technology-based research. Such an approach would involve an iterative process of prototype development, in which every element of the program is built and refined based on extensive feedback from target end-users. It is only through this careful, systematic (and expensive) process that the eventual product will achieve its intended purpose. Finally, given the usual many-year time lag from generation of an innovative idea to its funding and eventual publication of its research findings, *and* the swiftness with which technology advances, we must work to develop and use complementary and/or alternative methods to evaluate and disseminate findings involving cutting-edge technologies that maintain rigorous standards for scientific excellence. Greater use of within-subject and multiple-baseline designs may complement, for example, standard randomized controlled trials.

# Interventions in Forensic Settings: Juveniles in Residential Placement, Defendants in Drug Courts or Mental Health Courts, and Defendants in Forensic Hospitals as Incompetent to Stand Trial

Kirk Heilbrun, Naomi Goldstein, David DeMatteo, Allison Hart, Christina Riggs Romaine, *and* Sanjay Shah

### Abstract

Interventions for criminal justice–involved populations have been an increasing focus of theoretical and research attention, and have also been recognized as among the "next frontier" of priorities for the forensic mental health professions. In this chapter, we present a description of three different kinds of interventions with criminal justice populations. These interventions—for adjudicated delinquents, defendants diverted into specialized courts, and defendants hospitalized as incompetent to stand trial—represent a range of population ages, traditional versus relatively new modalities, and stages of the juvenile/criminal justice systems. Perhaps surprisingly, the more established of these interventions (juvenile placement and forensic hospitalization) have relatively less empirical data regarding their effectiveness than do the newer drug and mental health court modalities. In this chapter, we summarize the evidence that does exist, describe existing and recommended practices where indicated (unfortunately, often without the assistance of effectiveness data), and draw conclusions regarding our future research needs in light of this discussion.

**Key Words** : Drug courts, forensic treatment, Incompetence to Stand Trial, juvenile delinquency, mental health courts

Forensic psychology is often associated with assessment. Psychological assessment and specialized measures have been important in the advances made in this area over the last 20–30 years (Melton, Petrila, Poythress, & Slobogin, 2007). But interventions for populations that are involved in the legal system have been an increasing focus of theoretical and research attention in some areas, such as violence risk assessment and treatment (see, e.g., Quinsey, Harris, Rice, & Cormier, 2006). They have also been recognized as among the "next frontier" of priorities for the forensic mental health professions (Otto & Heilbrun, 2002).

It is perhaps timely, therefore, to present in this chapter a description of three different kinds of interventions with criminal justice populations.

These interventions—for adjudicated delinquents, defendants diverted into specialized courts, and defendants hospitalized as incompetent to stand trial—represent a range of population ages, traditional versus relatively new modalities, and stages of the juvenile and criminal justice systems. It is perhaps ironic that the more established of these interventions, juvenile placement and forensic hospitalization, have relatively less empirical data regarding their effectiveness than

do the newer drug and mental health court modalities. In this chapter, we summarize the evidence that does exist, describe existing and recommended practices where indicated (unfortunately, often without the assistance of effectiveness data), and draw conclusions regarding our future research needs in light of this discussion.

## Interventions
### Juveniles in Residential Placement

Since its inception at the turn of the 20th century, the U.S. juvenile justice system has struggled to balance the often competing demands of punishing and rehabilitating offending youth (Grisso, 1981). During the 1980s and 1990s, many states established punitive sanctions for youthful offenders. Recently, however, the majority of states have begun reforming their systems to keep more youth within the juvenile justice system and to provide much-needed mental health and aftercare services (Ziedenberg, 2006). Such changes have led to increasing demands for effective and replicable treatments that reduce recidivism.

In contrast to earlier reviews in the late 1970s and 1980s suggesting that "nothing works" in treating offending youth (Garrett, 1985), more recent research has demonstrated that treatments and interventions for juveniles can reduce recidivism (see, e.g., Alexander et al., 1998; Antonowicz & Ross, 1994; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998). Studies have also suggested that treatment within the juvenile justice system may be more effective at reducing recidivism than placement within the adult correctional system (Bishop, Frazier, Lanza-Kaduce & Winner, 1996; Fagan, 1995). These effects remain even when selection bias (i.e., differences between youth who remain in the juvenile system and those who are sentenced in criminal court) is statistically controlled (Myers, 2003). Such findings are encouraging to treatment providers working with offending youth.

This section of the chapter will review the empirically supported treatments for juvenile offenders, focusing on treatment provided within residential juvenile justice settings. Empirical evidence does not support specific comprehensive programs for youth in custodial placement. However, meta-analytic results, as well as studies of risk and protective factors, identify treatment components that may reduce recidivism with delinquent youth in residential placement.

## State of Empirically Supported Treatments for Juvenile Offenders

No comprehensive programming has yet been supported for use in custodial juvenile justice settings (Greenwood, 2005). In fact, based on the Office of Juvenile Justice and Delinquency Prevention (OJJDP) Model Programs' data, no programs have achieved even a "promising" level of empirical support for use in "correctional" settings (i.e., residential facilities that restrict the movement and activities of residents and serve as placements for adjudicated youth) (Office of Juvenile Justice Delinquency Prevention [OJJDP], 2008).

Research does support a number of community-based programs for reducing recidivism in juvenile offenders. For instance, multisystemic therapy (MST) has been shown to decrease delinquency and the incarceration rates of violent and chronic juvenile offenders for more than 2 years post-treatment (Henggeler et al., 1998). Multisystemic therapy is a community-based treatment that seeks to engage youth in treatment and reduce barriers to accessing services (Henggeler, Pickrel, Brondino, & Crouch, 1996). Master's level therapists provide about 60 hours of direct services over 3–6 months, working to empower the family to resolve and manage problems. Similarly, functional family therapy (FFT) (Alexander & Parsons, 1973) has been shown to reduce recidivism (Alexander et al., 1998). Unfortunately, both MST and FFT require intensive family participation that may be unrealistic with juvenile offenders in residential placements, where youth may be placed far from home, come from distressed families, or lack stable guardians (Guerra, Williams, Tolan, & Modecki, 2008). A family's ability and willingness to meaningfully participate in treatment may be severely limited for these youth. Thus, effective and empirically supported treatments are still needed within the highly structured, supervised, and treatment-intensive residential juvenile justice setting.

## Promising Treatments in Residential Settings
### TREATMENTS ASSOCIATED WITH REDUCTIONS IN RECIDIVISM

Although no comprehensive programs to reduce recidivism have been empirically evaluated for use in juvenile justice residential settings, some promising treatments have been identified for use in other types of residential settings. Like juvenile justice facilities, other types of residential settings provide 24-hour care, but they may or may not be secure.

Youth are often placed in such facilities for mental health and/or substance use needs, either voluntarily or by court order (OJJDP, 2008).

The OJJDP Model Programs database identifies three effective residential programs, empirically supported by quasi-experimental research, that are promising for adjudicated youth in placement (OJJDP, 2008). Two programs specifically target substance use (OJJDP, 2008). They include, but are not limited to, youth involved in the juvenile justice system. Although participation in both programs was associated with reductions in substance use, one program did not show reduced recidivism at 1-year follow-up (see Morral, McCaffrey, & Ridgeway, 2004) and the second did not consider recidivism as an outcome variable (see Morehouse & Tobler, 2000).

The third effective residential program identified by OJJDP—the Mendota Juvenile Treatment Center (MJTC) (see Caldwell & Van Rybroek, 2005)—combines the security provided in traditional correctional settings with the mental health treatment associated with psychiatric facilities. Adolescent males who have not responded favorably to traditional rehabilitative services in Wisconsin's juvenile justice system receive intensive, individualized therapy from experienced mental health professionals. The goal of treatment is to interrupt an escalating cycle of defiant behaviors and legal sanctions. The MJTC uses the Decompression Model (Monroe, Van Rybroek, & Maier, 1988) to keep youth from withdrawing or being withdrawn from treatment. Despite treatment-oriented intentions, staff members in many facilities focus primarily on behavioral control rather than treatment with aggressive youth (Caldwell & Van Rybroek, 2005). The MJTC seeks to maintain youth involvement in treatment by *increasing* individual treatment contact when additional security is required (Caldwell & Van Rybroek, 2005). Motivational interviewing approaches (see Miller & Rollnick, 2002) are used to foster change.

Youth in treatment at MJTC were significantly less likely to recidivate within 2 years than were youth who committed similar offenses and were referred for assessment, but not treatment, at MJTC. The MJTC youth were half as likely as these comparison youth to commit additional violent, serious offenses; there were no observed differences for misdemeanor offenses (Caldwell & Van Rybroek, 2005). This program may provide a useful model for the treatment of youth with substantial mental health needs. To date, however, it has not been extended to other centers or tested with female juvenile offenders.

Another OJJDP initiative, Blueprints for Change, identified promising mental health treatments for youth at different stages of the juvenile justice process (e.g., detention, residential treatment, aftercare) (Skowyra & Cocozza, 2007). Although Blueprints for Change primarily reviewed court liaison, mental health screening, and community reentry programs, it did identify one promising residential program. The Emotionally Disturbed Treatment Program (EDTP) in Corsicana, Texas, created and operated by the state's juvenile corrections agency, provides treatment for adjudicated youth with mental health disorders. Youth remain in placement for approximately 9 months, completing a 30-day evaluation period to verify the need for mental health treatment (Skowyra & Cocozza, 2007). Some 13.9% of youth who were enrolled in EDTP were incarcerated 1 year after they were released from secure confinement, compared with 25.6% of youth who were not enrolled (Texas Youth Commission [TYC], 2008). Youth who *completed* the EDTP had a lower rate of reincarceration at 1-year follow-up (8.5%) than did youth who did not complete treatment (17.2%; TYC, 2008). Smaller differences were observed in the cohort of youth followed for 3 years following release from secure confinement; 41.5% of youth enrolled in EDTP were reincarcerated, compared with 48.5% of youth who had not been enrolled (TYC, 2008). The mental health treatment at the EDTP includes "intensive psychiatric monitoring, increased psychological consultation, specialized counseling, and specially trained dorm staff" (TYC, 2008, p. 4). A detailed description of the actual treatment provided in the EDTP (i.e., the methods of psychiatric monitoring, the treatment techniques used in specialty counseling, and the training provided to dorm staff) was not available, illustrating one gap in the current juvenile justice treatment literature. The few programs with empirical support seldom provide the detailed treatment information that would allow other programs to integrate similarly effective techniques.

## TREATMENTS ASSOCIATED WITH REDUCTIONS IN BEHAVIORS RELATED TO RECIDIVISM

Treatments for anger and aggression have been designed specifically for juvenile offenders, and researchers have begun examining the impact of these treatments when delivered within residential juvenile justice settings. Anger replacement training (ART) was designed for aggressive juvenile offenders. Anger replacement training groups meet three times per

week, for 10 weeks, and emphasize the development of skills (e.g., thinking ahead, self-evaluation, self-rewarding, anger management, impulse control) and moral reasoning. Evaluations of program efficacy have shown positive effects for youth in many settings, including residential treatment facilities and secure confinement (Goldstein, 2004). To date, no studies have examined the effects of ART on recidivism.

Another anger management program designed specifically for girls in residential juvenile justice facilities is currently being evaluated. The juvenile justice anger management (JJAM) treatment for girls is an 8-week, 16-session, manualized, cognitive-behavioral group therapy program designed to teach girls anger-coping strategies, behavioral control techniques, and problem-solving skills to reduce physical and relational aggression. The JJAM uses role-plays, hands-on activities, and between-session practice assignments to help girls develop skills, solidify their learning, and use these skills when angry. The JJAM program addresses the hostile attribution biases often found in aggressive youth and provides girls with alternative methods of thinking about and reacting to anger-provoking events in their daily lives. The program was designed to address the needs of female juvenile offenders (e.g., abuse histories, low IQ and poor academic achievement, distress about unpredictable social support) and the frequency of co-occurring mental health problems in this population (e.g., substance abuse, attention-deficit hyperactivity disorder [ADHD], depression). A randomized, controlled pilot trial demonstrated significant reductions in anger, general aggression, verbal aggression, and indirect (relational) aggression for girls who completed the JJAM treatment in addition to the facility's treatment as usual (TAU); the control group completed only TAU. Medium to large effect sizes were observed for reductions in anger, verbal aggression, and indirect aggression. No recidivism data were collected in the pilot study (Goldstein, Dovidio, Kalbeitzer, Weil, & Strachan, 2007). Although these results appear promising, their interpretation from a small-scale pilot study requires caution. A full-scale, multisite, randomized controlled efficacy study is in progress and will include data on participants' recidivism rates.

### Challenges to Conducting Juvenile Justice Research

Clearly, further research is needed to identify recidivism-reducing treatments for use in residential juvenile justice settings. Few empirically supported treatments are available for use in these settings, partly because of the difficulties inherent in performing research with juvenile offenders in placement. As both "children" and "prisoners," juvenile offenders are a doubly protected population under the U.S. Code of Federal Regulations (45 CFR 46.402; 45 CFR 46.303) used by Institutional Review Boards. As "children," such participants must receive permission from a parent or legal guardian to participate in research. Identifying and contacting the relevant parties can be prohibitively time-consuming and difficult, especially in large states where youth may be placed in facilities far from home. Many youth in residential settings may be "wards-of-the-state," based on the Office for Human Research Protections' regulations (45 CFR 46.407), thus raising complex questions about who can provide permission and which regulations granting authorizing participation may apply. Questions such as these can prevent many eligible youth from participating in treatment research and reduce studies' sample sizes.

Exacerbating these challenges to research, the length of stay for youths in placement is often unpredictable. Youth may be released earlier than anticipated for any number of reasons (e.g., good behavior, an unexpected decision by a judge during a review hearing, poor adjustment to a given placement), or may remain in a particular residential facility only until a bed is available elsewhere. Such variability makes it difficult to ensure that a youth completes an entire treatment protocol, and that the beginning group of youth completes a closed-group intervention.

Furthermore, youth involved in the juvenile justice system can be difficult to track after leaving residential placement. Such youth tend to come from distressed families that may often change locations (Scanlon & Devine, 2001). This inconsistency creates obstacles to tracking youth for post-treatment outcome periods. Similarly, moving between jurisdictions can interfere with accurate collection of official recidivism data—new charges might be unknown to officials in the original jurisdiction from which the recidivism data are collected.

Treatment outcome research is also limited by definitions of "success." Many program evaluations consider placement in a less restrictive setting to be one kind of successful outcome (see, e.g., Drais-Parrillo, 2004). Although this can provide a more complex view of improvement than simple recidivism, such information is typically provided *instead of* data on additional arrests and adjudications.

Measuring treatment success using only future juvenile justice placements may be misleading, as placement decisions are often heavily influenced by factors unrelated to the individual or the offense (e.g., bed availability) (Bender, 2004).

## Empirically Supported Treatment Characteristics

Despite the challenges to conducting treatment outcome research within the juvenile justice system, many studies have examined the relationships between specific treatment characteristics and recidivism rates. Meta-analytic results have revealed several characteristics of treatment that appear related to recidivism.

### TARGETING CRIMINOGENIC NEEDS

Consistent with intervention theory describing risk, need, and responsivity (Andrews & Bonta, 2006), meta-analyses of studies of adult and juvenile offenders have indicated that treatment programs directly addressing criminogenic needs (those empirically associated with the risk of recidivism) are more effective than programs that do not target recidivism-related factors (Antonowicz & Ross, 1994). In fact, the effect size of treatment tends to be associated with the number of criminogenic needs targeted in the treatment program (Dowden & Andrews, 2000). This is important for two reasons. First, not all programs explicitly focus on reducing the risk of future offending. Some facilities may simply remove the individual from the community for a designated period of time. For instance, many widely publicized "get tough" policies seek to deter potential offenders from committing future offenses and focus less on the rehabilitation of the adjudicated individual (Myers, 2003). Other programs may address issues (e.g., self-esteem) that may be helpful to the individual's emotional well-being but are not associated with criminal behavior (Bonta & Andrews, 2007). Approaches that focus on broad psychological change do not reduce the risk of delinquency (Lipsey, 1995); if the goal is recidivism reduction, resources are better invested by targeting criminogenic needs (Dowden & Andrews, 2000). Second, the application of this principle is far from straightforward because it requires identification of criminogenic needs and an understanding of how these needs are associated with juvenile offending.

Cottle, Lee, and Heilbrun (2001) examined 30 potential predictor variables in a meta-analysis of 22 studies reporting reoffending outcomes for juvenile offenders. The two variables with the strongest relationships to recidivism were younger age at first commitment and younger age at first contact with the law. These age-related variables are static risk factors that cannot be altered through planned intervention. Many other identified risk factors, such as history of physical and/or sexual abuse or significant family problems, are difficult or impossible to change through treatment at a post-adjudication residential facility. However, treatment within residential juvenile justice programs can target dynamic risk factors—modifiable characteristics that, if altered, may decrease youths' risks for future offending.

### Nonsevere Psychopathology

Nonsevere psychopathology (e.g., stress, anxiety) was the strongest dynamic risk factor for reoffending found in Cottle, Lee and Heilbrun's (2001) meta-analysis. Notably, histories of severe psychopathology and psychiatric treatment were not significantly associated with reoffending. However, both nonsevere pathology and conduct problems were associated with reoffending. Studies involving large numbers of juvenile offenders and urban adolescents have noted that high impulsivity (Loeber, Farrington, Stouthamer-Loeber, Moffitt, & Caspi, 1998), as well as hyperactivity, concentration problems, and restlessness (Hawkins et al., 2000) were associated with delinquency. Attention deficits and irritability were also identified as risk factors for delinquency and crime, with moderate to large effect sizes (Agnew, 2005). Consequently, mental health treatment can address these symptoms as a potential mechanism for reducing recidivism.

There is an absence of empirically supported psychological treatments to address symptoms associated with hyperactivity, attention deficits, and irritability in juvenile offenders in residential facilities. However, empirically supported treatments (including psychopharmacological treatments) for many of these symptoms do exist for other populations in outpatient clinical settings. Later in this chapter, we will discuss ways to adapt non-psychopharmacological treatments for use within residential juvenile justice placements.

### Poor Problem Solving Skills

In a study of adult males under federal supervision, Zamble and Quinsey (1997) observed that men who reoffended and were returned to federal prison had much poorer coping skills than did comparison samples of nonrecidivating and nonoffending males. In another study, poor social problem-solving skills served as a risk factor for delinquency, with a medium to large effect size observed (Agnew, 2005).

Not surprisingly, the abilities to seek social support, act in a nonimpulsive manner, and use flexible and reflective coping strategies have all been identified as protective factors (Hanna, 2001). Treatments involving problem-solving training can help participating youth develop these protective skills (see Kazdin, 2003), thereby potentially modifying this risk factor for recidivism.

### Deviant Peers/Unstructured Time

Research has consistently found that youth with negative peer relations tend to be involved in more delinquent activity (Brendgen, Vitaro, & Bukowski, 2000; Chung & Steinberg, 2006; Hawkins et al., 2000; Haynie, 2002; Lipsey & Derzon, 1998). During adolescence, peer relationships become extremely important (see Guerra et al., 2008) and may become more influential than familial relationships (DeMatteo & Marczyk, 2005). Strained social relationships may cause youth to seek out accepting peer groups; if youth are not accepted by mainstream peers, they may become involved with delinquent peers (Patterson, Reid, & Dishion, 1992). Youth who value the opinions of their deviant peers may engage in delinquent activities to gain respect and become part of the group. Additionally, youth without meaningful peer relationships are at increased risk of engaging in delinquent behavior (Department of Health and Human Services, 2001). In sum, involvement with antisocial peers and lack of social ties between the ages of 12 and 14 has been identified as a critical risk factor for illegal behavior between the ages of 15 and 25 (Lipsey & Derzon, 1998).

Unstructured time also is a risk factor for delinquency (Agnew, 2005), whereas participation in structured, after-school, and community activities can serve as a protective factor for youth (DeMatteo & Marczyk, 2005). There is some evidence that involvement with prosocial peers decreases the likelihood of antisocial activities (Hawkins et al., 2000). However, the findings are mixed, with other studies finding no relationship between prosocial peers and antisocial activities (DHHS, 2001). Regardless, youth engaged in sports and other extracurricular activities have less unsupervised time in the community to engage in delinquent behavior. Although community reentry programs would be the most appropriate venues for promoting positive peer relationships and structured activities in youths' communities, these criminogenic risk factors can be targeted in residential placement as well. While in placement, youth can be encouraged to participate in prosocial activities (e.g., art, music, carpentry,

basketball) to promote interest in engaging in these types of activities post-release.

### Substance Abuse

Substance abuse, but not substance use, has been identified as a significant predictor of juvenile recidivism (Cottle, Lee, & Heilbrun, 2001). Substance abuse is defined as the maladaptive use of a substance, as evidenced by significant and recurrent negative consequences (e.g., failure to fulfill obligations at home, work, school, or in interpersonal relationships). To meet diagnostic criteria, the substance must be used for a period of at least 12 months, with continued use despite negative consequences (American Psychiatric Association, 2000). One rigorous epidemiological study on the prevalence of mental health disorders in juvenile offenders estimated that 46% of offending youth may meet criteria for a substance abuse disorder (Teplin, Abram, McClelland, Dulcan, & Mericle, 2002; see Veysey, 2008, for a review of juvenile justice prevalence studies). Recent estimates suggest that only 50% of youth diagnosed with a substance use disorder receive any substance use treatment during their placement in a secure facility (Skowyra & Cocozza, 2007). Consequently, providing effective substance use treatment to the large proportion of juvenile offenders who qualify for substance abuse diagnoses could substantially reduce recidivism rates.

### Beliefs Supporting Crime/Low Empathy

Beliefs about the acceptability of crime and low empathy have also been identified as risk factors for delinquency (Agnew, 2005). Youth who believe that crime is acceptable tend to show antisocial thinking that is often characterized by rationalizations about crime and negative attitudes about the law (Andrews & Bonta, 2006). Youth may acquire these antisocial attitudes and beliefs from parents, friends, or other cultural influences. For some youth, antisocial and illegal activities may be "normal" and preferred because of social ties and the perceived benefits of such a lifestyle (e.g., the youth sees neighborhood drug dealers obtaining money and respect) (Guerra et al., 2008).

It is very difficult to compete with youths' deeply imbedded beliefs about the acceptability of criminal lifestyles. If youth are ambivalent or unwilling to change, common didactic processes of teaching youth about the effects of crime on both perpetrator and victim may backfire and cause youth to defend their own beliefs about crime (Miller & Rollnick, 2002). Because of this strong adherence to beliefs,

there has been a recent effort to introduce motivational interviewing (MI) principles into juvenile justice settings (Miller & Rollnick, 2002). Motivational interviewing theory characterizes this oppositional reaction as the normal response of a person whose personal choice is being challenged (Miller & Rollnick, 2002). If a person is ambivalent about choices A and B, and there is an external advocate for choice A (e.g., from a treatment provider), the person will naturally begin to think of the benefits of choice B. As such, well-intentioned directions from treatment providers may have the unintended effect of decreasing the likelihood of choice A. Motivational interviewing is an interactive process, not a specific treatment, and it can be used to engage youth in conversations about the acceptability of criminal behavior. It can also encourage youth to consider prosocial ideas and alternative behaviors without receiving pressure from treatment providers that can elicit defensiveness and solidify antisocial views.

## MULTIFACETED AND STRUCTURED PROGRAMMING

Given the need to target a variety of criminogenic needs, it is not surprising that programs utilizing a variety of techniques are more effective than those using only a single method (Antonowicz & Ross, 1994). Multimodal programs that target concrete behaviors and skills, such as employment and problem solving, are more effective in reducing delinquency than are those that rely solely on individual and family counseling (Lipsey, 1992, 1995). Structured programming that focuses on skills and cognitions is also associated with better outcomes (Guerra, Kim, & Boxer, 2008). Although programs relying on individual or group therapy alone have not been found to be effective, counseling can be an important component of an effective, multimodal program. For example, counseling can help youth benefit from skills-building activities, case management, or educational and vocational training (Lee & McGinnis-Haynes, 1978). Incorporating structured therapy into wilderness programs can turn a previously ineffective approach into an effective one (Greenwood, 2005; Wilson & Lipsey, 2000).

## COGNITIVE-BEHAVIORAL TREATMENT MODEL

Meta-analytic results have shown that effective programs for both juvenile and adult offenders are significantly more likely to have clearly specified theories of delinquency or crime than were non-effective programs (Antonowicz & Ross, 1994). Programs based on cognitive-behavioral models for

treatment were most effective in reducing recidivism (Antonowicz & Ross, 1994). Cognitive-behavioral therapy (CBT)-based programming appears to be equally effective in correctional settings and community settings, and the specific type of CBT treatment does not seem to change the effectiveness of treatment (Landenberger & Lipsey, 2005). Notably, juvenile delinquency intervention programs that included a cognitive component were more than twice as effective as other programs (Izzo & Ross, 1990).

Programs using cognitive-behavioral therapeutic approaches seem to be particularly effective for several reasons. First, once youth learn to alter cognitions, they can generalize this skill to many settings and situations; purely behavioral techniques, however, rely on contingencies that tend to be situation-specific (Kazdin, Bass, Siegel, & Thomas, 1989). For example, if a youth is taught cognitive restructuring as part of problem-solving training, the youth can use this skill when facing problems at school, conflicts at home, tensions with friends, or difficulties at work. In contrast, the reinforcements and punishments that motivate behavior vary across these situations and can be unpredictable even within each situation. Despite this limitation of behavioral treatment, contingencies can be powerful motivators for behavior (Kronenberger & Meyer, 2001), and can thus be important in conjunction with the cognitive approach. A second strength of CBT-based programs is that they are inherently multifaceted. Cognitive-behavioral therapy–based treatments often integrate various tools and techniques, such as cognitive restructuring, behavioral activation, exposure, behavior prevention, problem solving, and psychoeducation (Brown, O'Leary, & Barlow, 2001; Ledley, Marx, & Heimberg, 2005). These techniques, combined with CBT's active and problem-focused approach to treatment (Ledley, Marx, & Heimberg, 2005), make CBT-based programs suitable for use in juvenile justice facilities. Several of the components frequently found in CBT-based programs are empirically supported for use within the juvenile justice system.

### Changing Cognitions

Programs that include a cognitive component are more effective in reducing recidivism than are programs that do not attempt to alter thinking (Antonowicz & Ross, 1994). One key to changing juvenile delinquents' behavior seems to be changing their cognitions (Lipsey & Wilson, 1998), and programs that teach specific skills within the broader domain of cognitive change, such as social skills, anger control skills, or cognitive restructuring, seem to be more

effective at reducing recidivism (Dowden & Andrews, 2000; Landenberger & Lipsey, 2005).

### Responsivity to the Individual

Responsivity implies that interventions are tailored to the unique needs, strengths, abilities, and learning styles of the recipients (Dowden & Andrews, 2004). Responsive programs that match services to the needs of the offender and integrate various learning techniques are more likely to produce significant differences between treatment and control groups (Antonowicz & Ross, 1994). The "collaborative empiricism" approach of most CBT-based treatments is responsive to the needs of the individual youth; therapists and clients work together, in collaboration, to examine which thoughts and behaviors are helpful to the client, and which are not (Young, Weinberger, & Beck, 2001). By collaborating with the client, rather than imposing preformed rules or answers, the treatment provider is able to respond to the unique needs of the individual offender.

### Effective Techniques

Juvenile offenders have many unique characteristics and differ from the general population of youth in several important ways that can affect treatment. Compared to nonoffending youth, juvenile offenders have lower IQ scores (Redding & Arrigo, 2005), higher rates of educational disabilities (approximately 45% of juvenile offenders, see Eggleston, 2008), and higher rates of ADHD (up to 68% of girls and 76% of boys in detention are estimated to meet criteria for ADHD, see Veysey, 2008). With the high rates of these problems, juvenile offenders receiving treatment are likely to have difficulties maintaining attention, organizing their thoughts and activities, and acquiring information taught didactically (Kronenberger & Meyer, 2001). The CBT treatment techniques of cognitive rehearsal (mentally practicing a behavior before performing it), role-playing (acting out real-life situations within the session), and scheduling (planning times to try new activities and behaviors) (Young, Weinberger, & Beck, 2001) can be used to work effectively with youth who may have intellectual, educational, and attentional deficits. These techniques can be used to help youth acquire specific skills and actively participate in treatment. Active learning techniques reduce the didactic portions of treatment and turn therapy from a passive experience into one involving active engagement in treatment.

Modeling is another component of many successful CBT-based interventions (see Kendall, Aschenbrand,

& Hudson, 2003; Webster-Stratton & Reid, 2001). Effective programs for juvenile and adult offenders often use therapists and staff members to actively model the attitudes and behaviors taught in the program (Antonowicz & Ross, 1994; Dowden & Andrews, 2004). Through modeling, treatment providers can capitalize on the effects of social learning, demonstrating problem-solving skills, social skills, and prosocial attitudes for youth with limited exposure to these positive behaviors and conceptions of the world. Modeling is a common technique in CBT, with therapists often modeling desired activities and behaviors before asking youth to use new skills.

#### FAMILY INVOLVEMENT

Of the treatments that have been empirically examined with adjudicated youth, those involving families seem most often to be identified as effective (Guerra, Kim, & Boxer, 2008; Henggeler et al., 1998; Ryan & Yang, 2005; Washington State Institute for Public Policy, 2004). Whenever possible, it is particularly important to include families of younger offenders and those likely to return to the home environment when released from residential placement (Guerra, Kim, & Boxer, 2008). In one long-term residential facility, youth who received more on-site family visits, were permitted more home visits, or received in-home counseling were less likely to have reoffended 2 years after release (Ryan & Yang, 2005). It is possible that this improvement could have resulted from the interest, dedication, and superior functioning of families that were involved with their children while they were in placement. However, the consistent reduction in recidivism found in randomized controlled trials (RCTs) of interventions that specifically target family functioning (e.g., MST, FFT) suggest that inclusion of families in treatment, when feasible, may promote treatment success.

### Empirically Supported Treatment Implementation Characteristics

In addition to identifying important treatment components, meta-analyses suggest several implementation issues that can alter the effect of treatments on recidivism.

#### LENGTH OF STAY

The length of time juvenile offenders remain in treatment can increase the effectiveness of the treatment, with longer residential treatments associated with lower recidivism rates (Billick & Mack, 2004;

Lipsey, 1992). In one study, youth who remained in treatment more than 11 months were less likely to recidivate than were those who received treatment for shorter periods of time (McMackin, Tansi, & Lafratta, 2004). Notably, however, there may be a curvilinear relationship between the length of treatment and treatment outcome. In one meta-analysis, the effect size associated with institutional treatment increased with the amount of treatment to a certain point, but then declined (Lipsey, 1992). It seems that enough (but not too much) treatment is needed. Further research is needed to establish the length of treatment that allows maximum benefits without resulting in iatrogenic effects. Additionally, this "ideal" length of stay may vary depending on characteristics of the youth, such as age, level of familial support, and access to prosocial activities and peers in the communities of origin.

TREATMENT INTEGRITY

Researcher involvement with the treatment program was strongly associated with the effect size of treatment (Lipsey, 1995). Researcher involvement did not appear to result in positive outcomes because of researcher bias or wishful thinking; rather, researcher involvement seems to be an indicator of treatment integrity (Lipsey, 1995). Generally, treatments that are designed and implemented as part of a research study are carefully monitored for consistency and fidelity to the model program. Studies involving treatments with such careful control and extensive training and supervision of treatment providers tend to produce larger effect sizes.

This finding is promising in that it demonstrates that well-trained, well-supervised, closely monitored treatments can result in recidivism reductions. However, it also suggests the need for caution when adopting treatments for standard use in juvenile justice programs. For instance, when Washington State attempted to implement MST with less oversight from the central training agency, MST was not associated with reductions in recidivism (Washington State Institute for Public Policy, 2004).

Consequently, the challenge for juvenile justice programs is to maintain treatment fidelity and integrity when using treatments outside of the research context. Procedures should be established for providing adequate supervision and ongoing checking to ensure that treatment is implemented as intended. It has been observed that it is easier to develop a valid instrument than to use it appropriately and effectively (Sarri et al., 2001), and the same can be said for treatment protocols.

Effective treatment implementation requires buy-in from staff at every level within the juvenile justice program, but particularly from the line staff who will deliver the treatment (Young, 2004; Young, Moline, Farrell, & Bierie, 2006). Additional research on successful implementation is needed to develop effective procedures for implementing treatment protocols in residential settings in which staff may be resistant to changes in programming and reluctant to deliver the newest treatments sent to them by program administrators (Young, 2004). Outcome studies rarely specify the strategies, components, and implementation issues that may be pivotal to delivering the same treatment in other residential facilities. Such "process evaluations" (Young, 2004) can provide detailed information about the implementation of the treatment protocol to guide treatment use following dissemination for clinical purposes.

## Modifying Treatments Empirically Supported with Other Populations for Use Within Residential Juvenile Justice Facilities

Given the absence of empirically supported treatments for youth in residential juvenile justice placement, treatments that have been supported with other relevant populations (e.g., adult inmates, at-risk adolescents) can be modified for use with juvenile offenders in residential facilities. Full-scale assessment of needed revisions, through adaptation and randomized controlled outcome trials, would be ideal in developing and empirically evaluating treatments for this population. However, such a development and evaluation process requires substantial time and funding to identify needed changes, adapt activities, rewrite treatment manuals, create implementation protocols, and evaluate the resulting program. On a smaller scale, practitioners can make minor changes to empirically supported individual and group treatments to make them relevant for and accessible to adjudicated youth.

ACCESSIBILITY OF TREATMENT CONTENT

Given the high rates of ADHD (Veysey, 2008) and educational disabilities common among juvenile offenders (Eggleston, 2008), treatment content must be made accessible to delinquent youth. First, language and sentence structure may need to be simplified and made culturally relevant for participating youth. The amount of reading and writing involved in session and homework activities may need to be reduced or eliminated. Often, the treatment content can be maintained, but worksheets

may need to be modified to include checklists that require less writing, or worksheets may need to be eliminated entirely and replaced with verbal statements or pictorial cues. Second, to engage youth with difficulties sustaining attention, treatment providers may need to reduce didactic portions of treatment and encourage learning through more interactive, hands-on activities that promote sustained attention. Allowing youth to have some control over what occurs in treatment (e.g., choosing a skill to practice or a situation to role-play) may also help to maintain attention and engage youth in treatment.

### FOCUS ON SPECIFIC SKILLS

As suggested by meta-analytic findings on effective programs, treatments should focus on specific skills, such as problem-solving or anger coping. Treatments should be modified to allow ample time to learn, practice, and apply the concrete, practical skills (e.g., problem-solving steps, anger control techniques) taught in treatment. Role-plays and homework assignments may be particularly useful for engaging youth in practicing new skills.

### BUILD IN PRAISE

Positive attention is a powerful reinforcement tool that is used in many empirically supported programs for children (see Weisz, 2004). Interest and attention from treatment providers may help to establish rapport and engage youth in treatment. Simple statements such as "Thanks for participating, John" and "Excellent example, Susan," should make youth more likely to repeat the desired behaviors. Such positive feedback can help provide the external motivation many youth with attentional difficulties require to remain engaged in activities (Anastopoulos & Barkley, 1990) or to complete homework assignments. To ensure that attention and praise are given, treatments for youth should include directions for treatment leaders to reward participation and desired behaviors.

### PREPARE FOR OPPOSITIONALITY

Juveniles in residential care have generally been separated from their home environments involuntarily. This unwanted separation and restriction of freedom, combined with the developmentally appropriate process of developing independence during adolescence (Bolton Oetzel & Scherer, 2003), can yield resistance to ideas and activities suggested by treatment providers. Preparing for such opposition can help providers roll with resistance and engage

youth in treatment. First, it may be helpful for providers to simply be aware that this opposition may occur, so as not to be surprised in treatment. Adolescents in general, and especially those with histories of abuse and neglect, may require time to develop trusting, therapeutic relationships with adults and may test boundaries through their behavior (Pearce & Pezzot-Pearce, 2007). Treatment providers must be prepared for the defensive behaviors youth may exhibit, and respond with consistent empathy and availability (Bolton Oetzel & Scherer, 2003). In responding to oppositional behaviors, the therapist can respect the feelings expressed by the youth, while continuing to require a certain amount of participation (Pearce & Pezzot-Pearce, 2007). For example, if a youth in treatment refuses to roleplay a scene involving his mother, the therapist can respond by acknowledging the youth's discomfort with and dislike of the activity, but ask him to give it a try, perhaps using a less sensitive topic such as an interaction with a teacher. The same tactic could work to prevent unsafe behaviors (e.g., throwing items, climbing on furniture) within treatment (Pearce & Pezzot-Pearce, 2007). That is, the treatment provider can acknowledge the feelings expressed by the youth (e.g., anger, frustration, sadness) but firmly maintain that the behavior is not allowable.

Allowing youth as much freedom and choice as possible while maintaining treatment integrity can prevent some opposition (Bolton Oetzel & Scherer, 2003). During treatment sessions, youth can choose the order to practice skills and the situations to use as examples for skills' practice. For example, in a group session reviewing anger-coping skills, each participant can choose which of the skills reviewed she most wants to practice. As group members roleplay the various skills, she can describe a scenario in which the skill could be useful. Even small choices, such as the color of folder to use for homework assignments, may help youth become engaged in treatment. Juvenile justice facilities typically have strict rules that allow little room for individual choice; providing youth with some control over treatment-related decisions may reduce oppositionality and increase willingness to engage in treatment.

### MODIFY ACTIVITIES TO BE DEVELOPMENTALLY APPROPRIATE

Given the low IQs (Redding & Arrigo, 2005), academic difficulties (Eggleston, 2008), poor attentional abilities (Veysey, 2008), and immature social development (Bolton Oetzel & Scherer, 2003) of many juvenile offenders, some treatments designed for younger

children may be cognitively appropriate for use with juvenile offenders. However, activities may need to be modified to make them developmentally appropriate to the interests of adolescents. For instance, activities using puppets to practice skills can be replaced with role-plays, and cartoon clips can be replaced with popular movie scenes as stimuli for discussion. Also, discussion topics may need to be altered, as adolescents may be more interested in talking about romantic relationships or problems with friends than about household chores or relationships with teachers.

### ADD TOPICS RELEVANT TO THE POPULATION

Youth in the juvenile justice system show high rates of substance abuse (Teplin, Abram, McClelland, Dulcan, & Mericle, 2002), and most have experienced traumatic events (Veysey, 2008). These issues often arise in treatment and should be handled responsibly. Treatment providers should be aware of common symptoms of trauma, including physiological responses, intrusive images, and behavioral constriction (Veysey, 2008). Youth should never be forced to disclose traumatic experiences, and treatment should focus on specific problems while building on the strengths of the individual (Veysey, 2008). When adapting any treatment for use in juvenile justice facilities, treatment providers should consider how traumatic experiences may affect youths' participation in treatment. Because of the prevalence rates observed in juvenile offenders, explicit discussions of other topics, such as substance use and abuse, may need to be added to existing treatment programs. Additional topics may be needed, depending on the specific treatment audience. For example, it may be important to address relational aggression and sexual abuse with female juvenile offenders (Sondheimer, 2001). The lack of familial support and home stability may be important to address in treatments for youth in foster care.

### MODIFY TREATMENT FOR CONFINES OF THE SETTING

Treatment providers may need to creatively adapt both the treatment structure and their implementation protocols for successful use in juvenile justice facilities.

*Modifying Treatments*
Certain components of treatment may need to be modified for use within the confines of a juvenile justice facility. Videotaping sessions, either for therapist supervision, for later review by the treatment participant, or for research purposes, may not be allowed because of confidentiality policies in residential juvenile justice settings. Instead, treatment providers may be able to audio-record sessions, or they may need to transcribe key information. Homework activities that would normally be completed with participation from parents or teachers can be modified to allow line-staff to assist youth. If staff participation is required, obtaining buy-in and participation from staff members is an important first step to implementing the treatment program.

Exposure-related activities present a unique challenge to implementing treatment in juvenile justice facilities. When treatment takes place in outpatient clinics, providers can arrange relevant practice situations or wait for such situations to arise. For instance, in anxiety treatments, therapists often take clients into the community to confront feared situations, such as standing atop a tall building or interacting with a waiter when ordering in a restaurant (Kendall, Aschenbrand, & Hudson, 2003). Treatment providers in juvenile justice facilities are more restricted, but they can create exposure activities for youth with the help of other program staff. When providing treatment within a residential setting, providers must also modify treatment to address both problems faced by youth within the facility (e.g., problems with facility peers and staff) and those they expect to confront upon return to the community (e.g., problems at home and school).

*Modifying Treatment Implementation*
Residential juvenile justice settings may have limited resources and space for treatment providers. With some creative planning, however, most treatment components can be successfully implemented. If a television/DVD is not available for showing movie clips, a laptop computer may be usable; if computers are not allowed, magazine pictures illustrating the key points can be shown to participants. Procedures common in outpatient therapy (e.g., carrying a paper and pencil for tracking homework assignments) must be carefully considered to ensure that youth are able to complete between-session assignments. Special access (e.g., permission to carry paper and a pencil) or procedures (e.g., having youth complete assignments with a staff member present) may need to be established, especially in facilities with strict security requirements. With careful consideration, between-session practice activities can still occur, and youth can benefit from the rehearsal of desired behaviors.

### Conclusions

Contrary to earlier ideas that "nothing works" with juvenile offenders, research suggests that careful treatment can reduce recidivism. Treatment programs based in cognitive-behavioral theory that target criminogenic needs and specific skills within a structured setting can reduce youths' risk of future offending. Further research is needed on how to best treat criminogenic needs and effectively implement treatment protocols while maintaining treatment integrity. Until more programs are empirically supported for use within the juvenile justice system, treatment providers can carefully modify treatments designed for other settings to meet identified criminogenic needs of youth within juvenile justice facilities.

## Defendants in Drug Courts or Mental Health Courts

Over the past 25 years, the number of drug-involved offenders entering the criminal justice system has increased dramatically. The "War on Drugs," which began in the 1970s and gained considerable momentum in the 1980s, contributed to an unprecedented expansion in the U.S. inmate population. Jail and prison admissions more than tripled in the ensuing years (Harrison & Karberg, 2003), with drug violations accounting for roughly 60% of the increase in the federal inmate population and over 30% of the increase in the state inmate population (Belenko & Peugh, 1998; Harrison & Beck, 2002). A review of recent data from the Bureau of Justice Statistics is informative. In 2004, an estimated 330,000 individuals were incarcerated for drug law violations, with drug offenders comprising 55% of federal prison inmates and roughly 20% of state prison inmates in the United States (Mumola & Karberg, 2006). Further, 17% of state inmates and 18% of federal inmates reported committing their crimes to obtain money for drugs (Mumola & Karberg, 2006). In 2004, 56% of state inmates and 50% of federal inmates reported using drugs in the 1 month prior to their offense, and 32% of state inmates and 26% of federal inmates reported being under the influence of drugs at the time of their offense (Mumola & Karberg, 2006). Finally, one in four violent offenders incarcerated as of 2004 reported committing their offenses while under the influence of drugs (Mumola & Karberg, 2006).

Given the documented relationship between drug use and criminal behavior, developing and implementing appropriate interventions for drug-involved criminal offenders has been a priority of the criminal justice system for decades. Historically, drug policy in the United States has vacillated between two competing approaches when dealing with drug-involved criminal offenders (Marlowe, 2002). On the one hand, drug use can be conceptualized as a *public safety* concern that requires a punitive correctional response. According to this view, drug use is illegal behavior, and illegal behavior should be met with a punitive response. Interventions consistent with this approach include imprisonment, in-prison rehabilitation programs, civil commitment, and community-based intermediate sanctions (e.g., electronic monitoring, house arrest, boot camps). On the other hand, drug use can be conceptualized as a *public health* concern that requires a treatment-oriented response. According to this view, drug addiction is a disease and, as such, the appropriate societal response is the provision of clinically appropriate treatment.

Unfortunately, neither the public safety approach nor the public health approach has resulted in meaningful reductions in drug use and criminal recidivism. Imprisonment, which is the mainstay of the public safety approach, has achieved little success. Roughly 50% of incarcerated drug-involved criminal offenders recidivate within 18 months of release from prison, and roughly 70% recidivate within 3 years of release (see Martin, Butzin, Saum, & Inciardi, 1999). The data concerning relapse to drug use are similarly disappointing. In some studies, approximately 85% of drug-abusing offenders returned to drug use within 1 year of being released from prison, and 95% returned to drug use within 3 years of being released from prison (e.g., Martin et al., 1999).

One could argue that imprisonment, by itself, should not be expected to necessarily lead to reductions in recidivism and drug use. As such, it may be informative to examine the effects of in-prison treatment programs specifically designed to reduce recidivism and drug use. Unfortunately, this approach has not fared much better. Most research suggests that in-prison rehabilitation programs are associated with small reductions in criminal recidivism and little to no reductions in relapse to drug use (see Marlowe, 2002, for a review of this research). A review of hundreds of studies of in-prison treatment programs found that these programs reduce criminal recidivism by, on average, 10 percentage points, from 55% for untreated offenders to 45% for treated offenders (Gendreau, Smith, & Goggin, 2001). Correctional treatment programs targeted specifically at drug-involved offenders have not produced encouraging results. For example, a large meta-analysis of over

1,600 program evaluations conducted between 1968 and 1996 found that group counseling interventions and boot camps had no appreciable effect on rearrest rates among drug offenders (Pearson & Lipton, 1999).

The limited success of the public safety approach led to a push for more treatment-oriented responses. Unfortunately, the public health approach has also failed to achieve meaningful results. Roughly one-half to two-thirds of individuals who schedule an intake appointment for drug use treatment fail to attend the intake session (Festinger, Lamb, Marlowe, & Kirby, 2002). For those who do show up for the intake session, research suggests that few will receive a sufficient dose of treatment. Between 40% and 80% of drug users drop out of treatment within 3 months (Stark, 1992), and 80%–90% drop out of treatment within 1 year (Satel, 1999). Research suggests that 3 months of treatment is the minimum threshold for observing dose-response effects, and 12 months may be necessary to observe clinically meaningful reductions in drug use, particularly for those with more severe drug use problems (see, e.g., Simpson, Joe, & Brown, 1997). Given that up to 90% of drug offenders drop out of treatment in less than 12 months, very few offenders are receiving an adequate dose of treatment. Moreover, even for those offenders who remain in treatment for at least 12 months, roughly 50% relapse to drug use within 1 year following termination of treatment (McLellan, Lewis, O'Brien, & Kleber, 2000).

### Defendants in Drug Courts

Fortunately, a new approach for dealing with drug-involved offenders has achieved considerably more success. This approach is part of a new breed of interventions known as problem-solving courts, which combine elements of the public safety and public health approaches. Rather than simply punishing offenders, which contributes to an ongoing cycle of arrest, incarceration, release, and rearrest, these special jurisdiction courts emphasize dispositions such as drug treatment, mental health treatment, the provision of social services, and ongoing judicial monitoring of offenders' progress. Moreover, many problem-solving courts provide for the dismissal of criminal charges and expungement of the offender's arrest record upon successful completion of the treatment program, which allows offenders to have a fresh start without the stigma of an arrest record. The theory underlying problem-solving courts is that recidivism can be reduced if the problems presumed to underlie criminal behavior, such as

drug abuse and mental illness, are treated with a range of services under the watchful eye of a court.

The modern era of problem-solving courts began in the late 1980s, with the development of drug courts. Drug courts were created in response to the overwhelming numbers of drug-related cases that were inundating the court system due to the War on Drugs. The first drug court was opened in Dade County, Florida, in 1989, under the guidance of then-State Attorney Janet Reno. As of year-end 2007, there were 2,147 drug courts operating in the United States (National Association of Drug Court Professionals, 2008), with many more in advanced planning stages. In addition to having drug courts in all 50 states, the drug court model is being used in three U.S. territories and eight countries (Huddleston, Freeman-Wilson, Marlowe, & Roussell, 2005).

Drug courts are separate criminal court dockets that provide judicially supervised drug abuse treatment and case management services to nonviolent drug-involved offenders in lieu of prosecution or incarceration. Participation in a drug court is voluntary, and eligibility is typically determined by the local prosecutor based on an offender's current charges, criminal history, and drug problem severity. The key components of drug courts include ongoing status hearings in court before a designated drug court judge, mandatory completion of drug abuse treatment, random weekly urine drug screens, and escalating sanctions and rewards for program infractions and accomplishments (National Association of Drug Court Professionals, 1997). Drugs courts come in two main varieties. In pre-plea drug courts, offenders who complete the program have their charges dropped and may be eligible for expungement of their current arrest record, which permits them to respond truthfully on an employment application or similar document that they have not been arrested for a drug-related offense. In post-plea drug courts, graduates may avoid incarceration, reduce their probationary obligations, or receive a sentence of "time served."

Drug courts are primarily intended to reduce drug use (which is believed to lead to criminal recidivism), and they typically employ a multiphased treatment model consisting of stabilization, intensive treatment, and transition. Commonly employed strategies to reduce drug use include group counseling, individual and family counseling, and 12-step self-help groups (National Association of Drug Court Professionals, 1997). Although the primary focus of drug courts is reducing drug use, drug courts often provide comprehensive services, including educational

and vocational training, CBT to address criminal thinking patterns, anger management, social services, and treatment for clients with co-occurring mental health disorders (National Association of Drug Court Professionals, 1997). Treatment is typically supplemented with case management services to assess the client's needs and progress.

Drug courts have served as the model for several other problem-solving courts, including mental health courts (for criminal offenders who have mental health needs), family dependency treatment courts (for child abuse, neglect, and dependency cases in which parental drug abuse is a key factor), community courts (for offenders charged with low-level "quality-of-life" offenses), domestic violence courts (for offenders charged with spousal abuse), and DWI courts (for alcohol-dependent or drug-dependent offenders charged with driving while impaired offenses). These problems-solving courts are firmly grounded in established principles of "therapeutic jurisprudence," which emphasize the law's ability to promote psychological well-being for those individuals who are subject to legal proceedings (see Wexler & Winick, 1996).

### RESEARCH FINDINGS ON DRUG COURTS

Over the past 15 years, researchers have conducted a large number of studies on drug courts. Overall, the findings are encouraging. Research has reliably demonstrated that drug courts outperform virtually all other strategies that have been used with drug-involved criminal offenders (Marlowe, DeMatteo, & Festinger, 2003). Drug courts appear to be quite successful in reducing drug use and criminal recidivism (e.g., Belenko, 1998, 1999, 2001, 2002; Belenko, DeMatteo, & Patapis, 2007; Government Accountability Office [GAO], 2005).

Given the recent proliferation of drug courts, it is important that researchers, clinicians, administrators, and policy makers have a clear understanding of whether these courts are effective and, if so, how they achieve their results. In this section, we will summarize the existing research on drug courts. Given the large body of existing research on drug courts, it is not possible to review each study. Therefore, we will focus primarily on quantitative, large-scale studies that address either or both of the two major outcomes of drug courts (reductions in criminal recidivism and reductions in relapse to drug use). By reviewing the existing research in these important areas, we hope to clearly define areas in which more research is needed.

Several researchers have conducted comprehensive reviews of the effectiveness of drug courts in reducing criminal recidivism and relapse. In reviews of nearly 100 drug court evaluations, Belenko (1998, 1999, 2001) concluded that roughly 60% of drug court clients attended at least 1 year of treatment, and approximately 50% graduated from the drug court program. These figures represent a substantial improvement in treatment retention over most probationary programs, in which fewer than 10% of clients attend 1 year of treatment (e.g., Goldkamp, 2000; Satel, 1999). Belenko (1999, 2001) also reported favorable statistics for drug courts in terms of decreased recidivism and drug use while clients are enrolled in drug court programs. According to Belenko (1999, 2001), most program evaluations that reported data on drug test results noted that the percentage of positive urine screens was less than 10%, which is lower than the typical percentage of positive urine screens among probationers. Moreover, Belenko (1999, 2001) reported that drug court clients have significantly lower rates of criminal recidivism during the program compared to similar offender populations under other types of community supervision.

In the majority of evaluation studies that have included a suitable comparison condition, drug court clients achieved significantly greater reductions in drug use and criminal recidivism compared to individuals on standard probation or intensive supervised probation (see Belenko, 1999, 2001; Marlowe, DeMatteo, et al., 2003). The magnitudes of the during-treatment effects were typically in the range of 20–30 percentage points, and the magnitudes of the post-treatment effects were typically in the range of 10 to 20 percentage points. Although these figures are not ideal, they are about two to three times greater than what is commonly obtained from prison, intermediate sanctions, probation, or community-based drug treatment programs.

Two RCTs also support the effectiveness of drug courts compared to standard criminal justice approaches. In a study of the Maricopa County (Arizona) Drug Court, drug court clients exhibited roughly a 15 percentage-point reduction in rearrest rates at 3 years post-discharge, with 33% of drug court clients rearrested within that time period compared to 47% of drug-abusing offenders in various probationary conditions (Turner, Greenwood, Fain, & Deschenes, 1999). An RCT in the Baltimore City Drug Court found that 48% of drug court clients, versus 64% of traditionally adjudicated control

clients, were rearrested within 1 year of admission (Gottfredson & Exum, 2002). The proportions of rearrested offenders were roughly the same within 2 years of admission (Gottfredson, Najaka, & Kearley, 2003).

The U.S. Government Accountability Office (GAO, 2005) recently completed a systematic review of 117 evaluations of adult drug courts published between May 1997 and January 2004 that reported criminal recidivism, substance use relapse, or program completion outcomes. Of the 117 studies, the GAO selected 27 evaluations of 39 drug courts that met its criteria for methodological soundness. Program completion rates varied considerably by program, from a low of 27% to a high of 66%. The GAO report focused heavily on the effectiveness of drug courts in reducing criminal recidivism and relapse to drug use. The GAO concluded that drug courts reduce during-treatment criminal recidivism to a greater degree than commonly used criminal justice alternatives, such as probation. The GAO also concluded that drug courts reduce post-program criminal recidivism (measured up to 1 year post completion), particularly for offenders who completed the drug court program. However, the GAO found mixed evidence supporting the effectiveness of drug courts in terms of reducing substance use relapse.

A recent meta-analysis by Wilson, Mitchell, and Mackenzie (2006) of 50 studies representing 55 drug court program evaluations is also informative. They included both published and unpublished studies that used experimental or quasi-experimental designs. The inclusion criteria specified that the studies had to use a comparison-group design and measure criminal activity. The meta-analysis revealed that the majority of studies found reductions in reoffending among drug court participants relative to participants in comparison groups. Of note, Wilson et al. (2006) found that the reduction in offending was 26% across all studies (and 14% in two high-quality RCTs). Interestingly, significantly larger effects were observed in the drug court programs that use either a pre-plea or post-plea model as opposed to a mixed/ad hoc approach (which lacks clear incentives for participation). There was also a (nonsignificant) trend in favor of drug courts that use a single treatment provider.

Wilson et al. (2006) concluded that the meta-analysis findings "tentatively suggest that drug offenders participating in a drug court are less likely to reoffend than similar offenders sentenced to traditional correctional options, such as probation" (p. 479). They labeled their conclusion as "equivocal" in light of the "weak" methodologies used in many of the studies (Wilson et al., 2006, p. 479). Of note, only five of the 55 studies included in the meta-analysis used an experimental design involving random assignment (and two of those studies had attrition rates of greater than 40%), whereas the remaining studies used quasi-experimental designs that suffered from serious methodological limitations. Nevertheless, Wilson et al. (2006) were optimistic because the experimental and higher-quality quasi-experimental studies provided evidence that drug courts produce desired outcomes beyond standard criminal justice system approaches.

## Defendants in Mental Health Courts
### Background
Recent statistics indicate that approximately half of all U.S. jail and prison inmates are suffering from a mental health problem (James & Glaze, 2006). According to the Bureau of Justice Statistics, at midyear 2005, 56% of state prison inmates, 45% of federal prison inmates, and 64% of jail inmates had identifiable mental health disorders, defined as a recent (within the previous 12 months) history of mental health symptoms (James & Glaze, 2006). The growing number of criminal offenders with mental health disorders has resulted in a revolving door characterized by arrest, incarceration, release, and rearrest (Steadman, Cocozza, & Veysey, 1999; Trupin & Richards, 2003). This disturbing cycle highlighted the lack of adequate treatment for offenders with mental health needs within the criminal justice system.

### Mental Health Courts
Mental health courts emerged in the late 1990s to address the increasing numbers of mentally ill offenders who are entering the criminal justice system. Mental health courts function as a convenient point-of-entry through which criminal offenders with mental health problems can gain access to community-based mental health treatment services. The underlying belief is that treating an offender's mental health problems may be an effective way to improve clinical functioning and reduce criminal recidivism. Mental health courts borrowed their underling philosophy—therapeutic jurisprudence—from their successful predecessors, drug courts (Odegaard, 2007; Rottman & Casey, 1999; Wexler, 2001). Mental health courts follow the principle of

therapeutic jurisprudence by providing comprehensive and judicially supervised behavioral health treatment services to criminal offenders with mental health disorders.

The first mental health court in the United States was established in 1997 in Broward County, Florida, and many other jurisdictions have developed mental health courts since that time. A recent government report indicates that there are more than 150 mental health courts in the United States, with many more in the advanced planning stages (Thompson, Osher, & Tomasini-Joshi, 2007; see also Erickson, Campbell, & Lamberti, 2006). Mental health courts handle both misdemeanor and felony offenders (depending on the jurisdiction) (Redlich, Steadman, Monahan, Petrila, & Griffin, 2005), and several juvenile mental health courts have been developed in recent years (Cocozza & Shufelt, 2006; Thompson et al., 2007). The mental health court model has been adopted by several other countries, including Canada, Australia, and the United Kingdom.

Mental health courts differ considerably by jurisdiction, but they share one goal. Broadly stated, the purpose of mental health courts is to divert criminal offenders with mental health needs away from traditional criminal justice processing and into judicially supervised, community-based mental health treatment (Boothroyd, Poythress, McGaha, & Petrila, 2003). Clients in mental health courts receive mental health treatment typically delivered by community-based treatment providers, often consisting of individual and group counseling, the provision of psychotropic medications, and intensive case management. Mental health courts also offer many of the same services as drug courts, including drug treatment, social services, and case management. Importantly, the client's progress in treatment is monitored by the presiding mental health court judge, and a series of escalating sanctions and rewards are used to punish clients for program infractions and accomplishments.

Despite similarities, describing a prototypical mental health court is not easy because they exhibit greater variability than do drug courts (Bernstein & Seltzer, 2003; Erickson et al., 2006; Redlich, Steadman, Monahan, Robbins, & Petrila, 2006). For example, although some courts require offenders to meet criteria for a specific mental health diagnosis prior to entry, other courts simply confirm a previous diagnosis (Erickson et al., 2006). Some courts require clients to attend status hearings several times per week, whereas others require less frequent hearings. The sanctions used for noncompliance with program requirements also differ (Griffin, Steadman, & Petrila, 2002), with some courts ratcheting up treatment requirements and other courts using brief incarceration or termination from the program (Erickson et al., 2006). Finally, after successfully completing the program, some courts dismiss the criminal charges, whereas other courts place the offenders on probation or impose a suspended sentence (Erickson et al., 2006; Griffin et al., 2002).

Despite variations in operation and structure, the majority of mental health courts share overlapping features. Some of more common features of mental health courts include: (a) a specialized court docket that employs a problem-solving approach for certain offenders with mental health needs, in lieu of more traditional criminal justice processing; (b) the provision of judicially supervised, community-based mental health treatment; (c) regularly scheduled judicial status hearings, during which each offender's progress in the program is evaluated, incentives are provided to reward adherence to program requirements, and sanctions are imposed to punish program infractions; and (d) the articulation of specific criteria indicating when a participant has successfully completed the program (Thompson et al., 2007). Moreover, research suggests that mental health courts are established for the same reasons as drug courts, which typically include a desire to increase public safety, facilitate the provision of mental health treatment to offenders with mental health needs, improve the quality of life for offenders with mental health needs, and make more efficient use of criminal justice and mental health treatment resources (Thompson et al., 2007).

Mental health courts follow one of three operational models. In the preadjudication model, the prosecution of the offender is deferred and, in exchange, the offender agrees to participate in a treatment program. In the post-plea model, the disposition of the offender's case is deferred while the offender participates in the treatment program. Finally, in the probation model, the offender is convicted and sentenced to probation, and participating in the treatment program is imposed by the court as a condition of the probation.

### Research Findings on Mental Health Courts

The research literature on mental health courts has grown in recent years, but it still lags well behind the large and well-developed body of literature regarding drug courts. Moreover, most of the literature regarding mental health courts consists of either basic descriptive studies, process evaluations, or

nonempirical policy/theoretical papers. As such, we know considerably less about the operations and effectiveness of mental health courts. Moreover, differences among mental health courts make it difficult for researchers to examine the effectiveness of these interventions in an empirically defensible manner (see Wolff & Pogorzelski, 2005).

In this section, we will summarize the existing research on mental health courts by focusing on quantitative studies that address either or both of the two major outcomes of mental health courts: reductions in clinical symptoms (including increased access to and utilization of treatment services) and reductions in criminal recidivism. As with the review of the drug court literature, we hope that this review will highlight areas in which more research is needed.

Given the goals of mental health courts, an initial question is whether mental health courts increase the provision of behavioral health services and lead to meaningful clinical improvement. An early study by Boothroyd et al. (2003) compared 121 mental health court clients and 101 criminal court clients to determine whether the mental health court impacted offenders' access to behavioral health services. The results revealed that the percentage of mental health court clients who received behavioral health services increased significantly, from 36% during the 8 months prior to their initial court appearance to 53% during the 8 months after their initial court appearance. For the offenders in criminal court, the likelihood of receiving behavioral health services remained virtually unchanged during the same time periods (29% vs. 28%). More recent research by Herinckx, Swart, Ama, Dolezal, and King (2005) examined linkage to community mental health services among 368 misdemeanor offenders in the Clark County Mental Health Court. Results revealed that mental health court clients received more hours of case management and medication management services, and more days of outpatient service, in the 1 year following enrollment in the court. Mental health court clients also received fewer hours of crisis services and fewer days on inpatient treatment in the 1 year following enrollment.

Despite some research suggesting that mental health court clients have greater access to behavioral health services than do their counterparts in traditional criminal courts, few researchers have examined whether such treatment leads to clinical improvement. One study to address this issue involved the random assignment of 235 offenders to either a mental health court or criminal court (Cosden,

Ellens, Schnell, Yamini-Diouf, & Wolfe, 2003). All participants showed improvements in life satisfaction, psychological distress, and independent functioning, but mental health court clients showed greater gains in developing independent living skills and reducing their drug use. More recent research (Boothroyd, Mercado, Poythress, Christy, & Petrila, 2005) examined clinical improvement among 97 mental health court clients and 77 offenders in criminal court. All participants were assessed at 1, 4, and 8 months after their initial court appearances using the Brief Psychiatric Rating Scale. Results revealed no significant main effects for type of court or receipt of treatment, and no significant interaction effect between type of court and receipt of treatment. Overall, there were no significant changes in participants' clinical condition related to the receipt of treatment services or participation in mental health court. These counterintuitive results led Boothroyd et al. (2005) to hypothesize that the failure to observe meaningful clinical improvement was due to the absence of court control over the type and quality of treatment services provided to participants.

As previously noted, the primary goal of mental health courts is to reduce criminal recidivism by treating mental health disorders related to criminal behavior. Several researchers have examined whether mental health courts achieve this goal. Although one study (Trupin and Richards, 2003) found that mental health court clients had fewer arrests postdischarge (over 9 months) compared to criminal court clients, subsequent research (Christy, Poythress, Boothroyd, Petrila, & Mehra, 2005) cast doubt on this finding. The latter investigators used a within-group and between-group design to compare recidivism rates for mental health court clients and comparable defendants who did not participate in mental health court. Although they found that the number of arrests for mental health court clients significantly decreased from 1-year pre to 1-year post entry into the court, they also found that the mean number of rearrests, felony arrests, proportion rearrested, and survival time to rearrest were not significantly different from those defendants who did not participate in the mental health court.

One group of researchers used an experimental design to examine the effectiveness of mental health courts in reducing criminal recidivism. Cosden et al. (2003, 2005) randomly assigned 235 offenders to a mental health court in Santa Barbara, California, with assertive community treatment ($n = 137$) or to a traditional criminal court that offered less

intensive case management services (*n* = 98). One-year post entry, mental health court participants had significantly fewer convictions for new offenses, and the charges of the mental health court participants were typically related to probation violations rather than to the commission of a new criminal offense (Cosden et al., 2003). Despite these positive findings, the outcomes at 2 years were less impressive. Participants in both groups increased arrests, and no change occurred in either the number of convictions or number of days in jail (Cosden et al., 2005).

In another study (Herinckx et al., 2005), investigators examined rearrest rates for 368 misdemeanor offenders participating in the Clark County Mental Health Court from April 2000 through April 2003. They compared rearrest rates in the 1 year preceding their enrollment in the court to rearrest rates in the 1 year following enrollment in the court. The results revealed significant reductions in arrests post-enrollment, with the mean number of arrests being significantly reduced from 1.99 pre-enrollment to .48 post-enrollment. Moreover, the overall crime rate was reduced by a factor of 4.0 at 1-year post-enrollment. Further, 54% of the clients had no arrests in the 1 year following enrollment, and probation violations were reduced by 62%. According to Herinckx et al. (2005), the most significant factor in determining the success of the mental health court clients was whether they graduated from the program. Graduates of the mental health court program were 3.7 times less likely to reoffend compared to nongraduates.

In more recent research, Moore and Hiday (2006) compared 82 offenders in a mental health court with 183 similar offenders processed in criminal court in the same county before the mental health court was established. Outcome variables examined included new arrests and offense severity from 1 year pre-entry to 1 year post-entry. The results of the between-group analyses revealed that the mental health court clients had significantly fewer new arrests and less severe criminal offenses during the 1-year follow-up period. Specifically, mental health court clients had a rearrest rate that was roughly one-fourth the rearrest rate of the offenders processed through the traditional criminal court. Interestingly, however, the rearrest rates for participants who did not complete the mental health court program did not significantly differ from the rearrest rates for participants who went through traditional criminal court.

Other research has also found mental health courts to effectively reduce recidivism. In a recent study, McNiel and Binder (2007) used a retrospective observational design to compare the occurrence of new criminal charges for 170 mental health court clients and 8,067 individuals with mental health disorders who were booked into an urban county jail after arrest during the same time period. Results revealed that participation in the mental health court was associated with longer time without any new criminal charges or new charges for violent crimes. As with the Moore and Hiday (2006) study, graduating from the mental health court was found to be an important correlate of reduced criminal recidivism. McNiel and Binder (2007) found that successful completion of the mental health court was associated with maintenance of reductions in criminal recidivism after the graduates were no longer under the supervision of the court.

### Summary of the Research on Drug Courts and Mental Health Courts

A large body of research supports the effectiveness of drug courts in terms of reducing both criminal recidivism and relapse to drug use rates. The results of several large-scale studies and systematic reviews suggest that participating in drug courts is associated with reductions in recidivism and drug use both during treatment and post-treatment. Moreover, other research suggests that drug courts are associated with significant cost savings (e.g., Belenko, Patapis, & French, 2005; Bhati, Roman, & Chalfin, 2008). Although more research is needed (as discussed later in this chapter), there is good reason to be optimistic about drug courts.

The picture is less clear when it comes to mental health courts. Although some research suggests that mental health courts increase access to behavioral health services, the research is mixed in terms of whether treatment leads to measurable reductions in clinical symptoms. The picture is also mixed with respect to reductions in recidivism. Although some research supports the belief that mental health courts reduce recidivism, other research has found few differences in recidivism rates between offenders in mental health courts and offenders in traditional criminal courts. On the whole, however, there is reason to be cautiously optimistic about the effects of mental health courts (see Herman, 2005; Kuehn, 2007). The weight of the evidence appears to suggest that mental health courts can lead to increased provision of behavioral health treatment services, improvements in clinical functioning, and reductions in criminal recidivism. As such, mental health courts appear to be fulfilling their basic objectives.

### Future Directions

Despite the large body of research supporting the effectiveness of drug courts, several important questions remain unanswered. Only a handful of studies have examined the impact of drug courts on post-program drug use and recidivism (Belenko, 2001; GAO, 2005; Harrell, Cavanagh, & Roman, 1999; Marlowe, Festinger, Dugosh, & Lee, 2005; Turner et al., 1999), and the limited results raise questions about the long-term effects of drug courts. For example, Marlowe et al. (2005) found that 10%–15% of drug court clients engaged in criminal behavior within 12 months of admission to drug court, and over 50% resumed drug use within that time period. Conducting studies with longer follow-up periods would enable us to draw more defensible conclusions regarding the long-term effects of drug courts.

Although we know that drug courts are effective, we know less about *how* they work. As such, more research is needed regarding the key components of drug courts. The essential elements of drug courts were described by the National Association of Drug Court Professionals in 1997, and several researchers have systematically examined some of these elements in an effort to get inside the "black box" of drug courts. For example, Marlowe and colleagues at the Treatment Research Institute at the University of Pennsylvania are conducting a program of experimental dismantling research examining the key components of drug courts, including the dosage of judicial status hearings and the administration of sanctions and rewards (Festinger, Marlowe, Lee, Kirby, Bovasso, & McLellan, 2002; Marlowe, Festinger, Dugosh, Lee, & Benasutti, 2007; Marlowe, Festinger, & Lee, 2003, 2004; Marlowe, Festinger, Lee, Dugosh, & Benasutti, 2006). Research regarding the appropriateness of the drug court intervention for all client types (e.g., low- vs. high-risk) would also be informative (DeMatteo, Marlowe, & Festinger, 2006).

The key limitation in drawing conclusions about mental health courts is the relatively small body of existing research. In contrast to drug courts, there is much less research on mental health courts, and most of the research consists of descriptive studies, process evaluations, program evaluations, and theory papers. The dearth of experimental studies is also noteworthy. As researchers seek to draw causal inferences about the effects of mental health courts, utilizing experimental designs will take on increased importance. Once the effectiveness of mental health courts is established through RCTs, it will be important to conduct a series of dismantling studies to identify the active ingredients of the intervention. Further, because drug courts and mental health courts share many features, an examination of the key elements of drug courts may be instructive for mental health court researchers.

### Conclusions

The development of drug courts and mental health courts has provided the criminal justice system with an integrated public safety/public health approach for handling the rising number of criminal offenders who have substance use problems and mental health disorders. There is reason to be optimistic about both of these strategies. A large body of research supports the effectiveness of drug courts, and a growing body of research supports the effectiveness of mental health courts. As more research is conducted in the coming years, researchers will be in a better position to draw empirically supported conclusions about these interventions.

## Defendants in Forensic Hospitals as Incompetent to Stand Trial

Individuals adjudicated incompetent to stand trial (IST) represent a distinctive group treated in public mental health facilities. These individuals are committed by the court prior to conviction of criminal charges and have particular treatment needs. We will describe the frequency of IST adjudications, the treatment needs, and available empirical evidence regarding treatment effectiveness for these individuals in this section of the chapter.

### Incompetence to Stand Trial

Competency to stand trial evaluations arise frequently in the criminal context. It was estimated in the 1980s that approximately 25,000 defendants were evaluated for competence to stand trial on an annual basis (Steadman, Monahan, Hartsone, Davis, & Robbins., 1982). There is apparently no more recent evidence regarding prevalence, but there is also no apparent reason to think this number of evaluations has decreased (Grisso, 2003). Some research (Poythress, Bonnie, Hoge, Monahan, & Oberlander, 1994) has suggested that attorneys formally raise the question of their clients' competence to stand trial in 5%–8% of cases, although they have concerns for as many as twice this number of individuals. Estimates for the number of individuals adjudicated IST has ranged from 10% (Melton et al., 2007) to 30% (Nicholson & Kugler, 1991). These individuals are suffering from a mental disorder or disability (most often a severe mental illness),

which significantly impairs their ability to participate effectively in the adversarial trial process (Bullock, 2002). The notion that a criminal defendant must be competent in order to be tried stems from the idea that defendants must be present at their trials to confront their accusers, question witnesses, and otherwise act in their own defense (Bullock, 2002). The trial of a competent defendant ensures a fair trial of adversaries and maintains dignity and integrity in criminal proceedings.

### The Legal Standard

The standard for determining a defendant's competency to stand trial that is used in most jurisdictions was set forth by the United States Supreme Court in *Dusky v. United States* (1960). The Court held that "the test must be whether [he] has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding—and whether he has a rational as well as factual understanding of the proceedings against him." Competency to stand trial refers to the defendant's mental state at the time of the adjudication of criminal charges. It is a legal decision, albeit one that is informed by clinical data. Defendants must be able to understand the charges against them and assist in their own defense (Melton et al., 2007).

### Disposition

Following the formal consideration of a defendant's competence to stand trial, the court may determine that the defendant is competent. If so, the process for adjudication of charges continues. If the defendant is found to be incompetent, however, criminal proceedings are suspended and the defendant may receive treatment to restore competency. Treatment to restore competency may be provided on an outpatient basis, but typically incompetent defendants are involuntarily hospitalized in a secure setting and receive inpatient treatment to restore their competence to stand trial (Bullock, 2002). Such hospitalization may not be for an indefinite period; under *Jackson v. Indiana*, the U.S. Supreme Court limited the state's ability to confine those adjudicated IST can only be confined to a psychiatric hospital for a reasonable period of time necessary to determine whether competency can be restored (Melton et al., 2007). Depending on the jurisdiction, the patient is then treated until competency is restored, or the relevant *Jackson* period specified by the jurisdiction has lapsed, whichever occurs first (Marques, Hayes, & Nelson, 1993). If the specified time period expires, the court may initiate conservatorship proceedings or dismiss the criminal charges and release the patient (Marques, Hayes, & Nelson, 1993).

### Characteristics of Incompetent Defendants

Competence to stand trial is the most frequently raised criminal issue in forensic mental health, involving defendants who often have extensive histories of involvement in both the legal and the mental health systems (Melton et al., 2007). A study of 539 men adjudicated IST revealed characteristically below-average education, few useful job skills, and few community ties (Steadman, 1979). Numerous studies have described the association between major mental disorders (typically schizophrenia and major affective disorders) and the adjudication of incompetence for trial (Riley, 1998; Rosenfeld & Wall, 1998). Certain symptom constellations in particular seem to interfere with the relevant functional legal capacities for assisting (higher levels of psychotic symptoms), whereas other domains of psychopathology (disorientation and low intellectual functioning) are more strongly associated with inability to understand charges and proceedings (Rosenfeld & Wall, 1998).

A study reviewing the competency evaluation reports for 468 defendants (Hubbard, Zapf, & Ronan, 2003) found that incompetent defendants significantly differed from competent defendants with respect to age, employment status, ethnicity, criminal charges, and diagnosis. Of the 468 defendants referred for competency, 19% were deemed incompetent by mental health evaluators. Most incompetent defendants were African American (67%), single (67%), and unemployed (59%). Some 72% of incompetent defendants had previous criminal histories, and 48% had previous psychiatric hospitalizations. Additionally, 34% of incompetent defendants were diagnosed with a psychotic disorder, and 40% were currently charged with a violent offense.

### Medication and the Right to Refuse Treatment

Most incompetent defendants are committed to secure mental health facilities following adjudication as IST. Medication remains the most common form of treatment for IST individuals. However, little research has been done on the direct effects of medication on the decisional abilities relevant to the original findings of incompetence (Roesch, Ogloff, & Golding, 1993). Additionally, there is a need for research on clinicians' ability to predict medication response within a specified period.

In *Washington v. Harper* (1990), the U.S. Supreme Court considered the question of whether an inmate who was either gravely disabled or represented an active threat of harm to self or others could be involuntarily medicated. Although recognizing that persons have a liberty interest in being free from involuntary medication, the Court nonetheless cited the state's right to treat dangerous prison inmates with antipsychotic medication against their will (Appelbaum, 2003). A second Supreme Court decision, *Riggins v. Nevada* (1992) dealt with a case in which a prisoner who had been medicated involuntarily before trial, and who was later found guilty and sentenced to death, petitioned to have his conviction overturned on the grounds that treatment to restore his competence (antipsychotic medication) had been administered illegitimately. The Court held that "the state might have been able to justify medically appropriate, involuntary treatment with the drug by establishing that it could not obtain an adjudication of Riggins' guilt or innocence by using less intrusive means" (*Riggins v. Nevada,* 1992).

Following these decisions, many lower courts attempted to craft rules governing when incompetent defendants could be treated. *Harper* and *Riggins* implied that the government could medicate even nondangerous defendants under certain circumstances, but the nature of such circumstances was unclear. The U.S. Supreme Court clarified its position and applied a balancing test in *Sell v. United States* (2003), holding that a defendant who is hospitalized as IST may be involuntarily medicated under some circumstances but not others (Heilbrun & Kramer, 2005). In *Sell*, the Supreme Court considered the legality of involuntarily administering medication to a criminal defendant in order to render that defendant competent to stand trial. This is a particularly important question related to the treatment of defendants who are IST. Because of the high prevalence of severe mental disorder within this population, the prescription of psychotropic medication is a very common form of treatment. Consequently, we will pay particular attention in this section of the chapter to the circumstances under which *Sell* suggests such medication can be administered involuntarily.

In *Sell*, the Court ultimately held that medication may be administered involuntarily if it (a) is medically appropriate, (b) is the least intrusive means of restoring competency, and (c) does not infringe on trial rights (such as the ability to communicate with one's attorney and testify relevantly) (Melton et al., 2007). The Court recognized three situations in which the government's interest in medication might be necessary. First, *Sell* permits the forcible medication of any defendant who is dangerous to self or others, if the medication is necessary to reduce dangerousness.[1] Second, *Sell* implies that any defendant who is incompetent to make treatment decisions can be forcibly medicated. Finally, the Court indicated that even a nondangerous defendant who is competent to make treatment decisions may be forcibly medicated to restore competency to stand trial when the charges are "serious" (Melton et. al., 2007).

The Court in *Sell* cited a balancing test to consider the circumstances under which forced medication of an incompetent defendant is appropriate. The court of jurisdiction must (a) find important governmental interests at stake in this case; (b) conclude that taking medication will significantly further those state interests; (c) conclude that the involuntary medication is necessary to further those interests and that any alternative, less intrusive therapies are not likely to produce the same results; and (d) conclude that administration of the drugs is medically appropriate, and in the individual's best medical interests in light of their condition. If a mentally ill defendant agrees to take the prescribed medication and the individual is considered competent to make that decision, there should be no legal dispute (Heilbrun & Kramer, 2005). Clinically, however, the implications of the holding in *Sell* may be more complex.

*Sell* has a number of implications for the assessment and treatment of defendants who are IST. It suggests that the constructs of voluntariness, competence to consent to treatment, and dangerousness will be important for policy makers, clinical administrators, and clinicians to consider in determining whether a given patient falls under the auspices of this decision. *Sell* also underscores the important of the working relationship between treatment teams and defendants who are hospitalized as IST. One study suggested that IST defendants generally do not refuse treatment for rational reasons, but because they deny their mental illness or have delusions about the medications—whereas clinicians' decisions to seek forcible medication are typically made for clinical, not legal, reasons (Ladds & Convit, 1994).

---

[1] Such a circumstance would probably mean that involuntary medication would be appropriate under an emergency treatment order, consistent with *Washington v. Harper,* in correctional and quasi-correctional facilities. The *Sell* decision did not change this.

Additionally, *Sell* highlights the importance of nonmedical treatment strategies (discussed later in this section) for defendants who are IST. Programs treating IST defendants should develop and strengthen nonchemical interventions that are most likely to yield improvement in functional-legal deficits, such as communication, information retentions, and reasoning (Heilbrun & Kramer, 2005).

The relevant and accurate assessment of clinical symptoms, functional-legal capacities, and related issues are important for treatment decisions and for recommendations to the court. The assessment of competence to stand trial has improved substantially during the last two decades, assisted by major conceptual and empirical reviews (see, e.g., Grisso, 1986, 2003), regular reviews of the research literature (e.g., Grisso, 1992; Cooper & Grisso, 1997; Mumley, Tillbrook, & Grisso, 2003), and the development of specialized assessment tools (see, e.g., Grisso, 2003). One particularly important "related issue" for treatment decisions involves the response style of those declining medication; this is an important consideration for clinicians and should be well-documented. When patients respond in a fashion that is other than reliable/honest (either by under-reporting or over-reporting symptoms and capacities), it becomes extremely important to identify the style leading to the inaccuracy and appraise the functioning of such individuals in a reasonably accurate way. This may be accomplished through the combination of assessment approaches and tools focusing specifically on response style (see Rogers, 1997), as well as by gathering third-party information from multiple sources. The implications for assessment and treatment will be different for those who are not accurately reporting their own symptoms and experiences to their treatment teams—some may be more likely to need psychotropic medication, others less.

### Skills-based Interventions for IST

Defendants who are IST constitute the majority of forensic patients receiving treatment in the United States. Under *Jackson v. Indiana* (1972), a defendant found IST cannot be hospitalized indefinitely. As a result, the treatment of incompetent defendants has become somewhat more focused in recent years. Several modes of treatment are being tried in various state hospitals. One trend currently observed involves the development of specialized forensic housing units for incompetent defendants, as contrasted with treating them within the larger forensic context (Cooper & Grisso, 1997). Initial phases of treatment for this population tend to be psychopharmacological and focus on reduction and control of psychotic symptoms (Cooper & Grisso, 1997). Typically, this treatment is then followed by educational programs, focused on restoring competency, for those who do not appear to have regained competency following this initial phase.

Roesch et al. (1993) emphasized that, prior to treating an IST defendant, the expected level of competency should be delineated in a specific manner, so that the treatment can be targeted toward appropriate behaviors or capacities as they relate to the restoration of competency (Roesch et al., 1993). They emphasized that, before one can specify treatments, it is necessary to clearly understand the necessary knowledge and ability a defendant needs in order to be considered competent (Roesch et al., 1993).

Siegel and Elwork (1990) evaluated a skills-based treatment program for incompetent defendants. Using random assignment, they compared the impact of an experimental group (skills-based training in knowledge and interaction skills relevant to competence to stand trial) with a control group (treatment as usual). The experimental condition included use of a videotape that described the roles of courtroom personnel and court procedure, as well as group problem-solving sessions in which problems arising from a subject's actual legal case were presented and discussed. Results showed greater improvement on a measure of competency-relevant capacities for the experimental group, and a greater number of staff recommendations of competent to stand trial (43% of the treated group, but only 15% of the controls, were considered competent by staff 45 days after treatment) (Siegel & Elwork, 1990). This study highlighted the potential impact of a "second-stage" intervention (following stabilization of symptoms through medication), targeting legally relevant capacities as the primary focus of treatment.

Brown (1992) described a treatment group for IST individuals that was organized into modules on trial participation. Successful outcomes were related to defendants' attention, cooperation, and concentration, with the program being less successful for individuals with impairments in these areas and for individuals harboring idiosyncratic or paranoid delusions concerning their cases.

### Characteristics of Treatment Approaches for IST

Treatment services for individuals who are IST can be divided into three categories: traditional, contemporary, and targeted (Heilbrun & Griffin, 1999).

Traditional mental health treatment services involve standard kinds of mental health interventions (e.g., diagnostic assessment for treatment planning purposes, medication, milieu therapy, and group and individual therapy for inpatients; medication, case management, and group and individual therapy for outpatients) that might be delivered to forensic patients in need of mental health intervention. Contemporary treatment services include psychoeducational, skills-based services and behavioral interventions, such as psychosocial rehabilitation. Finally, targeted treatment services include those interventions that are designed to address functional deficits relevant to legal standards (such as anger control or impulse control relevant to nonviolent behaviors, psychoeducational approaches to restore competency, and the teaching of responsible behavior required for legal compliance with conditional release criteria) (Heilbrun & Griffin, 1999).

Forensic treatment is directly affected by the law or the jurisdiction in which the forensic treatment takes place. Additionally, the setting in which the treatment is delivered is an important consideration. Typical settings include, but are not limited to hospital (high security and medium- to low-security), jail, and community. Finally, the goals for treatment of IST individuals could be clinical (focused on remission of symptoms and improvement in overall functioning), legal (designed to specifically address functional deficits that are directly relevant to legal standards), and hybrid (designed to improve both clinical symptomatology and functional deficits) (Heilbrun & Griffin, 1999).

#### APPROACHES TO TREATMENT

Various factors influence treatment approaches to individuals adjudicated IST. The first is the clinician's and/or facility's overall theoretical orientation and training model (Clark, Holden, Thompson, Watson, & Wightman, 1993). The second factor is the nature of the court order for which the patient is hospitalized; IST patients often require time-limited, active, and educative interventions, in concert with ongoing assessment of mental state and competency (Clark et al., 1993; Melton et al., 2007). Finally, the pathology of the patient will have an effect on the goals and objectives for treatment at the facility. Diagnostically, this patient population presents as more psychotic and severely disordered (Bullock, 2002; Heilbrun & Griffin, 1999). In addition to a number of other factors (e.g., severe personality disorders, substance abuse disorders, and subaverage intellectual functioning),

the combination of these clinical features with the status as criminal defendant result in an emphasis on medication and security concerns above standard treatment modalities.

For patients hospitalized as IST, the primary goal of treatment is to return the patient to the court as sufficiently improved to be considered competent for trial (Clark et al., 1993). Apart from the pharmacological intervention necessitated by the presenting symptoms, the treatment of such patients is largely psychoeducational (Clark et al., 1993; Marques et al., 1993; Wack, 1993). More traditional mental health goals, such as insight and the improvement of dysfunctional behavior, are considered in the context of how they relate to the needed legal capacities (Clark et al., 1993). Thus, symptoms or problems that would likely be the focus of treatment in other settings become more peripheral, and will only become the focus of treatment if they impinge directly on the patient's competency to stand trial (Clark et al., 1993; Wack, 1993).

### Empirically Supported Treatment Characteristics

#### TRADITIONAL CLINICAL SERVICES

Traditional clinical services involve standard mental health treatment interventions and include diagnostic assessment for treatment planning purposes, medication, short- and long-term individual and group psychotherapy, family therapy, parenting skills groups, substance abuse treatment, anger control, and relaxation techniques, as well as assertiveness training (Heilbrun & Griffin, 1999; Clark et al., 1993; Marques et al., 1993; Wack, 1993). Additionally, the ongoing assessment and treatment of individuals presumed to be dangerous is a traditional clinical service. Traditional clinical services differ from contemporary treatment services, which often include psychoeducational skills-based services and behavioral interventions (Heilbrun & Griffin, 1999). Additionally, traditional clinical services differ from a strictly cognitive-behavioral approach; however, many facilities blend traditional clinical services with a more cognitive-behavioral approach. At some facilities, like the Kirby Forensic Psychiatric Center, program activities that can enhance confidence, skills, knowledge, creativity, and self-esteem, as well as more traditional treatment modalities, are offered (Wack, 1993). In addition, the Kirby Center provides many other supportive psychoeducational, as well as insight-oriented, approaches that are considered within the purview of their traditional clinical services (Wack, 1993). For neurologically impaired

individuals, cognitive restructuring, biofeedback, and psychoeducation and retraining in memory and attention should be considered (Marques, 1993). The effectiveness of these interventions has not been described through empirical research, however.

*Substance Abuse Treatment*

Substance abuse treatment is an important component of traditional clinical services. Many patients have histories of substance abuse, which can affect every aspect of a patient's life, and successful treatment requires the patient's ability to recognize relapse and maintain the recovery process. At one inpatient forensic facility, Atascadero State Hospital, the substance abuse treatment includes a three-phase intervention covering chemical dependency, recovery, and relapse, and takes about 9 months to complete (Marques et al., 1993).

At a second forensic hospital (Taylor Hardin Secure Medical Facility), the substance abuse group is recommended for patients who have a history of substance abuse/dependence of at least 1 year duration and who are not actively psychotic, aggressive, or significantly mentally retarded. Objectives in the group include helping patients to recognize and admit they have a substance abuse problem, promoting motivation for dealing with the problem, identifying variables that relate to the maintenance of substance abuse, and discussing attitudes toward addiction (Dixon & Rivenbark, 1993).

*Restraints/Seclusion*

Special management interventions that are designed to deal with crisis situations or with patients who require special attention due to agitated, threatening, self-destructive, or aggressive behavior should be in place for IST individuals (Clark et al., 1993; Marques et al., 1993). These interventions should be designed to prevent, deescalate, or control aggressive and self-destructive behavior (Wack, 1993). Most facilities limit the use of restraints and seclusion to instances in which they are necessary to prevent the patient from harming self or others or causing substantial property damage (Clark et al., 1993). In Michigan, a related treatment option is the "quiet room," involving the placement of a patient alone in a room with a closed but unlocked door (Clark et al., 1993).

*Medication*

The primary role of medication in the treatment of IST patients has been discussed earlier in this chapter. In the context of traditional interventions, pharmacological treatment is regarded as an approach to rapidly improving the capacities of actively psychotic individuals in the domains of thinking, reasoning, and communication. This not only addresses a number of potentially legally relevant deficits, but also allows some patients to participate more fully in other treatment modalities (Wack, 1993).

CONTEMPORARY MENTAL HEALTH SERVICES

*Reality Orientation Groups*

Reality orientation groups are often effective among fairly low-functioning patients who have significant cognitive impairment such as memory, concentration, or attention deficits, and low intellectual functioning (Dixon & Rivenbark, 1993). Patients are involved in over-learning practices to help maintain their awareness of important personal information such as name, birthday, current date, family information, and important and recent events. Treatment utilizes cognitive and reality therapy problem-solving techniques; and efforts are made to apply these techniques in analyzing daily problems that occur on the treatment unit. These techniques are also applied hypothetically in the discussion of characteristic styles of interacting with others, particularly those styles that have contributed to past difficulties. At Taylor Hardin, the emphasis of the group is for patients to learn how to evaluate, and then make appropriate changes in, nonproductive or destructive habits and attitudes, which might include nonproductive interactions with the attorney representing them (Dixon & Rivenbark, 1993).

*Medication Education Group*

One of the most important factors in keeping patients functioning effectively, both within the facility and following return to court, is medication compliance (Dixon& Rivenbark, 1993). A group that provides medication education to patients about the main therapeutic benefits and possible side effects of medications, while focusing on the importance of taking medication regularly and as prescribed, is quite important among this population. Among other considerations, it can help to anticipate the problem of declining to take prescribed medication while incarcerated in jail, following return from the hospital but prior to disposition of charges.

TARGETED LEGAL SERVICES

Some research suggests that targeted legal treatment services could have significant value for increasing relevant knowledge and decreasing length of hospitalization for IST defendants (Siegel & Elwork, 1990). Interventions that focus on the capacities

and deficits relevant to understanding and assisting are among those most directly related to behaviors that will be considered in the subsequent legal decision of whether the defendant's competence to stand trial has been restored.

### Restoration of Trial Competency
### Psychoeducational Groups

Commonly, patients adjudicated as IST display severe psychiatric-behavioral problems, with a significant proportion having symptoms of schizophrenic illness. Thus, in addition to medication and other traditional interventions addressing the symptoms of mental illness, competency education classes are utilized for patients hospitalized as IST. Behavioral approaches to restoring trial competence may include role-playing and mock trials in simulated courtroom settings to teach patients legal pleas, courtroom procedures, basic legal concepts, and how to cooperate with the defense counsel, and to increase understanding of the courtroom procedures (Pendleton, 1980). Verbal and written instructions, cartoons, mock trials, and video equipment can be used; as appropriate, individuals sessions can be held and the patient's lawyer included (Wack, 1993). Progress toward fulfilling the various fitness criteria should be evaluated and charted continually, and treatment interventions should be adjusted accordingly to ensure compliance with the individualized treatment plan (Wack, 1993).

#### TARGETED HYBRID TREATMENT

Targeted hybrid treatment refers to treatment that addresses both symptoms and legally relevant deficits. For example, at the Kirby Forensic Psychiatric Center, in addition to psychoeducational approaches to enhance competency, a patient may be taught stress management techniques to aid in coping with stress in the courtroom, or a patient may receive focused short-term psychotherapy or cognitive therapy to deal with a specific problem interfering with his or her fitness to stand trial (Wack, 1993).

#### TREATMENT MODALITIES

Over the past two decades, many forensic facilities treating IST patients have transitioned away from the insight-oriented verbal therapies and moved toward cognitive-behavioral, neurobehavioral, and skill-oriented approaches (Clark et al., 1993; Marques et al., 1993; Wack, 1993). The Kirby Forensic Psychiatric Center recommends a therapeutic community model, providing the patients with some self-governing functions within the "community" (Wack, 1993). At Atascadero State Hospital,

a wide range of treatment approaches are used by the staff (Marques et al., 1993).

### Evaluation Component of Treatment Approaches Through Research

The past two decades have witnessed a trend toward more systematic and outcome-oriented approaches to IST treatment. At Taylor Hardin Secure Medical Facility, a treatment program is often evaluated with respect to measurable goals and objectives (Dixon & Rivenbark, 1993). The Trial Competency Program objectives include decreasing the length of stay and increasing the rate of concurrence between the hospital's dispositional recommendations and court decisions regarding competency. The effectiveness of this program is evaluated based on success of these goals (Dixon & Rivenbark, 1993).[2] For other programs, measurable goals and objectives may include length of stay, psychiatric symptomatology, levels of social and vocational functioning, and violent incidents (Wack, 1993).

Generally, it is important to integrate an evaluation component, both in measuring the attainment of in-treatment goals and objectives and to test the success of new and existing programs in reducing criminal recidivism. Studies to determine which offenders are most likely to respond to various hospital programs and particular treatment components should also be emphasized in future evaluation efforts. Finally, if treatment efforts are not effective after a reasonable period of time, clinicians need to render an opinion about restorability (or lack thereof) in light of *Jackson v. Indiana*, and proceed with initiating the process whereby the defendant may have charges dismissed and be considered for civil commitment (Roesch et. al., 1993).

### Conclusion

The "evidence" available to support the interventions made in juvenile placements, drug courts, and forensic hospitals varies by setting and level of intervention. One important influence involves the way

---

[2] It should be noted that hospital reports making recommendations regarding competence to stand trial are not independent of judges' decisions. Indeed, there is evidence that courts render decisions consistent with the recommendations of experts in a very high percentage of cases (Melton et al., 2007). This notwithstanding, it is appropriate for hospitals to use concordance between recommendations and court decisions as one indicator of service effectiveness.

in which each of these settings is structured. Juvenile placements and forensic inpatient treatment of IST patients are standard justice settings in which adjudicated individuals are placed for both security and intervention purposes. Research on interventions at the single-modality level (e.g., an innovative anger control group) is more feasible than at the program level (combining multiple interventions) or at the broadest policy level (comparing different levels of placement). Single-modality interventions are less likely to have a substantial impact on individuals being treated than are programmatic or policy interventions, but good research on the latter interventions is very difficult among individuals with high-security requirements. This may help to explain why specialty courts, a more recent form of intervention in the criminal justice system, have received a relatively large amount of research attention: Designing a study in which individuals who meet certain criteria are diverted to drug court or mental court or processed as usual according to random selection means that carrying out the study is feasible with the cooperation of local judges and attorneys.

Whether this can explain the patterns observed across the three kinds of interventions described in this chapter is an open question. What is clear, however, is that good, programmatic research with juveniles in placement and adult IST defendants is inconsistent to nonexistent, whereas research on specialty courts is flourishing. Until juvenile and adult systems are willing to test innovation while maintaining security, this will probably continue into the indefinite future.

### Future Directions

• Can in-program treatment of juvenile offenders be captured under a single umbrella, as MST has been for the community, to facilitate outcome research with careful attention to treatment integrity?

• Do a common set of principles govern the effective operation of drug courts and mental health courts?

• Can an effective "first stage" of treatment for IST defendants—focusing almost exclusively on medical stabilization—be developed in a community setting, and thereby substantially reduce the number of IST commitments to remote forensic hospitals?

# Clinical Neuropsychology

Robert J. McCaffrey, Julie K. Lynch, *and* Holly James Westervelt

## Abstract

The origins of clinical neuropsychology were founded in the diagnostic methods for identifying cerebral damage and, although this remains an important focus of the field, clinical neuropsychology is also focused upon understanding the functional consequences of neuropsychological dysfunction and on methods of treating or managing neuropsychological dysfunction. Neuropsychological research has also expanded beyond neurology to psychology, where delineating the neuropsychological correlates of psychological disorder has been of particular interest. Following a brief history of neuropsychology, this chapter discusses neuropsychiatric symptoms associated with neurological damage or disease. The discussion will then turn its focus to psychological disorders, with a review of the neuropsychological deficiencies that have been associated with various Axis I and Axis II disorders. The objective of this chapter is to provide information of potential utility to the psychotherapist or psychologist in understanding the neuropsychological underpinnings of psychological disorders, as well as the psychological and behavioral consequences of neurological conditions.

**Key Words:** Clinical neuropsychology, neuropsychiatric, neuropsychological correlates of psychological disorders, neuropsychological dysfunction, psychological/behavioral consequences of neurological conditions

## A History of Clinical Neuropsychology

As with any new field of psychology, an organizational infrastructure facilitates the growth and development of the discipline through publication outlets and society meetings. The history of clinical neuropsychology has been detailed eloquently by the late Arthur Benton (2000) in his book *Exploring the History of Neuropsychology.* Those readers old enough to have had been assigned Edwin G. Boring's (1950) *History of Experimental Psychology* as a textbook in a history of psychology seminar will undoubtedly appreciate the depth of coverage of clinical neuropsychology by Dr. Benton. Although a detailed presentation of the history of clinical neuropsychology is beyond the scope of the current chapter, a brief history of the development of clinical neuropsychology into a full-fledged discipline is in order.

## *Formal Organizations*

The founding of clinical neuropsychology as a discipline has been traced by Rourke and Murji (2000) back to the mid 1960s, through the formation of the International Neuropsychological Society (INS). Rourke and Murji (2000) outline the history of the INS into six phases: (1) 1965–1967 Conception and Gestation, (2) 1967–1973 Birth, (3) 1973–1976 Infancy and Toddlerhood, (4) 1976–1982 Early Childhood, (5) 1982–1985 Childhood, and (6) 1985–2000 Adolescence. Given the continued growth and development of clinical neuropsychology since 2000, we think it fair to say the field is well into early adulthood. The INS has a total worldwide membership of 4,500. It holds an annual North American meeting in February and a non-North American meeting in July. The society's journal is

the *Journal of the International Neuropsychological Society*.

During the infancy period of the INS, other organizations were going through their own development. The National Academy of Neuropsychology (NAN) was founded in 1975. Currently, NAN has over 3,300 members in all 50 states and in 24 countries, representing the diverse interests of scientist-practitioners, clinicians, and researchers in the field of neuropsychology. The annual meeting draws both scientists and practitioners via a conference of workshops, scientific presentations, and updates on issues facing practitioners.

The Council of Representatives of the American Psychological Association (APA) approved the creation of Division 40 (Clinical Neuropsychology) in 1979. Today, Division 40 has 4,462 members and is active in all facets of clinical neuropsychology both within and outside of APA.

### Training Issues

In the 1980s, clinical neuropsychology began to experience an identity crisis. What was the appropriate training in clinical neuropsychology? Who was a clinical neuropsychologist? How were the interest of the profession and the public best served? In 1981, a joint task force of the INS and Division 40 met to begin the arduous task of addressing these and other questions.

The late Manfred J. Meier proposed educational models for competency assurance in neuropsychology. Specifically, Meier (1981) presented four models:

• Model I. Clinical neuropsychology would be a subspecialty area in a traditional applied psychology program
• Model II. Clinical neuropsychology coursework would be provided through interdepartmental supporting programs in neuropsychology and the clinical neurosciences
• Model III. Clinical neuropsychology would be integrated in the scientist-practitioner curriculum for the PhD degree
• Model IV. Clinical neuropsychology would comprise a separate coordinated graduated curriculum with both PhD and PsyD components.

The most intensive training would occur in Model IV and would conclude with a competency based examination process (i.e., board certification). The issue of clinical neuropsychologist training was reexamined in 1997, during what has become known as the Houston Conference on Specialty Education and Training in Clinical Neuropsychology (Hannay,

Bieliauskas, Crosson, Hammeke, Hamsher, & Koffler, 1998). Although not without its critics (Reitan, Hom, Van De Voorde, Stanczak, & Wolfson, 2004), the conference did result in the publication of a set of aspirational training guidelines.

### Board Certification

Presently, three primary organizations are involved in the process of board certification in clinical neuropsychology. These are the American Board of Clinical Neuropsychology, admitted through its parent the American Board of Professional Psychology in 1984 (Goldstein, 2001); the American Board of Professional Neuropsychology, founded in 1982 and reorganized in 1989 (Horton, Crown, & Reynolds, 2001); and the American Board of Pediatric Neuropsychology, founded in 1996 and reincorporated in 2004. It is noteworthy that the APA does not endorse nor recognize any specialty examining boards in psychology (Goldstein, 2001). Although clinical neuropsychology is a relatively new specialty within psychology, it is clearly a separate discipline that is now found in clinics and medical centers around the world. In addition to providing services across the lifespan, clinical neuropsychologists also provide expertise in forensic settings.

## Clinical Neuropsychological Assessment

Neuropsychological evaluations are conducted for many reasons, including screening evaluations, diagnostic evaluations, assisting medical personnel with differential diagnosis, treatment planning, care planning, competency (i.e., the ability to make medical decisions, the ability to manage one's own finances, etc.), fitness-for-duty, and for forensic purposes both civil and criminal. The specific assessment tools used may vary according to the nature of the referral question and preferred approach of the clinician.

"Clinical neuropsychology is an applied science concerned with the behavioral expression of brain dysfunction" (Lezak, Howieson, & Loring, 2004, p. 3); hence, historically, clinical neuropsychologists have relied upon a fixed battery approach for general clinical use such as the Halstead-Reitan Neuropsychological Test Battery (HRNB; Reitan & Wolfson, 1993), the Luria-Nebraska Neuropsychological Battery (LNNB; Golden, Purisch, & Hammeke, 1991) and, more recently, the Neuropsychological Assessment Battery (NAB; Stern & White, 2003) (Table 30.1). Other batteries have been developed for assessing specific conditions such as the National Institute of Mental Health (NIMH) Core Neuropsychological Battery

**Table 30.1  Criteria for a neuropsychological test battery**

1. The battery should evaluate the full range of neuropsychological functions dependent upon the brain.
2. The battery should include tests of general brain functioning, as well as those that relate to specific areas of cerebral functioning.
3. The battery should employ "time-honored methods of clinical neuropsychology."
4. Each test in the battery must be validated for its sensitivity to brain damage/dysfunction.
5. The battery should provide a balanced sampling of behavior from each of the cerebral hemispheres.

for assessing HIV status (Butters et al.) and the Adult Environmental Neurobehavioral Test Battery (AENTB; Hutchinson et al., 1992) for assessing exposure to toxic substances. There are also screening batteries for general use when testing time is limited, for example, the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS, Randolph, 1998) serves as a general-use battery for screening purposes. For a more detailed discussion of these batteries and others see Strauss, Sherman, and Spreen (2006).

Another approach to neuropsychological assessment has been characterized as a "flexible" battery approach. Generally, the battery contains a set of core tests applied within individual diagnostic categories (e.g., dementia, cerebral vascular accident) supplemented by other tests based upon the individual patient's condition or other examination-related issues (Lezak et al., 2004).

Particularly with a flexible battery approach, the length and components of the exam can vary considerably. Brief exams may focus assessment solely on the skills that are relevant to address the question at hand. For example, an inpatient assessment of an elderly patient's decisional capacity may involve a thorough interview and, at times, only brief testing of the patient's basic attention and language skills, judgment, daily problem-solving abilities, planning, and memory. Other areas that have little relevance to the referral question may not be assessed at all (e.g., visuospatial skills). In contrast, most comprehensive examinations will assess multiple "core" cognitive domains, regardless of the specific referral question, given that the patient and referrer may not have appreciated deficits that may be meaningful in providing diagnostic information (particularly for profile analyses) or functional recommendations. Most commonly, areas examined will include attention, executive functions, language, motor skills, visuospatial skills, and learning/memory. Although not an exhaustive list, Table 30.2 lists these domains with examples of the skills that comprise them. Of note, neuropsychologists are not always in agreement in terms of how these domains are most accurately

described, operationalized, and best measured. Although there is a tendency to reify these constructs, clearly these are made-up concepts, with the terms being used to help communicate among patients, professionals, and researchers, and to provide a framework for understanding how these diverse cognitive skills may group together and interrelate.

The interpretation of neuropsychological test scores must take into consideration a number of biopsychosocial factors known to impact an individual's test performance, including age, gender, educational level, cultural background, and the patient's native language. In addition, as discussed in greater detail later in this chapter, the presence of an Axis I or Axis II condition may have a direct impact on an individual's test performance above and beyond that of any brain-related pathology. Other factors to consider in the interpretation of test data are base rates, practice effects, and effort, as elaborated below.

**Table 30.2  Commonly assessed cognitive domains**

| Domain | Exemplars of Associated Skills |
| --- | --- |
| Attention | Attentional capacity, sustained attention/sustained focus, divided attention, working memory/mental control, psychomotor speed |
| Executive Functions | Planning, organization, abstract reasoning, rapid word generation/verbal fluency, set shifting, multitasking, problem-solving, inhibition, judgment, concept formation |
| Language | Comprehension, repetition, naming, writing, reading, calculation, praxis |
| Motor Skills | Grip strength, fine motor coordination, fine motor speed |
| Visuospatial Skills | Construction, visuoperception |
| Learning/ Memory | Encoding/storage, retrieval, recognition |

### Base Rates

The term *base rate* refers to the prevalence of an event, usually a sign, symptom, or disorder that exists within a given population. For example, the base rate for the symptom of fatigue among patients with a diagnosis of Epstein-Barr syndrome is 100%, whereas the base rate of visual disturbances among studies of patients with diabetes is approximately 7% (McCaffrey, Palav, O'Bryant, & Labarge, 2003). Similarly, the base rate of the symptom "easily distracted" reported in the general population of elementary school children is 49%, and the base rate of "eye tics" among the general population is 0.0% (McCaffrey, Bauer, O'Bryant, & Palav, 2006).The interpretation of test findings must consider issues such as base rates in an attempt to determine if an individual score represents normal variability or is indicative of underlying brain pathology. By way of example, the difference between an examinee's Verbal IQ (VIQ) and Performance IQ (PIQ) on any of the Wechsler Scales may be found to be *statistically significant* ($p <.05$); however, a statistically significant VIQ–PIQ discrepancy may not be *clinically significant* if the discrepancy commonly occurred in the normative sample (i.e., the base rate). Since many tests are accompanied by computer-generated score reports that contain detailed statistical comparisons of scores, the base rate data presented in these score reports must be considered in the interpretation of the data.

The importance of the base rates of impaired test scores on a battery of neuropsychological assessment instruments has been examined by Heaton, Miller, Taylor, and Grant (2004), who report that, on 25 measures administered to a group of 1,189 neurologically normal participants, 15% had at least one impaired score, 13% had two impaired scores, another 13% had three impaired scores, 9% had four impaired scores, approximately 7% had five impaired scores, and another 7% had six impaired scores. Binder, Iverson, and Brooks (2009) have also evaluated normative studies of variability in healthy adults on several neuropsychological batteries and conclude that abnormal performance on some portion of neuropsychological tests in a battery is psychometrically normal. These reports indicate that the presence of some abnormal test scores does not necessarily indicate the presence of acquired brain dysfunction, since both low scores and intraindividual variability are frequently found among healthy adults. As quoted by Binder et al. (2009), Schretlen et al. (2003) stated, "the findings reported underscore the importance of basing clinical neuropsychological inferences about cerebral dysfunction on clinically recognizable patterns of performance in the context of other historical, behavioral, and diagnostic information, rather than on psychometric variability alone." The interpretation of neuropsychological data requires a solid understanding of brain–behavior relationships and the neurocognitive patterns associated with specific neurological conditions. This is the neuropsychological assessment model that Ralph M. Reitan has advocated since the inception of the Halstead-Reitan Neuropsychological Test Battery. It appears that the field of clinical neuropsychology has come full circle, and that knowledge of base rates for false-positive and false-negative results will become increasing important in the future.

### Repeat Assessment/Practice Effects

*Practice effects* refer to the change in an examinee's performance due to repeated exposure to an assessment instrument (McCaffrey, Duff, & Westervelt, 2000a, 2000b). For example, if the same group of patients were administered a memory test, such as the California Verbal Learning Test (CVLT), and then took the same test a week later, the performance on the second administration would be "better" due to having taken the same test 7 days earlier. The "better" performance on the second administration would not reflect any improvement in the groups' overall memory ability but rather practice effects. In some instances, practice effects are bothersome and need to be controlled for either experimentally or statistically in order to determine if an independent variable (e.g., medication X taken daily between administrations of the CVLT) actually was responsible for the groups' improved performance on the CVLT.

Although practice effects have been considered problematic by researchers and clinicians attempting to interpret changes in patients' performance across assessments, recent work has demonstrated that "practice effects" may have utility in the early diagnosis and/or prognosis of progressive neurological conditions. Specifically, Duff and colleagues in the Huntington's Study Group (2007) reported that, among three patient groups (older adults with mild cognitive impairment, individuals who were HIV positive, and individuals diagnosed with Huntington disease), practice effects accounted for as much as 31%–83% of the variance in the follow-up cognitive scores after controlling for baseline cognitive functioning. Therefore, the absence of the expected practice effect may be of prognostic value, and this is currently an active area of research. As an

example, the presence of mild cognitive impairment has been confirmed by examining practice effects over a 1-week test–retest interval (Duff, Beglinger, Van Der Heiden, Moser, Arndt, Schultz, & Paulsen, 2008), as well as by using multiple assessments on a single day (Darby, Maruff, Collie, & McStephen, 2002). These studies indicate that practice effects data have significant implication for early diagnosis and treatment intervention.

### Symptom Exaggeration/Examinee's Effort

The results of neuropsychological evaluations are used in making health-care decisions, as well as in civil and criminal legal proceedings, and these decisions may have a profound impact on an individual's life. As such, it is essential that the data upon which the clinician's opinions are based are rock solid, because if they are not, the opinion will lack a solid foundation and be of limited value to everyone involved. For example, will a 17-year-old high school junior who fell down an escalator at a local shopping mall and sustained a concussion be able to continue her educational and vocational dreams to become a pediatrician? Did the 15-year-old charged with capital murder have the ability to anticipate the consequences of his actions, in light of a history of developmental delays, limited formal schooling, and documented acquired brain injuries?

Clinical neuropsychologists cannot rely upon their clinical judgment alone when attempting to determine if the examinee participated fully in a neuropsychological evaluation. To determine if an examinee's level of effort was adequate to produce valid and reliable test scores, *symptom validity tests* have been developed. Although multiple symptom validity tests are available commercially, there are also a number in the development process. Regardless of the specific symptom validity test, they all contain a rich normative database, based upon both patient populations and analogue research studies.

### Neurobehavioral and Neuropsychiatric Symptoms Associated with Neurological Conditions

A wide variety of neurologic insults can result in subtle to profound behavioral and emotional changes. Although alterations in cognition and movement/motor skills as a consequence of brain insults may be anticipated, often patients and families are not prepared for the resultant changes in mood and behavior. It is not unusual for laypeople to be unaware that the brain is responsible for emotional and behavioral regulation. The assumption may be that these factors are separable from "brain functioning," and that "mind" or "personality" somehow remains outside of the functions of cells and is attributable to something more intangible. As with other brain functions, however, emotion and behavior can be affected by brain insult, with the presence and nature of the symptoms being dependent on the location of injury. These changes may not occur solely in reaction to a potentially life-altering injury or disease, but by virtue of the injury itself. These alterations may be the most apparent and debilitating symptoms resulting from an injury or illness, even in a patient who is cognitively relatively unscathed. At other times, such changes can go unrecognized and hence untreated, either overshadowed by cognitive or physical deficits or misattributed to external or volitional factors.

It is important to note that *any* psychiatric symptom can occur as a function of central nervous system (CNS) dysfunction, and the *neuropsychiatric* symptoms displayed may be seemingly contradictory (see Cummings & Mega, 2003, for an excellent and thorough review of the principles of neuropsychiatry). For example, it is not unusual to see both impulsivity and apathy within the same patient as a consequence of a brain insult. As with disorders such as schizophrenia, the symptoms may include deficit syndromes (akin to "negative" symptoms of schizophrenia), in which expected behaviors are lacking, or productive syndromes (akin to "positive" symptoms of schizophrenia), in which unexpected behaviors are present. As stated earlier, it should be stressed that the particular symptoms that are displayed are largely dependent on the location of the injury. Neuropsychiatric changes are often attributable to the frontal lobes, particularly the right frontal lobe, limbic system insults, or regions/circuits connected to these areas. From a cognitive perspective, some of these areas, such as the right frontal lobe, can be among most challenging brain regions to assess using more traditional neuropsychological measures, despite fact that the frontal lobes comprise as much as a third of the brain. For this reason, careful psychodiagnostic assessment is an essential component to many neuropsychological evaluations, particularly for those patients with suspected frontal systems involvement.

Although this section is not intended to provide a neuroanatomic review of neuropsychiatric symptoms, some of the behavioral syndromes will be presented according to the affected brain regions, as the resulting symptoms may be likely to co-occur by virtue of their shared neuroanatomic and neurophysiologic

underpinnings. It should be noted that disruption of the "frontal systems" circuits, involving primarily the frontal lobes, basal ganglia, and thalamus, can occur due to lesions anywhere along the circuits, although the syndromes are typically labeled according to their origins within the frontal lobe (i.e., dorsolateral circuit, orbitofrontal circuit, and medial frontal/anterior cingulate circuit; see Chow & Cummings, 1999 for a review of the frontal circuits).

### Orbitofrontal Cortex

Symptoms involving damage to this circuit are primarily characterized by *disinhibition*. Patients may be lacking in social judgment, are apt to blurt out inappropriate comments, to act without considering the consequences of their actions, and may joke inappropriately. When more subtle, this may present as a patient seeming overly familiar with his or her clinician. At extremes, patients may be much more blatantly inappropriate. An example is a 53-year-old patient with a behavioral variant of frontotemporal dementia who noted that he had begun yelling out racial slurs in public, although he had never harbored such sentiments prior to the onset of his dementia. Patients with damage to this region may also show a pronounced lack of empathy and have very little insight into their behaviors. This can be a challenging combination of behaviors for the significant others of these patients, as the patients may be frequently making insensitive, embarrassing, or even hurtful comments without appreciating the inappropriateness of the comments or the impact on the receiver. In the case of the patient noted here with frontotemporal dementia, he reported often feeling embarrassed after blurting out a racial slur, noting that the sentiment was incongruent with his belief system. In most instances, however, he felt a sense of power and cathartic release after expressing his thoughts so freely, and he typically had no regret about the other remarks, which his partner found to be often tactless, if not frankly offensive. *Utilization behavior* may also be present with orbitofrontal damage, with patients attempting to use objects within their view (e.g., a comb, pen), even though they have no purpose for doing so. This behavior may be thought of as a form of disinhibition, with patients failing to inhibit the use of the objects for which they have no need and responding strongly to environmental rather than internal cues. Indeed, for patients with orbitofrontal injuries, external stimuli become highly influential in driving behavior, resulting in a strong dependency on the environment for behavioral response options.

Last, emotional changes as a result to damage to this region can include potentially significant mood lability, at times presenting as either *mania* or *depression.*

### Dorsolateral Cortex

Damage to this circuit may result in symptoms that are typically considered to be more cognitive than behavioral in nature, and, hence, are more readily measurable by traditional neuropsychological assessment tools. These *executive deficits* can include problems with mental flexibility, planning, working memory, memory retrieval, problem-solving, and abstraction skills. Emotional changes may include *depression.*

### Medial Frontal Cortex

*Apathy* is one of the most characteristic behavioral changes associated with damage to this circuit, with patients demonstrating difficulty with drive, initiation, and maintenance of behaviors. Patients may seem emotionally flat and indifferent, and family members can often mistake apathy for depression or willful "laziness." At the most extreme presentation, patients with damage to this region may display *akinetic mutism,* initiating neither speech nor movements, although they are not paralyzed nor, typically, aphasic. As an example, a 50-year-old, college-educated man with a stroke involving the thalamus and basal ganglia had relatively mild cognitive impairment on examination, but was unable to work or care for himself due to his extreme apathy. He sat on his couch all day, and only with strict implementation of a contingency management reward system for coffee (the only reward to which he responded) did he reach the point at which he would toilet himself without prompting. He rarely spoke unless first spoken to. His wife noted that, during the summer, if left alone, he would not get up from the couch to open a window or turn on the air conditioner, even if the temperature in the house was approaching 100° F.

### Other Behavioral Disturbances

A number of other behavioral changes may be observed following frontal systems disruption, although they are not necessarily associated with any of the three neuroanatomic circuits noted earlier. Among those are:

#### ANOSOGNOSIA

*Anosognosia* refers to a lack of awareness of one's deficits. The term is derived from the Greek words "nosos," meaning disease, and "gnosis," meaning

knowledge. Most medical definitions of the term will relate the condition to a lack of awareness of one's paralysis, typically involving insult to the nondominant, most often right hemisphere, and the typical left-sided paralysis. In this context, the patient may also neglect the entire affected side, not recognizing those body parts as belonging to him or her. Far more common (and typically less transient), is a lack of awareness of one's cognitive deficits or changes in one's behavioral regulatory control. Patients with Alzheimer's disease, for example, are often anosognosic. They may express rather fleeting awareness of their memory deficits, particularly in the moment of being confronted with a lapse in memory, but may otherwise have little awareness of even profound deficits. The degree of anosognosia exists along a continuum, with some patients appreciating that there has been some change in their cognition, but not appreciating the full extent of these changes. Other patients may be densely anosognosic and state very adamantly that there is nothing wrong with them, even when confronted with obvious, significant deficits. Although Alzheimer's disease may be the condition most commonly associated with anosognosia, it can occur with virtually any kind of brain insult. Family members often interpret this symptom as "denial," assuming that the patient is aware of the problem but is pretending there is no deficit, and it is often helpful for family to understand that the "denial" is actually a neurologically based phenomenon that prevents the patient from appreciating his or her deficits. This symptom can have a mixed impact on the patient and family. In some ways, the patient is spared from the distress associated with being more acutely aware of the often-devastating changes that are occurring. On the other hand, the lack of awareness of the deficits can lead to tremendous resistance once the family or the clinician attempts to impose appropriate restrictions (e.g., ceasing driving) on a patient who cannot appreciate the need for them.

### CONFABULATION

*Confabulation* is sometimes referred to as "honest lying." Confabulation is often seen in conjunction with memory impairment, with patients "filling in the gaps" in their memories with false information. It should be stressed that this is not willful deception on the part of the patient; rather, the patient is not aware that the information supplied is false. The nature of the confabulations may be fantastical or mundane, and at times, family members may be bewildered as to why the patient is "lying" about seemingly inconsequential information. The content

of the confabulation may be "stimulus-bound," in that ideas are irrationally linked solely because they are spatially or temporally contiguous (Lezak, 1995), although often the source of the confabulation is not readily apparent. As an example, a hospitalized 53-year-old patient with bilateral basal ganglia lesions had pronounced confabulation that could be readily elicited with very slight suggestion. Upon meeting the patient for the first time, the examiner said, "Good morning. Haven't we met before?" The patient readily replied, "Oh yes. We met in California at my brother's wedding last year." Although it was fairly early in the morning, when next asked, "Have you had lunch yet?" the patient responded, "Yes—we ate together. I had a hamburger, and you had the soup."

### MISIDENTIFICATION SYNDROMES

This group of disorders is typically classified as a form of delusional syndromes and involves delusional misidentification of people or places. Among these are included *reduplicative paramnesia*, in which patients believe that there is one or more duplicate of a known person or place. An example is an 81-year-old woman with likely dementia with Lewy bodies who believed that there was more than one (perhaps as many as six) of her boyfriend, "Bob." She was never certain as to which "Bob" she would be encountering when they planned to meet—she described one as older and more stable, one as younger, more handsome and fun, and so forth, and she often referred to "Bob" as "they." A similar misidentification syndrome is *Capgras syndrome*, in which patients believe that someone known to them has been replaced by an imposter. With both Capgras syndrome and reduplicative paramnesia, some patients may believe that there are multiples of themselves. Another related misidentification is the *Frègoli syndrome*, in which the patient believes that someone well known to them is impersonating and taking on the appearance of an actual stranger. An example of the latter, a 60-year-old woman with a likely early degenerative condition believed that a stranger in her gym was actually a friend of hers from the past, disguised as another person. She remained adamant about this belief, despite the stranger (and several others) repeatedly providing her with convincing evidence to the contrary. With all of these misidentification syndromes, the symptoms may or may not be distressing to the patient, but are often distressing to the family. In the case of the latter patient, she was unconcerned by her belief that her friend was impersonating someone

else at her gym, although the gym member felt harassed.

### Other Delusions

Patients with brain insults can also present with other, perhaps more "typical" delusions, including unrealistic concerns about poverty, infidelity of their spouses, or their health status. As with other psychotic delusional states, the content of the delusion may be culturally dependent or driven by clear environmental or historical events relevant to the patient.

#### HALLUCINATIONS

As noted, any psychiatric symptom can result from brain insult, with hallucinations being no exception. In certain CNS disorders, such as dementia with Lewy bodies, hallucinations are common occurrences and may be fairly characteristic in nature (e.g., in dementia with Lewy bodies, the hallucinations are typically visual, and almost always of people or animals). Hallucinations caused by neurologic insult may be of any modality—auditory, visual, tactile, gustatory, or olfactory—which in some ways distinguishes some of these hallucinations from those more typically encountered in primary psychiatric disorders. For example, olfactory hallucinations are relatively unusual in schizophrenia, a disorder in which the hallucinations are often auditory, but may be seen as a result of certain brain tumors, migrainous or epileptic auras, ictal activity, and the like—again, with the nature of the symptom depending on the location of the lesion/event.

### Treatment

Neuropsychiatric symptoms may not be immediately present or apparent after the causative insult. They may be overshadowed by more prominent deficits or pressing medical concerns, or they may emerge over time as the brain damage continues to evolve following the insult or with disease progression. Once present, the presence and intensity of the symptoms may fluctuate, but are unlikely to remit entirely (Cummings & Mega, 2003). These symptoms can obviously diminish the quality of life of the patient and may have a profound impact on his or her interpersonal relationships. Moreover, the presence of neuropsychiatric symptoms, particularly psychosis, is also often associated with increased morbidity and sometimes mortality in associated disease states (e.g., Almeida & Xiao, 2007). Thus, the need for careful assessment and thoughtful treatment of these symptoms is critical. The appropriate treatment may depend on the cause, nature, and severity of the symptom, and may include medication, psychotherapy, family therapy, structuring of environment, psychosurgery, and, foremost, education. It is critical to educate the patient about the cause and prognosis of these symptoms, as well as to educate the patient's family about nature of neuropsychiatric symptoms as not necessarily reflecting willful behavior by the patient (e.g., appreciating apathy in a stroke patient rather than attributing the behavior to "laziness"). Of note, patients with neuropsychiatric disorders may be more likely to develop side effects from drug therapy (Cummings & Mega, 2003). This concern should not prohibit attempts at treatment, but may necessitate closer monitoring. It may also be necessary to ensure regular input from family or significant others regarding treatment response, especially if the patient does not have full insight into his symptoms or an appreciation of how his behavior impacts others. As noted, the cause of the symptom may also dictate appropriate treatment. For example, in dementia with Lewy bodies, which often presents with visual hallucinations, neuroleptic medications are contraindicated and should be used only very sparingly and with close monitoring, although there may not be similar concern with using neuroleptics in treating hallucinations originating from other brain insults. Last, attention to caregiver stress is critical. These significant others are faced with multiple challenges, which may include mourning the loss of a loved one as they once knew him or her, taking on the role of a caregiver, and managing difficult behaviors, potentially from a patient who may resent the caregiver's involvement. Although caregivers can often derive some clear rewards from their roles, helping them adjust to this role, providing the framework for understanding the patient's behavior, and monitoring for negative mood states in the caregiver is critical—for both the caregiver's and the patient's psychological well-being.

Psychologists or psychotherapists may become involved with neurologically impaired individuals in order to address some of the behavioral and/or emotional changes that are a direct result of the neurological condition, or to assist the individual and his or her family members in adjusting to changes in functioning and lifestyle that can follow neurological injury or disease. Psychotherapists who do not work with neurologically impaired individuals, however, also encounter patients with significant cognitive symptoms. Although associated with a psychological rather than neurological condition, the cognitive symptoms can present a significant

functional disability. The next section will review the neuropsychological characteristics of several psychological disorders.

## Neuropsychological Aspects of Psychological Disorders

Psychological disorders are often accompanied by cognitive symptoms. In the past, these cognitive symptoms were considered to be secondary to the psychological condition, with the expectation that cognitive difficulties would resolve as psychological symptoms remitted. In some cases, cognitive impairment was sufficiently severe to present as a dementia, and the term *pseudodementia* was used to refer to such psychologically based cognitive impairment. Over the years, however, it has become evident that cognitive impairment is not fully attributable to emotional symptoms. There is growing evidence that cognitive impairment persists after remission of psychological symptoms, and research has identified neuroanatomical abnormalities for some psychological disorders that could provide a neurological basis for the associated cognitive dysfunction. It has also become evident that the presence of cognitive impairment can significantly interfere with the psychological patient's functioning at home, school, and/or work. Therefore, neuropsychological impairment may be an important focus of treatment for some individuals with psychological disorders.

In this section, the neuropsychological correlates of anxiety disorders, mood disorders, somatoform disorders, and some of the personality disorders will be reviewed.

### Personality Disorders

The personality disorders that have received the most research with regard to neuropsychological functioning are borderline personality disorder (BPD), antisocial personality disorder, and schizotypal personality disorder. Little if any research on the neuropsychological correlates of the remaining personality disorders has been completed and, therefore, these disorders will not be included in this discussion.

#### BORDERLINE PERSONALITY DISORDER

Individuals diagnosed with BPD frequently have cognitive difficulties, particularly memory difficulties. Their memory for recent events may be problematic, and they may have difficulty remembering information from therapy sessions. Additionally, long-term recall of autobiographical information may be distorted. These memory difficulties are often considered

to be psychologically based, reflecting motivated forgetting, denial mechanisms, or resistance. Research into the neuropsychological correlates of BPD, however, has explored whether these cognitive symptoms and the characteristic behavioral symptoms of affective dysregulation and impulsivity are related to underlying neuropsychological impairment.

The majority of the research has found that individuals with BPD perform lower on neuropsychological testing than comparison samples; however, a distinct profile of neuropsychological dysfunction has not emerged, and findings across studies have been inconsistent. A recent meta-analysis (Ruocco, 2005) of ten studies revealed that individuals with BPD performed significantly lower than did healthy comparison groups on tests of attention, processing speed, memory, cognitive flexibility, planning, and visuospatial abilities. Planning ability, as measured by performance on the Tower of London, was the greatest areas of cognitive weakness, with BPD patients requiring more time on planning tasks and making more errors (Bazanis et al., 2002). In another review of the literature, Monarch, Saykin, and Flashman (2004) reported that verbal memory, attention, and executive abilities were the most frequently found areas of cognitive deficiency in BPD, although several studies found no evidence of neuropsychological dysfunction. Legris and van Reekum (2006) reviewed 29 studies and found that the most commonly compromised areas of neuropsychological functioning in BPD was attention, response inhibition, and initiation; planning, intellectual abilities, and spatial working memory were the least commonly found deficient. The inconsistencies in this literature are evident in these reviews.

A weakness in this research is that the study participants have often had comorbid psychological disorders, including antisocial personality disorder and major depressive disorder (MDD), both of which commonly co-occur with BPD. Kunert, Druecke, Sass, and Herpertz (2003) found no evidence of neuropsychological dysfunction in a BPD group who did not have an Axis I disorder or evidence of antisocial personality. Further, individuals with co-morbid BPD and MDD, and individuals with MDD, have been found to perform similarly on neuropsychological measures, suggesting that MDD underlies any neuropsychological dysfunction in BPD (Fertuck et al., 2006). However, Monarch et al. (2004) found evidence of impaired levels of performance on tests of verbal memory and attention/vigilance, along with significantly lower but not impaired range scores on measures of visuomotor speed, visual memory, spatial

organization, verbal intelligence, and language, in a BPD sample had no comorbid Axis I or Axis II disorders.

In summary of this clinical literature, there is growing evidence that BPD is associated with neuropsychological dysfunction, and there is some evidence that this is not entirely due to a comorbid psychological disorder or personality disorder. A specific pattern of neuropsychological deficits has not been identified, but it appears that attention, memory, and executive abilities are commonly compromised. It is important to recognize that, although the BPD groups perform at a significantly lower level than the comparison groups, test performances have not necessarily fallen within the impaired range. Further, not everyone with BPD has neuropsychological dysfunction. It is not clear whether neuropsychological dysfunction plays a causal role in BPD. There is some empirical work showing that children with borderline features evince weakness in attention/vigilance, cognitive flexibility, and abstraction. This suggests that neuropsychological dysfunction may be present early on in BPD, and has led to considerations that neuropsychological dysfunction is a feature BPD rather than a consequence of the disorder, and that it may underlie many of the symptomatic characteristics of BPD, including impulsivity and affective dysregulation. An association between neuropsychological dysfunction and self-injurious behavior has also been identified in BPD, although this requires further study (Bazanis et al., 2002; Legris et al., 2006; Monarch et al., 2004).

**ANTISOCIAL PERSONALITY DISORDER**

The neuropsychological functioning of individuals with antisocial behavior has received considerable research attention, primarily in an effort to develop an understanding of the etiology of this behavior. Clinical cases of individuals with brain injury who develop characteristics commonly associated with antisocial personality disorder and psychopathy have raised questions as to whether individuals with longstanding antisocial behavior or psychopathic personality have underlying neurological or neuropsychological dysfunction. The most famous clinical case of the development of socially deviant behavior following brain injury is Phineas Gage. Gage was a railroad worker who had an iron-tamping bar driven through the front of his head in a dynamite explosion. Following this injury, Gage, who had been a responsible and hard-working individual prior to injury, showed profound changes in his behavior, including impaired judgment, impaired planning

and organization, tactless and impulsive behavior, and emotional lability (Harlow, 1868). Subsequent clinical cases have revealed that marked personality changes of the type exhibited by Gage can occur with brain damage involving the prefrontal cortex, and these changes are commonly characterized by impaired decision making, impaired empathy/social insensitivity, social inappropriateness, emotional blunting, affective dysregulation, impaired goal-directed behavior, and lack of insight into the personality changes (Barrash, Tranel, & Anderson, 2000).

Much of the research on individuals with antisocial behavior that is not acquired from a brain injury has focused on executive functioning. This research has revealed a strong relationship between antisocial behavior and impairment in aspects of executive functioning including conceptual reasoning, response inhibition and impulse control, planning, mental flexibility, and initiation (Morgan & Lilienfeld, 2000). An emerging finding from this research is that the neuropsychological functioning varies among the different groups of individuals who exhibit antisocial behavior. There are a variety of groups of individuals with antisocial behavior, including individuals with antisocial personality disorder, conduct disorder, psychopathic personality traits, criminals, and juvenile delinquents. Inconsistencies in research findings appear to be due, in part, to variations in the antisocial behavior groups studied. This point was highlighted in a meta-analysis of 39 studies of executive functioning and antisocial behavior, which found that individuals with a history of criminal behavior or delinquency had greater impairment in executive abilities than did individuals with psychopathy, conduct disorder, or antisocial personality disorder. Individuals diagnosed with antisocial personality disorder tended to evidence the mildest level of executive dysfunction (Morgan & Lilienfeld, 2000).

The neuropsychological functioning of individuals with psychopathic personality appears to differ from individuals with antisocial personality disorder. Psychopathic personality is characterized by a lack of empathy and remorse, manipulativeness, fearlessness, impulsivity, superficial charm, shallow affect, and irresponsibility. Psychopaths appear to lack a conscience, and appear unconcerned about any punishment for their actions (Lykken, 2006). Although most psychopaths meet the diagnostic criteria for antisocial personality disorder, many individuals with antisocial personality disorder do not have psychopathic personalities. In terms of executive abilities, most of the research has identified a deficit in impulse control/behavioral inhibition,

with other aspects of executive functioning unimpaired (Blair et al., 2006; Hiatt & Newman, 2006; Hiatt, Schmitt, & Newman, 2004; Mitchell, Colledge, Leonard, & Blair, 2002). In addition, a deficiency in attentional regulation has been identified, with psychopaths showing a reduced ability to allocate attention to peripheral information while focused on a task. Language deficits have also been identified. Psychopaths show difficulty using connotation and understanding the emotional content of language (Hiatt & Newman, 2006; Hiatt, Schmitt, & Newman, 2004).

There has also been considerable study of neuropsychological functioning of children and adolescents with antisocial behavior and/or conduct problems. This research has found deficits in verbal and executive abilities. Children and adolescents with significant conduct problems tend to have low verbal intelligence, impaired verbal memory, poor auditory processing, poor attention, and impairment in executive abilities that include conceptual/abstract reasoning, initiation, planning, and response inhibition. The presence of comorbid attention-deficit hyperactivity disorder (ADHD) is associated with greater neuropsychological impairment (Lynam & Henry, 2001). A more recent examination (Raine et al., 2005) of the neuropsychological functioning of adolescents with a history of antisocial behavior found that difficulties might also involve nonverbal abilities. They found that adolescents with a history of antisocial behavior performed significantly lower than the comparison group on measures of verbal and nonverbal intelligence, verbal and nonverbal memory, and attention. Of some interest was that these neuropsychological weaknesses remained even when the antisocial behavior was no longer present; that is, children with a prior history of antisocial behavior, but who no longer exhibited this behavior, continued to manifest neuropsychological weakness compared to controls. In summary, then, this research indicates that neuropsychological dysfunction is present in children and adolescents who exhibit antisocial behavior and may play a role in the development of this behavior. Those children and adolescents with comorbid ADHD tend to have more severe neuropsychological dysfunction and a greater risk for more severe antisocial behavior.

SCHIZOTYPAL PERSONALITY DISORDER

The schizophrenia spectrum disorders, which include schizophrenia, schizoaffective disorder, schizoid personality disorder, and schizotypal personality disorder, are associated with cognitive dysfunction. Most research has been completed on schizophrenia and schizotypal personality disorder (SPD). In schizophrenia, there is severe and global neuropsychological impairment; that is, most aspects of cognitive functioning are severely compromised. In SPD, neuropsychological dysfunction is present but is more circumscribed and less severe than in schizophrenia. Some of the research has found that individuals with SPD, when compared to individuals without a psychological diagnosis, perform significantly lower across a broad range of neuropsychological abilities and, specifically, verbal intelligence (i.e., vocabulary, factual knowledge, word reading), spatial abilities, visuomotor abilities, attention, memory, working memory, abstract reasoning, and cognitive flexibility (Matsui, Sumiyoshi, Kato, Yoneyama, & Kurachi, 2004). Other studies, however, have found individuals with SPD to perform significantly lower than control subjects only on measures of verbal and/or visual memory, working memory, and abstract reasoning (Mitropoulou, Harvey, Maldari, et al., 2002; Mitropoulou, Harvey, Zegarelli, et al. 2005; Siever et al., 2002; Voglmaier et al., 2005), and the impairment in these areas is mild. There is some evidence that the neuropsychological functioning in SPD is characterized by deficits in working memory and information processing capacity, and that these deficits underlie all other cognitive symptoms/impairments found in this population (Barch et al., 2004; Harvey, Romero, Reichenberg, Granholm, & Siever, 2006; Mitropoulou et al., 2005; Moriarty et al., 2003).

Schizotypal personality disorder is characterized by impaired social and interpersonal functioning, with eccentric behavior and appearance, social discomfort, odd beliefs, and perceptual distortion. There may be an association between neuropsychological impairment and social/interpersonal dysfunction in this disorder, with greater working memory impairment and relatively lower intellectual abilities correlated with greater social difficulty (Mitropoulou et al., 2005; Trotman, McMillan, & Walker, 2006). Similar findings have been reported for individuals with schizophrenia (Trotman et al., 2006).

### Somatoform Disorders

The somatoform disorders are characterized by the presence of physical symptoms that cannot be fully explained by a medical condition. The symptoms are not intentionally produced; that is, the individual believes that the physical symptoms are due to a medical cause and is unaware of the underlying psychological factors that could explain the symptoms.

Physical symptoms such as pain, paralysis, blindness, and seizures are considered the more classic presentation in somatoform disorder. It has become clear over the years, however, that individuals can also report significant cognitive symptoms that cannot be explained by an underlying a medical/neurological condition or another psychiatric condition. Although individuals with these presentations are sometimes diagnosed with a somatoform disorder, there has been discussion within the field of neuropsychology as to whether the current *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) diagnostic criteria are adequate to apply to these conditions. One problem that has been identified is that the current criteria specify the presence of "physical symptoms," and cognitive symptoms do not easily fit under this rubric (Binder, 2007; Boone, 2007; Delis & Wetter, 2007; Larrabee, 2007). Despite questions of the correct diagnostic label, however, the fact that an individual can manifest cognitive symptoms that are sometimes severe and debilitating and that are not associated with an underlying neurological or medical conditions is important to appreciate. Reinforcement of the individual's belief that he or she is experiencing severe deficits that are due to an underlying neurological condition can serve to perpetuate and perhaps worsen the individual's symptom.

The neuropsychological presentations of individuals with somatoform-like conditions fall into two general groups. In some cases, the individual will report cognitive difficulties and are preoccupied with cognitive and functional difficulties; however, there is no objective evidence of difficulties on psychometric testing or in daily living. The cognitive symptoms reported are typically common and perhaps associated with stress, fatigue, or normal age-related changes, but the individual interprets these symptoms as indicators of a serious neurological condition (Boone, 2007). The clinical presentation of these individuals is similar to hypochondrias. The other group of individuals with somatoform-like conditions has clinical presentations that are similar to somatization or conversion disorder. These individuals have marked cognitive symptoms and marked difficulty in daily functioning in the absence of any medical or neurological condition that could explain these symptoms. On psychometric testing, they may perform well despite severe cognitive and functional difficulties, or the test findings may show some areas of impaired ability, but the nature and extent of the impairment are not compatible with

severe disability. In other cases, there may be evidence of severe cognitive impairment on testing that cannot be accounted for neurological factors (Cicerone & Kalmar, 1995; Delis & Wetter, 2007). The symptoms may be unusual and, in some cases, incompatible with a brain-related disorder. An example of unusual symptoms would be an inability to recognize family members and inability to recall other autobiographical information following a mild cerebral concussion.

In both conversion disorders and somatization disorders, psychological factors are conceptualized as the underlying cause of the physical/cognitive symptomatology. In somatization disorder, the individual has a tendency to express psychological distress physically or cognitively. In conversion disorder, the classic conceptualization is that emotional distress associated with a trauma is unconsciously suppressed and converted into physical/cognitive symptomatology by the individual. In both disorders, the primary gain from the physical/cognitive symptoms is decreased emotional distress. The symptoms often elicit changes in the individual's lifestyle that may serve as positive reinforcement for these symptoms. These results are referred to as *secondary gains*. An inability to continue with employment or to complete household responsibilities, or the positive attention, nurturing and/or assistance gained from others as a result of the physical/cognitive symptoms are examples of secondary gains that can play a significant role in the continuance of physical symptoms and disability. The fact that the symptoms are due to psychological factors has implications for the information provided to the patient regarding etiology and prognosis, as well as the treatment approach but does not diminish the significance of the individual's perceived symptoms and difficulties. It is important to recognize that the symptoms are "real" to the individual.

There has been limited examination of the neurobiological and neuropsychological correlates of somatoform disorders. The research on conversion disorder has been completed with individuals with physical or sensory symptoms, such as paralysis or numbness, and therefore it is not clear if these findings generalize to cases involving cognitive symptoms. It has been proposed that individuals with conversion disorder have a deficit in higher-level information processing (Roelofs, vanGalen, Eling, Keijsers, & Hoogduin, 2003; Sierra & Berrios, 1999; Tallabs, 2005). This deficit is thought to be due to psychological stress, which disrupts higher-level processing but does not impact lower-level information

processing. Lower-level information processing refers to the processing of information that occurs automatically, almost reflexively, with minimal cognitive effort or conscious awareness. Commonly referred to as *automatic processing*, this is the component of our information processing system involved when carrying out well-learned behavior or routines. Such tasks are completed effortlessly and without explicitly thinking about the behavior. In contrast, higher-level information processing requires explicit, effortful, conscious attention and processing. Higher-level information processing is required when involved in novel, nonroutine situations, where directed, effortful attention and processing is required to complete a task or carry out a behavior. A deficit in higher-level information processing with intact lower-level processing may explain the common observation that those individual with a conversion disorder may not have symptoms in situations where they are not thinking about the symptoms. More clearly, an individual with conversion paralysis of the arm may be observed to automatically move the arm to avoid hitting something or to reflexively catch a ball, but is unable to intentionally move the arm during a medical examination or physical therapy.

Brown (2004) has proposed a different conceptual model that subsumes both conversion disorder and somatization disorder. In this model, the automatic information processing system is the source of the problem. The automatic information processing system is the first level of processing at which various schemata are automatically activated, and this occurs without conscious awareness. In conversion and somatization disorder, it is theorized that a stimulus activates incorrect information regarding physical symptoms. Essentially, there is a mismatch between the current stimuli and the information that is activated and used to interpret the stimuli. The individual is unaware of the error in interpretation because the activation of the incorrect information occurs without his or her awareness. An important component of this model is self-focused bodily attention, as attention to bodily symptoms is necessary to activate the schema regarding physical symptoms. Self-focused bodily attention is often found in introspective individuals, individuals with depression or anxiety, or in the context of boredom. Self-focused bodily attention may also be a learned behavior developed within a family system, in which physical (or cognitive) symptoms were considered significant and likely reflective of serious illness. In addition, individuals encountering high levels of emotional distress associated with trauma can become focused on bodily symptoms to avoid thoughts or emotions associated with the trauma. Brown (2004) also discusses the various sources that contribute to our knowledge about physical symptoms, some of which may not be accurate. These include experiences when physically ill in the past, observations of others with a physical illness, or sociocultural conceptions of specific disorders and the symptomatology associated with these disorders, even if inaccurate. He notes that many individuals with a diagnosis of a somatoform disorder have a prior history of illness or exposure to other's illness, both of which have probably contributed to their beliefs regarding symptoms and disability associated with illness and/or injury.

## Mood Disorders

### BIPOLAR DISORDER

Neuropsychological dysfunction is associated with bipolar disorder. The most consistent findings across studies are impairment in attention, processing speed, verbal learning and memory, and executive abilities with respect to inhibitory control, conceptual reasoning/abstraction, cognitive flexibility, fluency, and working memory (Green, Cahill, & Malhi, 2007; Gruber, Rathgeber, Braunig, & Gauggel, 2007; Malhi et al., 2007). Some research has also found deficits in visual memory (Depp et al., 2007). There may be some variation in the pattern and severity of neuropsychological deficits during the depressed and manic/hypomanic phases of the disorder. Individuals with manic/hypomanic symptoms may have greater impairment in attention, processing speed, and inhibitory control than do individuals with depressed bipolar disorder (Gruber et al., 2007). Neuropsychological dysfunction appears to be present very early in bipolar disorder. A recent study of first-episode bipolar disorder patients found deficits in processing speed and executive abilities (i.e., poor abstraction/conceptual reasoning, poor mental flexibility, and poor inhibitory control). These researchers did not include a broad spectrum of neuropsychological functions, limiting their focus to executive functioning, so it is not known if other cognitive deficits are also present early (Gruber, Rosso, & Yurgelun-Todd, 2008). Although cognitive impairment is present at the onset of the disorder, there is some evidence that impairment is more pronounced in older individuals with bipolar disorder, particularly with respect to processing speed (Depp et al., 2007).

As symptoms remit, the cognitive functioning of bipolar patients improves, but there remains evidence of impairment even during the asymptomatic

phase of the disorder (Gruber et al., 2007; Malhi et al., 2007). Recent meta-analytic reviews have found that euthymic bipolar patients perform significantly lower than do healthy controls on measures of sustained attention, processing speed, verbal learning and memory, delayed visual memory, and aspects of executive abilities and specifically, verbal fluency, working memory, conceptual reasoning, and mental control/flexibility (Arts, Jabben, Krabbendam, & van Os, 2008; Torres, Boudreau, & Yatham, 2007). Several variables may contribute to the findings of cognitive dysfunction in euthymic patients, and these require further exploration. Many of the studies have included medicated patients, which raises the possibility that the findings of neuropsychological dysfunction in asymptomatic bipolar patients is due to medication effects; although at least one study did not find any evidence of a significant medication effect on neuropsychological testing (Martinez-Aran et al., 2007). Another factor of consideration is that the euthymic patients included in these studies may have had subclinical mood symptoms that impacted testing. However, some research has found evidence of neuropsychological dysfunction even when subclinical symptoms are controlled, although the pattern of deficits may be more circumscribed. Specifically, Mur, Portella, Martinez-Aran, Pifarre, and Vieta (2007) reported deficits in processing speed, cognitive flexibility, inhibitory control, and working memory in a sample of individuals with either bipolar I or bipolar II disorder when subclinical mood symptoms were controlled. Attention, verbal memory, and visual memory abilities were not significantly different from a comparison group. These researchers also examined a subgroup of the sample whose medication was limited to lithium rather than multiple medications. In this group, neuropsychological deficits were limited to poor inhibitory control. This finding suggests that euthymic bipolar patients prescribed multiple medications may evidence more extensive neuropsychological dysfunction. There is also evidence that euthymic bipolar patients taking multiple medications have greater psychosocial impairment (Martinez-Aran et al., 2007). Whether this is due to medication effects or the severity of the illness is not clear.

In light of evidence of neuropsychological dysfunction during asymptomatic phases, cognitive impairment has been discussed as a possible trait of bipolar disorder. Further, findings of neuropsychological dysfunction in first-degree relatives of individuals with bipolar disorder have raised the possibility that cognitive impairment is a genetic risk factor for this disorder. A meta-analytic review of 14 studies found that first-degree relatives performed significantly lower than did controls on measures of verbal memory and mental control/flexibility. The effect sizes were small, indicating that the cognitive difficulties were not as great as those found in bipolar disorder patients (Arts et al., 2008). Finally, neuroimaging studies have also found abnormalities in the prefrontal and subcortical brain regions of bipolar patients, which appeared to be present at the onset of the disorder (Green, Cahill, & Malhi, 2007; Gruber et al., 2008).

Neuropsychological functioning is associated with functional outcome in bipolar disorder, and has been found to predict functional outcome better than clinical variables such as premorbid adjustment, symptom severity, or history of psychosis or substance use. Of particular relevance is verbal memory and executive abilities (i.e., working memory, inhibitory control, and verbal fluency), both of which have been shown to have the strongest relationship with the occupational and interpersonal functioning of bipolar disorder patients than other cognitive functions (Martinez-Aran et al., 2007; Tabares-Seisdedos et al., 2008).

## MAJOR DEPRESSIVE DISORDER

Individuals with depressive disorders often complain of difficulty with concentration and memory. In some cases, neuropsychological evaluation reveals no objective evidence of cognitive impairment. In these cases, the cognitive difficulties appear to be secondary to emotional distress. In other cases, however, neuropsychological evaluation reveals areas of deficiency. It is well accepted that neuropsychological impairment can accompany MDD, but cognitive impairment has also been identified in individuals with other depressive disorders including dysthymia, depressive disorder not otherwise specified, and adjustment disorder with depressed mood. The severity and extent of neuropsychological impairment increases with an increase in the severity of the depressive disorder (Castaneda et al., 2008a; Elderkin-Thompson, Kumar, et al., 2003; Paelecke-Habermann, Phol, & Leplow, 2005). Although there has been some inconsistency in the research, the most commonly identified areas of cognitive impairment in depressive disorders are attention, psychomotor processing speed, and executive functioning involving cognitive flexibility, planning, problem solving, and fluency. Verbal and visual memory impairment has been identified as a correlate of depression in some studies (Castaneda et al., 2008a; Naismith et al.,

2003). Depressed individuals typically evince more difficulty on tasks requiring effortful attention and information processing, and there is some thought that poor performance on memory testing might reflect the effortful processing demands required for new learning, rather than impairment in memory ability per se (Gualtieri, Johnson, & Benedict, 2006). In addition, some research has linked memory impairment with illness chronicity, with those individuals who have a history of multiple depressive episodes showing memory impairment (Dotson, Resnick, & Zonderman, 2008).

Similar to the findings with bipolar disorder, neuropsychological dysfunction has been identified in asymptomatic individuals with MDD. Deficits may persist in executive functions (Castaneda, et al., 2008b; Clark, Sarna, & Goodwin, 2005), memory (Castaneda, et al., 2008b; Neu, Bajbouj, Schilling, Godemann, Berman, & Schlattmann, 2005), and attention (Paelecke-Habermann et al., 2005; Weiland-Fiedler et al., 2004) Additionally, neuropsychological dysfunction, and specifically impairment in cognitive flexibility, has been identified in unaffected first-degree relatives of individuals with MDD. These findings suggest that neuropsychological dysfunction may be a cognitive trait marker, or endophenotype, of MDD but this requires further scientific investigation (Clark et al., 2005).

Several factors have been found to be associated with an increased risk of cognitive impairment. Older individuals tend to have more prominent cognitive impairment in general, and particularly individuals with late-onset depressive illness, typically defined as having the first depressive episode after age 50. The chronicity of depressive episodes is also relevant in older individuals, with those having persistent depressive symptoms or multiple depressive episodes in later life showing greater decline in cognitive ability (Dotson et al., 2008; Elderkin-Thompson et al., 2003). Depression in older age groups can often be treatment resistant, and cognitive symptoms may not completely remit after depression subsides. The presence of an underlying neurodegenerative dementia is often raised in these cases. A concern about dementia is warranted, as depression can be an early sign of a neurodegenerative illness, such as Alzheimer disease (Dotson et al., 2008; Gualtieri et al., 2006).

Neuropsychological dysfunction is associated with functional disability in depressive illnesses. Cognitive impairment has been found to interfere with employment, education, and the ability to complete daily responsibilities in general (Jaeger, Berns, Uzelac, & Davis-Conway, 2006).

## Anxiety Disorders
Research on the neuropsychological correlates of anxiety disorder has largely focused on obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD), and therefore, this review will focus on these two disorders.

### OBSESSIVE-COMPULSIVE DISORDER
The neuropsychological functioning of individual's diagnosed with OCD has received a great deal of research attention, primarily in the interest of identifying the neuropathological substrates of this disorder. Obsessive-compulsive disorder has been associated with frontal-subcortical dysfunction, and specifically with abnormalities involving the pre-frontal region, caudate nucleus, and the anterior cingulate cortex (Chamberlain, Blackwell, Fineberg, Robbins, & Sahakian, 2005; Kuelz, Hohagen, & Voderhlozer, 2004). The neuropsychological correlates of OCD vary across research studies, perhaps associated with factors such as medication, symptom severity, age of onset, and comorbid psychological disorder (Kim, Park, Shin, & Kwon, 2002; Kuelz, Hohagen, & Voderhlozer, 2004; Segalas et al., 2008). Among this variability, however, there have been fairly consistent findings of impairment in aspects of executive abilities and nonverbal memory. Visuospatial abilities and processing speed have also been identified as areas of deficiency in OCD, but these findings have been variable across studies (Anderson & Savage, 2004; Castaneda, et al., 2008b; Chamberlain et al., 2005; Greisberg & McKay, 2003; Harris & Dinn, 2003). In regard to executive impairment, the most commonly reported area of deficiency is response inhibition; that is, the ability to inhibit a well-learned or habitual response. Cognitive flexibility has also been identified as a common area of deficiency in the executive abilities of individual with OCD. There have been inconsistent findings showing impairment in other aspects of executive functioning, and specifically, conceptual skills, verbal fluency, and planning (Andres et al., 2008; Kim et al., 2002; Kuelz et al., 2004). Some research suggests that memory impairment in OCD may be associated with executive dysfunction. Analysis of the pattern of performance on memory testing has revealed a deficit in organizing information to facilitate learning. Individuals with OCD typically will not have difficulty with memory tasks involving organized or structured information (Anderson et al., 2004 Greisberg & McKay, 2003; Kuelz et al., 2004; Penades, Catalan, Andres, Salamero, & Gasto, 2005). Impairment on nonverbal memory tests have

been the most frequent finding in OCD; however, verbal memory impairment has been identified in some studies, and this may emerge on those verbal learning tests that require application of organizational strategies for learning, such as word-list learning tests (Chamberlain et al., 2005; Greisberg & McKay, 2003; Kuelz et al., 2004). These findings suggest that memory techniques for organizing to-be-learned information may be an avenue for improving the memory functioning in individuals with OCD.

As with the mood disorders, there is growing evidence of persistence in neuropsychological dysfunction in individuals with OCD, even after symptoms are significantly reduced or have remitted. Although cognitive abilities improve, continued deficits in nonverbal memory and executive functioning during less symptomatic periods have been reported; however, persisting neuropsychological dysfunction has not been found in every study (Andres et al. 2008; Rao, Janardhan, Kumar, Kandavel, & Chandrashekar, 2008; Roh et al., 2005). Whether nonverbal memory and executive dysfunction are cognitive traits or endophenotypes of OCD remains an area of ongoing investigation.

POST-TRAUMATIC STRESS DISORDER
Individuals diagnosed with PTSD commonly report significant cognitive difficulties, usually involving concentration and memory. The frequency of cognitive symptoms in PTSD patients was a primary impetus for the scientific investigation of the underlying neuropsychological and neuropathological bases for these symptoms. Research has identified neuropathological abnormalities in PTSD involving the frontal and limbic regions of the brain (Dickie, Brunet, Akerib, & Armony, 2008; Vasterling & Brailey, 2005), and recent work suggests possible involvement of the parietal lobe (Weber et al., 2005). Neuropsychological dysfunction has also been associated with PTSD. Individuals with PTSD often evidence deficits in aspects of attention and specifically, sustained attention and working memory. Memory impairment is also a common neuropsychological correlate of this disorder and is characterized by deficiency in encoding and retrieval memory processes, but with generally intact storage (i.e., retention) ability. In addition, individuals with PTSD may be more susceptible to interference effects on learning (Koenen et al., 2001; Vasterling & Brailey, 2005). Executive dysfunction is also associated with PTSD involving response inhibition and verbal fluency (Castaneda et al., 2008b; Koenen et al., 2001; Vasterling & Brailey, 2005). There is some evidence

of a worsening of memory impairment in aging individuals with PTSD, which may be due to the chronicity of condition and/or aging effects (Golier, Harvey, Legge, & Yehuda, 2006; Yehuda, Golier, Halligan, & Harvey, 2004; Yehuda, Golier, Tischler, et al., 2005). Of some diagnostic importance is that retention processes remain uninvolved, which distinguishes this memory decline from the pattern typically associated with Alzheimer's disease.

The cause of the neuropathological and neuropsychological dysfunction in PTSD is an area of ongoing investigation (Vasterling & Brailey, 2005). Animal models have shown that stress can cause neurobiological and neuropsychological changes, and these findings support the view that PTSD is the cause of cognitive and neuropathological abnormalities identified in humans. There is also support, however, for the alternative viewpoint that neuropsychological dysfunction and neuropathological abnormalities are risk factors for PTSD. That is, those individuals who develop PTSD following trauma have pre-trauma cognitive and neurobiological compromise that increased their vulnerability to develop the disorder. Vasterling and Brailey (2005) suggests that neuropsychological dysfunction may be both a risk factor and a consequence of PTSD. Those who develop this disorder following a traumatic experience may have less cognitive resources to cope with the stress, and their cognitive functioning is further compromised with the onset of PTSD.

## Neuropsychological Treatment in Psychiatric Disorders
Neuropsychological rehabilitation, also referred to as *cognitive rehabilitation*, concerns the treatment of cognitive, behavioral, and emotional changes that are due to a neurological injury or condition, such as a traumatic brain injury or stroke. The approaches to neuropsychological rehabilitation are varied, but most emphasize restoration of cognitive/behavioral functions and training in methods of compensating for impaired functions. Scientific evidence supports the efficacy of cognitive rehabilitation of neuropsychological impairments due to neurological insult, and practice recommendations have been proposed based upon this research (Cicerone et al., 2000; Cicerone et al., 2005; Laatsch et al., 2007).

Neuropsychological rehabilitation is not a typical component in the treatment of psychiatric disorders. There are, however, certainly exceptions, with schizophrenia being the best example of a psychiatric disorder for which cognitive remediation techniques are often employed, and it is the example

that will be used here in describing the application of cognitive rehabilitation to psychiatric disorders.

Schizophrenia has been shown to impact virtually all cognitive domains. Although there may be tremendous variability among patients with regard to the extent and nature of the deficits, cognitive impairment can rightfully be considered a "core" aspect of the disease. Multiple studies have demonstrated that cognitive dysfunction in schizophrenia is strongly associated with poor psychosocial outcome, even more so than the clinical symptoms of the disease (Wexler & Bell, 2005). Cognitive deficits have also been shown to be strong predictors of response to psychiatric rehabilitation (McGurk, Twamley, Sitzer, McHugo, & Mueser, 2007), as well as predictors of work capacity and quality (Bell, Bryson, & Kaplan, 1999), independent living, social relationships/social skills, and ability to provide self-care (McGurk et al., 2007). Furthermore, current psychopharmacologic treatments have no notable benefit in treating the cognitive deficits associated with the disorder (Marder, 2006). As such, it is not surprising that cognitive functioning has been a target for intervention in schizophrenia, and there is a more than 40-year history of cognitive remediation programs in the treatment of the disorder (McGurk et al., 2007).

As in the treatment of cognitive deficits in neurologic disorders, two general strategies have been employed in the treatment of cognitive deficits in schizophrenia. These typically include compensatory strategies designed to circumvent deficits, and cognitive remediation techniques to enhance/restores deficient areas. Often, the latter involves extensive repetition of the same activity, under the assumption that this repetition leads to an increase in the number of active brain cells in regions of the brain that have been underutilized/avoided, and unrewarded (Wexler & Bell, 2005). Alternatively, programs may include "strategy coaching," in which patients are taught methods to facilitate memory recall (e.g., "chunking" information) and problem-solving skills, with the hope that the latter will provide better transfer of skills from the training setting to daily life (McGurk et al., 2007). Additional strategies include combining cognitive remediation with vocational rehabilitation, with the rationale that cognitive exercise may enhance vocational interventions, while in turn, work activity may provide appropriate opportunities for the practice and generalization of cognitive strategies (Wexler & Bell, 2005).

Some review papers that examined the impact of compensatory and restorative techniques have been discouraging, indicating that there appears to be minimal benefit beyond outcomes such as improvement on the trained task (without meaningful generalization) or on closely related but untrained measures (Wexler & Bell, 2005). A recent meta-analysis, however, more closely examined the impact of cognitive remediation on functional outcomes (McGurk et al., 2007). Results of the study showed highly consistent findings among studies, with a moderate effect of remediation on overall cognitive performance (0.41) despite notable variability in the setting, patients, and training methods. There was evidence of maintenance of those gains in the few studies that provided longitudinal follow-up. The effect size of remediation on improvement of clinical symptoms was smaller, but significant (0.28). The overall effect on psychosocial functioning was also small (0.35), but highly variable from study to study. For the latter outcome, McGurk et al. (2007) found that the impact on psychosocial outcomes was much greater in remediation programs that also provided adjunctive psychiatric rehabilitation (effect size = 0.47) than in those that did not (effect size = 0.05), or in programs that provide psychiatric rehabilitation alone (e.g., social skills training). They suggest that these findings challenge the assumption that improvement in cognition can lead to spontaneous improvement in psychosocial functioning, but, rather, that there may be some synergistic effect of these two treatment approaches.

## Conclusion

Clinical neuropsychology is a field that is concerned with understanding the relationship between brain functioning and cognitive abilities, emotional functioning, personality, and behavior. As presented in this chapter, emotional and behavioral changes are often the direct result of neurological injury or disease, and these changes can mimic psychological disorders. Perhaps such clinical observations have led, in part, to the investigation of the neurobiological bases and neuropsychological correlates of psychological disorders. Neuropathological abnormalities and neuropsychological dysfunction have been identified for several Axis I and Axis II psychological disorders. Recent findings showing neuropsychological dysfunction in asymptomatic individuals with psychological disorders, as well as their asymptomatic family members, has introduced the possibility that neuropsychological dysfunction is a trait marker and/or risk factor for certain psychological disorders. Research has also shown that neuropsychological impairment is a substantial factor in the level of

**Table 30.3  When is a neuropsychological consultation indicated?**

- Forgetting that the topic has already been discussed
- Short-term memory problems
- Needing things repeated over and over again
- Confusion/disorientation
- Frequently losing/misplacing items (e.g., house keys, mail)
- Perseveration; behaviorally or verbally
- Problems with paying bills on time
- Problems managing/maintaining finances
- Problems with following step-wise instructions (e.g., sequence of a cooking recipe)
- Getting lost while driving, especially in familiar locations
- Failure to maintain an accurate debit card or checking account balance (e.g., over-the-limit or insufficient funds notification)
- Change in personal hygiene (e.g., not bathing, brushing teeth, etc.)
- Change in personality (e.g., blurting out socially inappropriate comments)
- Inappropriate behavior (e.g., touching others inappropriately)
- Deterioration in maintaining their household (e.g., dishes not washed, kitty litter not attended to, refrigerated food not put away properly)
- Unsafe behaviors (e.g., forgetting and burning food on the stove, not closing and locking entry doors)

functional disability experienced by the individual with a psychological disorder.

Clinical psychology plays an essential role in caring for the neurologically impaired patient. Behavioral and cognitive-behavioral techniques can have utility in managing and/or modifying problematic behavior and emotional dysregulation. Psychological support and treatment also play an important role in assisting the neurologically compromised individual and his or her family in adjusting to the changes in functioning and family life that often accompanies neurological injury or disease. Neuropsychology can play a role in the treatment of individuals with psychological disorders. In some cases, the psychotherapist or clinical psychologist may have concern about a neurological cause for an individual's psychological and/or behavioral difficulties. Such questions commonly arise in older individuals, in whom the typical concern is about the presence of a neurodegenerative illness in the context of significant memory decline. In addition to diagnostic issues, however, neuropsychology can also be of benefit in understanding the neuropsychological functioning of individuals with psychological disorders. Further, research linking neuropsychological impairment to functional disability in some psychological disorders has potential treatment implications. Specifically, incorporating training in strategies to compensate for cognitive difficulties into psychotherapy sessions may be beneficial (Table 30.3).

# Psychological Interventions in Health-care Settings

Charles F. Emery, Derek R. Anderson, *and* Barbara L. Andersen

**Abstract**

Beginning in the 1980s, clinical psychologists have made significant contributions to the development, testing, and dissemination of psychological interventions for individuals undergoing stressful medical treatments or coping with chronic illness. This has been important, as there are elevated rates of mood and anxiety disorders among medical patients. Addressing the needs of patients with coronary heart disease (CHD), cancer, and cardio-pulmonary disease (COPD) is discussed. As is the case generally, cognitive behavior therapy (CBT), tailored to the specific medical illness/treatment circumstances of patients, plays a central role. More broadly, psychologists have been influential in contributing empirically based strategies to improve the health of all Americans. Effective behavior change methods for smoking cessation, dietary change, and increasing physical activity and improving fitness reduce morbidity and mortality and, of course, are key to reducing health-care costs. Thus, we urge psychological assessment and intervention as one element of standard, comprehensive, health care.

**Key Words:** Cancer, coronary, health behavior, psychological, stress

Medical advances of the 20th century have resulted in an increasing proportion of older adults (i.e., >65 years) in the United States. As the U.S. population ages, more and more health-care resources are needed for the management of chronic disease. In response, behavioral interventions in health-care settings have addressed psychological and behavioral correlates of chronic health problems. Coronary heart disease (CHD) and cancer are the leading causes of death, not only in the United States but also throughout the world. Long-term management of these and other conditions is required to reduce premature mortality and prevent associated morbidities. For example, comorbid mood and/or anxiety disorders are common among patients with either CHD or cancer. This chapter provides an overview of behavioral interventions used in health-care settings. We focus upon CHD and cancer and interventions designed to modify health behaviors (e.g., exercise, smoking) in any individual.

## Coronary Heart Disease

From their astute clinical observations, cardiologists Friedman and Rosenman provided an early (1964) test of the role of behavioral/psychological factors and the progression of CHD in their Western Collaborative Group Study (Rosenman et al., 1964). Assessing over 3,500 men, their conception and operationalization of the Type A behavior pattern (TABP) was both novel and innovative. Their finding that individuals with TABP were subsequently found to have a significantly higher incidence of CHD directed the next three decades of behavioral medicine research. Behavioral interventions for cardiac patients began with a focus on the modification of cardiac risk factors and TABP. A large randomized clinical trial (RCT), the Recurrent Coronary Prevention Project (RCPP), compared a cognitive-behavioral intervention for TABP and relaxation training to no treatment with 862 post-myocardial infarction (MI) patients (Friedman et al., 1986).

Significantly lower rates of recurrent cardiac events were found for the intervention arm. Moreover, intervention participants showed decreases in TABP (i.e., reduced hostility, time urgency, impatience), improved mood, and increases in self-efficacy (Mendes de Leon, Powell, & Kaplan, 1991).

Subsequent RCTs of interventions to reduce hostility or psychological distress generally have revealed positive outcomes for CHD patients, reducing either cardiac symptoms or psychological distress. Gidron et al. (1999) found that a hostility-reduction intervention for men with CHD was associated with lower hostility and diastolic blood pressure when compared with a group receiving information only. Cowan and colleagues (2001) found that psychosocial therapy for 129 survivors of sudden cardiac arrest was associated with reduced risk of cardiac death. The intervention included 11 individual sessions with three components: physiologic relaxation with biofeedback training focused on altering autonomic tone; cognitive-behavioral therapy (CBT) aimed at self-management and coping strategies for depression, anxiety, and anger; and cardiovascular health education.

### Interventions for Symptoms of Depression and Anxiety

During the past two decades, attention has shifted from TABP per se to the prognostic importance of stress and/or depression in CHD onset. Both epidemiologic and smaller RCTs have provided supporting data. The INTERHEART study of more than 30,000 adults worldwide, for example, indicated that psychosocial stress was associated with elevated risk of MI (Rosengren et al., 2004). Other data show that, among depressed individuals, there is a 65% increased risk of CHD; and among patients with CHD who are depressed, the risk of death is two to five times higher than normal risk estimates (Carney et al., 1988). It is not surprising that a high prevalence of anxiety disorders exists among patients with CHD (Todaro, Shen, Raffa, Tilkemeier, & Niaura, 2007), as the two disorders are often comorbid. In fact, anxiety symptoms alone have been found to predict MIs in men, independent of other psychological factors including depression, hostility, and TABP (Shen et al., 2008). Thus, treatment of depression and, more recently, anxiety has become a focus in rehabilitation efforts with CHD patients with the added possibility of preventing disease progression.

A second generation of trials has targeted post-MI patients who are at high risk for future events due to elevated depression or low social support. The Enhancing Recovery in Coronary Heart Disease (ENRICHD) trial enlisted 2,481 post-MI patients with elevated depressive symptom levels and/or low social support. Patients were randomized to receive CBT or usual medical care (Berkman et al., 2003). Cognitive-behavioral therapy was provided in individual sessions over a 6-month period (median of 11 sessions) or in a group format with relaxation training (approximately one-third of sample). Psychotropic medication (selective serotonin reuptake inhibitors, SSRIs) was also used for those with severe depressive symptoms at study entry or nonremission of symptoms during the initial 5 weeks. At 6 months post-treatment, patients in the intervention arm had significantly fewer symptoms of depression and increased social support. Longer follow-up (29 months average) showed no effect of the intervention on event-free survival. Several secondary analyses have been published. One, evaluating sex and racial group differences, showed a reduced incidence of cardiac death and nonfatal MI, but in white men only (Schneiderman et al., 2004). Another reported that patients with indicated low social support upon study entry had higher rates of death or recurrent MI, but the intervention was most effective for patients who entered the study with moderate levels of social support (Burg et al., 2005). Last, another secondary analysis indicated that standard components of CBT were effective in reducing depressive symptoms in the post-MI patients but did not appear to influence low social support (Cowan et al., 2008).

Rather than a psychological treatment, post-MI patients are often referred to exercise-based cardiac rehabilitation (CR), usually for 36 sessions (3 times a week for 12 weeks). As an adjunct, psychological interventions are also beneficial. Black and colleagues (1998) offered behavior therapy (one to seven sessions) to distressed patients entering cardiac rehabilitation following hospitalization for angina, MI, angioplasty, or coronary artery bypass graft (CABG) surgery (N = 60). Compared to no treatment (usual care) controls, intervention patients had significant reductions in depressive symptoms. Upon completion of CR, patients are routinely encouraged to maintain the lifestyle changes (e.g., increased physical activity, reduced fat intake, managing life stress) that have been instituted in CR, but there are few studies evaluating post-CR interventions. One multicenter, RCT evaluated patients at 3-year follow-up (Giannuzzi et al., 2008). MI patients (N = 3,240) were randomized to receive continued educational

and behavioral intervention or usual care. Analyses showed the intervention arm to have significantly better health behaviors (i.e., exercise, diet), lower psychosocial stress, and less use of prescription drugs than did patients in the control arm.

## Telephone-based Interventions

Telephone-based interventions may offer a less costly strategy for psychological treatment of cardiac patients. The Montreal Heart Attack Readjustment Trial (M-HART) (Frasure-Smith et al., 1997) was one of the first such trials. Post-MI patients ($N = 1,376$) were randomized to telephone intervention or standard care arms. Intervention participants received a call 1 week following hospital discharge and then monthly for 12 months. Any participant readmitted to the hospital or reporting significant psychological distress on the routinely administered General Health Questionnaire (GHQ) was then scheduled for a 1-hour home visit by a cardiology nurse who provided education, advice, reassurance, and referrals if necessary. The majority of patients (75%) in the intervention arm received five to six nurse visits. Outcome results indicated no study arm differences on cardiac mortality, all-cause mortality, or psychological outcomes. Oddly (and unfortunately), women in the intervention arm had higher all-cause mortality than did women in the control condition. Secondary analyses were conducted of 433 patients (36.0% women) from the M-HART treatment group who received two home visits after achieving a high psychological distress score (i.e., ≥5) on the GHQ. Patients with short-term reductions in GHQ scores were less likely to have high depression and anxiety at 1-year than were patients who did not experience short-term reductions (Cossette, Frasure-Smith, & Lesperance, 2001).

A pre-post, single-group study was conducted in Australia by Gallagher and colleagues (2003) among women ($N = 196$) who were hospitalized for coronary artery disease (myocardial infarction, CABG, coronary angioplasty, or unstable angina). During the 12-week intervention period, participants received telephone calls at 1, 2, 3, and 6 weeks after discharge from a nurse credentialed in cardiac rehabilitation and counseling. Analyses showed significant improvements in patients' psychosocial adjustment, as well as reductions in anxiety and depressive symptoms. Correlates of poor psychosocial outcomes included younger age (<55), being unemployed or retired, having poor psychosocial adjustment to illness at baseline, being readmitted to the hospital, or experiencing a stressful, personal event during follow-up.

Bambauer and colleagues (2005) enlisted 79 cardiac patients with mild to severe depression or anxiety (based on scores from the Hospital Anxiety and Depression Scale, HADS) 1 month following hospital discharge. Patients were randomized to usual care or to an intervention in which they received up to six 30-minute telephone counseling sessions focused on identifying cardiac-related fears. Results showed the intervention group had significantly greater improvements in self-rated health between baseline and 3 months post treatment, but there were no group differences at the 6-month follow-up.

Thus, the data regarding telephone interventions are equivocal. The M-HART data suggested that the telephone intervention may have inadvertently increased distress among some patients, especially women. The Gallagher et al. study indicates overall benefit, but notes lack of benefit in specific subgroups of patients who were relatively younger, unemployed, with low social support at study outset. The Bambauer data suggest that the benefits of a telephone-based intervention may be short-lived.

## Additional Treatment Considerations Among Cardiac Patients

Other approaches to reducing physical and psychological symptoms and enhancing quality of life have been utilized. Relaxation training appears to benefit cardiac functioning (e.g., reduced heart rate, increased heart rate variability, increased exercise capacity, reduced angina) as well as reduce cardiac morbidity and mortality (van Dixhoorn & White, 2005). Stress management interventions are associated with reduced incidence of both fatal and nonfatal MI (Rees, Bennett, West, Davey, & Ebrahim, 2004). Blumenthal and colleagues (2005) found that stress management training was as effective as exercise training in enhancing cardiovascular response to stress among patients with ischemic heart disease. Manchanda and colleagues (2000) found that a short-term, intensive yoga intervention was associated with stabilization of coronary stenosis and reduction of cardiac morbidity among patients with CHD. In addition, musical stimulation during cardiac catheterization has been associated with reduced symptoms of anxiety in comparison to standard care (Argstatter, Haberbosch, & Bolay, 2006). Listening to music has been found to reduce symptoms of anxiety, as well as reduce heart rate and systolic blood pressure among patients awaiting cardiac catheterization (Hamel, 2001). However, among patients who had had cardiac surgery during the prior 24 hours, listening to music was found to have

no effect on anxiety, pain, heart rate, respiratory rate, or oxygen saturation (Nilsson, 2009).

The preponderance of research in cardiac disease has been conducted with male samples. However, recent studies suggest gender differences in distress and social support that may be relevant to recovery (Emery et al., 2004; Janevic et al., 2004; Janz et al., 2001). Some studies suggest gender differences in response to behavioral treatments, whereas others do not. Michalsen and colleagues (2005) found that women were more likely than men to benefit from stress reduction/lifestyle modification on dimensions of depression and anger, and Janz and colleagues (2004) found reduced stress at 4-month follow-up among women with heart disease who had participated in a 6-week disease management intervention versus usual care. Yet, a RCT of a 1-year stress management program for 247 women with CHD found no effect of the intervention on depressive symptoms or vital exhaustion at the end of the intervention (Koertge et al., 2008). As noted earlier, the secondary analyses of ENRICHD data (Schneiderman et al., 2004) revealed that the intervention had no effect in reducing cardiac death and nonfatal MI among women. Thus, testing for the existence of gender differences (and exploring the biobehavioral mechanisms for such effects) is a fertile area for further research.

Illness knowledge may be another critical component associated with psychological well-being among cardiac patients. McKinley and colleagues (2009) conducted a randomized study of the effect of an educational counseling intervention on knowledge, attitudes, and beliefs about acute cardiac symptoms and their treatment among 3,522 patients with CHD. Results indicated that knowledge, attitudes, and beliefs scores increased significantly from baseline in the intervention group compared to the control group at 3 months and were sustained at 12 months. Higher perceived control over cardiac illness was associated with more positive attitudes, and higher state anxiety was associated with lower levels of knowledge, attitudes, and beliefs (McKinley et al., 2009). However, the effect of illness knowledge may be moderated by personality or coping style. Specifically, illness knowledge has been associated with greater distress among women with CHF who engage in repressive coping (i.e., tend to avoid experiencing negative emotions; Jackson & Emery, (in press) and with greater sleep disturbance, depression, and tension among post-MI men and women who engage in repressive coping (Shaw et al., 1985).

## *Conclusion*

Stress management appears to be beneficial for improving cardiac function and reducing cardiac mortality. The data underscore the importance of evaluating depression and anxiety among patients with CHD, as well as instructing patients with depression and anxiety disorders that they may be at elevated risk of developing CHD. Cognitive-behavioral therapy is the most efficacious psychological treatment for depression, but studies suggest that other components, such as those for improving patients' social support networks, are important and need to be included. It is not clear if telephone-based supportive and educational interventions are beneficial and in fact, may be contraindicated for some. Only subgroups of patients may benefit, such as those receptive to receiving information. Adjunctive treatments, such as listening to music and relaxation training, also appear to be helpful. Thus, the data present a complex picture in which CBT is a central approach, which is then tailored to best meet patient needs.

## Cancer

Psychological interventions are efficacious for reducing cancer stress (Andersen, 1992, 2002; Meyer & Mark, 1995). Interventions have varied from study to study (Goodwin et al., 2001; Spiegel, Bloom, Kraemer, & Gottheil, 1989); however, commonalities have included some form of active stress reduction (e.g., progressive muscle relaxation, guided imagery), information about the disease and treatment, an emotionally supportive context for treatment (with the "component" often being treatment in a group format), behavioral coping strategies (e.g., seeking information), cognitive-behavioral strategies (e.g., cognitive reframing, problem solving), and site-specific interventions (e.g., sun protection for melanoma patients). Despite their importance, components for improving health behaviors (Fawzy et al., 1990; Lepore, Helgeson, Eton, & Schulz, 2003) or adherence (Richardson et al., 1987) are usually not included.

### *Psychosocial Interventions*

Randomized clinical trials have typically contrasted intervention and control arms (e.g., no intervention, waitlist, usual care) and accrued patients unscreened for psychiatric disorders. With such patients, meta-analyses show interventions to be generally effective, with larger effect sizes for patients with the greatest level of distress (Schneider et al., 2010) and for

treating symptoms of anxiety versus depression (Sheard & Maguire, 1999). Using the Brief Symptom Inventory with over 8,000 patients newly diagnosed or beginning a new therapy (e.g. start of chemotherapy), BrintzenhofeSzoc and colleagues (2009) estimated that there were clinical levels of mood- or anxiety-related symptoms for approximately 30% of patients. Of the latter, they estimated depressive symptoms for 4%–9% and anxious symptoms for 8%–15%, with the largest percentage of patients, 10%–20%, having a mixed-symptom presentation. Other data show that both anxiety and depressive symptoms have independent, additive effects on impaired health-related quality of life (Brown, Kroenke, Theobals, Wu, & Tu, (2010).

Thus, mental health disorders among cancer patients occur at higher than expected base rates. In both early and recent surveys, it is estimated that 30% of patients studied met criteria for mood or anxiety disorders (Burgess et al., 2005; Derogatis & Melisaratos, 1983; Zabora, BrintzenhofeSzoc, Curbow, Hooker, & Piantadosi, 2001). Estimates for major depressive disorder (MDD) are 22%–29% for patients with early stage (stage I) disease (Raison & Miller, 2003) and 8%–40% for patients with advanced disease (stage II/III, or IV; Hotopf, Chidgey, Addington-Hall, & Ly, 2002), and the rates increase further with recurrence (Burgess et al., 2005). For the most common sites of disease, such as breast and gynecologic cancers for women, Zabora and colleagues (2001) found the prevalence of MDD to be 33% and 30%, respectively. Data suggest the numbers of patients with anxiety disorders to be lower, approximately 18%, with generalized anxiety disorder (GAD) being the most common disorder (Stark et al., 2002). As is the case for those without concurrent physical illness, depression and anxiety co-occur among cancer patients. Thirty-eight percent of cancer patients found to have anxiety disorders by Stark and colleagues (2002) also had MDD.

Intervention efficacy for cancer patients with comorbid depressive or anxiety disorders is unclear, due in part to the few trials conducted. To our knowledge, only seven of more than 200 RCTs either screened patients for clinical levels of distress or did not screen but did assess for psychiatric diagnoses. Across studies, the interventions were varied. A methodologically strong, early study was conducted by Telch and Telch (1986), who screened patients for high distress, and compared CBT to support group and control arms. The CBT group

was most effective in reducing distress, and this was one of the few studies in the literature showing the control group to worsen. Moorey and colleagues (1998) enlisted patients diagnosed with an adjustment reaction and found problem-focused CBT to significantly reduce depressive and anxiety symptoms compared to supportive counseling. Simpson and colleagues (2002) provided group treatment combining stress management and goal setting for breast cancer patients, 26% of whom had depressive or anxiety disorders, and found no significant improvement. Using a psychosocial group intervention with stage I/II breast cancer patients, 36% of whom had depressive or anxiety disorders, Kissane and colleagues (2003) reported no improvement in depressive symptoms but a trend toward reductions in anxiety symptomatology when using the supportive expressive therapy described earlier by Spiegel and colleagues (1989).

However, Kissane and colleagues (2003) reported positive outcomes of supportive-expressive therapy offered to breast cancer patients with metastasis, 32% of whom had a comorbid mood disorder. The intervention significantly reduced hopelessness and traumatic stress, improved social functioning, and ameliorated some mood disorders and prevented the emergence of new ones. To treat insomnia, Savard and colleagues (2005) offered stimulus control/sleep hygiene and cognitive restructuring and reported significantly improved sleep patterns and reduced depressed moods for breast cancer patients, 56% of whom had a psychiatric disorder. Although not determining psychiatric diagnoses per se, Nezu and colleagues (2003) enlisted breast cancer patients scoring within the clinical range on the Hamilton Interview for depression. They found individual problem-solving therapy to have positive effects across depression, distress, and quality-of-life outcomes.

In summary, suggestive support exists for the effectiveness of general psychosocial interventions among cancer patients with psychopathology. These interventions are tailored to help patients with the immediate, overwhelming stress of cancer. Such interventions "normalize" patients' worries, fears, and concerns. They offer active, behavioral-change strategies to cope, such as encouragement to seek information or ask their oncologist questions about the disease or treatment. Coping strategies such as progressive relaxation are taught to reduce the psychological and physiologic manifestations of anxiety and to prevent or reduce symptoms, such as nausea or fatigue from cancer treatments. These strategies

may have efficacy equaling standard therapy for mood or anxiety disorders, such as CBT, but no trials have tested this possibility.

### Biobehavioral Interventions

More recent treatments emphasize stress reduction, inclusion of some CBT elements (e.g., problem solving, assertive communication), and cancer-specific interventions for improving health behaviors and compliance with cancer therapies (Andersen, Golden-Kreutz, Emery, & Thiel, 2009). Based on the Biobehavioral Model of Cancer Stress and Disease Course (Andersen, Kiecolt-Glaser and Glaser, 1994), an RCT showed breast cancer patients (*N* = 227) randomized to the biobehavioral intervention (BBI) to have significant reductions in emotional distress, increases in social support from family members, improved diet, reduced variability in chemotherapy dose intensity, improved immunity (increased T cell blastogenesis), fewer signs/symptoms and treatment toxicities, and higher functional status. This same intervention appears to have stemmed disease progression. After a median of 11 years of follow-up, analyses showed that the intervention arm had a reduced risk of breast cancer recurrence (hazard ratio [HR] 0.55, *p* = 0.034) compared to the assessment-only arm (Andersen et al., 2008). Follow-up analyses also showed a reduced risk of breast cancer death following recurrence (HR, 0.41; *P*=0.014) (Andersen et al., 2010).

According to data supporting the Biobehavioral model, the acute stress occurring at the time of cancer diagnosis, if left untreated, can contribute a stable, lower quality of life (Golden-Kreutz et al., 2005), depressive symptoms (Golden-Kreutz & Andersen, 2004), and less meaning in patients' lives (Jim, Richardson, Golden-Kruetz, & Andersen, 2006). Data have also consistently shown cancer stress to covary with biological effects. Early data showed stress at diagnosis (Andersen et al., 1998) to covary with downregulated T blastogenesis and natural killer cell cytotoxicity (NKCC). Longitudinal data showed that these relationships remained for as long as 2 years after diagnosis.

This stress–immune trajectory may be of even greater relevance for cancer patients with comorbid psychiatric disorders. In fact, stress-related biologic alterations can elicit symptoms consistent with depressive or anxiety disorders. Immune activation has been hypothesized as a causal factor in depression, as proinflammatory cytokines have been shown to produce "sickness behaviors," such as fatigue, lethargy, anorexia, and low mood (Anisman & Merali, 2003).

Anxiety, too, is correlated with immune and endocrine function (Stein, Keller, & Schleifer, 1988). Both depression and anxiety are believed to contribute to further dysregulation of the HPA axis, an overactive inflammatory response, and decreased cellular immunity (Elenkov, Iezzoni, Daly, Harris, & Chrousos, 2005; Pace, Hu, & Miller, 2007; Stein et al., 1988; Zorrilla et al., 2001). Thus, cancer patients facing diagnosis with a comorbid psychiatric disorder may show evidence of a robust downregulation of immunity.

Other aspects of depression may be additionally important in the context of cancer. Negative health behaviors, such as smoking, can increase during period of stress, and when increased, they covary with a downward trend in immunity (Jung & Irwin, 1999; McAllister-Sistilli et al., 1998). Alternatively, if depressed patients engage in positive health behaviors, such as exercise, immunity may be enhanced and mood improved (Blumenthal et al., 1999; Stathopoulou et al., 2006; Trivedi, Greer, Grannemann, Chambliss, & Jordan, 2006). Another behavioral factor of possible importance is treatment adherence, as depression is a correlate of low of compliance (Lebovits, Strain, Schleifer, Tanaka, Bhardwaj, & Messe, 1990; McDonough, Boyd, Varvares, & Maves, 1996). In summary, patients with comorbid disorders are at greater risk for high rates of negative and low rates of positive health behaviors and lowered treatment adherence. Moreover, they are at risk for higher levels of morbidity (Delgado-Guay, Parsons, Li, Palmer, & Bruera, 2009) and poorer survival (Chida, Hamer, Wardle, & Steptoe, 2008).

Secondary analyses from the biobehavioral trial just described examined the applicability of the BBI to patients with comorbid psychopathology. Approximately 25% (*N* = 45 of 227) of the patients reported clinically significant depressive symptoms (i.e., CES-D short-form scores ≥10). Twenty-two patients (54%) were randomized to the assessment arm and the remaining 23 (44%) to the intervention arm. Using linear mixed-effects models and controlling for baseline levels, the BBI significantly reduced depressive symptoms as well as measures of fatigue and impairments due to pain. The intervention was also associated with reductions in inflammation, as operationalized with measures of white blood cell (WBC) count, neutrophil count, and helper-to-suppressor ratio. Further analyses showed that reduced inflammation occurred via the reduction in depressive symptoms. Thus, the biobehavioral intervention effectively treated depressive symptoms,

pain, and fatigue along with lowering inflammatory responses.

### Conclusion

Depressive and anxiety disorders among cancer patients are prevalent, unrecognized, and untreated (Evans et al., 2005), and there is recent evidence of elevated suicide rates among cancer patients as well (Miller, Mogun, Azrael, Hempstead, & Solomon, 2008). In fact, data suggest that breast cancer patients have an increased risk of suicide for as long as 25 years following diagnosis (Schairer et al., 2006). Interventions exist for treating psychological distress among cancer patients. To the extent that both CBT and psychosocial treatments have independent, active components, a combination treatment may be most effective overall. The "cognitive" component (i.e., addressing the disorder-specific cognitive diathesis, identifying and evaluating depressive/anxious cognitions, etc.) of CBT has been most often missing from cancer interventions. To the extent that psychosocial treatments additionally address the cognitive diatheses underlying psychopathologies and to the extent that traditional treatments, such as CBT, might additionally include disease-specific elements, a combination treatment could be more efficacious than either treatment alone. Regardless of the therapeutic model chosen, however, it is important that the professional community better address needs of cancer patients with comorbid psychopathology.

### Other Chronic Illnesses: Chronic Obstructive Pulmonary Disease and Diabetes

Although estimates vary, patients with chronic obstructive pulmonary disease (COPD) often have symptoms of depression (6%–42% of patients in the community) or anxiety (2%–50%; Dowson et al., 2001; van Ede, Yzermans, & Brouwer, 1999; Kim et al., 2000). Symptomatic of both types are limitations in functional abilities and activities of daily living (Graydon & Ross, 1995; Kim et al., 2000; Weaver, Richmond, & Narsavage, 1997). Fortunately, CBT interventions are efficacious in reducing distress and enhancing quality of life among patients with COPD. For example, Kunik et al. (2001) offered a 2-hour intensive CBT session incorporating cognitive intervention and relaxation training, followed by brief weekly telephone calls to prompt practice of skills over a 6-week interval and reported significant reductions in symptoms of anxiety and depression for their COPD participants.

A single-group study of CBT led by nurses found significant decreases in patients' distress and in medical service use (Heslop, De Soyza, Baker, Stenton, & Burns, 2009). Interestingly, an RCT found reduced symptoms of depression in patients receiving 20 sessions of acupressure over a 5-week period (Wu, Lin, Wu, & Lin, 2007). However, a study of patient case management (Egan, Clavarino, Burridge, Teuwen, & White, 2002) and another using patient education (Hesselink et al., 2004) found null effects on indicators of distress or well-being. In summary, the available data, although limited, suggest that CBT interventions may be more effective in reducing distress among patients with COPD than are educational or symptom-management interventions.

Similar findings have been reported for CBT offerings for patients with type 2 diabetes. A trial by Lustman and colleagues (1998) found a 10-week program of CBT efficacious for patients with comorbid depression. Other CBT trials have reported increased self-efficacy, reduced distress and mood (van der Ven et al., 2005), as well as enhanced well-being, reduced diabetes-related distress, and reduced anxiety and depressive symptoms (Amsberg et al., 2009). In sum, CBT interventions among diabetic patients with depression or disease-related distress demonstrate promise as a nonpharmacologic means of reducing distress and depression.

### Conclusion

Data support the utility of CBT for treatment of comorbid depression and anxiety among patients with COPD and diabetes. Cognitive-behavioral therapy interventions also are associated with further beneficial changes in psychosocial functioning (e.g., increased self-efficacy) and in physical functioning (e.g., reduced health care utilization). Thus, CBT appears to be an important treatment consideration among patients with chronic health conditions and comorbid psychological distress. Educational interventions do not appear to be useful in reducing depression-related distress. Complementary therapies (e.g., acupressure) may be beneficial for reducing psychological distress, but further research is needed.

### Cross-cutting Strategies
#### Health Behavior Interventions for Medical Populations

Psychological and behavioral interventions for health behaviors, especially physical activity and tobacco use, have been studied extensively. These interventions have a two-fold benefit: reducing patients' morbidity and mortality and, thereby, lowering

health-care costs. For some patients, a new chronic illness diagnosis may be the impetus to change one's heath behaviors (Keenan, 2009). Diagnosis offers a "teachable moment" to encourage positive health behavior change (Keenan, 2009; Pagoto & Ockene, 2009). Increasingly, physicians are using the "five A's—Assessing, Advising, Agreeing on goals, Assisting the patient to get support, and Arranging follow-up—to facilitate health behavior change (Ockene et al., 1996).

### Smoking

The research literature on smoking cessation is extensive. Unfortunately, diagnosis with CHD, COPD, or similar serious illnesses is not, for some, a sufficient reason to stop smoking. Results from minimal-care smoking cessation interventions (e.g., brief bedside counseling with minimal or no follow-up) yield only small effects (Bolman, de Vries & van Breukelen, 2002a,b), suggesting that perhaps more intensive intervention and follow-up is needed. The majority of the research shows that offering cardiac patients relatively brief interventions during their inpatient surgery stay with perhaps a telephone follow-up over ensuing weeks or months produce stronger outcomes.

In an early study, a nurse-led intervention for hospitalized cardiac patients found 61% of intervention arm patients to be abstinent at 12 months versus 32% of patients receiving usual care (Taylor, Houston-Miller, Killen, & Debusk, 1990). Data on intention to stop smoking were revealing: Patients who resumed smoking within 3 weeks after infarction or who expressed little intention to quit were, not surprisingly, unlikely to have stopped at the 12-month follow-up. Comparable positive outcomes have been found with an intervention of education and a focus on fear arousal and relapse prevention, showing a quit rate of 57% at 12 months following hospital admission versus a 37% quit rate among usual care controls (Quist-Paulsen & Gallefoss, 2003). Even more intensive interventions, however, yield outcomes within the same range. For example, provision of 60 minutes of bedside counseling with a nurse and with seven follow-up counseling calls for the 2 months following discharge resulted in 12-month abstinence in 54% of patients receiving advice to quit from physicians and nurses along with cessation educational materials (Smith & Burgess, 2009). Similar strategies and outcomes are found in studies of patients with COPD (Efraimsson, Hillervik, & Ehrenberg, 2008). However, the addition of motivational interviewing and related techniques during hospitalization may be more facilitative, especially when followed by supportive counseling. Across strategies, however, cessation is more likely when patients have a positive attitude toward quitting (Christenhusz, Pieterse, Seydel, & van der Palin, 2007).

As among cardiac and pulmonary patients, many cancer patients continue to smoke after diagnosis. This is especially concerning because there is evidence that smoking reduces the efficacy of chemotherapy and radiotherapy (Tsao, Liu, Lee, Spitz, & Hong, 2006; Videtic et al., 2003), slows surgical recovery (Shimizu, Nakata, Hirami, Maeda, & Tanemoto, 2008), impairs nutritional status (Gritz, 1991), affects performance status (Baser et al., 2006), and, in turn, increases the cost of medical care (Slatore, Au, & Hollingworth, 2009). A significant impediment to changing smoking behavior among cancer patients (as well as other patients) is the continuation of smoking among one's family. Unfortunately, rates of smoking cessation among relatives of patients with serious smoking-related disorders (e.g., lung or head/neck cancers) are only in the range of 7%–10% (Goksel, Ozol, Bayindir, & Guzelant., 2002). Thus, future smoking cessation efforts among medical patients should consider not only motivation among patients, but also the considerable influence of patients' familial and social networks (Christakis, 2004).

### Physical Activity

The encouragement of exercise (or even simple increases in physical activity) is seen as increasingly important to facilitate recovery and lower morbidity for many chronic illness groups. In addition to the cardiac rehabilitation studies described earlier, other studies have tested the utility of exercise, per se, for cardiac patients. Arrigo et al. (2008) found patients' monitoring of their physical activity, in combination with quarterly group meetings, led to significantly more regular physical activity at 1-year follow-up than was observed in a standard treatment control group. Intervention patients also achieved reductions in their body mass index (BMI) and blood lipid levels. Similarly, two behavioral counseling and goal-setting sessions plus use of a pedometer for the next 6 weeks for patients who were completing CR resulted in increases in number and duration of physical activity and walking at treatment's end, as well as after 6 months; psychosocial functioning was also improved (Butler, Furber, Phongsavan, Mark, & Bauman, 2009). A larger trial, the Extensive Lifestyle Management Intervention, offered to patients completing CR found reductions in overall cardiac risk,

total cholesterol, low-density lipoprotein (LDL) cholesterol, and systolic blood pressure (SBP). Surprisingly, no lifestyle differences were found between the intervention group and the usual-care control group (Lear et al., 2006). A similar trial with patients in Germany found that post-CR training in self-regulatory skills (exercise planning) led to greater exercise activity at 4-month and 12-month follow-ups than found in the control arm. In addition, this trial achieved a reduction in depressive symptoms for the intervention group (Clark et al., 2000). Far fewer studies of health behavior interventions have been conducted among patients with COPD. However, the data to date generally indicate that exercise is associated with reduced symptoms of anxiety and depression, as well as significant increases in functional performance and quality of life (Emery, Leatherman, Burker, & MacIntyre, 1991; Griffiths et al., 2000). In addition, data suggest that exercise may have beneficial effects on cognitive performance among patients with COPD (Emery, Schein, Hauck, & MacIntyre, 1998; Kozora, Tran, & Make, 2002).

Numerous exercise interventions have been conducted with cancer patients. Literature reviews suggest that exercise is, in general, associated with reductions in cancer-related fatigue (Cramp & Daniel, 2008), as well as with increased quality of life and cardiovascular fitness (McNeely et al., 2006). Many studies have enlisted only breast cancer patients and, for them, physical activity has been associated with multiple positive outcomes (e.g., increased physical endurance, reduced fatigue, improved quality of life, reduced psychological distress; Courneya, 2003; Mock, Dow, Meares, & Grimm, 1997; Segar, Katch, & Roth, 1998; Valenti, Giampiero, & Aielli, 2008). For long-term survivors, moderate-intensity physical activity is associated with greater vigor as well as lower fatigue and fewer depressive symptoms (Trunzo & Pinto, 2004; Pinto, Frierson, Rabin, Trunzo, & Marcus, 2005). On the other hand, a Cochrane review found little evidence for beneficial effects of aerobic or resistance exercise for treatment-related side effects (e.g., fatigue, psychosocial distress, physiological changes) during adjuvant (chemotherapy) treatment (Markes, Brockow, & Resch, 2006). Similarly, a meta-analysis by Jacobsen and colleagues (2007) found limited evidence for the utility of psychological and activity-based interventions for treating cancer-related fatigue in cancer patients. Thus, the data regarding health and psychological benefits of exercise among cancer patients are not straightforward. It appears that physical activity is beneficial for survivors, especially breast cancer patients, but that fatigue may be especially difficult to reduce.

Lastly, exercise routines and benefits for patients with diabetes are moderated by the severity of the disease. For those with diabetes that can be managed via alterations in diet (type 2), exercise studies have documented reduced cholesterol levels and improved fitness for patients (Rimmer, Silverman, Braunschweig, Quinn, & Liu, 2002). For these same patients, physical exercise can be used for weight reduction and to achieve improved insulin sensitivity (Horton, 1988). However, for insulin-dependent (type 2) diabetics, exercise regimens require close physician monitoring, as patients may become hypoglycemic during or following exercise (Horton, 1988).

### Multitarget Health Behavior Interventions

Health behavior interventions of the future will be designed to address multiple health behaviors. For example, studies will focus on the importance of energy balance, and include dietary and exercise components in tandem. Clark and colleagues (2009) found that a self-directed intervention group for cardiac patients reduced cardiac symptoms and contributed to weight loss at 18-month follow-up compared to the outcomes for the control group. The large Multisite Cardiac Lifestyle Intervention Program studied the interactions of health behavior changes influencing cardiac risk among more than 800 CHD patients. After 3 months, intervention patients were found to have significant reductions in overall coronary risk. Reductions in dietary fat intake predicted reductions in weight, total cholesterol, and LDL cholesterol, and interacted with increased exercise to predict reductions in perceived stress. Increases in exercise predicted improvements in total cholesterol and exercise capacity (for women). Increased stress management was related to reductions in weight, total cholesterol/high-density lipoprotein (HDL) cholesterol (for men), triglycerides, hemoglobin A1c (in patients with diabetes), and hostility. Schuler and colleagues (1992) found that a 12-month program of exercise and low-fat diet among coronary artery disease (CAD) patients was associated with reduced cardiac risk factors (e.g., body weight, cholesterol), as well as with less progression of coronary lesions. Other studies have documented that changes in diet, stress management, exercise, social support, and smoking contribute to reduced cardiac medication use, better quality of life, and reduced cardiac risk among postmenopausal women with CHD (Koertge et al., 2003).

### Conclusion

Smoking cessation interventions have generated equivocal results, with more intensive interventions resulting in higher quit rates than brief interventions or usual care. Despite the greater success of intensive interventions, low motivation for quitting remains a barrier among cardiac and cancer patients, reflecting an ongoing need for enhanced motivational techniques among medical patients to increase positive attitudes toward smoking cessation. In addition, consideration of the environmental and social factors that may hinder patients' cessation may be especially important.

Exercise interventions among cardiac patients have resulted in increased functional capacity, reduced cardiac risk (including lower cholesterol levels), and less depressive symptomatology. Exercise interventions among cancer patients have revealed mixed results. Physical activity interventions have been associated with multiple positive outcomes among breast cancer patients and survivors. However, recent reviews have indicated limited benefits of exercise for the most common symptom, fatigue. Exercise interventions appear beneficial for other medical groups, such as patients with COPD or diabetes. Finally, interventions that target multiple problem behaviors, such as poor dietary habits and low physical activity rates, show considerable promise, as evidenced by the reduced risk of cardiac disease and improved quality of life.

### Uptake of Behavioral Interventions: Trial Accrual, Retention, and Adherence

In the general case, psychosocial factors often covary with medical treatment adherence, with poor adherence hastening disease progression and/or death. Such is the case for patients with cardiac disease (Frasure-Smith, Lespérance, & Talajic, 1995; Ruberman, Weinblatt, Goldberg, & Chaudhary, 1984; Williams & Littman, 1996) or cancer (Ayres et al., 1994; Brown, Levy, Rosberger, & Edgar, 2003). This problem is not limited to medical treatments, as low accrual, high dropout, or inadequate adherence to the treatment protocol occurs for behavioral trials (Allison et al., 2004; Butler et al., 2009; Chang, Hendricks, Slawsky, & Locastro, 2004; Manne, Ostroff, & Winkel, 2007; Ostroff, Ross, Steinglass, Ronis-Tobin, & Singh, 2004). For example, Butler and colleagues (2009) recruited 212 cardiac patients into a behavioral intervention utilizing pedometer monitoring, behavior counseling, and goal-setting exercises. Of the 212 recruited, 90 (42%) refused randomization. After randomization, 32 out of 122 (26%) did not complete the intervention. Self-reported barriers to adherence included work commitments and medical problems. In a behavioral intervention study for chronic heart failure patients, Chang and colleagues (2004) found that 39 of 124 (31%) patients who consented to participate did not return for the baseline assessment. Studies of patients with cancer have documented similar difficulties.

The Multiple Family Group (MFG) intervention study for head and neck cancer patients implemented aggressive accrual and retention methods, but still had high dropout rates (Ostroff et al., 2004). Only 80 of 174 (46%) eligible families returned completed surveys. Of the remaining 80 families that returned surveys and were informed of the MFG workshops, only 15 (19%) completed the 6-hour workshop. Patients who did not participate in the study stated that they did not need family support, or they could not attend for practical reasons, such as living too far from the study site (Ostroff et al., 2004). In a couple-focused intervention for breast cancer patients and their caregivers, Manne, Ostroff & Winkel (2007) randomized 120 couples to the intervention group, 42 (35%) of whom became treatment dropouts.

As with treatments of any type, barriers exist, both practical and emotional, to enrolling in and completing psychological/behavioral interventions trials. Nonetheless, research demonstrates that, without intervention, psychological symptoms such as depression are associated with poorer compliance with medical treatment (McDonough et al., 1996; Richardson et al., 1987). The same is true for compliance with health-behavior change efforts. Kronish and colleagues (2006) found that depression was associated with lower rates of smoking cessation, exercise, and CR attendance in a study of 560 acute coronary syndrome patients. Glazer and colleagues (2002) found that depressive symptoms predicted dropout from CR.

According to Evenson and Fleury (2000), the commonly reported reasons for CR dropout or poor adherence include patient reports of low motivation, engagement in concurrent exercise programs or efforts, and/or lack of time. Work and financial concerns (including inadequate insurance coverage) have been reported by patients in other studies (Evenson & Fleury, 2000). Ostroff and colleagues (2004) reported that the need to travel a significant geographical distance was a major concern for patients who dropped out of the MFG study conducted at Memorial Sloan Kettering Cancer Hospital

in New York City. Barriers such as the latter may spur alternative forms of delivering intervention content (e.g., telephone counseling, Internet websites).

In addition to understanding barriers to adherence, studies have also identified factors associated with participant retention. Leatham and colleagues (2009) found that providing more information to potential participants decreased the accrual rate, but if the participant consented to participate, retention was higher. Also, providing information (e.g., flyers or postings) to potential participants in advance provided additional time to consider participation and discuss the matter with family and friends, and ultimately led to higher accrual.

## Conclusions

Although behavioral interventions have been associated with improved physical and emotional functioning among medical patients, participant retention in behavioral intervention trials is often problematic. Obstacles to low accrual and retention may include illness severity, employment or other time commitments, and the inconvenience of lengthy travel times; however, psychological symptoms, particularly depressive ones, also have been associated with lower rates of adherence. Thus, the data tentatively support the importance of conducting assessments of motivation, social support, and psychological well-being among medical patients entering a behavioral change program, with the goal of identifying patients who may require participation accommodations or additional support. Evaluation of barriers to behavioral change among medical patients, with the goal of modifying behavioral interventions to enhance adherence and success with behavioral change, is needed.

## Conclusion

Elevated rates of mood and anxiety disorders among patients with CHD, cancer, and COPD highlight the importance of psychological assessment and intervention in health-care settings. Numerous meta-analyses suggest that highly distressed patients, particularly those with significant depressive symptomatology, are at risk for greater medical morbidity and hastened death, highlighting the need for psychological and/or behavioral assessment at critical points in illness trajectories (e.g., diagnosis, post MI, diagnosis of cancer recurrence).

Cognitive-behavioral therapy is an effective strategy for the treatment of clinical depression and anxiety disorders in the general population, and studies indicate that CBT is effective in reducing depression and anxiety among medical patients as well. However, CBT does not appear to be beneficial for improving perceived social support. Other interventions also have been useful in enhancing health and well-being. Among cancer patients, biobehavioral treatment strategies have been employed, and among cardiac patients stress management and relaxation techniques have been successful. The research literature has yet to identify the specific components of treatments that are responsible for reducing psychological distress or for influencing disease morbidity and mortality. Additionally, the tailoring of treatment to individual differences among patients is also needed. For example, studies of cardiac patients have identified interventions that do not appear to benefit women (e.g., telephone-based counseling from the M-HART study and psychosocial intervention in the ENRICHD trial), but the mechanisms for the apparent sex difference in treatment outcomes are not known. Further research is needed to provide evidence in support of specific intervention treatments, and to clarify the necessary components of treatment for producing specific outcomes (e.g., reduced depression, reduced physical symptoms, increased survival).

Mode of intervention delivery may be one determinant of treatment efficacy. To date, treatment delivery has primarily been through in-person group or individual treatment. However, telephone-based interventions appear to be beneficial for some cardiac patients. Use of the Internet for delivery of interventions has yet to be widely utilized. Prior studies indicate that telephone-based interventions may not be beneficial for all patients, and it is likely that Internet interventions too may benefit some but not all. In the area of health behavior change, cell phones may be useful in monitoring both positive (e.g., physical activity) and negative (e.g., smoking) health behaviors during the course of treatment. These technologies are providing new opportunities for both for intervention delivery and data collection.

Health-care providers are beginning to acknowledge that health behavior change (e.g., smoking, diet, physical activity) is central to effective chronic disease management. Psychologists can assist in the evaluation of both health behaviors and psychopathology, and also provide an awareness of environmental factors that may undermine patient efforts to initiate and maintain behavior change. If psychological assessment and intervention among medical patients are routine offerings in medical care, patients' hesitance to participate may be reduced, and they may be less reluctant to self-identify their unaddressed needs.

# Behavioral Interventions in Public Health Settings: Physical Activity, Weight Loss, and Smoking

Beth A. Lewis, Eric Statt, *and* Bess H. Marcus

## Abstract

This chapter discusses three health behaviors that significantly impact public health. Specifically, physical activity behavior, weight loss, and smoking cessation are associated with many health benefits, including decreased risk of cardiovascular disease, type 2 diabetes, and cancer. These three health behaviors are important modifiable risk factors that can have a significant impact on health. Unfortunately, only half of Americans are physically active at the recommended levels. Additionally, 66.3% of Americans are overweight or obese. Finally, despite the health problems related to smoking, about one-fifth of Americans continue to smoke cigarettes. We provide an overview of the theoretical models commonly used in intervention studies and summarize the research evidence from randomized trials. Finally, we review three different intervention approaches for improving health behaviors, including an individual-level approach for physical activity, a community-level approach for weight loss, and a group-based approach for smoking cessation.

**Key Words:** Cigarette use, exercise, interventions, obesity, overweight, physical activity, smoking cessation

In this chapter, we discuss three health behaviors— physical activity, weight loss, and smoking cessation— that significantly impact public health (Centers for Disease Control [CDC], 2005; National Heart, Lung, and Blood Institute/National Institute of Diabetes and Digestive and Kidney Diseases [NHBLI/ NIDDK], 1998; Renehan, Tyson, Egger, Heller, & Zwahlen, 2008; U.S. Department of Health and Human Services [USDHHS], 2001a, b). These health behaviors are associated with many health benefits, including decreased risk of cardiovascular disease, type 2 diabetes, and cancer. Therefore, modifying these health behaviors can have a significant public health impact. For each behavior, we will review the prevalence, recommendations, health benefits, the-oretical models commonly used in interventions, evidence from randomized controlled efficacy trials, and applied application examples. The theoretical models section will not include an exhaustive

summary of all of the available models, but will summarize the models most frequently used for the particular health behavior.

## Physical Activity
### Physical Activity Prevalence and Recommendations
The American College of Sports Medicine (ACSM) recommends that adults participate in 30 minutes or more of moderate-intensity physical activity on 5 or more days per week or 20 minutes or more of vigorous-intensity physical activity on 3 or more days per week (Haskell et al., 2007). Moderate- and vigorous-intensity physical activity can be combined to meet the above recommendations. Only 45%–50% of Americans meet or exceed this recommendation (USDHHS, 2001b). Therefore, approximately half the U.S. population is at an increased risk of cardio-vascular disease, cancer, type 2 diabetes, and other

health problems. Consequently, promoting physical activity participation is an important public health issue.

## Health Benefits of Physical Activity

Physical activity is associated with decreased rates of all-cause mortality among both men and women (USHHS, 2001a). Specifically, physically active individuals have a 30% lower risk of mortality than inactive individuals. The leading cause of death among Americans is cardiovascular disease. One-third of Americans have some form of cardiovascular disease, including hypertension, coronary heart disease, heart failure, or stroke (Rosamond et al., 2008). In recent years, cardiovascular disease has decreased due to decreased cholesterol levels, a decline in cigarette use, and better controlled blood pressure levels. Unfortunately, one modifiable risk factor for cardiovascular disease that has remained relatively constant is physical activity participation (USDHHS, 2001b). Research indicates a strong relationship between physical activity and reduced rates of cardiovascular disease (USDHHS, 2001b). Therefore, increasing physical activity among Americans has the potential to make a significant public health impact on decreasing rates of cardiovascular disease.

The leading cause of death among men and women below 80 years of age is cancer (Jemal et al., 2008). It is estimated that 38% of women and 45% of men will be diagnosed with cancer during their lifetime (USDHHS, 2001b). Participation in regular physical activity has been shown to reduce the risk of certain types of cancers, especially breast and colon cancer. For example, individuals who participate in 3–4 hours of physical activity per week that is at least of moderate intensity, have a 20%–40% reduced risk of breast cancer and a 30% reduced risk of colon cancer (USHDDS, 2001b). Additional research is needed to determine if greater amounts of physical activity are associated with greater risk reductions.

Physical activity is also important for preventing and treating *metabolic syndrome*, which refers to a combination of medical disorders that increases the risk of diabetes and cardiovascular disease (USDHHS, 2001b). Physical activity has also been shown to prevent type 2 diabetes and plays a significant role in its treatment. The role of physical activity for treating type 1 diabetes is less clear, although it appears that physical activity may be helpful. Finally, physical activity has also been shown to be helpful in preventing and treating gestational diabetes (i.e., diabetes during pregnancy) (USDHHS, 2001b).

Physical activity can be helpful for weight loss and for weight maintenance following weight loss. However, the amount of physical activity needed for weight loss is significantly higher than the recommendations listed earlier (USDHHS, 2001b). For a modest weight loss of 1%–3%, it is estimated that individuals need to walk for 4 miles per hour for 150 minutes or more or jog for 75 minutes per week at a pace of 6 miles per hour. However, a higher duration of physical activity is recommended for individuals seeking weight losses greater than 1%–3%. Regarding weight maintenance following weight loss, it is estimated that individuals would need to walk 54 minutes per day at a pace of 4 miles per hour or jog 26 minutes per day at a pace of 6 miles per hour. Calorie restriction is also a very important component of weight loss and weight maintenance, and this component will be explored more thoroughly in the weight management section.

Physical activity has been shown to improve mental health. For example, Blumenthal and colleagues (2007) found that physical activity participation was just as effective as antidepressant medication in a randomized controlled trial in reducing the incidence of depression. Interestingly, studies indicate that moderate and high levels of physical activity are just as effective as low levels of physical activity in combatting depression (USDHHS, 2001b). Physical activity is also associated with a reduced risk of anxiety disorders (USDHHS, 2001b).

Finally, physical activity is associated with musculoskeletal and functional health. For example, physical activity reduces the risk of hip fractures (USDHHS, 2001b). Additionally, resistance training, such as weight-lifting, improves bone mineral density (USDHHS, 2001b). Regarding functional health, research indicates that physical activity delays the cognitive decline associated with aging and the onset of dementia. Studies suggest that physical activity may also be helpful in treating symptoms of Alzheimer disease.

## Theoretical Models
### SOCIAL COGNITIVE THEORY
Social cognitive theory (SCT) is one of the most common theories used in physical activity intervention studies (e.g., Marcus et al., 2007a,b; Wilcox et al., 2008). Social cognitive theory postulates that there are multiple influences on behavior, including both cognitive and social variables (Bandura, 1986). One construct frequently associated with SCT is self-efficacy. Bandura (1986) conceptualizes self-efficacy as one's confidence in being able to carry out a specific

behavior. Related to physical activity, self-efficacy refers to one's confidence to be physically active in certain situations (Marcus, Selby, Niaura, & Rossi, 1992). For example, an individual may have high self-efficacy to be physically active during manageable work weeks but low self-efficacy during busy work weeks. Other theoretical constructs related to SCT include outcome expectations, enjoyment, and decisional balance. Outcome expectancy refers to an individual's estimate that participating in physical activity will lead to a particular outcome. Examples of expectancies include improved mood, increased energy, and better sleep. Enjoyment of physical activity is an individuals' ratings of various attributes of physical activity (Kendzierski & DeCarlo, 1991). Examples include physical activity leading to gratification, exhilaration, and/or invigoration.

Social support is also considered part of SCT. Social support has been defined as feeling loved, cared for, and valued, as well as having a sense of belonging (Cobb, 1976). Three constructs of social support theory that relate to physical activity include supportive climates, support networks, and social integration (Laireiter & Baumann, 1992). Support networks include specific individuals who can provide support for the individual adopting and maintaining physical activity, such as family members, co-workers, and friends. For example, social support persons can remind the individual about the importance of physical activity or even participate in physical activity with the individual. Research indicates that high social support from family members is related to increases in physical activity (Courneya & McAuley, 1995; Oka, King, & Young, 1995). Supportive climates refer to the quality of the social relationships. For example, this could refer to how committed the support person is in assisting the person adopting increased physical activity. Finally, social integration refers to being integrated with a social group that has the same objective as the client, such as physical activity adoption.

#### THE TRANSTHEORETICAL MODEL

The transtheoretical model (TTM) is another common model utilized in physical activity intervention studies (e.g., Dunn et al., 1997; Marcus et al., 2007a,b). This theory posits that individuals move through a series of stages as they adopt and maintain physical activity (Marcus & Lewis, 2003; Prochaska & DiClemenete, 1983). Specific stages include: precontemplation (not intending to become physically active), contemplation (intending to become physically active in the next 6 months), preparation

(physically active sometimes, but not at the recommended levels), action (physically active at the recommended levels, but for less than 6 months), and maintenance (physically active at the recommended levels for 6 or more months). The TTM also posits that individuals use different processes of change as they progress through the stages. Specific behavioral processes include: (1) committing oneself; (2) reminding oneself; (3) enlisting social support; (4) rewarding oneself; and (5) substituting alternatives (Marcus, Rossi et al., 1992). Specific cognitive processes include: (1) comprehending benefits; (2) increasing knowledge; (3) increasing healthy opportunities; (4) being aware of risks; and (5) caring about consequences to others. Additionally, the TTM conceptualizes that the importance of the theoretical constructs may vary across time. For example, it is assumed that cognitive processes change prior to behavioral processes, based on the assumption that individuals modify their cognitions before engaging in behavioral strategies to change a behavior. Another construct related to the TTM is decisional balance. Decisional balance refers to weighing the pros and cons of becoming physically active. It is hypothesized that the pros and cons change as individuals progress through the stages of change (Marcus, Rakowski, & Rossi, 1992).

### Efficacy of Physical Activity Interventions

Studies indicate that theory-based physical activity interventions are efficacious for increasing physical activity. A variety of types have been tested using randomized controlled trials including face-to-face interventions (e.g., Dunn et al., 1999), Internet (Marcus, Lewis, et al., 2007), telephone (e.g., King, Haskell, Young, Oka, & Stefanick, 1995), and tailored print (e.g., Marcus, Napolitano et al., 2007). Below we provide a brief summary of the evidence for each type of intervention.

#### FACE-TO-FACE

Research indicates that face-to-face interventions are effective for increasing physical activity; however, there is some evidence that non face-to-face interventions may be more effective. For example, Dishman and Buckworth (1996) conducted a review of 127 studies published between 1965 and 1995 and found larger effect sizes for interventions using non face-to-face methods (e.g., print mailings, telephone) when compared to completely face-to-face interventions. Furthermore, face-to-face interventions have several limitations. First, face-to-face interventions are costly, given the staff time involved

in delivering the interventions. Additionally, unlike non face-to-face interventions, such as telephone calls, face-to-face interventions present time, child-care, and transportation barriers to participation. The authors of this review reported an overall success rate of 70%–88% regarding the percentage of individuals increasing their physical activity.

### INTERNET-BASED INTERVENTIONS

The support for Internet-based intervention is mixed. Some studies show positive results, whereas other have found no effect of the intervention (for a review see Ciccolo, Lewis, & Marcus, 2008). One problem is that many of these studies did not use control groups and compared the Internet intervention to other types of interventions. In many of these studies, change in physical activity was found over time, but no differences were found between groups. For example, Marcus and colleagues randomized 249 sedentary participants to one of three interventions: Internet-based, print-based, or physical activity websites that were currently available to the public (e.g., American Heart Association, American College of Sports Medicine). Participants in the tailored Internet arm were regularly prompted to access a physical activity intervention website and received tailored feedback based on responses to questionnaires. The print intervention received the same tailored feedback, and this was an approach that has been shown to be effective (Marcus et al., 1998; Marcus, Napolitano, et al., 2007). Participants in all three arms self-monitored their physical activity using an Internet-based or paper log, depending on the arm, and were given incentives for self-monitoring. Results indicated that participants in all three arms of the study significantly increased their physical activity from baseline to 6 and 12 months; however, no differences were found among groups. Specifically, the Tailored Internet group increased from a median of 0 minutes per week at baseline to 120 minutes per week at 6 months and 90 minutes per week at 12 months. The Standard Internet group increased from a median of 10 minutes per week at baseline to 90 minutes per week at 6 months and 80 minutes per week at 12 months. The Tailored Print Group increased from a median of 0 minutes per week at baseline to 112.5 minutes per week at 6 months and 90 minutes per week at 12 months. It is possible that the self-monitoring alone was the efficacious component for the Standard Internet arm.

### TELEPHONE AND PRINT INTERVENTIONS

Research indicates that telephone and print interventions are efficacious for increasing physical activity (Eakin, Lawler, Vandelanotte, & Owen, 2007; Marcus, Napolitano et al., 2007). For example, Eakin and colleagues (2007) conducted a review of telephone-based interventions for physical activity and dietary behavior change and found that 69% of the telephone-based physical activity interventions were efficacious. There is some evidence that tailored print-based interventions may be more efficacious than telephone-based interventions. For example, Marcus, Napolitano, and colleagues (2007) randomly assigned 239 sedentary participants to one of three conditions: telephone, tailored print mailings, and contact control condition. Participants in the telephone and print interventions significantly increased their physical activity relative to the contact control condition at 6 months; however, at 12 months, the print-based intervention was more efficacious than the telephone-based intervention. Specifically, the print group increased from a mean of 20.19 minutes per week at baseline to 129.49 minutes per week at 6 months and 162.37 minutes per week at 12 months. The telephone group increased from a mean of 19.75 minutes per week at baseline to 123.32 minutes per week at 6 months and 100.59 minutes per week at 12 months. The contact control group increased from a mean of 19.36 minutes per week at baseline to 77.67 minutes per week at 6 months and 81.92 minutes per week at 12 months. It is possible that as the number of contacts decreased between 6 and 12 months, participants in the print-based intervention made an easier transition to maintaining physical activity with fewer contacts than did participants in the telephone intervention. More research is needed to better understand the relative efficacy and cost-efficacy of print and telephone interventions.

## Application of Physical Activity Interventions: Individual-level Approach

The following summarizes a physical activity intervention that could be applied at an individual level. This particular intervention could be administered in face-to-face sessions or via the telephone. The overall concepts of the intervention are based on the Transtheoretical Model (Prochaska & DiClemenete, 1983; Marcus & Lewis, 2003) and SCT (Bandura, 1986), both described earlier. More information regarding individual-level approaches can be found in Marcus and Forsyth, 2008.

### PHYSICAL ACTIVITY ASSESSMENT

The first component of the intervention is to assess how much physical activity the client is currently

participating in. The best strategy for assessing physical activity is to ask the client to think back over the previous week and recall how many minutes of physical activity he or she engaged in each day. If the previous week was not a typical week in terms of physical activity, then the previous week should be assessed. If 2 weeks prior is still not typical, then the client should recall how much physical activity he or she does in a typical week on average during the previous 3 months. Taken together, both the frequency (number of times per week) and duration (number of minutes per session) should be documented.

Physical activity should be defined to the client as anything that feels as hard, or harder than a brisk walk. It can also be described as something that feels like being late for an appointment, trying to catch a bus, or trying to get out of the rain. Basically, physical activity is any activity that elevates heart rate. Additionally, the activity should be done for at least 10 continuous minutes to be considered physical activity. Once the baseline level of physical activity is determined, the physical activity prescription can be generated by the counselor.

### PHYSICAL ACTIVITY PRESCRIPTION

The physical activity prescription will depend upon the client's current level of physical activity. If the client is participating in no physical activity, he or she should start with two 15-minute brisk walks done during a 1-week timeframe. The frequency of the physical activity should first be increased, followed by increases in duration. More specifically, the number of days should gradually increase to 5, followed by an increase in the duration to 20, 25, and finally 30 minutes. The client can also divide his or her physical activity into 10 minute bouts throughout the day, or perform it all at once.

The client can choose the type of physical activity; however, many clients will choose brisk walking, given it is inexpensive, convenient, special equipment is not needed, and it is medically appropriate for almost everyone. Clients should be instructed to walk briskly enough to feel their heart rate increase (typically, a pace of 3 to 4 mph). In cases of inclement weather, walking at the mall is often a good option. Also, clients may want to consider purchasing a treadmill if possible, which offers various settings, including inclining the walking deck to create more challenging workouts. In general, it is the client's decision regarding the type of physical activity.

### MONITORING INTENSITY

Clients should be instructed to perform their physical activity in the moderate or harder range. The counselor calculates their target heart rate by taking 220 minus their age and then multiplying that number by 60%–70% for the moderate range. If the client wishes to be physically active in the vigorous range, the number should be multiplied by 75%–80%. Clients should check with their doctor before stepping up the intensity of their workouts to the vigorous level. The easiest and most accurate way to monitor heart rate is by using a heart rate monitor watch. The watch displays the current heart rate of the client by detecting heart rate using a band that is worn right below the chest. However, if a heart rate monitor is not worn, heart rate can be assessed manually by placing the index and middle finger on one side of the neck. The client should monitor his or her heart rate for 15 seconds and multiple by 6. This should be done every 15 minutes during physical activity.

When being physically active outside, another way to monitor progress is by using a global positioning system (GPS) watch. The GPS watch uses satellites to monitor distance walked or jogged. On the watch, the time, heart rate, current pace, and calculated mileage is displayed. This watch can be motivating to clients to increase their intensity by increasing their pace and overall mileage. Many clients find it useful to obtain the same feedback provided by a treadmill while being able to enjoy the outdoors.

### SAFETY ISSUES

There are safety issues to consider when participating in physical activity. First, it is important to do a 5-minute warm-up and end with 5 minutes of cool-down. On extremely hot or cold days, it is important to walk inside (such as at a mall), do an exercise video, use home equipment, or go to the gym. If the client's preference is to always do outdoor activities, encourage him or her to do the physical activity in the early morning or evening during hot, humid weather. Clothing should be loose fitting, and staying hydrated is very important. In cold weather, outdoor activities should be avoided if it is icy due to the risk of falling. However, if it is not icy, it is fine to do physical activity outside as long as the client dresses in layers and wears protective clothing such as a scarf, hat, and mittens. Many running stores offer special clothing that can be worn in cold weather.

It is important to wear safety equipment during certain types of physical activity. For example,

a bicycle helmet when bicycling is always recommended. It is also recommended to do physical activity during the daylight hours; however, this may not always be feasible. If doing physical activity outdoors at dawn, dusk, or evening, the client should wear bright-colored clothing equipped with reflectors. It is also important to have at least one physical activity partner when engaging in physical activity at night. Clients often report that they "zone out" while being physically active. Remind the client to stay alert to passing traffic, especially at intersections; never assume that drivers can see pedestrians. Finally, it is important for the client to listen to his body. If he experiences pain, tightening of the chest, or a pain down one side of the arm, physical activity should be discontinued immediately and medical personnel should be alerted.

For clients who plan to walk, run, or bicycle outside, the general rules of the road should be discussed. For example, walkers and runners should walk or run against traffic, and bicyclists should stay on the side of the road that follows the flow of traffic. Obviously, walkers and runners should use the sidewalks whenever possible. Given the foot traffic on sidewalks, it is sometimes safer for bicyclists to ride on the road rather than on the sidewalk.

### SELF-MONITORING AND GOAL SETTING

Two of the most important components of a physical activity intervention are goal setting and self-monitoring. Participants should be given a log to document their physical activity. It is useful to have the log look like a calendar, so that the client can write down the duration and type of activity done each day. Clients may also find it useful to put stars on a posted calendar so others can see their achievements.

Progress toward goals should be assessed at the beginning of each session, and a new goal should be set at the end of the session. If goals were met, the client should be reinforced for meeting those goals, and he should reward himself for meeting his goal. If goals were not met, an assessment of what particular barriers interfered with accomplishing the goal should be conducted. It is important to give the client feedback on how she is doing and identify any ups and downs regarding achieving goals. The counselor and client should strategize regarding how to attain the goals.

The goals should be specific, attainable, and measurable. For example, vague goals such as "I will do my best" should be avoided. If the client is currently doing no activity, he or she should avoid setting a goal of jogging five times per week for 30 minutes each time. As an example, a more attainable and specific goal might be, "I will walk for 15 minutes at lunch and 15 minutes after dinner, 3 days this week." It is important to remember that achieving a goal is important for increasing confidence.

Both short- and long-term goals should be set. The short-term goal should include specific goals for the next week, and long-term goals should include the next 6 months. The ultimate goal should be to engage in physical activity five or more times per week for 30 minutes or more each session, and this should likely be the long-term goal. The weekly short-term goals should gradually increase activity in order to eventually reach the long-term goal.

It is often helpful to compare physical activity adoption with some other behavior the client has successfully adopted or stopped previously. The client should be asked why he or she was able to make that particular change, and what helped with her success. Also, assess what factors interfered with success in the long term. What had to be given up to make time for physical activity and how much value was placed on what was given up should also be assessed. Overall, it is important to help the client find more time in the day to be physically active.

### BENEFITS OF PHYSICAL ACTIVITY

The many benefits of physical activity should be discussed with the client. It will be important to discuss the benefits that are particularly relevant for the client. For example, if the client has a family history of cardiovascular disease, the fact that physical activity significantly reduces the risk of cardiovascular disease should be emphasized. As discussed previously, other long-term benefits of physical activity include reduced risk for some types of cancer (e.g., colon, breast), stroke, osteoporosis, obesity, and type 2 diabetes. Although it is important to discuss the long-term benefits of physical activity, many clients find the immediate benefits of physical activity more rewarding and therefore, it is important to also emphasize these benefits. For example, many clients find that physical activity improves mood, sleep, anxiety, energy level, and overall functioning. Many clients report that, after beginning a physical activity program, they have less fatigue and are more energized throughout the day. This should be emphasized with the client, given that one of the barriers to physical activity is often feeling fatigued. The client should be reminded that on days when he or she feels tired, although it may seem counterintuitive,

physical activity may actually help give him or her a boost of energy.

## SOCIAL SUPPORT

Social support is one of the key factors in helping a client adopt physical activity. The counselor should assess if a spouse or significant other can support physical activity, and if there are specific things they can do to encourage physical activity. This could include engaging in physical activity with the client, reminding them to be physically active, or taking care of household responsibilities, such as childcare, while the client engages in physical activity. If the spouse or significant other is not supportive, the counselor should assess why they are not supportive. Some common reasons include taking away time from the significant other, expenses related to physical activity, and difficulty completing household tasks. It is sometimes helpful to do a joint session with both the client and significant other to assess any resistance to the client's becoming physically active.

Social support can also come from other family members, friends, and the work environment. For example, some work environments encourage physical activity by offering on-site facilities, release time from work for physical activity (especially during lunch), and reimbursement for gym memberships. Friends can also be an important source of support for physical activity. Physical activity can become a social event, by meeting a friend at the mall to walk or exercising at the gym with a friend next to you on the elliptical trainer. Clients can also be encouraged to tell their friends about their plan for adopting physical activity, so that these friends can encourage and reward the client for meeting his or her goals.

## ENJOYMENT

To increase the likelihood of maintaining physical activity, it important to make physical activity as enjoyable as possible, and to ensure it is not aversive. The counselor should assess what the client likes and dislikes about physical activity. For example, changing the type of physical activity that the client does on a monthly basis can help decrease boredom. Changing the environment can also be helpful; for example, engaging in physical activity outside if physical activity is normally done inside. If the client is physically active at a gym, listening to music or watching television can be helpful. Other tips include engaging in physical activity with other people, buying an exercise video, trying a new exercise

class, or buying a new piece of exercise home equipment.

## SELF-EFFICACY

Self-efficacy for physical activity refers to one's confidence for being physically active in challenging situations. Self-efficacy can be assessed by asking how confident the client feels about engaging in physical activity during the following five situations (rated on a 5-point Likert scale ranging from not at all confident to extremely confident): (1) Feeling tired; (2) in a bad mood; (3) not having time; (4) on vacation; and (5) when it is raining or snowing (Marcus, Selby, Niaura, & Rossi, 1992). The counselor should regularly convey to the participant that she believes the client will succeed in adopting physical activity. The counselor can discuss specific strategies for overcoming low self-efficacy for physical activity during one or more of the situations listed. If the client rates his confidence at a 1 or a 2, think about why he does not feel confident and discuss ways to increase confidence. If the rating is a 3, talk about what he likes the most and least about physical activity and consider ways to make physical activity more enjoyable. If the rating is a 4 or a 5, make plans for making sure physical activity becomes a habit. It is important to instill confidence that, if clients are not physically active for a short period of time, they can resume their physical activity as soon as possible. Instill confidence that the client can continue her physical activity program despite difficult times (e.g., increased stress, poor mood, busy work week).

## MAKING PHYSICAL ACTIVITY A HABIT

Once the client successfully adopts physical activity, it is time to start talking about making physical activity a habit. The counselor should discuss any benefits the client may have noticed as a result of physical activity, such as more energy, better weight management, and improved mood. Encourage the client to periodically remind herself about how she benefits from continuing with the physical activity program. The counselor should also discuss what the participant had to give up for physical activity and how important the things are that she had to give up. The client and counselor can think about any obstacles that might arise in the future that could interfere with her ability to stay active. A plan for how to deal with these potential issues should be created. Work with the client to instill confidence that she can start up the physical activity program,

if she should stop for any reasons. Remind the client how far she has come, and continue to praise her for her effort.

The counselor might make a suggestion to try a new activity or to ask someone else to do physical activity with them. The client might want to think of someone he or she would like to serve as a role model to. Another good strategy is to decide on the number of miles to accumulate from now until the next session. Agree on a small gift for accomplishing goals, and set up a plan for significant others to reward the participant for physical activity. The client's environment should include posted reminders about physical activity. Finally, "all or none thinking" should be avoided. If he or she misses a session or two, the program is not lost, and the client should hurry to get back in the habit.

RELAPSE PREVENTION

The counselor should discuss the possibility that a lapse will occur when maintaining physical activity over the long term. It is important to prevent the lapse from turning into a relapse, which refers to not being physically active for more than 1 week. Discuss how the client will get back on track and identify the trigger(s) for lapse. For example, many individuals stop being physically active when they get sick, and once physical activity is discontinued, an individual fails to begin the program again once he or she feels better. In this situation, the counselor would discuss with the client the importance of getting back to the physical activity program after being sick. Also, discuss with the client what will keep him or her motivated to get back on track. In summary, the counselor and client should make a plan for preventing a lapse or relapse from occurring.

## Weight Loss
### Prevalence of Obesity

The prevalence of obesity and being overweight has steadily increased in recent years, especially among men (Ogden et al., 2006). Specifically, 66.3% of adults are overweight or obese, and 32.2% are obese. The prevalence of extreme obesity (body mass index [BMI] of ≥40) is 2.8% in men and 6.9% among women. It appears that obesity increases with age, in that 36.8% of adults ages 40–59 are obese, which is higher than the 32.2% observed in the general public. Obesity is defined as a BMI of 30 or above, overweight is a BMI between 25–30, and normal weight is considered between 18.5 and 25. Body mass index is calculated by assessing weight in relation to height. The specific calculation is weight in

kilograms divided by the square root of height in meters. Other indicators of obesity commonly used in the literature are waist-to-hip ratio and waist circumference.

### Health Consequences of Obesity

Overweight and obesity are associated with numerous health problems, including type 2 diabetes, dyslipidemia (i.e., disruption in the amount of lipids in the blood), coronary heart disease, hypertension, gall bladder disease, stroke, sleep apnea, respiratory problems, osteoarthritis, and cancers, especially endometrial, prostate, and postmenopausal breast cancer (NHBLI, NIDDK, 1998; Renehan et al., 2008). Research indicates that the most significant health risk associated with obesity is type 2 diabetes. For example, in the Nurses Health Study, BMI was the most significant predictor of type 2 diabetes after adjusting for age (Colditz, Willett, Rotnisky, & Mason, 1995). When compared to women with a BMI of 21, women who had a BMI of 25 had a five-fold increased risk of diabetes, a 28-fold increase for those with a BMI of 30, and a 93-fold increase among those with a BMI of 35 or greater. Additionally, women who gained between 8–10.9 kg during the time of the study had a 2.7-fold increased in the risk of diabetes when compared to women whose weight did not change. Regarding men, after adjusting for age, the increased risk was 2.2-fold for a BMI between 25 and 26.9, 6.7-fold for a BMI between 29 and 30, and 42-fold for men whose BMI was 35 or greater, when compared to men with a BMI of less than 21 (Chan, Rimm, Colditz, Stampfer, & Willett, 1994). Additionally, a waist circumference of more than 40 inches is associated with an increased risk of diabetes by 3.5-fold after controlling for BMI (Lean, Han, & Seidell, 1998).

Research indicates that obesity is a significant predictor of coronary heart disease among both women and men. In the Women's Health Study (prospective cohort study of 38,987 women), both physical inactivity and higher BMI were individual predictors of coronary heart disease (Weinstein et al., 2008). The increased risk was 54% for overweight-active women, 87% for obese-active, 8% for normal weight-inactive, 88% for overweight-inactive, and 253% for obese-inactive. In a study among men, after adjusting for age, men who had a waist-to-hip ratio greater than or equal to .95 or a waist circumference of greater than or equal to 36.8 had a significantly increased risk of coronary heart disease (Rexrode, Buring, & Mason, 2001). Men in the highest quintile of waist circumference had a 60%

increase in coronary heart disease, and those in the highest waist-to-hip ratio quintile (.99) had a 50% increased risk. It should be noted that when BMI was controlled for, these relationships were significantly attenuated. Among men in the highest BMI quintile, the risk of coronary heart disease was 200% and was 252% for myocardial infarction.

Polednak (2008) recently published a study estimating that 50,535 of new cancers among women and 33,966 of new cancers among men diagnosed in 2007 were attributed to obesity. Therefore, obesity accounts for 6% of all new cancer cases. The association between obesity and cancer was observed for endometrial cancer, kidney cancer, gallbladder cancer, breast cancer, adenocarcinoma of the esophagus, liver cancer, and colorectal cancer (Polednak, 2008). The estimates of this recent study are larger than what has been observed in previous studies; however, previous studies have included fewer types of cancers than those in the Polednak study.

Finally, obesity is a significant predictor of sleep problems. For example, one study found that 50% of men and 33% of women with a BMI above 35 reported snoring and sleep apnea, compared to 15.5% of the normal-weight participants (Grunstein, Stenlof, Hedner, & Sjostrom, 1995). This is important, given that sleep apnea is associated with myocardial infarction and stroke. Additionally, snoring is a significant risk factor for sleep-related strokes (Palomaki, Partinen, Erkinjuntti, & Kaste, 1992).

## *Theoretical Models*

### LEARNING THEORY

Learning theory forms the basis for many weight loss interventions (Brownell, 1998). One component of learning theory is *operant conditioning,* in which individuals receive positive reinforcement, which in turn increases a particular behavior. Specifically related to weight loss, participants who change their diet and increase physical activity are typically rewarded with weight loss. Other important components of learning theory that are commonly applied to weight loss include goal setting, self-monitoring (i.e., documenting everything one eats during the day and documenting physical activity), and stimulus control (e.g., keeping junk food out of the house). Feedback is also a common component of weight loss interventions. For example, research indicates that a higher rate of self-weighing is associated with greater weight loss and therefore, daily weighing is recommended (Linde, Jeffery, French, Pronk, & Boyle, 2005).

### ECOLOGICAL MODEL FOR HEALTH PROMOTION

McLeroy and colleagues (1988) proposed the Ecological Model for Health Promotion, which has been applied to weight loss interventions. This theory postulates that five factors influence behavior change. The first component includes interpersonal factors, which refer to characteristics of the individual such as behavior, attitudes, self-concept, and knowledge. Interpersonal intervention strategies include mass media, educational programs, organizational incentives, and support groups. This intervention strategy focuses on changing behavior at the individual level, including changing attitudes, intention to comply with behavioral norms, and knowledge. The second component is interpersonal processes, which refer to social networks and social support systems. These could include friends, families, co-workers, neighbors, and acquaintances. Interpersonal intervention strategies focus on changing the individual's behavior through social influences. The third component of the ecological model is institutional or organizational factors, which refer to social institutions. This is an important component, given that a majority of people spend much of their time in organizational settings ranging from daycare, primary and secondary school, university, and the workplace. The intervention focus should be on how characteristics of the organization can be used to instill behavioral changes. The fourth component is community factors, which are relationships among institutions, informal networks, and organizations. The community can include families, neighbors, friendship networks, voluntary agencies, schools, health providers, and/or political entities. The final component is public policy, which refers to laws and policies at the local, state, and national level. Specifically, policy development activities can include increasing public awareness, creating advocacy groups to lobby for obesity-related laws and policies, and/or passing legislation related to obesity.

### NEW MODEL FOR BEHAVIORAL MAINTENANCE

Several models have been applied to weight loss, including the theory of reasoned action (Ajzen & Fishbein, 1980), the Health Belief Model (Rosenstock, Strecher, & Becker, 1988), and the theory of planned behavior (Ajzen, 1991). These tend to focus on the premise that positive expectations about the outcome of behavior change predict weight loss. The problem with these models is that they focus on the initiation of a behavior and do not explain how behavior is maintained.

Rothman (2000) postulates that the factors involved in behavioral maintenance are different from the factors involved in behavioral initiation. Specifically, Rothman theorizes that individuals will maintain a behavior if they are satisfied with their accomplishments. Therefore, the feeling of satisfaction as a result of changing a behavior suggests that initially changing the behavior was the correct decision. Individuals maintain the behavior to maintain the positive situation and to avoid a negative state. Specifically related to weight loss, individuals work to maintain their weight loss because they are happy with their decision to lose weight and the weight loss results.

## Efficacy of Weight Loss Interventions

### BEHAVIORAL GROUP-BASED INTERVENTIONS

Structured group behavior weight loss programs are the most efficacious nonmedical intervention for overweight and obesity (Wing, 2004). These interventions include cognitive restructuring (i.e., restructuring thoughts that are more consistent with weight loss), stress management, physical activity, self-monitoring (e.g., writing type of food and related calories into a food diary each day), social support, and relapse prevention. Participants typically eat a low-fat, balanced diet (1,200–1,800 calories per day depending on starting weight) and engage in physical activity (30–60 minutes per day). The groups are typically run by trained behavioral counselors. The weight loss typically reported by the behavioral group interventions is 10% of baseline weight over approximately 6 months (Wing, 2004). One limitation of the group-based intervention is that it is expensive and typically not reimbursed by health insurance. Other barriers to group-based interventions are time, childcare and transportation. Therefore, researchers have begun to examine other non face-to-face interventions, such as Internet interventions, for weight loss.

### INTERNET-BASED INTERVENTIONS

Saperstein and colleagues (2007) recently completed a review examining the efficacy of Internet-based interventions for weight loss. Five of the six studies reviewed indicated that Internet-based weight loss interventions were efficacious. There is also some evidence that more intensive interventions lead to better efficacy. For example, Tate and colleagues (2001) randomly assigned participants to either a 6-month Internet behavior therapy intervention or an Internet education intervention. The education intervention participants received access to links for Internet weight loss resources. Participants in the behavior therapy intervention received access to the links plus lessons via e-mail, self-monitored, and received individualized therapist feedback. Participants in the Internet behavior intervention lost significantly more weight than did individuals in the Internet education intervention (4.1 kg vs. 1.6 kg at 6 months). In a follow-up study, Tate and colleagues (2003) randomized participants to either basic Internet or to Internet plus behavior e-counseling. Both groups were instructed to submit weekly weights. Again, the behavior counseling group lost significantly more weight than the basic Internet group (4.4 kg vs. 2.0 kg at 12 months). Given the high cost of individualized Internet-based feedback, more research is needed regarding how to better automate Internet interventions without reducing efficacy.

### TYPE OF DIET

Nordmann and colleagues (2006) conducted a meta-analysis that included studies that have compared traditional low-fat high-carbohydrate diets to low-carbohydrate diets. Findings from this meta-analysis indicated that low-carbohydrate, non–calorie restriction diets were at least as efficacious as traditional low-fat, higher-carbohydrate diets that did restrict calorie intake. Unfortunately, there were several limitations to these studies, including high attrition rates, short duration, and small sample sizes. Recently, Gardner and colleagues (2007) randomized female participants to one of four conditions: (1) Atkins (≤20 grams of carbohydrates for the first 2–3 months and then ≤50 grams of carbohydrates); (2) Zone (40% carbohydrate, 30% protein, and 30% fat); (3) LEARN (55%–60% of food from carbohydrates and <10% of food from saturated fat, increased physical activity, caloric restriction, behavior modification strategies); and (4) Ornish (10% of energy from fat). The LEARN and Zone diets had specific goals for caloric intake, whereas the Atkins and Ornish diets did not. The LEARN and Atkins diets emphasized multiple strategies, such as preparation and relapse prevention strategies. The LEARN diet had the greatest emphasis on behavior modification. Results indicated that weight loss was greatest for women on the Atkins diet when compared with the other diets at 12 months. Specifically, participants in the Atkins diet lost 4.7 kg, the Zone 1.6 kg, LEARN 2.6 kg, and Ornish 2.2 kg.

### MAINTENANCE

Despite the positive effects of weight loss interventions, the evidence for maintaining weight loss in

the long-term is discouraging. For example, Fappa and colleagues (2008) recently conducted a weight loss intervention review and concluded that support for long-term weight loss maintenance is weak. Based on this review, it appears that booster sessions following the conclusion of the weight loss interventions may be an important component for weight loss maintenance. Additional research is needed to better understand effective strategies for long-term weight loss maintenance.

## COMMUNITY-BASED INTERVENTIONS

Given the widespread obesity epidemic (Ogden et al., 2006), researchers and policy makers have called for community-based interventions that have the potential to make a significant public health impact (Horowitz et al., 2008). Byers and Sedjo (2007) recently reviewed community-based interventions for obesity and concluded that there is little evidence regarding the efficacy of these types of interventions. However, the lack of efficacy is likely due to the lack of large-scale intervention trials in this area. Therefore, despite the lack of efficacy, community-based interventions should be implemented and evaluated in the real-world setting to establish their effectiveness. The U.S. Surgeon General has released a "call to action" regarding community-based interventions (USDHHS, 2001b). The remaining part of this section will therefore focus on community intervention strategies and this "call to action."

## Application of Weight Intervention: Community-level Approach

The following community-level approach will be based on the social ecological model in that the environment will be an important component of the intervention. We will summarize strategies that can be used in a variety of settings, including schools, community centers, worksites, health-care centers, and health insurance companies. We will address what community leaders, policy makers, school administrators, and health-care providers can do to address the obesity epidemic.

## LEVERAGING COMMUNITY ORGANIZATIONS

Several community-level organizations are in a position to influence community member eating behaviors, including churches, local organizations, fitness centers such as the YMCA, daycare centers, and community centers. For example, healthy lifestyle education classes could be offered to community members of these organizations. Experts in nutrition and physical activity participation could hold

sessions within these organizations and encourage community members to enlist each other's support for making healthy lifestyle choices. This model works best when community members are already involved with one another and are, therefore, able to provide support to one another. It is also possible to leverage events like harvest parties, community field days, and festivals to disseminate healthy-eating messages and to foster community efforts for healthy lifestyle changes (Economos & Irish-Hauser, 2007).

## CHANGING THE BUILT ENVIRONMENT

Many neighborhoods are designed for motorists rather than bicyclists and walkers, which is important given that research indicates that higher levels of "walkability" (defined as higher density, pedestrian-friendly design, proportion of residents walking to work, and land-use diversity) is correlated with a decreased risk of overweight and obesity (Smith et al., 2008). Additionally, research indicates that land layout is significantly related to overweight and obesity (Ewing, Schmid, Killingsworth, Zlot, & Raudenbush, 2003). Many suburbs that were built in previous decades are subject to what has been termed "suburban sprawl," in which it is necessary for community members to own an automobile. The "suburban sprawl" effect makes it difficult for community members to bicycle or walk to their local grocery store or library. Additionally, research indicates that individuals who live near wooded walking paths and sidewalks containing shops are more likely to be physically active than are individuals not living near these amenities (Corti, Donovan, & Holman, 1997). Therefore, increasing access to walking paths and sidewalks with shops may increase physical activity, which in turn may play a role in decreasing obesity.

The Prevention Institute profiled 11 different case examples of implementing changes to the built environment for purposes of improving health (Prevention Institute, 2004). Many of these case examples were directly related to leading a healthier lifestyle. One case example was the Evergreen Cemetery Jogging Path. In this example, a predominately Latino, urban community in California rallied community-wide support to create a safe, 1.5 mile walking/jogging path. Previously, community members did not have access to open spaces or parks in their neighborhood. In another example, community members of Rochester, New York, increased access to healthy food by organizing the building of a full-service supermarket into a community that lacked a single grocery store. In Denver, Colorado,

a community/academic organization transformed vacant lots into a community garden in an urban neighborhood. Finally, 20 well-respected arts, culture, and academic institutions formed the Fenway Alliance and revitalized the culture district by improving walkability through major infrastructure projects in Boston, Massachusetts.

## U.S. SURGEON GENERAL'S CALL TO ACTION

The U.S. Surgeon General published a report outlining community-level strategies to prevent obesity in five settings (USDHHS, 2001b). These are outlined in more detail below.

### Family and Communities

Communities and families are at the foundation of adopting and maintaining a healthy lifestyle. Families can share their knowledge with their friends, children, and community members. It is important to increase consumer awareness of the health problems related to being overweight and/or obese. Community coalitions should be formed to developed opportunities for healthy food choices and opportunities to engage in physical activity. Community members should encourage the food industry to provide reasonable beverage and food portion sizes. The availability of nutritious foods that are prepared away from home should be increased. More community-based obesity prevention and treatment programs should be created. It is important to empower families to manage weight within their own family through skill building in parenting, behavioral management, and meal planning. The efforts to encourage health eating patterns that are consistent with the Dietary Guidelines for Americans should be expanded. Demonstration grants should be provided to inner cities, where healthy affordable foods are often not available. The consumption of at least five servings of fruits and vegetables should be supported. Community environments that promote and support breast-feeding should be created to decrease weight retention during the postpartum phase. Time spent watching television and other sedentary behaviors should be decreased at the family level. Demonstration grants should be given to community leaders who address the lack of public access to safe places in which to be physically active and the lack of affordable physical activity programs. Finally, community leaders should pass important public policy regarding increasing accessible sidewalks, stairs, and walking and bicycle paths.

### Schools

A majority of children spend a large portion of their time each day in school and therefore, this is an ideal setting to prevent overweight and obesity. Schools have a unique opportunity to engage children in healthy eating and physical activity, and to communicate important healthy eating and physical activity messages. Public schools should not simply focus on health and physical education, but also modify the school's physical and social environment so that it is conducive to healthy lifestyles. It is important for schools to ensure that meals offered for breakfast and lunch are nutritious. It is also important that health education helps students develop the skills necessary to enjoy healthy eating and physical activity. Schools should also adopt policies ensuring that beverages and foods available on school grounds are consistent with a healthy lifestyle. This can be a complex issue, given that many schools bring in substantial revenue via vendors of sugared drinks. Schools that provide choices in addition to the main school lunch offerings should have healthy options presented through school stores and vending machines. Schools may consider prohibiting vending machines and school stores that compete with healthy school lunches. It is important to have adequate time for students to eat their school lunches, as well as adequate time for physical activity during recess. All children should receive regular physical education that will help develop the knowledge, skills, and behaviors essential for lifelong physical activity. Extracurricular physical activity programs should also be included. Finally, schools should encourage after-school programs that implement time for physical activity and healthy snacks.

### Health-care

The health-care industry provides a unique opportunity to intervene on healthy eating and physical activity. Many individuals look to their health-care providers for advice regarding health and therefore, these providers are in a unique situation to help individuals achieve their weight loss goals. It is important that health-care providers and health-care students are trained in prevention and treatment strategies for obesity. Partnerships among health-care providers, schools, faith-based groups, and other community organizations should be formed to target the environmental and social causes of obesity. Additionally, obesity should be clarified as a disease for reimbursement coding. Currently, most nutrition and physical activity interventions for obesity are not reimbursed

by insurance companies, and classifying them as a disease may be the first step in changing health insurance reimbursement policies.

*Media and Communications*

One strategy recommended by the U.S. Surgeon General's report is to conduct a national campaign that fosters public awareness of the health benefits of healthy diet choices and the importance of maintaining a healthy weight. It is also important to encourage reasonable consumer goals for weight management programs and products. Via media outlets, many products promise lofty weight loss goals, and this leads to frustrations and dropout by participants in the programs when the goals are not attained. It is important to incorporate healthy eating and regular physical activity messages into television programming targeting youth. For example, a recent magazine advertisement, asks, "Which do you think your kid will think is cooler?" The advertisement goes on to show a picture of an apple and a juice box. This type of advertising needs to be examined by policy makers to determine if it is potentially harmful to children. Finally, media professionals should be encouraged to utilize actors' influences as role models for healthy eating and physical activity.

*Worksites*

A majority of Americans spend most of their day at work and, therefore, the worksite has the potential to make a significant impact on lifestyle choices. Workers can benefit from flexible work hours that allow them to create opportunities for regular physical activity. It is important to have protected time for lunch, so that time is available for physical activity, and healthy food options also should be available. Worksites can create incentives for workers maintaining a healthy body weight. Health insurance companies, offered through the worksite, should offer physical activity and weight management programs. For example, many health insurance companies are beginning to offer subsidies for health club memberships, as long as the members visits the gym a certain number of times (Lewis, Martinson, Anderson, & Sherwood, 2006). Finally, it is important for the work environment to promote and support breast-feeding, given that this can lead to effective weight loss for some individuals during the postpartum phase.

## Smoking Cessation
### Smoking Prevalence

The Centers for Disease Control (CDC) estimates that 20.8% of adults (45.3 million) in the United States smoke cigarettes (CDC, 2007a). Approximately, 23.9 % of 18- to 24-year-olds smoke cigarettes, 23.5% of 25- to 44-year-olds, 21.8% of 45- to 64-year-olds, and 10.2% of individuals over the age of 65. Regarding ethnicity, 32.4% of Native Americans smoke cigarettes, 23.0% of African Americans, 21.9% of Caucasians, 15.2% of Hispanics, and 10.4% of Asians. For educational levels, the highest prevalence is among adults with a general education development (GED) diploma (46.0%) or 9–11 years of education (35.4%), and the lowest prevalence is among individuals with an undergraduate degree (9.6%) or a graduate degree (6.6%; CDC, 2007b).

### Health Consequences of Cigarette Use

Smoking is the number one preventable cause of death in the United States (USDHHS, 2001a). Each year, over 438,000 people die from smoking related illness. Of the 438,000 people who die prematurely from smoking-related illness, approximately 59.5% are male and 40.5% are female (CDC, 2005). In data collected by the CDC from 1995 through 1999, the American Cancer Society (ACS) reports on average male smokers lost 13.2 years of life expectancy and female smokers lost 14.5 years. Smokers also experience a decrease in quality of life as a result of smoking (American Cancer Society [ACS], 2007a).

In a review of CDC data compiled since 2000, the ACS indicates that both disease and quality-of-life issues are prevalent for smokers. It is estimated that 8.6 million people had at least one chronic disease related to a history or prevalence of smoking (ACS, 2008). Disease issues for this group include chronic bronchitis, emphysema, coronary heart disease, strokes, and cancer. Additionally, smokers can find managing daily activities challenging due to limitations in breathing and moving.

### Smoking and Morbidity

Cigarette smoking is responsible for approximately 90% of lung cancer deaths in men and 80% in women. Since 1950, lung cancer for women has increased 600%. By 1987, it became the leading cause of cancer-related death among women (USDHHS, 2001a). Novotny and colleagues (1998) indicate that the risk of dying from lung cancer is 22 times greater for men and 12 times greater for women who smoke than for nonsmokers. Cigarette smoking also increases the risk of dying from coronary heart disease by two- to three-fold. In relation

to chronic obstructive lung diseases, approximately 90% are attributable to cigarette smoking. Smoking is responsible for more deaths each year than the combined effects of human immunodeficiency virus (HIV), illegal drug use, alcohol use, motor vehicle injuries, suicides, and murders (CDC, 2005).

Smoking cessation is associated with significant health benefits. For example, the U.S. Surgeon General (2004) published the following sequence of benefits that begin immediately upon quitting:

- *20 minutes after quitting*: Heart rate and blood pressure drop.
- *12 hours after quitting*: Carbon monoxide levels in blood drop to normal.
- *Between 2 weeks and 3 months after quitting*: Heart attack risk drops, circulation improves, and lung function increases.
- *Between 1 month and 9 months after quitting*: Coughing and shortness of breath decrease.
- *1 year after quitting*: Risk of coronary heart disease is half of that of a smoker's.
- *Between 5 years and 15 years after quitting*: Risk of stroke is reduced to that of a nonsmoker.
- *10 years after quitting*: Lung cancer death rate is about half that of a smoker; risk of cancers of the mouth, throat, esophagus, bladder, kidney, and pancreas decrease.
- *15 years after quitting*: Risk of coronary heart disease is back to that of a nonsmoker.

Using data collected from 1997–2001, the CDC determined that the annualized health-related economic loss to the United States was $167 billion dollars due to cigarette smoking, with $75 billion attributed to direct medical costs and $92 billion dollars to lost productivity (CDC, 2005). This calculates to approximately $3,561 per adult smoker per year (CDC, 2000, 2003, 2007). In summary, given the strong relationship between smoking and premature death, low quality of life, and the costs associated with cigarette use, smoking cessation initiatives are necessary to improve public health in the United States. It is also important to focus on programs that prevent smoking initiation among adolescents and young adults.

## Theoretical Models

### TRANSTHEORETICAL MODEL

The TTM has been described previously in this chapter and therefore, this section will focus solely on the TTM as applied to smoking cessation. Fava and colleagues (1995) postulate that the TTM's five stages of change "provide temporal organization" for monitoring the individual's progress through a smoking cessation program. The five stages of change are precontemplation (smoker has no intention of quitting within the next 6 months), contemplation (smoker is considering quitting within the next 6 months), preparation (smoker is planning on quitting within the next 30 days, and has made one attempt to quit within the last year), action (the smoker has been continuously abstinent from 1 day to 6 months), maintenance (smoker has been continuously abstinent for more than 6months). The behavioral and cognitive processes described in the physical activity section can also be applied to smoking cessation.

### COGNITIVE-BEHAVIORAL THERAPY

Cognitive behavior therapy is the leading type of intervention for treating psychological conditions (David & Szentagotai, 2006). The cognitive component of CBT has roots in Albert Ellis' ABCDE model (Ellis, 1962). According to this model, "A" refers to an individual perceiving an event as either rational or irrational, which then creates a belief or cognition. This belief will then lead to "B," which are the emotional and cognitive consequences. The rational beliefs will lead to "C," the functional consequences or irrational and dysfunctional consequences. Next, "D" refers to the individual actively disputing his or her irrational beliefs (restructuring the thought). Finally, "E" refers to assimilating the more rational thoughts with the outcome and has a positive impact on the individual's cognitive, emotional, and behavioral responses (David & Szentagotai, 2006; Ellis 1994). The cognitive component of CBT emphasizes the human condition and the effect of changing dysfunctional thoughts. There is a focus on making a fundamental shift in the way an individual perceives, reflects upon, and processes his or her life circumstances (Dobson & Kahtri, 2000). Cognitive-behavioral therapy assumes that an individual's behavior is significantly mediated by his or her process of cognition, and therefore changing dysfunctional cognition will lead to change in behavior.

The behavioral component of CBT for smoking cessation has its foundations in operant conditioning, which is the premise that adding something positive (i.e., positive reinforcer) or taking away something negative (i.e., negative reinforcer) following a behavior will lead to increases in that behavior. Specifically related to smoking, the relaxed feelings resulting from smoking can serve as a positive reinforcer and the alleviation of stress can serve as a negative reinforcer, with both leading to an

increase in smoking behavior. Specific behavior strategies for smoking cessation will be discussed later in the application section.

### RELAPSE PREVENTION

Relapse prevention strategies are key to long-term smoking cessation. Relapse prevention theorists differentiate between lapses and relapses. A *lapse* refers to a single event in which a smoker consumes tobacco following a period of recovery. Some individuals may be able to effectively cope with this "slip" and quickly return to smoking cessation. Others may continue to use tobacco and move closer to relapsing. A *relapse* refers to the smoker who has been unable to maintain his or her therapeutic gains and returns to smoking (Marlatt & Gordan, 1985). Much of the success or failure regarding relapse rests in the individual's ability to demonstrate his or her new skills acquired through therapy.

Three factors play a role in relapse prevention: lifestyle factors, intrapersonal factors, and interpersonal factors. Lifestyle factors include having a poor image of roles regarding social functions, such as school, work, and/or church. Intrapersonal factors involve negative physical states, poor mood, impulsive decision making, and temptations. Interpersonal factors could include lack of support from peer groups, social pressure, relationship conflicts, and poor social skills (Daley & Salloum, 1999). To effectively avoid the transition of a lapse into a relapse, the therapeutic plan must include strategies that identify, interrupt, and reverse episodes of lapses. For example, the counselor could identify factors, such as stress, that may trigger a relapse and strategize alternative ways to deal with this smoking trigger. Additionally, ongoing stress may result in a lapse becoming a relapse and, therefore, stress reduction strategies to use during a lapse should be emphasized.

## *Efficacy of Smoking Cessation Programs*
### NICOTINE REPLACEMENT THERAPY

Stead and colleagues (2008) recently conducted a Cochrane review evaluating the efficacy of nicotine replacement therapy (NRT). Based on the 111 qualifying studies, they concluded that all commercially available forms of NRT (i.e., transdermal patch, nasal spray, gum, inhaler, tablets/lozenges) increase the chances of a successful quit attempt. Specifically, they estimated that NRT increases quit rates by 50%–70%. This was found regardless of setting, and efficacy appears to be independent of the intensity of additional support for smoking cessation. The exact quit rates vary depending on the type of

sample. As an example, if the quit rate without pharmacotherapy was estimated at 15%, the authors of the review concluded that NRT would add an additional 8%, to make the total quit rate 23%.

### COMPUTER-BASED INTERVENTIONS

Walters and colleagues (2006) conducted a review of 19 studies examining the efficacy of computer- and Internet-based interventions. Forty-seven percent of the studies demonstrated long-term smoking cessation success. The quit rates were highly variable across studies, with a majority ranging from 21% to 26%; however, a few studies reported quit rates as low as 4%. The heterogeneity of the methods across the studies makes it difficult to determine consistent predictors of efficacy. However, based on this review, the first-generation intervention, which included mailing tailored computer-generated feedback reports, was associated with better outcomes (57% of the studies reported better efficacy for the intervention group vs. the comparison group).

Bock and colleagues (2009) recently conducted a review assessing the content and quality of smoking cessation websites available to the public. Of the 23 websites meeting their inclusion criteria, these websites scored significantly higher in quality ratings when compared to their review published in 2004 (Bock et al., 2004). Specifically, the websites had significantly improved on practical counseling, providing advice to quit, motivational strategies to quit, and recommending pharmacotherapy. Fifty-nine percent of the studies offered at least one interactive feature. Overall, it appears that quality websites are currently available to the public; however, the authors concluded that additional improvements are still needed.

### GROUP AND INDIVIDUAL-LEVEL THERAPIES

Stead and Lancaster (2005) conducted a Cochrane review evaluating the efficacy of group-based therapies relative to self-help materials or no intervention and compared group therapy to individual therapy. Fifty-five trials met the criteria for inclusion. The authors concluded that group therapy was superior to self-help and other less intensive therapies. However, there was no adequate evidence to determine whether group therapies were more efficacious than individual-level therapies. However, it is important to note that group therapies have advantages over individual-level therapy in that more clients can be managed by a given facilitator, which results in lower cost.

Fiore and colleagues (2000) conducted a meta-analysis examining the effectiveness of interventions

using various types of behavioral therapies. Interventions that had statistically significant abstinence rates tended to include practical counseling, such as skills training, problem solving, relapse prevention, and stress management (odds ratio [OR] = 1.5); support during a client's treatment phase (OR = 1.3); focus on increasing social support for the client (OR = 1.5); and use of adverse smoking procedures (OR = 1.7).

## Application of Smoking Cessation Intervention: Group-level Approach

The following applied intervention example focuses on delivering the intervention to a group of approximately 8–12 participants. However, the basic concepts could also be applied at an individual level. Nicotine replacement therapy is recommended as an adjunct to any therapy (Fiore et al., 2000; Stead & Lancaster, 2005), and therefore we will discuss this therapy prior to the group-level approach. It is also important to note that motivational interviewing is another popular intervention for smoking cessation. The general principles of motivational interviewing are giving advice, removing barriers, providing choice, decreasing desirability, practicing empathy, providing feedback, clarifying goals, and actively helping. More information on motivational interviewing is available elsewhere (Miller & Rollnick, 1991).

### NICOTINE REPLACEMENT THERAPY

Nicotine replacement therapy can increase the success rate of any intervention by treating the withdrawal symptoms following smoking cessation. The NRT instructions should be read carefully, given that side effects can be unpleasant when used inappropriately. The FDA has approved five types of NRT, including the nicotine patch (transdermal nicotine systems), nicotine gum (nicotine polacrilex), nicotine nasal spray, nicotine inhalers, and nicotine lozenges (ACS, Guide to Quitting Smoking, 2007b). Nicotine replacement therapy can be used effectively for a set period of time, and discontinuing NRT should be done gradually as instructed. Some individuals may experience withdrawal symptoms as NRT is discontinued. Physicians commonly prescribe adjunct medications to help with the smoking cessation process. For example, bupropion (Zyban) is an extended-release antidepressant specifically used to treat nicotine withdrawal. Another example, varenicline (Chantix), interferes with nicotine receptors in the brain to decrease the pleasure of nicotine and lessen withdrawal symptoms (ACS, Guide to Quitting Smoking, 2008). It is important

to note that varenicline and NRT should not be used at the same time.

### COGNITIVE-BEHAVIORAL THERAPY

The following intervention is based on the Commit to Quit (CTQ) program (Marcus et al., 1999), which uses CBT for smoking cessation that can be applied at the group level. The Substance Abuse and Mental Health Services Administration (SAMHSA), which is part of the U.S. Health and Human Services Department, has deemed the Commit to Quit program an evidence-based program. Therefore, the complete Commit to Quit manual is available through the SAMHSA website at http://nrepp.samhsa.gov/. The program emphasizes stress management, developing self-awareness regarding cues that trigger smoking desire, reconfiguring habitual smoking environments, acquiring skills to avoid lapses, improving body image, and managing weight.

The program operates on the assumption that smoking is a learned addiction, the habit is learned over time, and addiction may lead to withdrawal. Goals for the program include the gradual elimination of smoking, the reduction of present nicotine levels in the body, the elimination of the need for cigarette smoking by teaching relaxation and self-talk to deal effectively with stressful situations, and the elimination of excessive weight gain associated with smoking cessation. Components of the program include self-monitoring, the daily recording of smoking habits, the establishment of a quit date (i.e., date smoking cessation will occur), stress management training, development of a set of self-instructions to help counter maladaptive thoughts that may lead to smoking, learning relaxation techniques to handle everyday stress in a more positive manner, and weight management, which includes increasing activity and making better food choices to decrease the likelihood of gaining weight.

Various modalities are used to increase the breadth of learning. For example, home activities create awareness of real-time issues associated with smoking. Group activities are done on-site to reinforce cognition surrounding the positive rationale for quitting. Handouts are also used to increase learning. Additionally, physical activity and general wellness (e.g., good nutrition) are also emphasized to help with the weight gain commonly following smoking cessation.

### BEGINNING STRATEGIES FOR SMOKING CESSATION

Three basic strategies are used for the reduction of the number of cigarettes smoked per day; these

include temporal control, situational control, and access to cigarettes. *Temporal control* is a time-based technique in which the goal is to limit the number of cigarettes smoked over a set period of time. *Situational control* involves limiting smoking to specific situations. *Access to cigarettes* refers to changing the place where cigarettes are stored in one's surroundings. All of these strategies are designed to increase awareness of the habits involved with smoking and to delay the smoking process. This delay will, in turn, create a moment for the client to evaluate the need for the cigarette and make a choice to resist the urge to smoke. These strategies are often combined to increase their effectiveness.

### SELF-MONITORING

Self-monitoring cards are used to record information around smoking while the client is at home. There is a card for each day of the week, and the cards are placed around the package of cigarettes with a rubber band. The cards allow the client to quickly and effectively categorize his or her smoking tendency. The card includes time of day, activity at time of smoking, an emotion rating (i.e., bored, depressed, happy, relaxed, etc.), and a "need rating" of 1, 2, or 3 (1 being high need). This process increases personal awareness and understanding of the smoking patterns. It also adds the component of "hassle" to smoking, given that the client is required to take an extra step to have a cigarette. The self-monitoring cards are utilized throughout the group sessions as discussion and learning points.

### SOCIAL SUPPORT

Developing social support involves enlisting the aid of others to help the individual quit. There are two ways to use social support. The first involves enlisting current support from friends, family, and co-workers in the quitting process. The second is through the use of a buddy system, in which both individuals are attempting to quit smoking. In this situation, there are five central points: (1) stay in regular contact; (2) praise success and problem-solve together; (3) do not use time together to complain; (4) offer encouragement, understanding, and empathy; and (5) commit to holding each other as capable and to a high standard.

### PREPARATION FOR QUITTING

Starting the process of quitting begins with date selection. Initially, morale will be high, as there are positive feelings surrounding this change. As the date draws closer and withdrawal symptoms may begin to become prominent, morale will wane. It is at this point that the strategies learned will become important to success. Lapses can become compounded with a failure to recognize the moment and to intervene in a positive manner. Thoughts of failure based on unrealistic expectations can overtake one and lead to failure across the board, as opposed to a simple mis-step. It is especially important at this moment that connection to the program is maintained. Failure to do so isolates the individual and will lead to forces that may become too strong to overcome. Recognizing this prior to the actual quit date, and thus creating contingencies and scripts to follow in this event, will create the opportunity for greater success in the cessation program. In the end, lapses are learning tools, not failures. Another technique used by many is the replacement of cigarettes with snacks. Although this can be effective, it is important to reach for a low-fat, low-calorie snack versus a high-fat, high-calorie snack. Reading labels is an important skill here, as many low-fat snacks can be high in sugar and thus high in caloric content.

### RELAPSE AVOIDANCE

Relapse is both a physiological and psychological phenomena. As nicotine clears the system in a few days, the physiological component can be overcome rather quickly. However, relapse can also occur much later, and this involves the psychological component. It is important for participants to determine what situations will potentially lead to a lapse, and having a plan for dealing with high-risk situations should be discussed. Triggers can include times of emotional distress as well as positive situations. Removing potential triggers is an important strategy for avoiding relapse. Alcohol may be associated, as well. It does not take long for a relapse to become too strong to overcome. Negative self-talk associated with failure to keep the "oath of abstinence" can creep in and overtake the individual, leading to giving up altogether. Anticipation of high-risk situations should assist in reducing this likelihood. This awareness is developed through the close use of self-monitoring cards, which allow the smoker to create scenarios likely to engender temptations and urges. These can lead to the development of a personalized relapse plan.

Limiting access to cigarettes is also an effective process for avoiding relapse. Rules for this behavior are: (1) Do not keep any cigarettes in the home, car, or office; (2) never smoke a cigarette that is given to you; (3) never buy cigarettes in the place you are

about to relapse in, for instance a restaurant; and (4) after buying a pack a cigarettes and smoking one, throw the rest away.

## SMOKING AS A LEARNED ADDICTION

Over many years, smoking becomes associated with specific situations, thoughts, and feelings, which are referred to as triggers. Situations (drinking coffee), thoughts (I need a break from this work), and feelings (tension) will become strong cues to smoke. Therefore, developing coping mechanisms will assist the client in his or her pursuit of a smoke-free life. The client should list specific triggers, which starts the process of creating new coping mechanisms. Relaxation techniques become important at this phase to combat nervousness from withdrawal and psychological dependency. Other coping skills include changing behavior, such as walking instead of smoking; changing thoughts, by using positive self-talk instead of negative self-talk; and altering bodily reactions by using relaxation techniques to relieve stress. Activity is stressed as a positive replacement for smoking.

## MANAGING WITHDRAWAL

Most withdrawal symptoms will be dramatically reduced by the third and fourth week of cessation. Continued development of strategies and identification of triggers is necessary. Awareness of negative self-talk can lead to the ability to reframe this through positive imagery and relaxation techniques. Making lifestyle changes, such as changing to tea from coffee, will help in managing situational triggers. Reinterpretation of withdrawal symptoms as the body's natural correction will also reframe the discomfort on a cognitive level. Development of a written plan for both situational and bodily reaction triggers and the associated coping mechanism will assist in successful retraining.

## NEGATIVE SELF-TALK

Negative self-talk should also be addressed. The use of thought-stopping and positive thinking is a learned skill and must be practiced to be effective. One example of negative self-talk is rationalization, "I feel worse now than when I was smoking." The response could be, "STOP, this is withdrawal and will only last a few days. I will survive." Another example is nostalgia, "This cup of coffee would taste much better with a smoke." The response could be, "STOP, those times are gone now. It won't be long until I enjoy my good health even more." The group

can use written materials to better understand the thought-stopping process.

## SLIP CARDS

Slip cards are also useful tools at this stage of the program. They allow detailed information to be gathered when an individual has a lapse. They also offer possible delays in the smoking process, given that they contain a set of instructions to be read prior to smoking. Continuing to practice the process of "letting go" through relaxation techniques should be stressed.

## MAPS: MULTIPLE APPROACHES FOR THE PREVENTION OF SMOKING

For a lapse to not become a relapse, strategies must be established to create a successful environment once a lapse has occurred. It is important to understand that, even in the face of a relapse, specific steps can be followed to continue the work that has been accomplished. Specific steps include: (1) Start self-monitoring immediately; (2) limit access to cigarettes; (3) set another quit date; and (4) implement the strategies that the individual has learned during this program. Connection to the program is vital in this circumstance.

Weight gain is also an area that should be addressed. The first strategy to address weight gain is to increase activity to offset the reduction in metabolic rate that follows nicotine elimination. The second is to be aware that snacking may replace the old habit of smoking. Strategies to avoid high-sugar snacks, often craved when quitting smoking, should be implemented.

## STRESS AS A TRIGGER

Stress can serve as a significant trigger for smoking. Awareness of the level of life stress will allow the client to make choices as to how much he or she is willing to take on while going through this important behavior modification. Opportunities to reduce life stress should be identified and explored.

## FOCUS ON TIME MANAGEMENT

Time management is a skill that will allow the client a better opportunity to manage everyday stress that may trigger relapse. Seven steps have been identified to help manage time appropriately: (1) Create time every day to organize and plan your day; (2) break big tasks into small steps and prioritize them; (3) utilize categories to describe prioritization such as "must do," "hope to do," and "do if there is time";

(4) beware of peak energy times and use them to your advantage; (5) concentrate on one task at time; (6) take short breaks when you feel fatigue coming on; and (7) celebrate the finishing of tasks for the day and find positive rewards for meeting smoking cessation goals.

## PROBLEM-SOLVING SKILLS

Developing problem-solving skills is a behavior that can replace the need to smoke. Once rational skills are in place, stress can be reduced, given that there is a sense of control over life events. Steps in the development of these skills are (1) Identify the problem or trigger; (2) brainstorm solutions; (3) evaluate the solutions and rate them; (4) pick the best solution; and (5) use the chosen solution the next time a trigger appears. Using a worksheet to practice this skill will provide a framework for the client. In this phase of the program, skill development is essential for success once the program has completed. At this point, it is important to continue to review all materials and constructs to ensure a full understanding of their use and power for the client.

## PROGRAM REVIEW

At the end of the intervention, it is important to remember that this is just the beginning for the group members. Fears surrounding the idea of no longer smoking may arise and therefore, it is important to stress the "one day at a time" model. It is important to review the basic concepts of the program with the group members and discuss triggers that may occur in the future. Additionally, it is important to encourage the client to seek out ways to become more physically active, given that this may help alleviate the weight gain that commonly occurs following smoking cessation, and that physical activity may be a useful strategy for coping with urges to smoke. The earlier physical activity section offers some practical tips for helping clients adopt and maintain physical activity. Finally, as mentioned previously, all of the preceding subsections are derived from the Commit to Quit program. More information regarding this program can be found at http://nrepp.samhsa.gov/.

## Abstract

This chapter illustrates the mental health clinician's relationship with behavioral emergencies. The chapter begins by distinguishing the terms *behavioral emergency* and *behavioral crisis,* and underlying themes among all behavioral emergencies are identified. Given that most clinicians will face a behavioral emergency in their careers, the importance of enhancing the process of educating and training practitioners for such situations far beyond the minimal training that currently exists is highlighted. The chapter continues by exploring various aspects of evaluating and managing high-risk patients (i.e., those who exhibit violent tendencies toward themselves or others, and those at risk for victimization). It includes a discussion of the benefits and limitations to estimating life-threatening risk factors and specific protective factors. The chapter concludes by discussing the emotional impact that working with high-risk patients has on clinicians, and an emphasis is placed on the importance of creating a supportive work environment.

**Key Words:** Behavioral crisis, behavioral emergency, high-risk patients, risk factors, suicide, victimization, violence

A couple in their late 20s has come to you because they have been having intense arguments that seem to revolve around the wife's desire to have some independent activities in her life. She complains that her husband is too controlling and gets upset when she engages in activities that do not include him, such as going out with her girlfriends. He states that she is neglectful of their life together at home. After a session or two, it is revealed that there have been times when their arguments have led to physical abuse, in which the husband has beaten his wife. It also becomes clear that the young woman now wants out of the marriage, but she is frightened by her husband's violent temper. In the context of a session, she brings up the possibility of a trial separation. The husband is obviously upset and does not agree. At the end of the meeting, you counsel them about how such a difficult and emotional topic could lead to an escalation of anger and further

physical abuse. They both say that they will not let anything like that happen.

Two days later, you receive a phone call from the wife. She reports that, in fact, they had a terrible argument after the therapy session and her husband threatened her with a knife, saying that he would kill her and himself if she left him. She fled to her sister's house, where she has been staying, but she now believes that she has seen her husband sitting outside in his car watching the house. She is not sure what to do.

As we shall see later in this chapter, there is evidence that such a high-risk scenario, or one similar to it, could occur to any clinician with an active practice. If you were that clinician, how might you evaluate and manage such a situation? Clearly, your response could have very serious consequences for your patients or clients, as well as for yourself. It is a situation that we refer to as a potential *behavioral emergency.*

In our view, a behavioral emergency exists (a) when a patient or client is at *imminent* risk of intentionally behaving in a way that will result in serious harm or death to self or others, or (b) when a patient or client is at *imminent* risk of being a victim of serious harm or death. Fortunately, there are relatively few situations in clinical practice that would be considered behavioral emergencies. They include serious suicidal states, potential violence to others, situations of grave risk to a relatively defenseless victim (e.g., a severely battered spouse or an abused child), and states of very impaired judgment in which the individual is endangered.

As used in the definition above, the term *imminent risk* means that, in the clinician's opinion, there is a risk that the patient will harm or kill him- or herself, or others, "in the next few minutes, hours, or days" (Pokorny, 1983, p. 249). It has been pointed out, however, that, since patients who appear to be at imminent risk are usually excluded, or removed, from research studies for ethical and clinical reasons, there are actually no empirical investigations of imminent risk (Kleespies, Niles, Kutter, & Ponce, 2005). Simon (2006), in discussing the risk of suicide, has recently made this point in a more pronounced way by maintaining that the term *imminence* defies definition (at least in any measurable terms), and that there are, in fact, no known short-term risk factors that identify when, or if, a patient will attempt or complete suicide.

Despite this state of affairs, potential behavioral emergencies (such as the one described earlier) happen, and, when they happen, the mental health clinician's skill and coping resources can be seriously tested. One would hope that the clinician forms an opinion of the likelihood of imminent risk based on the available evidence known about the individual patient. It should be clear, however, that a statement implying that a patient or client is at imminent risk for harm to self or others is a clinical judgment; and, as Simon (2006) has pointed out, such judgments should not be taken as implying prediction. As will be discussed later, the prediction of statistically rare events such as suicide, violence, or victimization is beyond our current capabilities.

In this chapter, we will further illustrate what is meant by a behavioral emergency by contrasting it with the concept of a *behavioral crisis*, a term with which it has often been confused. We will then contend that an inter-relatedness exists among the major behavioral emergencies that goes beyond the simple fact that they can be life-threatening events. Next, we will present evidence that virtually any

mental health practitioner can, from time to time, have a behavioral emergency to deal with in his or her clinical practice. A case will be made that, therefore, all psychology practitioners should receive education and training in evaluating and managing such situations. We will then offer a framework for estimating the risk of life-threatening behaviors, and proceed to discuss the evaluation and management of the suicidal patient, the potentially violent patient, and the patient who is vulnerable to victimization. We will conclude with a discussion of the emotional impact that work with high-risk patients can have on the clinician and the need for a work environment that supports the practitioner when managing such cases.

## Behavioral Emergencies Versus Behavioral Crises

As Callahan (1998, 2009) and Kleespies (1998, 2000) have pointed out, the concepts of behavioral emergency and behavioral crisis have been frequently confused or erroneously used interchangeably. They further note that it is important to understand the distinction between these concepts because it frequently drives our thinking, our decision-making, and our interventions when dealing with potential emergencies. A behavioral crisis is a serious disruption of the individual's baseline level of functioning, such that his or her usual coping mechanisms are inadequate to restore equilibrium. It is an emotionally significant event in which there may be a turning point for better or worse. It does not necessarily imply danger of serious physical harm or life-threatening danger (as in an emergency). Working for an emergency service or in an emergency room, however, one is asked to assess a variety of psychological crises, and sometimes these crises can contribute to the development of emergencies. An important part of the work is attempting to distinguish between crises that may lead to emergencies and those that, in all likelihood, will not.

As alluded to earlier, the confusion between the concepts of *crisis* and *emergency*, of course, extends to the level of intervention. Callahan (1998) has found that many clinicians seem to think that crisis intervention is needed when an individual is suicidal or potentially violent. Although this could be the case in situations of low risk, when risk is high, the most appropriate response is not crisis intervention, but *emergency intervention*. An emergency intervention implies three things: (1) an immediate response to perceived imminent risk, (2) management to prevent harm or death, and (3) resolution

of the immediate risk within a single encounter. Crisis intervention, on the other hand, typically implies (1) a response within 24–48 hours, (2) therapy to develop or reestablish the ability to cope, and (3) resolution within four to six sessions. In clinical practice, there seems to be a heuristic value in making a distinction between these concepts.

## The Inter-relatedness of Behavioral Emergencies

For many years, Plutchik and his colleagues (e.g., Plutchik, Botsis, & van Praag, 1995) have theorized that suicide and violence reflect an underlying aggressive impulse that is modified by variables that they have referred to as *amplifiers* and *attenuators*. To support their theory, they have cited evidence of the overlap of suicidal and violent behavior in hospitalized psychotic adolescents and in incarcerated juvenile delinquents, as well as in adult psychiatric inpatients. In this same vein, Mann, Waternaux, Haas, and Malone (1999) conducted a study in which they interviewed 347 consecutive admissions to a psychiatric hospital and found that rates of lifetime aggression and impulsivity were significantly greater in suicide attempters than in those who had never attempted suicide. They concluded that, in estimating the risk of future suicidal acts, clinicians should factor in lifetime impulsivity and/or aggression. Similarly, Apter et al. (1995) assessed 163 consecutive admissions to an adolescent psychiatric inpatient unit for depression, suicidal behaviors, and violent behaviors. They found that both depression and violent behavior correlated significantly with suicidal behavior scores, but there was no significant correlation between violent behaviors and depressive symptoms. The authors hypothesized that two types of suicidal behavior may occur during adolescence: (1) a planned desire to die secondary to depression, and (2) behavior related to problems with aggression and impulse control.

Of course, it is obvious that violence begets victims; but, as Kilpatrick (2005) has pointed out, victimization can also contribute to suicidality and to the perpetration of violence in the future. In analyzing the data from a National Survey of Adolescents (Kilpatrick et al., 2003) involving more than 4,000 interviewees ranging in age from 12 to 17, Kilpatrick (2005) noted that victimization increased the risk of suicide attempts after controlling for risk of depression, post-traumatic stress disorder (PTSD), and drug use disorders. It was also found that, after controlling for other mental health problems, victimization increased risk for the perpetration of violence.

Finally, in a 7- to 8-year follow-up with this study, it was found that young women who were victimized as adolescents and developed PTSD were at high risk for revictimization. In addition, Ehrensaft et al. (2003) examined data gathered prospectively on a community sample of 543 children over a period of 20 years to test the relationship between childhood maltreatment, power-assertive punishment in childhood, and exposure to violence between parents on subsequent risk for adult partner violence. Among other things, they found that physical injury by a caretaker directly increased the probability of using similar violent tactics of conflict resolution in future intimate relationships. They also found that exposure to violence between parents posed the greatest independent risk for being a victim of any act of partner violence. Although the development of a conduct disorder in adolescence mediated the effect of child abuse, exposure to violence between parents and power-assertive punishment were nonetheless additional and potent predictors of the perpetration of violence on partners.

The findings of Kilpatrick et al. (2003) and of Ehrensaft et al. (2003) are supported by the extensive literature reviews of Kolko (2002) on child physical abuse, and of Berliner and Elliott (2002) on the sexual abuse of children. Kolko has summarized many studies demonstrating that a history of physical abuse in childhood puts individuals at greater risk of future aggression, poor anger modulation, impulsivity, and violent behavior; whereas Berliner and Elliott have noted numerous studies showing that a history of sexual abuse in childhood can lead to greater risk of depression, anxiety, lower self-esteem, and suicidal behavior. Thus, interpersonal victimization (particularly in childhood and adolescence), in addition to at times being a behavioral emergency itself, also appears to be a distal contributing factor in the development of other, future behavioral emergencies.

Despite these findings, the inter-relatedness of behavioral emergencies has not been a major focus of clinical or research attention until very recently. Rather, as Lutzker and Wyatt (2006) have pointed out, suicide research, violence research, and research on interpersonal victimization have been regarded as relatively independent areas of study. These authors further note that, for truly effective clinical service and research, one area should inform the other, and collaborative efforts are more likely to lead to more effective outcomes. One of the objectives of the current chapter is to promote such collaborative thinking, clinical service, and research.

## The Incidence of Behavioral Emergencies

Behavioral emergencies are clearly not limited to events that occur in an emergency room. As stated earlier, they can occur in any mental health clinician's practice. In this section, we present data relevant to the incidence of such events in practice.

### Patient Suicidal Behavior

Investigators have found that it is likely that a mental health professional will experience some form of client or patient suicidal behavior at some point in his or her career. McAdams and Foster (2000), for instance, reported that 23% of professional counselors who were surveyed experienced at least one client who committed suicide. Specifically among psychologists, Pope and Tabachnick (1993) found that approximately 29% of their national sample reported experiencing a completed suicide by one of their clients or patients; and the rate among psychiatrists has been reported to be as high as 51% (Chemtob, Hamada, Bauer, Kinney, & Torigoe, 1988; Ruskin, Sakinofsky, Bagby, Dickens, & Souza, 2004). Similarly, a study surveying social workers found that approximately 33% reported experiencing a suicide attempt or completion by a client at least once in their careers (Jacobsen, Ting, Sanders, & Harrington, 2004).

As would be expected, mental health trainees are also not immune to experiencing issues related to client suicidal behavior. In a study surveying psychology graduate students about their predoctoral training years, Kleespies, Penk, and Forsyth (1993) found that 97% had at least one patient (and sometimes many more) who reported suicidal ideation at some point during their graduate training. Further, 29% reported having had a client commit suicide, and 11% experienced having a client commit suicide. In the aforementioned study by McAdams and Foster (2000), of the 23% of professional counselors who reported having had a client commit suicide, approximately one-quarter of them were student counselors. Moreover, in surveys of psychiatric residents, Brown (1987), and, more recently, Ruskin et al. (2004) found that 31%–33% (or 1 in 3) residents reported having a patient who completed suicide during their residency years.

### Patient Violent Behavior

In addition to having a client or patient who engages in behaviors that could result in self-harm, many mental health professionals experience being victims of threats and sometimes physical violence themselves. Statistics gathered by the Bureau of Justice between 1992 and 1996 revealed that 80 of every 1,000 mental health professionals was the victim of some form of nonfatal workplace victimization each year (Arthur, Brende, & Quiroz, 2003). According to Warchol (1998), this rate of victimization is higher only for police officers, security guards, taxi drivers, prison guards, and bartenders.

MacDonald and Sirotich (2001) have suggested that clinicians under-report patient aggressive behavior, yet studies continue to support the fact that mental health professionals are at significant risk of being verbally and/or physically assaulted by those whom they are treating. For instance, a survey of 1,131 mental health professionals revealed that 61% reported being verbally and/or physically assaulted by a client or patient, and 29% reported that they had feared for their lives at least once during their professional careers (Arthur et al., 2003). Further, from a national survey of 340 psychologists, Guy, Brown, and Poelstra (1990) reported that almost 50% of their sample had been threatened with physical attack by a client or patient, and 40% reported actually being attacked. It is notable that 41% of the physical attacks reportedly occurred in public psychiatric hospitals and 22% in private psychiatric facilities. Of those who were attacked, 30% reported suffering some form of mild physical injury, and 10% reported moderate injury (Guy et al., 1990).

Further analysis of those who reported being victimized in the study by Guy et al. (1990) revealed that 46% of all attacks on therapists involved graduate students and trainees, and another 33% took place during the clinician's first 5 years after completing the doctoral degree. Guy and Brady (1998) offer some potential explanations for these findings. They include the suggestion that new therapists may be less apt to identify cues of violence, they may allow aggressive behavior to escalate as a result of setting and enforcing fewer limits or boundaries, and clinicians early in their careers may be more likely to work in inpatient settings with more severely impaired patients.

### Patients as Victims of Violence

It is not unlikely for a patient to have a history of some type of victimization, often beginning in childhood. For instance, the prevalence rates of childhood sexual assault (CSA) among women tend to consistently range between 15% and 33% (Polusny & Follette, 1995). Tewksbury and Mustaine (2001) reported that 22% of male undergraduates across 12 universities reported having been a victim of

sexual assault at some point in their lives, and approximately 27% of college-aged women reported having a history of CSA (Arata, 2002). In a study consisting of 941 participants, approximately 22% of women and 4% of men reported that they were a victim of at least one sexual assault after the age of 15, with 61% of these women and 59% of these men also reporting an experience of at least one CSA (Elliott, Mok, & Briere, 2004). Studies of gay/bisexual men reveal a prevalence of sexual victimization between 12% and 28% (Tewksbury, 2007). Further, in a survey of psychologists and family therapists, 42% of the clients being seen reported a history of CSA (Follette, Polusny, & Milbeck, 1994).

The prevalence of physical assault victimization in childhood, as well as in adulthood, is also remarkably high. MacMillan et al. (1999) reported that 24% of children surveyed reported experiencing some form of physical assault (e.g., biting, kicking, punching, beating, burning, shaking, or other form of physical harm). Among adults in a relationship, a national survey reported that 22.1% of women and 7.4% of men report that they had been a victim of intimate partner assault at some point in their lifetime (Tjaden & Thoennes, 2000), and the prevalence of physical aggression among treatment-seeking couples has been as high as 74% (Ehrensaft & Vivian, 1996).

### The Need for Training in Evaluating and Managing Behavioral Emergencies

Consistent with the findings just noted, a Task Force Report on Education and Training in Behavioral Emergencies[1] (Kleespies et al., 2000) has emphasized that virtually all psychologists who are active clinicians have behavioral emergencies of one type or another in their practice. The Task Force Report also recommended that all psychology practitioners be educated and trained to deal with such emergency situations.

Despite the Task Force Report and the data on the incidence of patient life-threatening behaviors presented earlier, the profession of psychology appears to have done little of a systematic nature to prepare clinicians specifically to cope with these critical events. As noted in the report, a study by Kleespies et al. (1993) found that only an estimated

55% of a sample of former graduate students in clinical psychology had some form of didactic instruction on suicide during their graduate school years. The instruction (when given) was quite limited (i.e., one or two lectures). In a subsequent survey of psychology internships and psychiatry residency programs, Ellis and Dickey (1998) found that psychology programs seemed to lag behind psychiatry programs in suicide-related training in most formats (e.g., seminars, journal clubs, case conferences, and assigned readings). Even in a format that psychology utilized to a greater extent (i.e., workshops), the overall utilization rate was low. In an earlier study, Bongar and Harmatz (1991) conducted national surveys of the Council of University Directors of Clinical Psychology Programs and the National Council of Schools of Professional Psychology and found that, when all the efforts of these groups were combined, only 40% of all graduate programs in clinical psychology offered some form of training in the study of suicide.

In their survey of patient violence, Guy et al. (1990) reported that the psychologists in their sample had a mean of 1 hour of clinical training on the management of patient violence during their predoctoral training years. After graduation, the mean was 2.3 hours. Could it be that lack of adequate training is related to the findings that less experienced therapists are at greater risk from patient violence?

In terms of working with victims of violence, such as sexually abused children, Alpert and Paulson (1990) reported that most professional degree programs in psychology did not incorporate CSA as an area of training. Moreover, in a national sample of psychologists, Pope and Feldman-Summers (1992) reported that *very poor* was the rating most frequently given to graduate training in the areas of sexual and physical abuse.

Twenty years ago, Covino (1989) suggested that psychology graduate and professional school programs were deficient in teaching the skills needed for dealing with behavioral emergencies. The survey of after-hours coverage in psychology training clinics by Bernstein, Feldberg, and Brown (1991) provided support for his contention. Twenty-five percent of the clinics in their sample provided no emergency coverage. Among those that did, there were reports of disarray in the emergency policies and procedures, concern that the services would not be sufficiently responsive, and uncertainty about continuity of student and supervisor availability, particularly during vacations and semester breaks.

---

[1] This Task Force Report was completed for the Section on Clinical Emergencies and Crises, Section VII of Division 12 (Society of Clinical Psychology) of the American Psychological Association.

The authors suggested that this state of affairs reflected a general inattention to emergency services in the field of professional psychology.

As noted earlier, behavioral emergencies confront the clinician with the need to make decisions that can have very serious, possibly irreversible, consequences. There can be far-reaching emotional, ethical, and legal repercussions. Society at large, through our legal system, holds psychologists responsible for observing a reasonable standard of care in managing behavioral emergencies. They can be held liable for negligence in malpractice litigation if their emergency care is found to be substandard. In this regard, if psychologists are to have a sound basis for fulfilling the duties attendant on their professional role, it seems crucial that they be provided with specific education and training on the evaluation and management of emergency situations.

It is very important to acquire a knowledge base about suicide risk and the risk of violence and victimization. Kleespies (2009) has proposed a curriculum for such a knowledge base. Applying a knowledge base in practice and with good supervision, however, leads to skill development and true clinical competency. When a patient or client is threatening suicide or is potentially violent, the situation can be anxiety arousing for the seasoned professional, let alone for those who are in training and less confident of their clinical abilities and status. A *mentor model* for learning under such conditions seems advisable, and the clinical internship seems to be an ideal site in which it can be applied. In this model, an experienced clinician and an intern are paired in settings such as an emergency room or an urgent care clinic or on a mobile crisis team. The intern then has the opportunity to observe and work with a professional who has been successfully engaged in this type of clinical work. Cases can be discussed on site and subsequently in a supervisory session. While the intern initially is more of an observer, the supervisor can gradually shift greater responsibility for the evaluation and management of cases to the professional-in-training. It is during this process of gradually increasing skill and responsibility that some inoculation to the stress involved in these emergency situations occurs—and stress inoculation is so very important to clear decision-making in situations where tensions can run high.

As Driskell and Johnston (1998) have pointed out, it is important to distinguish between *training* and *stress training*. These authors indicate that most training, which is focused on skill acquisition and retention, takes place under conditions designed to maximize learning—a quiet classroom, practice under predictable conditions, uniformity of presentation, and so forth. Some tasks, however, must be performed under conditions that are very different from a training classroom (e.g., conditions that include time pressure, ambiguity, a heavy task load, and distractions). The evaluation and management of behavioral emergencies can involve such circumstances, and it can be difficult to maintain effective performance and decision-making when there has been no training under such high-stress conditions.

## A Framework for an Evidence-based Approach to Estimating the Risk of Life-threatening Behaviors

Although it was suggested as an approach to estimating the risk of suicidal behavior, the framework proposed by Rudd and his associates (Rudd & Joiner, 1998; Rudd, Joiner, & Rajab, 2001) can be extended to organizing risk factors and estimating the risk of life-threatening behaviors more generally. Rudd and his colleagues proposed that the clinician think in terms of predisposing or distal risk factors, acute or proximal risk factors, and protective factors. Extended to life-threatening behaviors more broadly, distal risk factors form the groundwork upon which suicidal or violent behavior can take root. They are what make the individual vulnerable when proximal risk factors occur. Proximal risk factors, on the other hand, are closer in time to the life-threatening behavior itself, and tend to act as precipitants. They are not, however, in most circumstances sufficient in themselves to explain the occurrence of life-threatening behavior. Rather, in combination with a significant set of distal factors, they can create the conditions needed for life-threatening behavior to occur. Protective factors are conditions or characteristics (such as good social support or value-based inhibitions) which, if present, may decrease the risk of life-threatening behavior, but, if absent or diminished, may increase it. Although these are factors that might help the clinician be more specific about who may not engage in suicidal or violent behavior, research on them, as we shall see, has unfortunately been underdeveloped.

Rudd and Joiner (1998) suggested that the degree of risk for suicide can be estimated by weighing these three types of factors. They presented a gradation of suicide risk ranging from minimal to extreme that we propose may also be a fruitful way of estimating risk for violence or victimization. A person at minimal risk for life-threatening behavior might have no known distal risk factors or proximal risk factors and multiple protective factors, whereas

someone at moderate risk might have some distal factors, some proximal factors, and some protective factors that are beginning to weaken. Those in the extreme range, who may have multiple distal and proximal risk factors and lack protective factors, are more likely to be at imminent risk.

### The Limitations of Risk Estimation

This framework obviously provides only a *rough* guide for risk estimation in a clinical setting. As mentioned earlier in this chapter, the prediction of such rare events as suicide or homicide is not possible with the knowledge base and methodology currently available, and it would be misleading to imply that we can be more precise. Suicide, for example, has a base rate of approximately 12.4 per 100,000 in the general US population (McIntosch & Drapeau, 2012), whereas the homicide rate tends to be far lower at approximately 4.8 per 100,000 (US Bureau of Justice Statistics, 2011). Estimates of the suicide rate in the psychiatric population have been about five- or six-fold that of the general population, or approximately 60–72 per 100,000 (Tanney, 1992). Our clinical acumen as mental health practitioners and the existing assessment instruments at our disposal are simply not sensitive and specific enough to detect such infrequent events so that we might know with any degree of certainty which patients will actually commit suicide or homicide.

To further illustrate the difficulties of risk estimation, let us look at what is generally acknowledged as our best single predictor of suicide, a past suicide attempt. The problem with this predictor is that *only* an estimated 10%–15% of suicide attempters ever complete suicide, whereas an estimated 60%–70% of suicide completers commit suicide on the first known attempt (Maris, 1992). Thus, although a history of a suicide attempt heightens risk, the absence of such a history clearly cannot be taken as diminishing it. Possibly making suicide prediction still more difficult, Maris (1992) has argued that suicide completers and suicide attempters may represent separate but overlapping populations, as evidenced by the fact that the ratio of male-to-female completers is approximately 4:1, but the ratio of male-to-female attempters is approximately 1:4.

## Evaluating the Acute Risk of Suicide

In presenting risk and protective factors in the sections that follow, space does not permit an exhaustive review. We have therefore limited ourselves to some of the major factors that have been supported by the empirical evidence in the literature. (For more extensive reviews of suicide risk and protective factors, please see Kleespies & Dettmer, 2000a; Miller & Emanuele, 2009; Miller & Glinski, 2000; and Sullivan & Bongar, 2009.)

### Distal Risk Factors

#### DEMOGRAPHIC FACTORS

Historically, the elderly (≥75) have had the highest rate of suicide in the United States, but, in recent years, the middle-aged (ages 45–54) have had suicide rates that exceeded those of the elderly. Youth suicide (ages 15–24 and 25–34) rose through the 1980s and early 1990s, then seemed to peak in the mid-90s and to decline significantly compared to the previous decade (McIntosch & Drapeau, 2012). As noted earlier, men are nearly four times more likely than women to complete suicide, whereas women are four times more likely than men to engage in nonfatal suicidal behavior. In terms of race/ethnicity, Native Americans have the highest suicide rates in the United States. Whites typically have a suicide rate that is two to three times higher than blacks, and white males account for approximately 70% of all suicides in the United States. Socioeconomic status is not a strong predictor of suicide.

#### SERIOUS MENTAL ILLNESS

Serious mental illness has emerged as one of the strongest distal predictors of suicide; and, of course, certain mental illnesses can be both distal and proximal risk factors (as, e.g., when there is an acute exacerbation of depression in a patient with a preexisting diagnosis of chronic or recurrent depression). Literature reviews have summarized findings that over 90% of adults and adolescents who commit suicide suffer from a major psychiatric disorder (Kleespies & Dettmer, 2000a; Miller & Emanuele, 2009; Miller & Glinski, 2000; Sullivan & Bongar, 2009). Further investigation has found that only certain diagnoses are associated with a significantly elevated risk. The above-noted reviews identified mood disorders (primarily depression), alcohol abuse, and schizophrenia as diagnoses most strongly associated with a heightened risk in adults. An estimated 80%–85% of adults who complete suicide suffer from at least one of these diagnoses, and comorbidity only heightens risk. Other diagnoses that have been empirically associated with an increased risk of suicide include combat-related PTSD (Bullman & Kang, 1994), bipolar II disorder (Rihmer & Kiss, 2002), and several personality disorders, most prominently borderline personality disorder (Duberstein

& Witte, 2009). In adolescents, suicide attempts have been associated with major depression, substance use disorders, and conduct disorders, as well as with psychological characteristics such as impulsivity and poor affect regulation (Lewinsohn, Rohde, & Seeley, 1996; Miller & Emanuele, 2009).

FAMILY-RELATED FACTORS

A family history of suicide and suicidal behavior has been found to be a significant predictor of suicide attempts (Brent, Bridge, Johnson, & Connolly, 1996; Moscicki, 1997). The families of suicidal individuals often exhibit impaired communication and problem-solving skills (McLean & Taylor, 1994), and suicidal behavior might, in some cases, be a learned strategy for communicating with family members or coping with difficult situations. With adolescents, investigators have identified poor parent–child communication and negative family interactions as risk factors (King, Segal, Naylor, & Evans, 1993). In addition to transmitting a direct risk for suicidal behavior, elevated risk of suicide in family members might also be due to the genetic or environmental transmission of characteristics associated with suicidal behavior, such as depression or impulsivity (Brent, 2001).

## Proximal Risk Factors

ACUTE RISK FACTORS WITHIN
HIGH RISK DIAGNOSES

There has been some evidence that suicide risk profiles vary across different high-risk diagnoses (Clark & Fawcett, 1992; Clark, 1998). Kleespies and Dettmer (2000a) outlined the acute risk factors for each of these diagnoses. In terms of the diagnosis of depression, Fawcett et al. (1987), in a large prospective study, identified several symptoms that heighten risk for the depressed person. These symptoms include severe anhedonia, global insomnia, severe anxiety (and/or panic), and current alcohol abuse. The clinician would do well to observe caution when a depressed patient presents with some or all of these symptoms. Among individuals with schizophrenia, prospective studies have found suicide risk most associated with feelings of hopelessness, depression, obsessive-compulsive features, paranoid ideation, and subjective distress (Cohen, Test, & Brown, 1990; Peuskins et al., 1997). Risk is greatest for male schizophrenic patients under the age of 40, and occurs when these patients are not acutely psychotic but have a heightened awareness of the debilitating aspects of their illness and suffer with depression.

The findings of retrospective studies examining risk factors for suicide among individuals with alcohol abuse disorders have suggested that comorbid depression and the recent loss of a significant relationship are acute risk factors for suicide in this population (Murphy, 1992). Suicide among individuals with alcoholism is generally more likely in mid-life and after a prolonged history of alcohol abuse and dependence. As Murphy (1992) has also noted, it occurs predominantly during an active phase of drinking. Among drug abusers, cocaine abuse has been associated with an elevated risk of suicide (Marzuk et al., 1992). Clinical reports have suggested that cocaine abusers are at highest risk if they have been heavy users and experience depression during withdrawal.

ACUTE RISK FACTORS FOR ADOLESCENTS

An acute crisis can usually be identified in the lives of adolescents who exhibit suicidal behavior. As noted earlier, these crises typically elevate risk in the context of a mental or emotional disorder. Precipitants to suicidality include family problems (e.g., physical abuse, sexual abuse, disciplinary action, argument with parent), problems in social relationships (e.g., breakup with a romantic partner, argument with a friend), the loss of a relative or friend (e.g., through moving or death), the suicide or suicide attempt of a friend or relative, legal problems, substance abuse, and serious medical illness (Lewinsohn et al., 1996; Miller & Emanuele, 2009; Wagner, 1997).

## Protective Factors

Many individuals who would seem to be at heightened risk for suicide based on a review of risk factors such as those noted manage to cope successfully without becoming suicidal. Observations of such resilience have stimulated interest in identifying protective factors (i.e., characteristics of the individual or the environment that may buffer the impact of distressing symptoms or stress). When present, these characteristics increase resilience and decrease the risk of suicidal behavior; when they are absent, the risk is increased. Protective factors are thus important considerations in assessing suicide risk. Although the research on protective factors for suicide is underdeveloped relative to research on risk factors, several factors have received some empirical support.

FAMILY RELATIONSHIPS

Good family relationships appear to offer significant protection against suicidal ideation and behavior. In adults, strong family relationships, being married or in a committed relationship, and having children under the age of 18 living at home have been found to

reduce suicide risk (Fawcett et al., 1987; Lester, 1987). In studies of adolescents, family connectedness and cohesion have been identified as strong protective factors, significantly lowering the risk of suicidal ideation and behavior (Resnick et al., 1997; Rubenstein, Heeren, Housman, Rubin, & Stechler, 1989). With adolescents in particular, it can be preventive if family relationships can be strengthened or improved.

Supportive relationships outside of the family seem to confer protection against suicide risk. Friendships have been found protective in adults as well as in adolescents. Although supportive relationships with a few close friends have been found protective in adults, acceptance and integration into a social group has been found more protective for adolescents (Rubenstein et al., 1989). In addition, an adolescent's sense of connectedness to school has been identified as protective against suicide (Resnick et al., 1997).

REASONS FOR LIVING
Linehan, Goodstein, Nielsen, and Chiles (1983) identified a set of beliefs that differentiate individuals with and without suicidal ideation. They developed a scale to assess these *reasons for living* (e.g., responsibility toward family and children, moral objections to suicide, fears of social disapproval, and fears of pain involved in suicide). The results of subsequent studies have offered support for the assertion that reasons for living, such as those just identified, serve as protective factors against suicidal behavior in adolescents and adults (Gutierrez et al., 2002; Jobes & Mann, 1999). Other studies have identified additional protective factors, including hopefulness and spiritual well-being, a purpose for living, and employment (Stack, 2000).

## Managing the Acute Risk of Suicide
There is no absolute rule for when a suicidal patient can be managed and treated on an outpatient basis or when one must make an emergency intervention and hospitalize the patient. The clinician needs to be guided by a carefully considered estimate of the level of risk. He or she should also consider whether some of the patient's risk factors are dynamic (i.e., risk factors that are changeable as opposed to being static). Interventions that can decrease dynamic risk factors can tip the scale on ambivalence in a positive direction. The sections that follow offer some guidance for making the difficult decision to proceed on an outpatient basis or to hospitalize.

### When Is Outpatient Management Feasible?
Clinicians may be inclined to hospitalize patients with suicidal ideation because they feel it is safer, and because they have a high index of concern about liability issues. Many patients with suicidal ideation, however, can be treated successfully on an outpatient basis, and level of risk is the key issue in making this decision. Generally, outpatient management for patients at either mild or moderate risk has been found to be feasible and safe (Rudd et al., 2001; Sullivan & Bongar, 2009). An example of a patient at moderate risk might be someone with a few distal risk factors (e.g., a diagnosis of chronic schizophrenia, male gender, age <40), some proximal risk factors (e.g., discouragement about difficulties in functioning, mild to moderate hopelessness, episodic suicidal ideation with a plan but no immediate intent), and some protective factors that are beginning to weaken (e.g., the patient lives with supportive parents who are aging and having health problems). For such patients, Rudd and Joiner (1998) have suggested the following contingencies in outpatient management: (1) an increase in outpatient visits and/or in telephone contacts; (2) frequent assessment of suicide risk; (3) recurrent evaluation for hospitalization while the risk continues; (4) 24-hour availability or coverage; (5) reevaluation of the treatment plan as needed; (6) consideration for a medication evaluation or change in regimen; and (7) use of professional consultation as warranted. For patients at milder risk, recurrent evaluation and monitoring of suicide potential may suffice.

There is some accumulating evidence that cognitive-behavioral approaches to treatment have been successful in reducing suicidal ideation and the risk of suicide attempts (Rudd, Joiner, Trotter, Williams, & Cordero, 2008). These approaches tend to emphasize the learning of problem-solving and adaptive coping skills. Linehan (1993) has advocated an approach oriented toward changing patterns of dichotomous thinking and learning skills to help regulate strong emotions. She has reported that, with such treatment, patients with borderline personality disorder who are suicidal can be treated as outpatients without a high frequency of hospitalization (Linehan, Armstrong, Suarez, Allmon, & Heard, 1991).

### When Is Emergency Intervention Necessary?
Emergency intervention is necessary when the level of suicide risk becomes severe. It often begins with an effort to resolve or reduce a crisis that has precipitated an increase in suicidal intent. At times, it is

possible to achieve such a resolution and have the patient continue to pursue outpatient follow-up. As Comstock (1992) has pointed out, however, hospitalization is indicated when it is not possible to establish or reinstate a treatment alliance, when crisis intervention techniques fail, and when the patient continues to voice intent to commit suicide in the immediate future. Although there is no evidence that hospitalization ultimately prevents suicide, it does provide a relatively safer environment during a period of heightened suicide risk. Typically, 1 or 2 hours with a patient who maintains imminent suicidal intent are sufficient to convince clinicians to hospitalize.

Since most suicidal patients seem to have ambivalence about taking such a final action as suicide, the majority who require hospitalization agree to voluntary admission. When patients evaluated at imminent risk refuse to be hospitalized, however, the clinician is confronted with a decision about involuntary commitment. This decision can be difficult because we know that the estimation of suicide risk is not always reliable, and involuntary hospitalization may create barriers to effective treatment in the form of heightened resistance to forming or maintaining a therapeutic alliance (Comstock, 1992). As Kleespies, Deleppo, Gallagher, and Niles (1999) have pointed out, however, it nonetheless remains the clinician's responsibility to decide if hospitalization is needed. In the final analysis, the decision to hospitalize involuntarily must be based on sound clinical judgment that considers the risk–benefit ratio and the estimated imminence and severity of the suicide risk. In making such trying decisions, it may be helpful to keep in mind that, once hospitalization has occurred, resistant patients often begin to perceive the caring nature of the clinician's actions and reestablish a treatment alliance.

## Evaluating the Acute Risk of Violence

Actuarial methods of assessing the risk of violence have been considered superior to clinical methods. There is, however, an emerging and promising alternative to either a solely clinical or strictly actuarial approach. This approach has been referred to as structured professional judgment. The structured professional judgment model attempts to draw on the strengths of both the clinical and actuarial approaches to decision-making (Borum, Lodewijks, Bartel, & Forth, 2010). In structured professional judgment, the clinician typically uses a set of key evidence-based risk factors to guide his or her judgment. The evaluator reviews all relevant clinical data, and his or her clinical impression is taken as an appropriate and potentially valuable part of the assessment process. The evidence-based set of risk factors, however, constitutes a guide to the exercise of the clinician's judgment. Such a set of risk factors has typically been referred to as a decision support tool and is usually available in manual form. Decision support tools are not standardized psychological test instruments. Many of them have been assessed for their reliability and predictive validity, but they have been viewed as more of an *aide memoir* for the clinician.

One of the decision support tools that has generated a great deal of research and clinical interest in recent years is the Historical-Clinical-Risk Management-20, or the HCR-20 (Webster, Douglas, Eaves, & Hart, 1997). It involves coding 20 variables that the support tool's authors have determined to be evidence based in the research literature on estimating violence risk. There are 10 Historical items (i.e., previous violence, young age at first violent incident, relationship instability, employment problems, substance use problems, major mental illness, psychopathy, early maladjustment, personality disorder, and prior supervision failure), 5 Clinical items (i.e., lack of insight, negative attitudes, active symptoms of major mental illness, impulsivity, and unresponsiveness to treatment), and 5 Risk management items (i.e., plans lack feasibility, exposure to destabilizers, lack of personal support, noncompliance with remediation attempts, and stress). Each item is coded on a 3-point scale with 0 indicating that the item is not present, 1 indicating the possible or partial presence of the item, and 2 indicating that the item is clearly present. Interested parties can find an extensive and annotated bibliography (Douglas, Blanchard, Guy, Reeves, & Weir, 2010) that documents the empirical support for the HCR-20. In the sections that follow, we describe a number of the significant distal and proximal risk factors and protective factors that the clinician should keep in mind when doing an evaluation for risk of violence.

### Distal Risk Factors
#### DEMOGRAPHIC FACTORS
It is well known that violence is more common among adolescents and young adults, but, as McNiel (2008) has pointed out, this is not exclusively the case. Elderly patients who suffer from dementia, for example, have an increased risk of violence (Kalunian, Binder, & McNiel, 1990). It is also commonly known that, in the general population, males

are far more likely to be violent than females (US Bureau of Justice Statistics, 2008). Among patients with acute mental illness, however, women have been found to be as likely as men to become violent, whereas males with mental illness remain more likely to engage in more injurious forms of violence (Monahan et al., 2001). When other factors, such as socioeconomic status are controlled, race/ethnicity has not been found to be a strong predictor of violence. Lower socioeconomic status, however, is associated with increased risk (Swanson, Holzer, Ganju, & Jono, 1990).

## SERIOUS MENTAL ILLNESS

In general, the diagnosis of a major mental illness is a risk factor for violence. It is important to qualify that statement, however, by noting that most violence in our society is not committed by the mentally ill (Fazel & Grann, 2006), and we should be careful not to demonize those with mental illness as extremely violent. As is the case with risk for suicide, certain mental illnesses are both distal and proximal risk factors for violence. With regard to the risk for violence, these diagnoses include schizophrenia, schizoaffective disorder, bipolar disorder, and major depression (McNiel, Gregory, Lam, Binder, & Sullivan, 2003). In addition, military veterans with PTSD (Beckham, Feldman, Kirby, Hertzberg, & Moore, 1997; Kulka et al., 1990), especially those with a history of war zone violence (Hiley-Young, Blake, Abueg, Rozynko, & Gusman, 1995), and patients with cognitive disorders secondary to brain injury (Monahan et al., 2001) have been found to be at increased risk.

Certain personality disorders, particularly antisocial personality disorder and, to a lesser degree, borderline personality disorder, have been associated with violent behavior (Moran et al., 2003). These disorders are marked by an impulsive lifestyle and poor behavioral control. Conduct disorders in adolescents, as well as attention deficits and hyperactivity, have been found to predict violence in adolescence and adulthood (Satterfield & Schell, 1997).

## HISTORICAL AND DISPOSITIONAL FACTORS

It is well known that the best single predictor of future violence is a history of violent behavior (Gardner, Lidz, Mulvey, & Shaw, 1996; Monahan, 2006; Monahan et al., 2001). In addition to inquiring about a history of violence, McNiel (2009) has recommended evaluating for seriousness of past violence, frequency of past violence, and whether there is an escalating pattern of violence. Other relevant factors include whether past violence was planned or impulsive, the circumstances under which past violence was likely to occur, and whether there were particular precipitants to past violence.

The risk level for future violence increases when there has been an early onset of violent and aggressive behavior. Individuals who have engaged in violent acts, delinquent offenses, and substance abuse before the age of 12 are more likely to engage in violent and criminal activities over the course of their lifespan (Farrington, 1991; Tolan & Thomas, 1995). It is important to note that many adolescents (and particularly male adolescents) have incidents of minor violence (e.g., one or two fights) in their teenage years, but do not go on to become violent adults. In general, the greater the number of violent acts, the greater the likelihood of future violence. Borum (1996) has noted that a recent history of five or more acts of violence indicates a 50% probability of future violence.

It has been noted earlier in this chapter that childhood maltreatment, physical abuse, and exposure to violence between parents increase the risk of perpetration of violence in adulthood (Ehrensaft et al., 2003; Kilpatrick et al., 2003). It is thought that these experiences model, reward, or reinforce the use and display of violence (Otto, 2000). Others have hypothesized that they disrupt bonding or socialization during childhood (Klassen & O'Connor, 1994). Smith and Thornberry (1995) have cited some evidence that the seriousness of antisocial behavior varies proportionally with the severity of childhood maltreatment.

A constellation of affective, interpersonal, and behavioral characteristics referred to as *psychopathy* has been found to be a clear risk factor for violence in a number of studies (e.g., Forth, Hart, & Hare, 1990; Harris, Rice, & Quinsey, 1993; Quinsey, Rice, & Harris, 1995) Psychopathy, as defined by Hare (1998), is said to refer to characteristics that include "egocentricity; impulsivity; irresponsibility; shallow emotions; lack of empathy, guilt, or remorse; pathological lying; [and] manipulativeness" (p. 188). Hare (1991) developed a 20-item measure of the concept called the Hare Psychopathy Checklist – Revised (or PCL-R). The PCL-R has been found to be a good predictor of violence in diverse populations (i.e., not only among criminal offenders, but also among schizophrenic and personality disordered individuals) (Harris et al., 1993). Psychopathy is said to be overlapping but distinct from antisocial personality disorder (which tends to be defined more exclusively by antisocial acts or behaviors). It is considered a static factor

since treatment programs have not been effective in making substantial changes in psychopathic individuals.

## *Proximal Risk Factors*

### ACUTE MENTAL ILLNESS AND SUBSTANCE ABUSE

As pointed out by McNiel et al. (2003) and Tardiff (2003), schizophrenic patients are at most risk of violence when they are having a psychotic episode, and bipolar patients are at most risk when they are having a manic episode. In this regard, schizophrenic patients and manic patients are at elevated risk during the time period immediately preceding hospitalization, whereas manic patients continue to be at risk during the initial days after hospitalization. With manic patients, it is thought that, in the initial days of hospitalization, they react with aggression when efforts are made at containment and limit setting.

Monahan et al. (2001), in the MacArthur Violence Risk Assessment Study, sampled admissions to acute civil inpatient facilities that were preceded by violent incidents. They found that, of the many hundreds of violent incidents studied, 54.1% were preceded by drinking just before the incident and 23.0% were preceded by use of illegal drugs. They concluded that alcohol was a major predictor of violent assaults on the part of the patients studied. They also reported that more men than women in their sample had histories of violent acts along with concomitant alcohol dependence issues, and that men were more likely than women to be using alcohol and drugs prior to committing a violent act.

Wallace, Mullen, and Burgess (2004) have noted that active substance abuse significantly increases the risk of violence when it co-occurs in persons with serious mental illness. Swanson (1994), for example, studied mental illness, substance abuse, and community violence in a sample of 10,000 people. He found that mental disorder alone was twice as likely to be present in violent individuals as compared to those who were nonviolent. He also found that substance abuse alone and in combination with a co-morbid mental illness was five times as likely to be present in the violent as opposed to the nonviolent group.

### CLINICAL SYMPTOMS AS PROXIMAL RISK FACTORS

McNiel (2009) has noted that certain clinical symptoms are relevant as factors for estimating short-term risk for violence. In a sample of decompensating patients who were evaluated at the time of admission to a psychiatric unit, McNiel and Binder (1994) found that the symptoms described as hostile-suspiciousness, agitation-excitement, and disturbed thinking (unusual thought content/hallucinations) were associated with aggressive behavior in the first hours or days after admission. Not surprisingly, others have reported that patients who had difficulty managing their anger were at elevated acute risk for violence (Doyle & Dolan, 2006). Link and Steuve (1994) identified a delusional state that they referred to as *threat/control override*. This term refers to a delusional state in which the person feels personally threatened to the point that he or she feels justified in overriding self-control to eliminate the threat. Such beliefs have been found to predict violent behavior by male patients in the community (Teasdale, Silver, & Monahan, 2006). Finally, so-called *command hallucinations* (i.e., a voice telling the patient to harm or kill someone) have been found to increase the acute risk of violence, particularly if the command is consistent with a delusional belief (e.g., a patient who hears a voice telling him to attack one of his former teachers whom he believes has plotted to ruin his life) (Monahan et al., 2001).

### SITUATIONAL OR CONTEXTUAL FACTORS

As Otto (2000) has pointed out, it is important to consider victim specificity and victim availability when assessing risk for violence. Especially in cases where the risk of violence is limited to one or two people, whether the individual or individuals live in close proximity or somewhere across the country can make a difference when the patient has limited means or ability to travel. In patients with major mental illness who become violent, family members are at high risk. Stranickas, McNiel, and Binder (1993) found that, of 113 acute psychiatric patients admitted after a violent event, 56% of them had assaulted a family member. It has long been known that mothers who live with adult children who have schizophrenia have an increased risk for violent victimization by their children (Estroff, Swanson, Lachiotte, Swartz, & Bolduc, 1998).

Although there is no empirical evidence linking weapon availability and risk for violence in individual cases, it can clearly be said that most homicides in the United States are by firearm (US Department of Justice Statistics, 2008). It seems sensible to assume that those who have ready access to weapons, if they become violent, are more likely to engage in more serious forms of violence. Indirect support for this position can be found in the study by Kaplan and Gelig (1998), in which higher rates of gun-related violence were reported in locales with greater access to guns.

### Protective Factors

As noted in an earlier section of this chapter, research on protective factors for suicide risk is an underdeveloped area. Hart (2001) has pointed out that such is also the case with violence risk assessment. In fact, inquiry into protective factors for violence may be even less developed than research into protective factors for suicidal behavior. There has been an effort to examine treatments that might result in violence "risk reduction" (Monahan & Applebaum, 1999), but there has been little emphasis on "personal strengths, resources, and protective or 'buffer' factors" (Hart, 2001, p. 21). Certainly, good personal and family support have been viewed as protective factors, as has involvement in a treatment and support program (Estroff & Zimmer, 1994). Some studies have noted factors that are, in essence, the reverse of known risk factors and might, therefore, reduce risk. Thus, in their large-scale study including a community sample, Hanson, Cadsy, Harris, and LaLonde (1997) reported that nonabusive men were less likely to have experienced violence during childhood, to have antisocial personality features, to be experiencing subjective distress and marital maladjustment, to have attitudes tolerant of spouse abuse, and to engage in impulsive behaviors. Clearly, further research on protective factors is needed and might prove helpful in improving the specificity of who is less likely to engage in violence.

## Managing the Acute Risk of Violence

If an evaluator has made an informed clinical judgment that a patient or client is at acute risk of becoming violent to others, he or she must formulate a plan for managing the risk. The plan will, of course, depend on the immediacy of the risk and the capacity of the patient to exercise or gain self-control. Monahan (1993) has suggested three types of intervention for dealing with the patient or client who is a risk to others: intensifying treatment, hardening the target, and incapacitation of the patient or client. Given that incapacitation usually means hospitalization, the decision to use one or the other (or more) of these interventions generally parallels the decision, discussed earlier, to manage the suicidal patient either on an outpatient or inpatient basis.

### Interventions to Manage Risk
#### INTENSIFYING TREATMENT
With the patient or client who does not appear to pose an imminent risk of violence, and who has some capacity to modulate or modify his or her behavior,

it is possible to intensify treatment in the community as a way of managing risk. Thus, the clinician can increase the frequency of therapy sessions, have telephone safety checks with the patient, have the patient enter a more structured outpatient or partial hospitalization program, have the patient enter a substance abuse treatment program (if needed), develop a plan for 24-hour emergency coverage, and make frequent reassessments of the level of risk. Initially, the focus of therapy sessions should be on techniques or methods that might reduce the risk associated with current, acute risk factors (e.g., increasing insight, anger management techniques, increasing frustration tolerance, improving affect regulation, and so forth).

Of course, as VandeCreek and Knapp (2000) have cautioned, it behooves the clinician to be aware of his or her state statutes that may regulate what actions a treatment provider is to take in managing a patient's or client's risk of violence. Some may require that the intended victim be warned, in addition to intensification of treatment.

#### HARDENING THE TARGET
Warning the intended victim(s) and/or alerting law enforcement has become known as *hardening the target*. In the case of the potential victim, it makes it possible for him or her to take protective measures. After the Tarasoff case in California, warning the intended victim became known to clinicians as the "duty to warn" (*Tarasoff v. Regents of University of California*, 1974). The California court, however, reviewed the case 2 years later and revised their opinion to what has now become known as the "duty to protect" (*Tarasoff v. Regents of University of California*, 1976). In effect, the Court's revised opinion was that therapists have a duty not simply to warn an intended victim, but to protect the intended victim or victims of their clients or patients. The Court, in this revised opinion, also noted that there can be a number of ways to meet this obligation. Warning the individual in question may be one way, but it is not the only way or, depending on the circumstances, necessarily the best way.

Borum (2009) has noted that warning the intended victim can be frightening to the individual and should be reserved for those times when other interventions have been rejected by the patient or are not feasible. If a warning is given, his advice is that the clinician be careful in reviewing the nature and seriousness of the threat, and then work with the individual to find sources of assistance and develop protective measures.

### INCAPACITATION

Incapacitating a patient or client means utilizing measures that directly decrease the person's ability to act out in a violent manner. These measures can include involuntary hospitalization, sedating medication, and physical restraints or seclusion. These are obviously very intrusive interventions and should only be used in situations where the danger of serious harm is great and less restrictive means have failed or will not be effective. The use of these means is typically regulated by law and institutional or agency policy. Their use is sometimes necessary to avoid a worse alternative (i.e., serious harm or death of an intended victim). They are not a solution to the longer-term risk of violence, but prevent immediate harm. They may also allow a diagnostic evaluation and initiation of treatment that may have longer lasting benefit.

## When There Is Immediate Risk to the Clinician

If a clinician works with patients who have the potential to lose control in his or her practice setting, the safety of the patient, the clinician, other patients, and colleagues are all of critical importance. Particular attention should be given to the environment in which such patients are seen. Objects that could easily be used as weapons should be removed. As Kleespies and Richmond (2009) have pointed out, the office or interview room should be arranged so that, in the event of a serious threat to safety, the clinician will have easy access to an exit, or can obtain help quickly. In a clinic or hospital setting, a panic button that alerts the police or security service can be very helpful when a patient seems on the verge of losing control. Under such circumstances, those in private practice should have a means by which to quickly notify a receptionist or colleague for assistance.

In addition to aggressive verbal statements or threats, clinical experience has informed us that there are certain behavioral signs of potential loss of control or dangerousness. These may include psychomotor restlessness, such as pacing, fidgeting, clenching fists, startle response, grinding teeth, or inability to sit down; affective and facial changes that reflect either hostility, fear, or paranoia; and the tone and loudness of the patient's speech. The clinician should pay careful attention to such behaviors. It may be helpful to develop an internalized algorithm for how one will respond if levels of aggression or threat increase.

An initial response might be to observe that the patient or client seems upset; then ask if he or she can talk about it. If such an empathic approach fails, the clinician might ask if he or she should be worried about his or her safety. Another approach might be to inform the patient that you would like to help him or her, but it's difficult to do so if his or her behavior is making you concerned and nervous. At times, taking a break can also reduce tension.

If a patient or client is not responsive to verbal efforts to reduce tension or set limits, the next level of response will probably depend on the environment and the availability of assistance. Those who work in a counseling center or private practice setting may wish to terminate the session (if it is safe to do so) or contact security officers. If the situation is serious enough, the clinician might complete a temporary involuntary commitment so that local police can take the patient to a more secure setting, such as an emergency room, where he or she can be evaluated further. In such instances, the assistance of a colleague who can make the appropriate phone calls, or stay with the patient while the clinician calls, can be invaluable.

There are typically more options for response for those who work in more secure settings such as an emergency room, a hospital, or an urgent care clinic. In these settings, medical staff can offer the patient tranquilizing medication (if appropriate), or the patient might agree to voluntary hospitalization. If the patient is losing control, there is typically a code team that can be called, and, if worse comes to worse, the patient can be incapacitated as noted earlier (see Kleespies and Richmond [2008] for a more complete discussion of this topic).

## Evaluating the Risk of Interpersonal Victimization
### Distal Risk Factors
#### DEMOGRAPHIC FACTORS

As McCart, Fitzgerald, Acierno, Resnick, and Kilpatrick (2009) have pointed out, there are age, gender, and racial differences in the prevalence of interpersonal victimization. Findings from the National Crime Victimization Survey (Catalano, 2006) have indicated that nearly half (47%) of those victimized by rape, robbery, aggravated assault, and simple assault are between the ages of 12 and 24. Yet, this segment of the population is less than 25% of the total US population. The risk of victimization by violent crime decreases after age 24.

Young women are more likely to be victims of rape and other sexual assault, whereas men are more likely to be victims of robbery and physical assault (Hapke, Schumann, Rumpf, John, & Meyer, 2006). Women

are more likely to be assaulted by an intimate partner, friend, or acquaintance, whereas men are more likely to be assaulted by a stranger (Catalano, 2006).

In terms of race, the CDC (2003) has reported that African American men and women constitute 28% of all nonfatal crime victims while constituting only 12% of the population. They constitute 47% of all homicide victims. Further, the CDC has noted that African American men and women and Hispanic American men and women, across all age groups, are approximately 60% more likely to be victims of violent crime than are European American men and women. Native Americans, however, have the highest rate of violent crime victimization of any ethnic group in the United States (Greenfield & Smith, 1999).

## SERIOUS MENTAL ILLNESS

Patients with serious mental illness (SMI) tend to be vulnerable to victimization. In fact, Teplin, McClelland, Abram, and Weiner (2005) compared rates of violence against adults with SMI to general population rates reported in the National Crime Victimization Survey and found that violent crime against those with SMI was nearly 12 times higher. Some of the most common experiences of victimization were assault and theft, and approximately 25% of those with SMI reported being victimized in the year preceding the study. Lifetime history of victimization reportedly reaches 88% among persons with SMI (McFarlane, Schrader, Bookless, & Browne, 2006).

## FAMILY AND HISTORICAL FACTORS

Experiences of violence in the family of origin have been linked to victimization in adult relationships in a number of studies (Desai, Arias, Thompson, & Basile, 2002; Ornduff, Kelsay, & O'Leary, 2001). In the study by Desai et al. (2002), data from a nationally representative sample of men and women indicated that male and female victims of childhood physical and sexual abuse were two to five times more likely to experience a physical or sexual assault in adulthood. Despite these findings, there has been considerable debate about this issue. Schumacher, Feldbau, Slep, and Heyman (2001), for example, did a review of studies and concluded that, at most, physical victimization as a child was only weakly related to adult, intimate partner victimization, but emotional victimization as a child may have a more significant effect.

Witnessing violence between parents has also been linked to being a victim of intimate partner violence in adulthood (Hotaling & Sugarman, 1986). Reviews, however, have not been consistent in this regard, and Schumacher et al. (2001) concluded that witnessing interparental violence had only a small effect on the risk of victimization in adult relationships. In spite of the controversy, the frequency with which an association between the experience of violence in childhood and adult victimization has been reported suggests that these experiences be taken advisedly as "red flags" that the patient may be vulnerable to becoming a victim.

Quigley and Leonard (2000) have noted that violence early in marriage appears to be predictive of subsequent marital violence. Likewise, Kemp, Rawlings, and Green (1991) reported that a history of being victimized in an adult relationship was related to revictimization in violent relationships. In fact, Kilpatrick, Acierno, Resnick, Saunders, and Best (1997) found that, compared to women who had never been physically or sexually assaulted, risk of a new assault increased in a linear fashion for those with a history of one assault, two assaults, and three or more assaults. Further, prior violence by the same partner has been found to be related to an increased risk of physical injuries sustained by abused women (Thompson, Saltzman, & Johnson, 2001).

## Proximal Risk Factors

Several factors have been identified as proximal risk factors for victimization in intimate partner relationships (Riggs, Caulfield, & Fair, 2009).

## CURRENT CONFLICT AND VERBAL AGGRESSION IN THE RELATIONSHIP

It is not surprising that there have been a number of studies in which it has been found that conflict or argument often preceded violence in an intimate relationship (e.g., Cascardi & Vivian, 1995). In a study by Hyden (1995), 90% of couples reported that the violence in their relationships happened during an argument or verbal altercation, and data from the US Department of Justice has presented very similar findings (Greenfield et al., 1998). Moreover, Murphy and O'Leary (1994) conducted a longitudinal study on spousal abuse that indicated that there was an increase in arguments prior to the initiation of physical violence.

## TERMINATION OF A RELATIONSHIP

The termination of a relationship, especially a relationship that has been marked by violence, may be a situation during which a woman is at increased risk of victimization at the hands of her former partner. Women who are estranged from their

partners, as opposed to those who are in intact couples, have been found to be at increased risk of abuse and even murder (Wilson & Daly, 1993; Wilson, Daly, & Wright, 1993). Ellis and Wright (1997) also found a positive association between conjugal violence and estrangement. In a 1998 report, the US Department of Justice stated that women who are separated from their husbands have a rate of victimization that is three times higher than divorced women, and it is 25% higher for separated women relative to married women (US Department of Justice, 1998).

ALCOHOL USE

In a sample of domestically violent men seeking treatment for either domestic violence or for alcohol abuse, Fals-Stewart (2003) found that male-to-female aggression was eight to 11 times more likely to occur on days when men drank than on days of no alcohol consumption. This same study also found that violence was more likely to occur during male partners' drinking or shortly after drinking episodes as compared to long after the drinking had ceased. The exact mechanism by which alcohol use contributes to violent behavior remains a matter of speculation. Some have suggested that it disinhibits the perpetrator, whereas others have thought that it erodes relationship satisfaction. O'Farrell, Fals-Stewart, Murphy, and Murphy (2003) have found that partner violence decreased substantially after alcoholism treatment (from 56% to 25%) and that those patients who remained abstinent were only half as likely (15%) to engage in domestic violence as those who resumed some alcohol use (32%).

PERCEIVED DANGER

It has been suggested that a woman's previous experiences of violence perpetrated by her male partner are likely to have given her a sense of when she is in danger. Weisz, Tolman, and Saunders (2000) have provided evidence to support this position. They studied a sample of women whose partners had been arrested for domestic violence and found that the women's predictions of risk were strongly associated with subsequent violence during a period of 4 months. In fact, the women's ratings were better than ratings generated through the use of a list of established risk markers.

## Protective Factors

As with protective factors for violence, there have been few studies of protective factors for interpersonal victimization. In a study by Rickert, Wieman,

Kissoon, Berenson, and Kolb (2002), physical violence against women seen in a public family planning clinic was found to be less likely if the women had a higher education level and were older when they first gave birth. Among a sample of Mexican American women, Lown and Vega (2001) reported that good social support was associated with less risk of physical abuse. Such limited empirical data, however, does not provide a great deal of guidance for the clinician who is attempting to be more specific about whether or not his or her patient is likely to become a victim of domestic or intimate partner violence. Until such time as research on protective factors develops, practitioners must use their best judgment on a case-by-case basis about factors that may attenuate risk.

## Managing Incidents of Interpersonal Victimization

A number of therapeutic approaches have been suggested as acute interventions for dealing with the reactions of victims following a violent or traumatic event. Critical incident stress debriefing (CISD; Mitchell & Everly, 1996) was one such intervention but many now consider it to be contraindicated. It was originally developed for emergency first responders such as firefighters and police officers, who were required to meet in a group immediately after a traumatic incident to talk about their emotional reactions. Education about coping techniques was also provided. The effort was intended to diminish distress and prevent the development of PTSD. Unfortunately, randomized controlled trials of CISD have not found it to be beneficial (Mayou, Ehlers, & Hobbs, 2000; Rose, Brewin, Andrews, & Kirk, 1999) and some studies have raised questions about it being harmful or of exacerbating symptoms (Bisson, Jenkins, Alexander, & Bannister, 1997). Moreover, given some of the recent findings on how the majority of people who experience trauma are resilient and do not develop PTSD (Bonanno, 2004), it hardly seems wise to attempt to require CISD for every victim of trauma.

The apparent failures of CISD have led clinicians and researchers to recommend a less invasive and more supportive approach during the initial aftermath of trauma or violent victimization. It is termed "psychological first aid" and it was developed by the National Child Traumatic Stress Network and the National Center for PTSD (NCTSN and NCPTSD, 2006). The National Institute of Mental Health (NIMH, 2002) has now adopted this type of intervention as a best practice. It is regarded as more in keeping with the empirical findings on risk and

resilience after trauma. It is only provided for those who request help, and it has four components: information gathering, safety planning, practical assistance, and offering information on coping.

If the trauma survivor requests help and is willing to talk about the incident, *information gathering* focuses on identifying the victim's immediate needs (e.g., for safety and shelter) and on screening for incident-related and psychological factors that might suggest an increased risk of developing longer-term emotional problems. It is, of course, important to create a supportive relationship and environment in which the victim can feel safe in revealing details about events that may have been experienced as embarrassing and degrading.

Once the victim's needs have been identified, *safety planning* and *practical assistance* can be offered. The clinician and the victim need to work together to ensure that the victim has a safe place to stay (e.g., a safe house for victims of domestic violence) and to identify any potentially dangerous situations that the victim may encounter in the community. They can then formulate plans for how the victim might keep himself or herself safe if dangerous situations arise. Emergency phone contacts should, of course, be a part of the plan. Since some victims can become suicidal or may wish to retaliate in a violent way against a perpetrator, it is important to inquire about such thoughts or plans, and, if necessary, work to prevent harm to self or others.

Offering practical assistance can help to counter the feelings of helplessness and hopelessness that victims often experience. Assistance with contacting social service agencies that can offer financial aid, information about accessing legal services, or information about housing can help to relieve many worries and concerns. Any victim with physical injuries or possible physical injuries should be encouraged to seek medical attention, whereas those who have suffered sexual assault should be informed about the importance of being evaluated for the risk of sexually transmitted diseases or pregnancy.

The victim should also be provided with information on the emotional reactions he or she might experience, as well as with *information on coping* with stress. Thoughts about being at fault or to blame for what happened can be discussed and countered. Good self-care, such as getting rest and engaging in enjoyable activities, can be encouraged. Relaxation techniques can be taught. By actively coping in these ways, the victim can start to regain a sense of control in his or her life.

As noted earlier, most people who suffer trauma seem to have coping resources and are resilient in the face of these very difficult experiences. If, however, after 4–6 weeks, the individual has shown no improvement in the distress and symptoms that he or she has been experiencing, or his or her condition has grown worse, the clinician should consider doing a more thorough diagnostic evaluation, so that appropriate treatment might be recommended. A discussion of the assessment instruments that might best be used, and of the empirically based treatments that are available, is beyond the scope of this chapter. For such a discussion, the interested reader is referred to Fitzgerald, McCart, and Kilpatrick (2009).

## Coping with the Impact of Negative Events

Earlier in this chapter, we discussed the incidence of patient suicide, of patient violence toward clinicians, and of patients as victims of violence. The findings indicate that, given our current state of knowledge and skill and, at times, despite the best of care, we are not able to prevent all such negative outcomes. Moreover, as Kleespies and Dettmer (2000b) have suggested, the very sensitivity that enables individuals to become excellent clinicians may also leave them vulnerable to the emotional distress that can follow in the aftermath of such events. The potential impact on the treating clinician has been well documented (e.g., Chemtob, Bauer, Hamada, Torigoe, & Kinney, 1988; Guy, Brown, & Poelstra, 1991; Hendin, Haas, Maltsberger, Szanto, & Rabinowicz, 2004; Kleespies & Ponce, 2009; Kleespies, Penk, & Forsyth, 1993; McCann & Pearlman, 1990; Pope & Tabachnick, 1993).

When there is a patient suicide, it is not uncommon for the clinician to report feelings of shock, disbelief, failure, self-blame, guilt, shame, helplessness, anxiety, and/or depression. He or she may also have concerns about responsibility, malpractice suits, censure from colleagues, and damage to reputation (i.e., concerns that can complicate dealing with one's personal reactions to the death). Clinicians who were assaulted by a patient often state that they experienced a dramatically increased sense of vulnerability in the aftermath. The greater the extent of any physical injury, the greater the sense of fear and vulnerability that followed. Working with individuals who have been the victims of interpersonal violence can lead therapists to be concerned about their competency and ability to help those who are suffering (Astin, 1997). They may develop anxiety, intrusive thoughts about the client's experiences, and emotional numbing. They may also employ avoidance

strategies to minimize discussion of traumatic material in sessions (McCann & Pearlman, 1990).

There is a need for clinicians who work with patients or clients who present with the behavioral emergencies noted earlier to reflect upon how they might cope with their feelings and reactions should a negative event occur. There have been a number of single case reports of what proved helpful to clinicians coping with the aftermath of a patient suicide (e.g., Alexander, 1991; Berman, 1995; Spiegelman & Werth, 2005). Kleespies et al. (1993) sought data from a larger sample on this topic and found that psychology interns found it most beneficial to seek emotional support and opportunities to review the case with their supervisor. For those at the professional level, talking with a colleague who knew the patient or who had had a similar experience has been reported as helpful in reducing isolation and providing support. Kolodny, Binder, Bronstein, and Friend (1979) have written about how meaningful it was for four therapists to meet over the course of a year to discuss their reactions to patient suicides that each had experienced.

Many of the suggestions for coping with the aftermath of patient suicidal behavior apply as well to coping with the aftermath of violent patient behavior. Some clinicians who are threatened or actually assaulted are either resilient (Bonanno, 2004) or seem to go through a natural recovery process and prefer to cope on their own. Others may wish to do as suggested by Guy and Brady (1998)—find a trusted colleague with whom to discuss the issues and sort through any feelings of guilt or responsibility for the patient's behavior. If issues of personal vulnerability and safety seem to be affecting the victim–clinician's ongoing clinical work, an alternative is to enter or reenter personal therapy to work through the issues. In the state mental health system in Massachusetts, Flannery and his colleagues (Flannery, Fulton, Tausch, & DeLoff, 1991) have developed a program that has been used by clinical staff who have been assaulted by patients. It is referred to as the Assaulted Staff Action Program (ASAP), and it provides support and "psychological first aid" to those staff who wish to utilize it. If a patient assault occurs, an ASAP team member contacts the individual staff member to offer support and see if the person is receiving any needed medical care. The team member discusses whether the victim feels able to manage his or her feelings and continue to work. He or she also offers to check back in 3 days and 10 days to see how the person is doing.

In terms of coping with the impact of work with patient victims, some experts in the field have emphasized the need to attend to professional needs like continuing education, ongoing supervision, and consultation with colleagues who are sensitive to the difficulties of dealing with traumatized patients or clients (Deiter, Nicholls, & Pearlman, 2000; Trippany, White Kress, & Wicoxin, 2004). They have also recommended balancing this type of work with other, less stressful work, and with play and rest. Bober and Regehr (2006), however, did not find an association between trauma clinicians' stress scores and time devoted to leisure, self-care, or supervision. They recommended having a focus on structural changes to protect trauma therapists. Thus, a significant structural change might include distributing caseloads in a manner that limits exposure to trauma patients.

## Conclusion

Evaluating and managing patients or clients who engage in life-threatening behaviors, or whose lives are threatened, is a complex and trying part of clinical practice. In the preceding section, we have noted some of the ways that clinicians have found to deal with negative outcomes when they occur. Efforts to work with cases in which such destructive or self-destructive behavior can occur can be supported or made difficult by the environment or system within which the clinician functions. That is to say, clinical sites and training programs can be more or less sensitive or insensitive to the needs of clinicians who undertake the stressful work of dealing with patients or clients who are at high risk. They can foster a health-promotive environment (Stokols, 1992) in which clinicians feel supported and protected by the administration in their efforts to work with and learn from difficult cases; or they can focus on defending narrowly defined institutional interests, thereby creating an environment in which clinicians feel isolated and left to fend for themselves (as, for example, with a patient suicide). It seems clear to us that those health-care systems that take the former approach will reap the benefit of having clinicians who feel less stressed and better able to pursue what they perceive as the best interests of their patients.

### Future Directions

From a clinical perspective, there is a need to have the evaluation and management of behavioral emergencies recognized as an area of practice in which all psychology practitioners should achieve competency.

Training in this area should begin with the teaching of a knowledge base through graduate coursework and should be followed (on internship) by the type of *stress training* discussed earlier in this chapter. From a research perspective, it has been noted that suicide research, violence research, and research on interpersonal victimization have, to a large degree, developed along independent lines. There appears to be a need to explore the inter-relatedness of these behavioral emergencies to see if collaboration and cross-fertilization might lead to greater progress in understanding and preventing life-threatening behaviors.

**Abstract**

This chapter on clinical interventions with children and adolescents has four primary goals: (1) to review early efforts to identify evidence-based psychosocial treatments for youth and their families; (2) to provide an overview of current evidentiary support for the treatment of the four most prevalent psychiatric disorders in youth: anxiety disorders, mood disorders, attentional disorders, and oppositional/conduct disorders; (3) to examine relational and developmental factors that qualify and potentially moderate these efficacious treatments; and (4) to speculate on the future of psychotherapy research and practice with youth. Our review indicates that several evidence-based interventions are available, although with few exceptions they are cognitive-behavioral ones. However, we conclude that the evidence base even for these interventions is not overly robust at this time, and that we must evaluate other commonly practiced interventions such as play therapy, family systems therapy, and psychodynamic-based therapies before their routine use can be endorsed. We also identify important developmental, contextual, and relationship variables that qualify these efficacious findings and encourage the pursuit of additional process and outcome research. We conclude our discourse by suggesting that we must move beyond reliance upon manual-based treatments to the development of principle-based interventions that draw upon these specific evidence-based interventions but move beyond and unify them. Although much progress has occurred in the past 50 years, much work remains to be done. This is an exciting time in the child and adolescent psychotherapy arena.

**Key Words:** Behavioral and emotional disorders, child and adolescent psychotherapy, cognitive behavioral treatment, evidence-based treatment, process and outcome research

Over 50 years ago, Eysenck (1952) published his now (in)famous review of the effects of adult psychotherapy. Boldly, he proclaimed that psychotherapy practices at that time were no more effective than the simple passage of time. Subsequently, Levitt (1957, 1963) reviewed the child and adolescent psychotherapy literature and arrived at the same conclusion. These reviews were disquieting, and they led many clinicians, researchers, and policy analysts to question the continued viability of the psychotherapy enterprise for children, adolescents, and adults.

Fortunately, as noted by Kazdin (2000), these reviews also served as a wake-up call to the profession

of clinical psychology and related mental health disciplines. In the clinical child and adolescent arena, significant advances in the study of developmental psychopathology, refinements in the psychiatric diagnostic nomenclature, attention to evidence-based assessment and treatment practices, and improved experimental designs for the study of treatment process and outcome have all occurred in the ensuing years. These developments, in turn, have resulted in well over 1,500 treatment studies (Durlak, Wells, Cotton, & Johnson, 1995; Kazdin, 2000) and seven major meta-analyses examining the effects of child and adolescent psychotherapy (Casey & Berman, 1985; Durlak, Fuhrman, & Lampman, 1991;

Kazdin, Bass, Ayers, & Rodgers, 1990; Miller, Wampold, & Varhely, 2008; Weisz, Jensen-Dose, & Hawley, 2006; Weisz, Weiss, Alicke, & Klotz, 1987; Weisz, Weiss, Han, Granger, & Morton, 1995). As noted by Weersing and Weisz (2002), there is little doubt that psychotherapy—as it is practiced these days—produces beneficial outcomes for youth and their families. Consistently, reviews show that psychotherapies for youth and their families outperform waiting list and attention-placebo control conditions; moreover, in several studies, it is becoming clear that some forms of psychotherapy work better than others. As a result, much progress has been made, and we can conclude that the field of clinical child and adolescent psychology has moved beyond the simple question, "Does psychotherapy work for youth?" to identify the efficacy of *specific* treatments for youth who present with *specific* behavioral, emotional, and social problems. Clearly, the field has moved beyond the generic question of whether psychotherapy "works" for youth and their families to a more specific one that seeks to determine the evidence base for various treatments and the conditions under which those treatments are effective. This is an exciting time in the field of psychotherapy research and practice with youth.

This chapter has four major goals: (1) to review efforts to identify evidence-based psychosocial treatments for youth and their families; (2) to provide an overview of the evidentiary support for the treatment of the four most prevalent psychiatric disorders in youth (anxiety disorders, mood disorders, attentional disorders, and oppositional/conduct disorders); (3) to examine relational and developmental factors that qualify and potentially moderate these efficacious treatments; and (4) to look to the future of psychotherapy research and practice with youth.

## On the Nature of Evidence-based Treatments

The development and identification of evidence-based treatments (EBTs) is part of a larger zeitgeist labeled *evidence-based medicine* (Sackett, Richardson, Rosenberg, & Haynes, 1997, 2000). At its core, evidence-based practice is an approach to knowledge and a systematic strategy for improving treatment outcomes (Ollendick & King, 2004). The evidence-based approach is not wedded to any one theoretical position or orientation. Rather, it holds that treatments, of whatever theoretical orientation, need to be based on objective and scientifically credible evidence—evidence that is obtained largely

through randomized clinical trials (RCTs). In an RCT, youth with a specific presenting problem or disorder are randomly assigned to one treatment or another treatment, or to some control condition, such as a waiting list or an attention-placebo condition, and the effects of these conditions are evaluated. Although such a design is not without problems, it appears to be the best scientific strategy for ruling out biases and expectations (on the part of the youth, the youth's parents, *and* the therapist) that can result in misleading research findings. Evidence-based practice also values information or opinions obtained from observational studies, logical intuition, personal experiences, and the testimony of experts. However, such information is viewed as less acceptable from a scientific, evidentiary-based standpoint. It is not discounted; it simply occupies a lower rung on the ladder of evidentiary support.

In 1995, the Society of Clinical Psychology Task Force on Promotion and Dissemination of Psychological Procedures issued its report on "empirically validated" psychosocial treatments (see also Chambless, 1996; Chambless & Hollon, 1998). The task force committee was comprised of members from different theoretical orientations, including psychodynamic, interpersonal, family systems, and cognitive-behavioral points of view. This diversity in membership was intentional, in as much as the committee wished to emphasize a commitment to identifying *all* psychotherapies of proven worth, not just those emanating from one particular school of thought. However, defining empirically validated treatments proved to be a difficult task. Of course, from a scientific standpoint, no treatment is ever fully validated and, as noted in the task force report, there are always more questions to ask about any treatment, including questions about the essential ingredients of treatment, moderator variables that predict treatment outcome, and the mechanisms or processes associated with behavior change. In recognition of this state of affairs, the term "empirically supported" was adopted subsequently to describe treatments of scientific value—a term that many agreed was more felicitous than "empirically validated." Herein, we will use the more generic term, "evidence-based" treatment.

Three categories of treatment efficacy were proposed in the 1995 report: *well-established treatments*, *probably efficacious treatments*, and *experimental treatments*. Subsequent to that initial report, Chambless and Hollon (1998) proposed a fourth category, *possibly efficacious treatments*. The primary distinction between well-established and probably

efficacious treatments was that a well-established treatment should be shown to be superior to a psychological placebo, pill, or another treatment, whereas a probably efficacious treatment need only be shown to be superior to a waiting list or no treatment control condition. In addition, effects supporting a well-established treatment should be demonstrated by at least two different investigatory teams, whereas the effects of a probably efficacious treatment need not (for example, the effects might be demonstrated in two studies from the same investigatory team). For both types of empirically supported treatments, it was posited that characteristics of the clients should be well specified (e.g., age, sex, ethnicity, diagnosis), and the clinical interventions should be conducted with treatment manuals. Furthermore, it was required that the outcomes of treatment be demonstrated in "good" group design studies or a series of controlled single-case design studies. "Good" designs were those in which it was reasonable to conclude that the benefits observed were due to the effects of treatment and not due to chance or confounding factors such as passage of time, the effects of psychological assessment, or the presence of different types of clients in the various treatment conditions. Randomized clinical trials—group designs in which patients were assigned randomly to the treatment of interest or one or more comparison conditions—and carefully controlled and executed single-case experiments were recommended as good designs. The additional category suggested by Chambless and Hollon (1998), *possibly efficacious treatment*, possessed all the characteristics of a probably efficacious treatment with the exception that the treatment only need to be shown to be effective in one study, not the two studies associated with the probably efficacious category of evidence. *Experimental treatments* were those treatments not yet shown to be at least possibly efficacious. This category was intended to capture treatments frequently used in clinical practice but that have not yet been fully evaluated, or newly developed ones not yet put to the test of scientific scrutiny. The development of new treatments was strongly encouraged. It was also noted that treatments could "move" from one category to another depending on the empirical support available for that treatment *over time*. For example, an experimental treatment might move into probably efficacious or well-established status as new findings become available. The categorical system was intended to be dynamic, not static or fixed.

## Evidence-based treatments for Child and Adolescent Behavior Problems and Disorders

The 1995 Task Force Report on Promotion and Dissemination of Psychological Procedures (1995) identified 18 well-established treatments and seven probably efficacious treatments using the criteria just described. Of these 25 efficacious treatments, only three well-established treatments for youth (behavior modification for developmentally disabled individuals, behavior modification for enuresis and encopresis, and parent management training programs for children with oppositional defiant behavior) and one probably efficacious treatment for children (habit reversal and control techniques for children with tics and related disorders) were identified. As noted in that report, the list of empirically supported treatments was intended to be representative of efficacious treatments, not necessarily exhaustive. In recognition of the need to identify additional psychosocial treatments that were potentially effective with children, task forces were set up by the Society of Clinical Psychology (Division 12 of the American Psychological Association) and its offspring, the Society of Clinical Child and Adolescent Psychology (Division 53 of the American Psychological Association). The two independent task forces joined efforts and, in 1998, published their collective reviews in the *Journal of Clinical Child Psychology*. Reviews of empirically supported treatments for children with autism, anxiety disorders, attention-deficit hyperactivity disorder (ADHD), mood disorders, and oppositional and conduct problem disorders were included in the special issue. As noted by Lonigan, Elbert, and Johnson (1998), the goal was not to generate a comprehensive list of treatments that met criteria for empirically supported treatments for *all* disorders; rather, the goal was to focus on a number of high-frequency problems encountered in clinical settings serving children with mental health problems. As such, a number of problem areas were not reviewed (e.g., eating disorders, substance use, reactive attachment disorder, childhood psychosis).

In a subsequent review of empirically supported psychological interventions for adults and youth published in the *Annual Review of Psychology*, Chambless and Ollendick (2001) noted that other work groups had been instrumental in identifying empirically supported treatments as well. Namely, books edited by Roth and Fonagy (1996) and Nathan and Gorman (1998) identified other treatments and

evaluated many of the same treatments identified by the Society of Clinical Psychology and the Society of Clinical Child and Adolescent Psychology. In general, the criteria used by the various groups were similar to those used by Division 12, although some relatively minor differences were evident (see Chambless & Ollendick for details). At that time, Chambless and Ollendick identified 108 empirically supported treatments (including both well-established and probably efficacious treatments) for adults and 37 for children and adolescents—an obvious increase over those reported in 1995. Yet, Chambless and Ollendick suggested considerable caution in as much as no well-established treatments had been identified for the treatment of such common problems as the mood and anxiety disorders in youth (although probably efficacious treatments were evident for these disorders). Moreover, rarely did any one treatment have more than the two requisite studies to support its well-established or probably efficacious status (with the exception of parenting programs for oppositional and conduct problem youth and for youngsters with ADHD). It was also evident that *all* of the probably efficacious and well-established treatments were based on behavioral and cognitive-behavioral principles at that time. As a result, using these criteria, evidentiary support for frequently practiced treatments from other theoretical orientations (e.g., play therapy, family systems therapy, psychodynamic therapy) was notably lacking.

More recently, under the auspices of the Society of Clinical Child and Adolescent Psychology, the evidentiary support for the most prevalent psychiatric disorders in youth has been reexamined once again (Silverman & Hinshaw, 2008). Of significance, the evidence base has increased substantially since that reported by the Task Force (1995), the early Society report (1998), and the review by Chambless and Ollendick (2001). We now turn our attention to the evidence base for psychosocial interventions that exist at this time.

### Anxiety Disorders

Anxiety disorders are among the most common mental health problems in youth, with prevalence rates approximating 12% in community samples and 36% in clinical samples (cf., Kessler, Berglund, Demler, Jin, Merikangas, & Walters, 2005). The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) specifies that all of the anxiety disorders of adulthood can be identified in youth (i.e., generalized anxiety disorder [GAD],

specific phobia [SP], social phobia [SOC], panic disorder [PD], agoraphobia [AG], obsessive-compulsive disorder [OCD], and post-traumatic stress disorder [PTSD]), as well as one "childhood" disorder that occurs prior to age 18 (separation anxiety disorder [SAD]). In addition, past research based on earlier versions of the DSM included two additional diagnoses (i.e., overanxious disorder [OAD] and avoidant disorder [AD]) that have been subsumed under GAD and SOC in DSM-IV, respectively.

Surprisingly, no controlled between-group design outcome studies examining the efficacy of psychosocial treatments for youth experiencing anxiety disorders, other than simple or specific phobia, existed until recent years. However, several early controlled case studies provided preliminary support for the likely efficacy of behavioral and cognitive-behavioral interventions with these youth (Eisen & Silverman, 1993; Ollendick, 1995; Ollendick, Hagopian, & Huntzinger, 1991). Cognitive-behavioral treatment for anxiety disorders in youth, as used by Kendall and his colleagues (e.g., Kendall et al., 1992), is based on these early studies and is focused on both cognitive and behavioral interventions. Cognitive strategies are used to assist the youth to recognize anxious thoughts, to use awareness of such cognitions as a cue for managing anxiety, and to help them cope more effectively in anxiety-provoking situations. In addition, behavioral strategies such as modeling, in vivo exposure to the anxiety cues, role play, relaxation training, and reinforced practice are used. In the first manualized between-group study, Kendall (1994) compared the outcome of a 16-session treatment to a waitlist control condition. Forty-seven 9- to 13-year-old youth were assigned randomly to treatment or waitlist conditions. All the youth met diagnostic criteria for one of the anxiety disorders, and over half of them were comorbid with at least one other psychiatric disorder. Treated children improved on a number of dimensions; perhaps the most dramatic difference was the percentage of children not meeting criteria for an anxiety disorder at the end of treatment—64% of treated cases versus 5% of the waitlist children. At follow-up 1, 3, and 7 years later, improvements were maintained (Kendall, Safford, Flannery-Schroeder, & Webb, 2004; Kendall & Southam-Gerow, 1996). In a second RCT, Kendall et al. (1997) reaffirmed the efficacy of this procedure with 94 youth (also 9–13 years of age) randomly assigned to cognitive-behavioral and waitlist control conditions. Seventy-one percent of the treated children did not meet diagnostic criteria at the end of treatment, compared to 5% of those in the

waitlist condition. Very recently, the efficacy of this approach has been further validated in the Child-Adolescent Anxiety Multimodal Study (Walkup et al., 2008). In this study involving 488 youth between 7 and 17 years of age, 60% of youth receiving cognitive-behavioral treatment were diagnosis-free at the end of treatment, compared to 55% of youth receiving sertraline and 24% of youth receiving a drug placebo. In addition, 81% of youth receiving both sertraline and cognitive-behavioral treatment were diagnosis-free, suggesting the additive effects of combinatorial treatment.

Subsequent to Kendall's first randomized clinical trial, his cognitive-behavioral therapy (CBT) approach was evaluated independently by a different investigatory team in Australia (Barrett, Dadds, & Rapee, 1996). Youth (between 7 and 14 years of age) were assigned randomly to one of three groups: cognitive-behavioral treatment, cognitive-behavioral treatment plus a family intervention, and a waitlist control. The cognitive-behavioral treatment was intended to be a replication of that used by Kendall (although it was shortened to 12 sessions). At the end of treatment, 57% of the anxious children in the cognitive-behavioral treatment were diagnosis-free, compared to 26% of the waitlist children; at 6-month follow-up 71% of the treated children were diagnosis-free (waitlist children were treated in the interim). In the cognitive-behavioral plus family anxiety management treatment condition, parents were trained in how to reward courageous behavior and how to extinguish reports of excessive anxiety in their children. More specifically, parents were trained in reinforcement strategies including verbal praise, privileges, and tangible rewards to be made contingent on facing up to feared situations. Planned ignoring was used as a method for dealing with excessive complaining and anxious behaviors; that is, the parents were trained to listen and respond empathetically to the children's complaints the first time they occurred but then to withdraw attention if the complaints persisted. In this treatment condition, 84% of the children were diagnosis-free immediately following treatment, a rate that was maintained at 6-month follow-up. The augmented parent condition was found to be superior to cognitive-behavioral treatment directed toward the child alone at post-treatment and 6-month follow-up. However, in more recent studies, parent involvement has not always shown superior outcomes (Ollendick, Davis, & Muris, 2004).

Following these early studies, a large number of RCTs have been undertaken, with all of them examining the efficacy of CBT interventions in various formats and with different anxiety disorders (e.g., individual vs. group, child vs. family, GAD, SOP, SP, OCD, PTSD). Most of the studies have shown comparable outcomes regardless of the format of treatment or the specific anxiety disorders treated. Overall, significant reductions in symptoms or diagnoses have been observed in about 60%–70% of youth, compared with about 5%–20% of youth in waitlist comparison groups. In their recent review, Silverman, Pina, and Viswesvaran (2008) concluded that these CBT interventions meet the criteria for probably efficacious status in as much as they have been shown to be superior to waitlist control conditions. Moreover, they identified a host of other variations on these standard procedures that possess possibly efficacious status. Surprisingly, no interventions were found to enjoy well-established status even at this time—none was shown to be superior to another efficacious treatment or a placebo condition in two well-controlled studies conducted by different investigatory teams.

### Mood Disorders

Mood disorders evidenced by children and adolescents include major depressive disorder (MDD) and dysthymia. Epidemiological studies suggest the prevalence of these affective disorders in youth to be between 1.5% and 8.0% (Angold, Costello, & Erkanli, 1999; Costello et al., 1996). The diagnostic criteria for MDD and dysthymia in youth are similar to those specified for adults, with the exception that youth may experience irritability instead of depressed mood. In addition, weight and appetite disturbances may be manifested by failure to make developmentally appropriate weight gains (rather than loss of weight) and dysthymia can be diagnosed in youth after 1 year of symptoms, in contrast to the 2 years required for adults (APA, 1994). Overwhelmingly, research suggests that depression in youth is characterized by significant distress and interference and, left untreated, negative long-term outcomes.

The efficacy of psychosocial interventions in the treatment of youth with affective disorders was reviewed early on by Kaslow and Thompson (1998). Psychodynamic, interpersonal, cognitive-behavioral, and family systems interventions were examined for child and adolescent samples. Seven treatment outcome studies with children with elevated levels of depressive symptoms (but not a diagnosis of depression) were identified. All of the interventions were conducted in a group format and in school settings. Most treatments entailed less than 20 sessions and

all were cognitive-behavioral or psychoeducational in nature. Commonly used interventions included social skills and social competency training, self-control therapy, cognitive restructuring, and problem-solving approaches. Collectively, these studies revealed that these similar although not identical approaches were efficacious in reducing depressive symptoms in children who were not formally diagnosed as depressed. In addition, treatment gains were maintained at follow-up intervals ranging from 4 weeks to 2 years. The majority of the studies adequately described the characteristics of the samples, used treatment manuals, and showed that the treatments were superior to waiting list control conditions and, in at least one study conducted by Stark and colleagues, superior to an alternative treatment (traditional school counseling groups). Although positive outcomes were noted in these seven studies, only the self-control behavioral treatment program developed by Stark and colleagues (Stark, Reynolds, & Kaslow, 1987; Stark, Rouse, & Livingston, 1991) reached the criteria for probably efficacious status, as defined by the 1995 Task Force. No treatments met criteria for well-established status at that time.

In their early review, Kaslow and Thompson (1998) also examined the status of psychosocial treatments for adolescents with depression. As with children, seven treatment outcome studies were identified, five of which examined variants of CBT (self-control therapy, problem solving, relaxation training, social skills, and cognitive restructuring); one examined interpersonal psychotherapy (which addresses the interpersonal, social, and developmental issues common to adolescents with special attention to problems associated with depression); and the other compared cognitive-behavioral approaches to systemic-behavioral family therapy (which combined techniques from functional family therapy and a problem-solving model and included a focus on parenting and developmental concerns) and to a nondirective supportive control condition. Adolescents ranged in age from 13 to 18 years and were in the ninth to twelfth grades. Six of the seven treatments were delivered in a group format (one used individual therapy), and four of the interventions were conducted in a school setting (three were administered in outpatient clinic settings). As with the child studies, all seven studies showed positive outcomes for the various treatments, reflecting superiority of the active treatments over waitlist control conditions. However, none of the active interventions proved to be superior to one another, reflecting both the absence of differences in the few studies that made

such comparisons and the dearth of treatment outcome studies conducted at that time. Furthermore, only the Adolescents Coping with Depression (CWD-A) program conducted by Lewinsohn, Clarke, and colleagues (Lewinsohn, Clarke, Hops, & Andrews, 1990; Lewinsohn, Clarke, Rohde, Hops, & Seeley, 1996; see also Clarke, Rohde, Lewinsohn, Hops, & Seeley for long-term follow-up of these treated youth) provided an indication of the replicability of findings associated with any one treatment, and then only within the same group of investigators. No treatments for adolescents met criteria for well-established status at that time, but the CWD-A treatment by Lewinsohn and colleagues was determined to be a probably efficacious one.

In their recent review, David-Fernon and Kaslow (2008) provide a more optimistic, albeit still guarded, picture of the treatment of child and adolescent depression. As with the earlier review, the self-control program of Stark and colleagues continued to meet probably efficacious status for children. In addition, they reported that the Penn Prevention Program (cf., Jaycox, Reivich, Gillman, & Seligman, 1994; Yu & Seligman, 2002) also possessed probably efficacious status at this time. This intervention, also based on a CBT model, was designed to address depressive symptoms (although not necessarily depressive disorders) in at-risk children and early adolescents. It too is a school-based program, although one recent trial has examined it in a primary care setting (Gillham, Hamilton, Freres, Patton, & Gallop, 2006). The program consists of two primary components: a cognitive component and a problems-solving component. The cognitive component teaches the youth to identify negative beliefs, evaluate the evidence for them, and to generate more realistic alternatives. The social problem-solving component focuses on goal setting, perspective taking, decision making, and self-instruction. Overall, the program has been shown to be more effective than waitlist or no intervention control programs.

Although the number of treatment studies for adolescents has greatly increased in recent years, no treatment has emerged as a well-established one at this time (David-Ferdon & Kaslow, 2008). Both CWD-A and a relatively new treatment, interpersonal psychotherapy for adolescents (IPT-A; Mufson et al., 1999; Mufson, Weissman, Moreau, & Garfinkel, 2004; Roselló & Bernal, 1999; Young, Mufson, & Davies, 2006), enjoy probably efficacious status. Interpersonal psychotherapy for adolescents addresses a variety of adolescent problem areas, such as interpersonal disputes and conflicts,

role transitions, grief, and family and relational problems. The program helps youth develop effective strategies (e.g., improved communication, expression of affect related to changes in relationships, development of new social support systems) to deal with their problems areas. The treatment usually consists of 12 individual sessions conducted over a 12- to 16-week period. In most trials, recovery rates (i.e., percent diagnosis free) for the CWD-A and IPT-A treatments range from 50% to 85%, very similar to those found in the treatment of anxiety disorders in youth. Follow-up studies demonstrate that these programs produce lasting effects up to 2 years in duration. In addition to these two probably efficacious interventions, David-Ferdon and Kaslow (2008) also identified a number of possibly efficacious programs including attachment-based family therapy (Diamond, Reis, Diamond, Siqueland, & Issacs, 2002).

### Attention-Deficit Hyperactivity Disorder

Attention-deficit hyperactivity disorder is also a prevalent psychological disorder in childhood, with studies typically showing prevalence rates ranging from 3% to 7% (APA, 2000). In addition, the DSM-IV delineates three subtypes of the disorder based on the two symptom dimensions of inattention and hyperactivity-impulsivity: ADHD, predominantly inattentive type (ADHD-I), ADHD, predominantly hyperactive/impulsive type (ADHD-H/I), and ADHD, combined type (ADHD-C; APA, 2000). Attention-deficit hyperactivity disorder is often associated with significant short- and long-term impairment and is a risk factor for the development of additional psychological problems across the lifespan.

In 1998, as part of the Society of Clinical Child and Adolescent Psychology report, Pelham, Wheeler, and Chronis (1998) reviewed the status of psychosocial treatments for ADHD in children (very few studies were conducted with adolescents at that time) and concluded that behavioral parent training (BPT) programs and behavior contingency management (BCM) programs in the classroom met criteria for well-established treatments, as specified by the 1995 Task Force; however, cognitive therapy, standard cognitive-behavioral interventions, and their variants (e.g., social skills training) failed to meet such criteria. In fact, these latter treatments failed to show significant improvements and were not recommended as front-line interventions. Moreover, other interventions such as play therapy, family therapy, and psychodynamic therapy had not been systematically evaluated in RCTs.

Pelham et al. (1998) noted further that, although psychostimulant medications possessed relatively immediate and positive effects on many domains of functioning in children with ADHD and are well-established interventions, they did not produce long-term changes in academic achievement, classroom deportment, and peer relationships. Moreover, consistent with other EBTs, about 60%–80% of children with ADHD respond positively to a central nervous system stimulant regimen; the remainder shows either no response or an adverse response. Furthermore, of those children who do respond, the behavior of the majority is not normalized. That is, they continue to display relatively high rates of problematic behaviors. Given these findings, Pelham et al. (1998) recommended the inclusion of behavioral programs aimed at addressing these persistent and refractory behaviors. As noted earlier, BPT and BCM programs have been recommended either to supplement the gains observed with stimulant medication or to use on their own accord.

Behavioral parent training and BCM programs are frequently combined in comprehensive behavioral programs. In typical BPT programs, parents are given a series of readings about the principles of behavior modification and are taught standard behavior management techniques, such as time-out, response-cost, point systems, and contingent attention. Usually, these techniques are taught in a series of outpatient sessions lasting 10–20 weeks. At the same time, therapists work closely with the child's teachers to develop similar BCM strategies that can be implemented in the classroom by the teachers; in addition, they assist the teachers in developing daily report cards that provide feedback to parents about their child's performance in the classroom. Typically, parents are asked to provide consequences for targeted classroom behavior at home (e.g., special rewards, time-out, response cost). Such programs consistently show mild to moderate improvements in both classroom and home settings. Pelham et al. (1998) further noted that these positive findings are enhanced when a consulting professional is available (in addition to the therapist) to work closely with the teachers and parents. Under such conditions, greater control (and fidelity) is obtained over treatment implementation. Finally, these effects are enhanced even more when the peer relationships of ADHD children are specifically addressed. For a number of years, Pelham and his colleagues (e.g., Pelham & Hoza, 1996) have conducted an intensive Summer Treatment Program that has as a major purpose the improvement of social relationships in these children.

The program is in effect 9 hours a day for 6–8 weeks and combines behavior management techniques with academic activities and sports skills training in a summer camp format.

Until recently, the question of whether treatments should be administered individually or in combination with one another remained unanswered. In the largest RCT ever conducted for the treatment of ADHD, the Multimodal Treatment Study of Children with ADHD (MTA Study; MTA Cooperative Group, 1999) attempted to answer this question by comparing behavioral treatment alone (primarily consisting of BPT and BCM, along with the summer program), stimulant medication alone, a combined treatment, and a community control treatment. Overall, the study found that stimulant medication alone and the combined treatment were significantly more effective than the behavioral treatment alone and the community control, which did not differ from one another. In addition, the combined treatment did not significantly differ from the stimulant medication alone condition for core ADHD symptoms.

Since the time of this initial publication, data from two follow-up points have been published (2 years after treatment and 3 years after treatment; MTA Cooperative Group, 2004; Jensen et al., 2007). Although the groups involving MTA medication management (i.e., medication alone and combined) continued to show advantages at the first follow-up, the effect sizes were approximately half of what they were at the time of the initial outcome analyses. Interestingly, results recently published from the 3-year follow-up found no differences between treatment conditions, although remarkable improvements were seen in all four of the groups, suggesting that any form of treatment may result in relatively long-term treatment gains (Jensen et al., 2007).

In a recent review of this literature, Pelham and Fabiano (2008) affirmed the earlier conclusions of Pelham et al. (1998): namely, BPT and BCM remain well-established psychosocial treatments, and stimulant medications remain a well-established pharmacological intervention. They also showed that behavioral peer interventions (BPI) were well-established at this time. Behavioral peer intervention programs are typically implemented as part of summer treatment programs that are typically day-long programs conducted for 6–8 weeks, delivering 200–400 hours of treatment. Daily activities in these programs include intensive social skills training, coached group play in recreational activities, concurrent contingency management systems (e.g., point

systems, time-out), and home-based report cards (see Pelham, Fabiano, Gnagy, Greiner, & Hoza, 2005). These programs also focus on teaching sports skills and team membership skills. Frequently, BPI programs are embedded in BCM and BPT programs. As a result, it is difficult to disentangle the effects of each of these programs; nonetheless, their combined effects are well-established.

Pelham and Fabiano (2008) reaffirmed earlier findings related to the inadequacy of cognitive therapies, CBTs, and other more traditional therapies. They could find no evidence that these treatments were effective in treating ADHD. They recommended strongly against their routine use. As a result, none of these interventions was described as probably efficacious or even possibly efficacious for children with ADHD.

### Oppositional/Conduct Problems

Youth with oppositional and conduct problems comprise a heterogeneous group who engages in a broad array of behavior problem ranging from relatively minor defiance and temper tantrums to more serious violations such as physical aggression, destructiveness, stealing, and juvenile delinquency. Oppositional defiant disorder (ODD) refers to a recurrent pattern of developmentally inappropriate levels of negativistic, defiant, disobedient, and hostile behavior toward authority figures. Conduct disorder (CD) consists of more severe antisocial and aggressive behavior that involves serious violations of others' rights or deviations from age-appropriate norms. The prevalence of these disorders is estimated to be between 2% and 16%, depending on the population, ascertainment methods, and diagnostic measures used (Greene & Doyle, 1999; Loeber, Burke, Lahey, Winters, & Zera, 2000). In the absence of effective treatment, a significant subset of these youth become delinquent, and a significant minority become antisocial adults.

In their early review of the efficacy of psychosocial treatments for these youth, Brestan and Eyberg (1998) identified one well-established treatment and a host of probably efficacious treatments for these youth. Parent management training (PMT, very similar to BPT as defined by Pelham et al., 2008) was found to have strong empirical support and to warrant well-established status. Parent management training based on Patterson and Gullion's book, *Living with Children*, is derived from operant principles of behavior change and is designed to teach parents to monitor targeted deviant behaviors, observe and reward incompatible behaviors, and

ignore or punish deviant behaviors. This program has been shown to be more effective than psychodynamic and client-centered therapy interventions, in addition to no-treatment control groups. Overall, this approach was shown to possess robust effects in studies conducted with youth referred by schools, family physicians, and juvenile courts; in addition, these positive effects were obtained by several different investigatory teams.

Several programs were viewed as probably efficacious by Brestan and Eyberg (1998) including Webster-Stratton's (1984, 1990, 1994) parent training program, which is similar to that of Patterson and Gullion (1968); however, it is used primarily with very young, oppositional children who are at risk for developing more serious conduct problems. It includes a videotape series of parent-training "lessons" based in developmental and social learning theory. It is typically delivered to parents in small groups with therapist-led group discussion of the videotape lessons. The treatment has been tested in several studies, but all by the same investigatory team. It has been compared to waitlist control groups and to alternative parent training formats and found to be successful. For the most part, these studies have typically included children between 4 and 8 years of age.

In addition to these two treatments, Brestan and Eyberg (1998) identified a host of other treatments that met criteria for probably efficacious status. Some of these were variants of parent training, whereas others included child-centered and context-relevant treatments such as anger control training, anger coping training, parent–child interaction therapy, problem-solving skills training, rational-emotive therapy, and multisystemic therapy (MST). Most of these treatments were evaluated in well-controlled and well-designed outcome studies and simply awaited systematic replication by a second research team before advancing to well-established status.

In their more recent review, Eyberg, Nelson, and Boggs (2008) reported on a large number of additional studies that have been conducted in the past 10 years. Surprisingly, however, only PMT based on Patterson and Gullion's book was found to enjoy well-established status at this time. No new treatments were found to be well established. However, 15 treatments were found to possess probably efficacious status and a handful to possess possibly efficacious status. It is evident that much research remains to be conducted before we have an armamentarium of well-established treatments for youth with conduct problems. Considerably more research on a wide range of youth who live in a variety of familial and community contexts is required. The pioneering work conducted by Henggeler and colleagues on MST (Borduin et al., 1995; Henggeler & Lee, 2003; Henggeler, Melton, & Smith, 1992; Henggeler et al., 1986) and the work by Sanders and colleagues (Bor, Sanders, & Markie-Dadds, 2002; Sanders, 1999; Sanders, Markie-Dadds, Tully, & Bor, 2000) on the positive parenting program (Triple P) represent the kind of work that will likely yield the best pay-off. MST is provided in the family's natural environment (e.g., home, school, community) and generally lasts up to 6 months in duration. Usually, the families are in contact with the therapists several times a week (both in person and by phone), and therapists are available at all hours to assist the family. Sanders's (1999) Triple P program is a multilevel system of treatment, with five levels of treatment designed to match child and family needs based on the problem severity of any one family. The levels range from a universal prevention program for all youth and families to a parent training program for clinically diagnosed youth to programs that target stressors in the family, such as parental depression or marital problems associated with child behavior problems.

### Summary Comments: Evidence-based Treatments with Youth

It is evident that only a few well-established treatments have been identified for the treatment of child behavior disorders at this time. No well-established treatments have been identified for the treatment of depression or anxiety in youth. Moreover, only one treatment has been shown to possess well-established status in the treatment of youth with oppositional and conduct problems, and only two treatments have been shown to possess well-established status in the treatment of children with ADHD. Although a stable of interventions can be described as probably efficacious, it is evident that support for even these interventions is often meager. Rarely does any treatment have more than the two requisite studies that support its well-established or probably efficacious status (with the exception of parenting programs for oppositional and conduct problem children and for children with ADHD). It should also be evident that most of these probably efficacious and well-established treatments are based on behavioral and cognitive-behavioral principles, with the exception of interpersonal psychotherapy for adolescents with depression. To some extent, however, we do not really know whether frequently practiced treatments

from other orientations work or do not work (e.g., play therapy, family systems therapy, psychodynamic therapy); in many instances, they simply have not been evaluated.

## Developmental Context of Evidence-based Treatments for Youth

Clinicians working with children and adolescents are faced with a daunting challenge not shared by their adult therapist counterparts. Between preschool and late adolescence, children undergo enormous developmental changes in their cognitive, linguistic, emotional, interpersonal, and biological systems. Clinicians are faced, not only with individual differences, but with developmental differences as well. Over two decades ago, Kendall, Lerner, and Craighead (1984), and Ollendick and Hersen (1984) suggested that the "same" intervention delivered to children at different ages could produce dramatically different results owing to developmental differences in child capacities. In this respect, one class of change processes—interventions—could be constrained or facilitated by another class—developmental processes (Shirk, 1988).

Increasingly, research on child and adolescent treatment has drawn on basic principles of *developmental psychopathology* (Cicchetti & Rogosch, 2002; Silverman & Ollendick, 1999; Toth & Cicchetti, 1999). In their framework for developing EBTs for youth, Kazdin and Kendall (1998) proposed that the starting point for treatment development is research in developmental psychopathology that clarifies the nature and origin of mechanisms of dysfunction. Treatment, then, is geared toward remediating or compensating for pathogenic mechanisms that contribute to maladjustment. Similarly, a developmental psychopathology perspective is essential for the identification of boundaries of treatment effectiveness. A basic tenet of developmental psychopathology is that most forms of maladjustment result from the dynamic interplay among multiple developmental systems (Toth & Cicchetti, 1999). Insofar as children and adolescents present to treatment with different developmental capacities, social environments, and genetic liabilities, the same treatment should not be expected to produce uniform effects, even for youth with the same disorder (Shirk & Russell, 1996; Shirk, Talmi, & Olds, 2000; Silverman & Ollendick, 1999).

How might developmental processes impact treatment response to youth EBTs? A number of alternatives can be identified. First, children's developing capacities could limit (or facilitate) their ability to utilize specific treatment interventions. For example, children's emerging cognitive capacities, such as the capacity for self-monitoring, could impact their ability to identify emotional or situational cues that are critical for self-instructions. Consistent with this view, an early meta-analysis of CBT for children and adolescents (Durlak et al., 1991) found rather substantial age-related treatment effects. Cognitive-behavioral therapy with adolescents, presumably at a relatively advanced level of cognitive development, produced effects that were twice as large as those with younger children. Alternatively, typical social development could lead to a different pattern of age-related treatment effects. Developmental changes in autonomy and peer influence could mitigate the effects of interventions that rely on parent influence, such as parent management training, as in the treatment of ADHD or ODD, and in parent-augmented treatment in the mood and anxiety disorders. In this case, one might expect an inverse relationship between developmental level and effect sizes for PMT or the augmented conditions. In fact, an early review of parent training interventions reported diminished effects with increasing age (Strain, Young, & Horowitz, 1981) and, in the Barrett et al. (1996) study of anxious youth, the augmented treatment was found to be less effective for adolescents than for children.

A second alternative involves developmental differences in age of *onset* of a specific disorder. For example, research has supported the distinction between early-onset versus adolescent-onset conduct disorder (McMahon, Wells, & Kotler, 2006). These developmental patterns are associated with different liabilities (e.g., neuropsychological impairments that could impact treatment response). Similarly, negative cognitions may play a very different role in childhood-onset depressive disorders than in adolescent depression. For example, there is evidence that cognitions operate as *mediators* between stressful life events and depressive symptoms in childhood, but function as *moderators* during adolescence (Turner & Cole, 1994). Given this difference in function, one might expect interventions that target negative thinking to have different effects for children and adolescents.

A third and related alternative is that *duration* of emotional or behavioral problems could impact treatment outcome. By virtue of their age, older children have greater risk for disorders of longer duration than do younger children. Problems can become increasingly entrenched over time as a function of environmental contingencies or neurobiological changes. In addition, parents who have lived

with child problems for a longer time may become less optimistic about change and, in turn, less motivated to continue treatment (Dishion & Patterson, 1992). Thus, treatment response is likely to be inversely related to problem duration. To the degree that older children are more likely to have problems of longer duration than are younger children, treatment effects might be expected to decrease with age.

For the most part, the search for potential developmental predictors or moderators of treatment outcome has focused on child age. Age represents a proxy for developmental processes, a stand-in for adaptive or maladaptive processes that take time to develop and unfold. And, as the foregoing alternatives suggest, age could be a proxy for processes that either facilitate or impede treatment efficacy. In the next section, age-related patterns in EBT outcomes for anxiety and depressive disorders, ADHD, and conduct problems are reviewed. Age trends are considered in terms of alternative developmental processes.

### Age as a Predictor or Moderator of Evidence-based Treatment Effects with Youth

Age can function as either a predictor or moderator of treatment outcomes. As a predictor, age would be associated with outcomes, change in symptoms, or loss of diagnosis, regardless of treatment condition. For example, in a comparative trial involving several treatment conditions, age would be a predictor of outcome if it were significantly related to changes across treatment conditions. If, however, age were to be differentially related to treatment outcomes, that is, the magnitude or direction of effect varied as a function of treatment condition, then age would be a moderator of treatment outcome. Given the limited number of comparative outcome studies in the EBT literature, age is most typically conceptualized as a predictor of treatment response.

#### AGE AND THE TREATMENT OF ANXIETY DISORDERS

A "family" of CBT interventions has been shown to be probably efficacious across a range of anxiety disorders in children and adolescents (Ollendick & March, 2004; Silverman et al., 2008). Most research has concentrated on children between the ages of 7 and 14, with fewer studies of young children or adolescents. Nevertheless, a number of studies suggest potential age-related trends in response to CBT for anxiety. Southam-Gerow, Kendall, and Weersing

(2001) examined predictors, including child age, of treatment response among children ages 7–14 who received CBT for anxiety disorders in a specialty clinic. Poor treatment response was operationalized as the presence of any anxiety diagnosis following a full course of CBT. Analyses revealed a number of predictors of poor response, including higher levels of internalizing symptoms at pretreatment, higher maternal depression, and older child age. Child age continued to predict poor response even when analyses controlled for the other predictors.

Unlike the meta-analysis of CBT by Durlak and colleagues (1991), increasing age was not associated with greater treatment benefit among youth with anxiety disorders. As such, these results are inconsistent with a developmental facilitation perspective (e.g., increasing age is associated with greater capacity to utilize and benefit from interventions). It is possible that the facilitating effects of development on treatment response are unique to disruptive problems, in which deficits in cognitive processes such as self-monitoring and perspective-taking are prominent. However, because CBT, especially Kendal's Coping Cat approach to anxiety reduction, involves both cognitive and behavioral components, it is possible that children at different ages respond to different facets of the intervention (e.g., relaxation training versus restructuring or modifying self-talk). Further, as Southam-Gerow et al. (2001) point out, it is not clear if the diminished response of older children is a function of poor developmental fit between the activities that comprise Coping Cat or the result of anxiety problems of longer duration.

In a second study, Barrett et al. (1996) examined age as a potential moderator of treatment outcome in CBT for child anxiety. Children between the ages of 7 and 14 received either individual CBT or CBT with an additional family anxiety management (FAM) component. Results indicated that younger children responded more favorably (fewer retained their anxiety diagnosis) to CBT + FAM than did older children. A similar pattern was not obtained with individual CBT alone. Thus, age moderated the association between treatment and outcome. It appears that the inclusion of a family component was especially useful for younger children. From a developmental perspective, these results might be attributed to greater parent influence over younger than older children, or possibly to the greater importance of parent-assisted coping among younger children. Although this pattern of results clearly needs to be replicated, it raises an important developmental

question: Might greater treatment benefits be expected from the addition of family or parent components in EBTs for younger compared to older youth? Unfortunately, studies comparing individual treatments with individual plus family or parent components have not evaluated this possibility.

## AGE AND THE TREATMENT OF DEPRESSION

In their meta-analysis of 34 RCTs for youth depression, Weisz, McCarty, and Valerie (2006) compared treatment effects for children under the age of 13 with outcomes for adolescents. Their results did not indicate differential efficacy across the two age groups, with overall effects in the small to medium range for both groups. It should be noted, however, that the meta-analysis included all randomized trials for child and adolescent depression, and not just studies of well-established or probably efficacious treatments. Based on their review of EBTs for youth depression, David-Feron and Kaslow (2008) reached a rather different conclusion; they concluded "the limited data suggest that psychosocial interventions are more effective for adolescents than for children and for younger adolescents than older adolescents." It is not clear if these discrepant conclusions stem from non-overlapping samples of outcome studies or from a differential focus on diagnostic response versus symptom change. Of equal importance, a comparison of effects for children and adolescents is complicated by the fact that the "same" treatment, for example, CBT, is not the "same" (i.e., identical) for child and adolescent depression. An evaluation of developmental effects at the level of specific treatment components (e.g., cognitive restructuring), is likely to yield less ambiguous results than are broad comparisons of multicomponent treatments (Shirk & Russell, 1996).

There is some evidence to suggest that younger adolescents respond more favorably to CBT for depression than do their older counterparts (Brent, Kolko, Birmaher, Baugher, Bridge, Roth, & Holden, 1998; Clarke, Hops, Lewinsohn, & Andrews, 1992; Curry et al., 2006). As in the case of CBT for anxiety disorders, this pattern is not consistent with a developmental facilitation perspective that would predict greater capacity to utilize cognitive interventions, and consequently better outcomes, with increasing cognitive maturity. Other predictors of treatment response may shed light on this age trend. A number of studies have shown that symptom severity, hopelessness, suicidal ideation, and cognitive distortions

are related to poor treatment response. These risk factors appear to accumulate with number of depressive episodes; by virtue of their age, older adolescents have a greater chance to experience more or longer episodes of depression.

## AGE AND THE TREATMENT OF ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Behavioral interventions, including behavioral parent training, behavioral classroom management, and intensive social skills training, have been shown to produce reductions in ADHD-related behaviors (Pelham & Fabiano, 2008). Most of the research on these treatments, however, has focused on school-aged children, with substantially fewer studies of preschoolers and adolescents available (Pelham & Fabiano, 2008). Overall, the bulk of the evidence suggests that behavioral interventions for ADHD are effective across the elementary school-age years (Pelham & Fabiano, 2008). Continuity in beneficial effects into adolescence is less well-established.

Two studies by Barkley and colleagues (Barkley, Guevremont, Anastopoulos, & Fletcher, 1992; Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001) provide some evidence for efficacy of family-based programs for adolescents with ADHD. In the first study, families were assigned to one of three conditions: behavioral management training (BMT), problem-solving communication training (PSCT), or structural family therapy. All three treatments produced reductions in negative communication, conflict, and anger during conflict, as well as improvements in ratings of school adjustment. Despite these positive outcomes, clinically significant change was very low across all groups, including the behavior management condition in which only 10%–29% of adolescents showed significant change depending on outcome measure. In a second study, Barkley et al. (2001) compared BMT with PSCT for adolescents with ADHD. Again, both treatments produced significant improvements in family conflict but with no differences between therapies. Using a measure of reliable change as an index of clinical significance, only 23% of families showed clinically significant benefits.

Results from these two studies suggest that behaviorally oriented therapies that focus on parent management skills or family communication are associated with behavioral improvements at home and at school. However, the limited magnitude of change indicates that these treatments are far from optimal for adolescents. It is certainly possible that

developmental differences in the duration of ADHD problems and family patterns associated with such problems make change more difficult with adolescents than with children. Although symptoms of hyperactivity and impulsivity often improve with age, it may be the case that the cumulative effect of persistent attention symptoms engenders high levels of academic and social impairment, or that adolescents with ADHD, compared to children, present with greater comorbidity that complicates treatment progress. Alternatively, it may be the case that parent-focused interventions, such as BMT, are less effective with teens owing to developmental changes in autonomy and a corresponding reduction in response to parent reinforcement.

### AGE AND THE TREATMENT OF OPPOSITIONAL/CONDUCT PROBLEMS

Although only one treatment, PMT, has met criteria as a well-established treatment for conduct problems (ODD/CD), a number of treatments have been found to be probably efficacious, including problem-solving skills training and MST. It is noteworthy that these treatments have been constructed with development in mind; that is, PMT and problem-solving skills training have concentrated on elementary school-age children, whereas MST has targeted adolescents.

Results for age-related trends in parent management training are mixed. In their analysis of 26 studies of PMT, Serketich and Dumas (1996) found somewhat larger treatment effects for elementary school-aged children than preschool-aged children. However, neither McMahon and colleagues (1985) nor Beauchaine and colleagues (2005) found age-related effects for Helping the Noncompliant Child or the Incredible Years interventions, respectively. In one large-scale study of PMT, Ruma, Burke, and Thompson (1996) found that adolescents had a lower rate of clinical recovery from disruptive behavior problems than did preadolescents.

As reflected by these discordant results, a clear pattern of age effects is difficult to discern, although some evidence suggests that adolescents might be less responsive to parent management interventions. It is certainly possible that poorer response by adolescents results from developmental changes in autonomy and peer influence that diminish parent behavioral leverage. However, evidence also indicates that adolescents present with more severe and long-lasting conduct problems than do younger children seen in PMT (Kazdin, Holland, & Crowley, 1997; Ruma et al., 1996). Age effects in treatment response may reflect developmental changes in the nature and severity of disruptive problems that emerge during adolescence.

### Summary Comments: Development and Youth Evidence-based Treatments

Across all four clinical disorders, there is some evidence for age trends in treatment response. In general, results suggest that younger children respond more favorably than older children or adolescents to CBT for anxiety, PMT for conduct problems, and possibly to behavioral interventions for ADHD. Age trends for depression are less clear, although emerging results suggest that younger adolescents respond more favorably to CBT than do older adolescents. Overall, there is relatively little evidence for a developmental facilitation perspective. In general, younger children appear to respond better to EBTs than do older children, especially when adolescents are considered. But this tentative conclusion must be tempered by the existence of inconsistent findings, variations across disorders, and the absence of clear data for some age groups. Where age trends do exist, they appear to be more consistent with developmental models that consider age of onset, problem duration, or the accumulation of liabilities as explanatory variables. In general, although not in all cases, problems of long duration and high severity are associated (confounded) with child age, thus reflecting the adage that age is a proxy for processes that take time to develop and unfold.

As the current review suggests, simple clinical formulations such as *younger children respond more favorably to behavioral interventions whereas older children respond better to cognitive interventions* must be qualified by both disorder and treatment specifics. Although such "rules of thumb" make intuitive sense, existing data provide relatively little support for such a principle. Of course, given that many EBTs involve multicomponent packages, and given the dearth of dismantling studies, it is not evident which components, be they cognitive, behavioral, or relational, actually account for treatment changes.

On a more positive note, most EBTs have been developed for specific age groups, most commonly preschoolers, school-aged children, or adolescents. In fact, the absence of robust age effects may be due to the attenuation of age range in most EBT outcome studies. This is by no means a criticism, but rather a virtue. Most youth EBTs have been constructed with development in mind. Consequently, modest or mixed findings for age-related treatment effects should not be viewed as a license to use a specific empirically supported treatment with youth of

widely varied ages, but rather as an indication to use EBTs with the specific age group for which they were designed.

## Relational Context of Evidence-based Treatment for Youth

Perhaps it goes without saying that all of the foregoing EBTs are delivered through face-to-face contact with a therapist. Although bibliotherapy and internet-mediated programs have been developed, especially in the prevention area, most current EBTs for youth and their families occur in the context of an interpersonal relationship. The importance of the therapeutic relationship has long been recognized by child and adolescent clinicians of different theoretical orientations (Axline, 1947; A. Freud, 1946, Kendall, 1991; Ollendick & Cerny, 1981; Patterson & Chamberlain, 1994), however most research over the last 25 years has focused on the identification, manualization, and evaluation of specific treatment procedures. The search for EBTs has been based on the assumption that "specific factors," those procedures that distinguish one form of therapy from another, are likely to account for greater improvements in youth treatments than variations in "nonspecific factors," those features that are common across therapies. Indeed, recent meta-analytic results showing the superiority of EBTs over usual-care treatments are consistent with this perspective (Weisz et al., 2006).

Other reviews, however, have presented a more cautious portrayal of youth EBTs. For example, in their review of studies comparing youth EBTs with active control conditions, Jensen, Weersing, Hoagwood, and Goldman (2005) found that EBTs were superior to active control conditions of similar intensity in only about half of the reviewed studies. Similarly, results were equivocal when differences in "dose" of putatively active ingredients were compared. More recently, Miller et al. (2008) conducted a meta-analysis of direct comparisons of treatment modalities for the same four youth disorders reviewed here—anxiety, depression, ADHD, and conduct problems. In this review, they included only comparisons between EBTs and active, bona fide treatments, that is, not placebo or attention controls. Consistent with the narrative review, this study revealed small comparative effects ($d$ = .22). The combined results of these reviews suggest that the impact of EBTs cannot be fully attributed to specific factors that are unique to these treatments. Instead, it is very likely that features that are common across bona fide therapies account for significant outcome

variation, a finding that is consistent with results from the adult therapy literature (see Luborsky et al., 2002; Messer & Wampold, 2002).

Of all the nonspecific factors, the therapeutic relationship has received the most attention in the child and adolescent research literature (Shirk & Karver, 2003; Karver, Handelsman, Fields, & Bickman, 2006), and a review of treatment manuals, whether for youth- or parent-focused interventions, reveals a common concern with building a collaborative, working relationship. Our aim, then, is not to argue that nonspecific factors are more important than specific factors in youth treatment, but rather to rise above this traditional polarity to draw attention to emerging "relational principles" that could complement the focus on treatment procedures. To this end, the empirical literature on the therapeutic alliance and treatment participation in youth therapy were examined for common themes.

### Therapeutic Alliance in Child and Adolescent Treatment

Evidence indicates that the alliance between client and therapist is one of the most consistent predictors of treatment outcome across types of problems and types of therapies (Martin, Graske, & Davis, 2000). A small but growing set of studies shows that therapeutic relationship variables are associated with outcomes in child and adolescent therapy as well (Shirk & Karver, 2003; Karver et al., 2006). Specifically, Shirk and Karver (2003) found modest but comparable associations between measures of therapeutic relationship and outcomes across behavioral and nonbehavioral, manualized and nonmanualized, and adolescent and child therapies.

Consistent with the adult literature (Bordin, 1976; Horvath & Luborsky, 1993), the alliance in child and adolescent therapy has been conceptualized as a multidimensional construct (Shirk & Karver, 2006; Shirk & Saiz, 1992). Across self-, therapist, and observer reports two dimensions—emotional bond and task collaboration— have emerged as core features of the alliance (Estrada & Russell, 1999; Shirk & Saiz, 1992). A third dimension found in the adult literature, agreement on treatment goals, has received less attention, perhaps because of the low rate of goal consensus found in child and adolescent therapy (Hawley & Weisz, 2003). In brief, the alliance in youth treatment has been viewed as a *collaborative bond* between patient and therapist (Kazdin, Marciano, & Whitley 2005). Of course, because youth are rarely self-referred and typically reside with adult caregivers, youth treatment involves

multiple alliances, that is, between therapist and youth, as well as between therapist and parent(s). In fact, for some forms of youth therapy, such as PMT, the child's problems may be targeted by working directly with the parent. In such cases, the critical alliance, then, is between therapist and parent. In other cases, parents can be involved as consultants, co-therapists, or collateral patients (Kendall, 1991), and typically parents are at least involved as the transporter of the child to the clinic. The alliance in child treatment, then, is both multidimensional and multirelational. Typically, therapists are faced with establishing and maintaining a collaborative bond with both youth and adult caregivers.

Early research on the therapeutic relationship, including the alliance, focused on nonbehavioral therapies delivered in usual-care contexts (Shirk & Karver, 2003; Shirk & Russell, 1996). Although such treatments were widely practiced, few had received empirical scrutiny. Recently, there has been growing interest in the contribution of the alliance to outcome in EBTs. Specifically, the alliance has been examined in CBT for child anxiety disorders and adolescent depression, and in behavioral PMT for children with disruptive behavior disorders.

Two published studies have examined the contribution of the alliance to outcome in CBT for child anxiety disorders. In the first study, Kendall (1994) examined associations between the children's perceptions of the therapeutic relationship and a broad set of outcome variables. Although Kendall found a pattern of significant correlations between child-reported alliance and child-reported anxiety outcomes, these results were not found across different sources of outcome data. In fact, the vast majority of correlations were small and nonsignificant. As Kendall noted (1994), children gave therapists very positive alliance ratings overall, which may have limited associations. In a second study, Kendall et al. (1997) found a similar pattern of results in their replication study of CBT for child anxiety disorders. Again, results revealed very modest and nonsignificant associations between child-reported alliance and outcomes, with an average correlation of less than .01. Thus, in both studies of alliance–outcome relations for childhood anxiety disorders, results provide minimal evidence for the contribution of the alliance to outcome. It should be noted, however, that in both studies, the alliance was assessed at post-treatment, which could have truncated the range of alliance scores thereby limiting associations with outcomes.

Two studies have reported on alliance–outcome relations in CBT for adolescent depression. In the first, Kaufman, Rohde, Seeley, Clarke, and Stice (2005) examined the mediating role of the alliance in group CBT. Their results showed higher alliance scores in the more effective CBT condition, compared to a life skills training condition, but alliance was not significantly predictive of outcome in either condition. In contrast, Shirk, Gudmundsen, Kaplinski, and McMakin (2008) found significant associations between alliance and change in depressive symptoms in their study of individual CBT for adolescent depression. Results were stronger for associations between adolescent-reported alliance and outcomes than for therapist-reported alliance; however, the average association between alliance and outcome across sources was very similar to results obtained in the meta-analysis by Shirk and Karver (2003). It is not clear if the discrepant findings of these two studies are the result of differences in modality (group vs. individual CBT), alliance measure, or some other factor.

In the area of disruptive behavior disorders, Kazdin and colleagues (Kazdin, Holland, & Crowley, 1997; Kazdin & Wassell, 1999; Kazdin & Whitley, 2006; Kazdin, Marciano, & Whitley, 2006) have conducted a series of studies on alliance–outcome relations in PMT and problem-solving skills training with youth. These studies have consistently demonstrated links between parents' alliance with their therapists and reductions in externalizing problems. In their most recent study, Kazdin et al. (2006) found that child–therapist alliance predicted treatment progress in youth problem-solving skills training. In addition, parent–therapist alliance in PMT predicted improvements in parenting, as well as child improvements in externalizing behavior. Importantly, Kazdin and Whitley (2006) showed that alliance–outcome relations in PMT could not be explained by variations in pretreatment client characteristics, such as parents' level of social functioning. Although this finding clearly needs to be replicated, it suggests that the alliance is a relational construct that emerges through the course of interactions between patient and therapist.

Taken together, then, results are mixed on alliance–outcome relations in youth EBTs. The most consistent findings come from research on youth with disruptive behavior disorders. Notably, the most consistent results have been obtained with parents rather than youth. It is possible that the use of self-report alliance measures is a less optimal

assessment strategy with youth than with parents, perhaps due to positive biases that truncate the range of alliance scores among youth. In addition to predicting outcomes, parent–therapist alliance also predicts treatment dropout (Kazdin et al., 1997). A similar result has been obtained in usual-care therapy delivered in community clinics (Hawley & Weisz, 2005). In this study, parent–therapist alliance predicted premature termination, whereas youth–therapist alliance predicted changes in youth symptoms. Overall, then, emerging results suggest that cultivating a strong working alliance with parents may be essential for successful delivery of EBTs to youth. Perhaps this is not surprising, given the important role of parents in youth treatment. Typically, parents make decisions about initiating and terminating treatment, and often they are responsible for transporting children and adolescents to sessions even when they are not being seen themselves (Ollendick & Cerny, 1981).

Thus, an emerging evidence-based principle is that the alliance in youth treatment is multirelational. Initial evidence indicates that alliance formation with adult caregivers may be as, if not more, important than alliance formation with youth for the delivery of EBTs. Specifically, the formation of a working alliance with adult caregivers appears to be critical for treatment continuation and, in turn, the delivery of an adequate dose of EBT.

It is noteworthy that most research on alliance–outcome relations in child and adolescent therapy has focused on the youth rather than on their caregivers. As a result, we know relatively little about the best methods for building alliances with parents. There is some evidence to suggest that parent–therapist alliance may be related to parent perceptions of treatment relevance, credibility, and effectiveness (Kazdin et al. 1997; Nock, Ferriter, & Holmberg, 2007; Nock & Kazdin, 2001), but most of this work has focused on treatment attendance and adherence rather than alliance per se. Although a number of studies have shown that parent attendance and adherence can be enhanced through brief preparatory interventions or ongoing enhancement strategies, such as contingencies for homework adherence or collateral supportive parent sessions (see Nock & Ferriter, 2005, for a review), there is a dearth of research on specific therapist strategies for building and maintaining a positive parent alliance. Research on the alliance in child and adolescent treatment should be expanded to include both youth patients, as well as their adult caregivers.

## Treatment Participation in Child and Adolescent Therapy

A second nonspecific factor that has received some attention in the child and adolescent therapy literature is treatment participation. Although participation has been equated with session attendance in some studies—and clearly exposure to efficacious treatment protocols is essential—virtually all EBTs demand more than session attendance and exposure to treatment components. Across diverse therapies, EBTs involve both an active therapist and an active patient. The efficacy of EBTs does not reside in the manual or merely in the therapist's fidelity to the manual, but rather in the client's active participation in the tasks or procedures specified by the manual. For example, the impact of homework assignments in most EBTs presumably is less about its assignment by the therapist and more about its completion by the patient. Similarly, a therapist can be exceptionally skilled in the construction of an exposure hierarchy, but if the patient fails to engage in exposure trials, it is unlikely that he or she will attain the benefits of the evidence-based procedure. It is the patient who changes, consequently, any comprehensive account of change processes must include patient behavior as well as therapist behavior over the course of therapy. As a broad construct, treatment participation provides a window on the patient's contribution to the beneficial effects of EBTs. A review of EBT manuals for children and adolescents reveals a consistent principle—children and adolescents are not passive recipients of therapy, but rather active participants in their own treatment. Although interventions that exclusively target parent behavior represent an exception to this pattern, youth-focused EBTs require active child and adolescent participation in sessions. Presumably variations in this common factor could account for substantial differences in treatment outcomes.

A substantial body of evidence from the adult psychotherapy literature indicates that patient participation, typically defined as patient self-disclosure, initiation of difficult topics, and verbal elaboration in response to therapist prompts or inquiries, is predictive of patient-, therapist-, and evaluator-reported outcomes across therapeutic approaches (Eugster & Wampold, 1996; Gomes-Schwartz & Schwartz, 1978; O'Malley, Suh, & Strupp, 1983). In light of results suggesting treatment equivalence for some adult disorders, it has been suggested that the specific form of treatment may be less important for successful outcomes than the patient's active

participation in whatever treatment is offered (Eugester & Wampold, 1996; Luborsky, Rosenthal, Diguer, Andrusy, Levitt, Seligman, & Krause, 2002).

In their meta-analysis of relationship variables in youth and family therapy, Karver et al. (2005) identified ten studies that examined associations between youth treatment participation and outcome. Overall, their results showed a modest effect for treatment participation, with estimates ranging widely between null and large effects. Given the wide range of measures, heterogeneity of therapies and patients, and varied designs (controlled vs. uncontrolled), such a broad range is not unusual. As an example, one study of eclectic therapy delivered in a usual-care setting to children with varied disorders showed that youth participation accounted for 20% of outcome variance. Although such a finding is very promising, it does not appear that any of the studies included in the meta-analysis involved the evaluation of treatment participation in an EBT.

A study by Chu and Kendall (2004) appears to be the only study to have examined the role of treatment participation in an EBT for youth, in this case, CBT for children with anxiety disorders. Patient participation was defined as the child's behavioral involvement in therapy tasks, self-disclosure, verbal initiation, and task-relevant verbal elaboration. Negative indicators of participation included child withdrawal, avoidance, and passivity. Level of child involvement measured at mid-treatment was predictive of positive treatment outcomes, as indexed by the absence of an anxiety disorder diagnosis and reductions in impairment. Involvement in early sessions did not predict positive outcomes, but positive shifts in involvement between early and mid-treatment were highly predictive of diagnostic improvement. Interestingly, most youth showed a negative shift in involvement over the course of treatment (perhaps because treatment moved toward participating in exposure trials). Children who showed a large negative shift were far more likely to retain their anxiety diagnosis. As Chu and Kendall (2004) observed, "growing signs of withdrawal, avoidance, and diminished participation may signal to the therapist that strategies to reengage the child may be required." Although prospective correlations between child involvement and outcome are a necessary step toward establishing a causal relation, they are by no means sufficient. However, the case is somewhat strengthened by the absence of associations between pre-treatment child characteristics and level of involvement. Nevertheless, it remains possible that early symptom change could affect children's level of treatment involvement.

The contribution of parent participation to outcome has been examined in the youth literature as well. In their meta-analysis, Karver et al. (2005) identified six studies that examined the contribution of parent participation to outcome. Again, participation was assessed with a wide variety of instruments, but unlike the research on child participation, five of the six studies were conducted in the context of behavioral or cognitive-behavioral therapy. All five studies showed significant positive association between participation and outcomes. In general, these results reflected the importance of the level of parent participation in parent-focused treatments such as PMT. Systematic research on parent "resistance" in PMT by Patterson and colleagues (see Patterson & Chamberlain, 1994) are consistent with these results. Their research indicates that parent nonadherence within and between sessions accounted for as much as 40% of change in parenting behavior, which was strongly associated with subsequent improvement in child behavior. Thus, once again, we find stronger evidence for parent relationship predictors than for child predictors in youth EBTs, essentially due to the absence of research on youth participation in EBTs.

A common feature of most EBTs for youth, and an important index of treatment participation, is between-session homework. Research with adults has revealed consistent relations between homework adherence and positive treatment outcomes. In their meta-analysis of the effects of homework on treatment response, Kazantzis, Ronan, and Deane (2000) found that interventions that included homework were more effective than interventions that did not. Similarly, Thase and Callan (2006) reported in their review of the literature on homework adherence in cognitive-behavioral treatment of adult depression that adherence was a moderate, but consistent, predictor of improvement. Remarkably, research on homework adherence in youth treatment is virtually nonexistent. This is especially surprising given that academic difficulties, including homework completion, are a common form of impairment among referred youth. Thus, homework completion in treatment, as in school, might be especially challenging for children and adolescents with significant mental health problems.

In one of the few studies to examine the role of homework adherence in a youth EBT, Clarke, Hops, Lewinsohn, Andrews, Seeley, and Williams (1992) examined the association between homework

completion and outcome in group CBT for adolescent depression. Homework completion was assessed for each session and correlated with diagnostic recovery and change in self-reported depressive symptoms. Although both correlations were in the expected direction, both were very small and failed to attain statistical significance. In a second study with a very small sample of depressed adolescents in group CBT, Gaynor, Lawrence, and Nelson-Gray (2006) found associations that were more consistent with results from the adult literature. However, the small sample size of eight indicates the importance of replication.

In summary, despite substantial evidence from the adult therapy literature for the importance of treatment participation, research on participation in youth therapy, including EBTs, is quite limited. Given that children and adolescents rarely self-refer, often minimize their problems, and frequently fail to acknowledge a need for change, substantial variation in treatment participation might be expected among youth. Yet the contribution of in-session involvement and between-session adherence largely has been ignored, despite the possibility that it could account for significant outcome variance. Demonstration of the contribution of treatment participation to treatment outcome could open a new avenue for strengthening EBTs by improving treatment participation and adherence. Although the idea is intuitively appealing, it currently lacks an empirical foundation with youth.

### Summary Comments: Relational Context of Evidence-based Treatments for Youth

Emerging evidence suggests that the beneficial effects of EBTs for youth are the result of both specific treatment procedures that are unique to evidence-based interventions and of nonspecific factors that are common across a wide range of therapies. The relative contribution of these factors has yet to be clearly established. Relational processes, such as the therapeutic alliance and treatment participation, have received some consideration in the empirical literature, but the evidence base is so thin that it is difficult to derive evidence-based principles. Across virtually all empirically supported protocols for youth, the importance of establishing a strong therapeutic alliance and engaging children, adolescents, or their parents in active participation in the tasks of therapy are clearly recommended. Yet, research on the contribution of these factors to treatment outcome in EBTs for youth is only beginning to emerge.

Currently, existing research suggests that it is important to view the alliance in youth therapy as multi-relational. Initial results indicate that clinicians need to attend, not only to their alliance with the youth, but also to the alliance with adult caregivers. Neglect of the parent–therapist alliance could have grave implications for treatment continuation and, in turn, adequate exposure the effective components of EBTs. And while exposure to evidence-based procedures is necessary for therapeutic benefits, active participation by youth and/or parents is likely to be critical as well. However, this second principle—effective treatment involves an active therapist *and* an active patient—is currently "on loan" from the adult literature. Although it is built into the structure of evidence-based protocols through specific therapist–patient activities, variations in youth or parent participation have received very limited consideration. Hopefully, the next generation of treatment research will consider such process variables, as they may reveal new alternatives for strengthening EBTs.

### Conclusion

The last 50 years has witnessed a remarkable change in the field of child and adolescent psychotherapy. An inadequate and unsteady empirical foundation has been replaced by a firm (and deep) base of outcome studies. Across multiple meta-analyses of this literature, results indicate that child and adolescent psychotherapy produces significant change in emotional, social, and behavioral problems. Accordingly, a relatively dismal view has been replaced by a more optimistic and well-grounded perspective. In turn, the field has redirected its attention to identifying efficacious treatments for specific disorders. The question for youth therapy researchers has shifted from "does child and adolescent therapy work" to "what works for youth with different types of problems?"

As our review indicates, substantial progress has been made toward addressing this question. Across four prevalent child and adolescent disorders, a number of treatments are now considered to be probably efficacious and many more as possibly efficacious. Although these results are promising, it is evident that only a handful of interventions have been shown to be well-established, and that more work needs to be done to establish the efficacy of interventions for other understudied problems such trauma reactions, eating disorders, childhood psychosis, self-injurious behavior, and complicated patterns of comorbidity that frequently present in

community clinics (Ollendick, Jarrett, Grills-Taquechel, Seligman, & Wolff, 2008; Weisz et al., 1987).

Despite the growth in child and adolescent outcome studies over the last five decades, remarkably few studies have been designed to address specific mechanisms of therapeutic action. As a result, research on mediators of youth treatment effects is in a nascent state. Thus, although it is evident that many youth treatments produce beneficial effects, there is much less certainty about what actually produces these effects. In part, this ambiguity stems from a focus on the evaluation of full treatment packages that typically include multiple therapeutic components, and from the tendency to assess change or response at the end of treatment rather than at multiple points during the course of therapy.

Although some might argue that the identification of mechanism is relatively unimportant as long as treatments "work," the fact that virtually all existing youth therapies produce substantial variability in treatment response, including 30%–40% of youth who fail to respond, identification of active therapeutic ingredients could provide the basis for treatment refinement and enhancement. Initial patterns might be detected by evaluating associations between variations in therapist delivery of and youth involvement in specific therapy components and measures of treatment outcome (Shirk & Karver, 2006). Of course, this strategy would need to be followed by dismantling studies that experimentally vary specific components across randomized groups.

Similarly, research on moderators of outcome is relatively limited. Our review of one important moderator, developmental level, revealed that few studies actually test for moderation, but rather are limited to predictors of change. With regard to developmental level, exclusively defined in the literature as child age, the pattern of age-related trends in treatment response appears to depend on the type of treatment, type of disorder, and the age range evaluated. Importantly, however, many EBTs have been devised with development in mind; that is, most manual-guided therapies have been developed specifically for either elementary school children or adolescents. With the exception of conduct problems, fewer treatments have been developed and tested with preschool children.

Of course, other potentially important moderators of treatment outcome remain to be examined (see Ollendick et al., 2008). Some that have received limited attention in the youth literature are gender, ethnicity, family disadvantage, comorbidity, and parental psychopathology. Although studies are very

limited at this time, suffice it to indicate that, as with age, the few findings available are mixed and highly complex, with some studies demonstrating the effects of moderation for these variables and others failing to do so. Unfortunately, firm conclusions cannot be drawn at this time.

### Implications for Clinical Research and Practice

Typically, current effectiveness trials compare treatment-as-usual (TAU) with a manual-guided therapy, and emerging evidence suggests that such structured therapies outperform an eclectic blend of youth treatments (Weisz et al., 2006). A reasonable inference, then, is that clinical outcomes will be improved when youth practitioners abandon TAU and adopt manual-guided therapies that have been shown to be effective. Of course, this conclusion implies that effective youth therapists will need to master a vast library of treatment protocols, or will need to specialize in the treatment of a limited set of disorders in order to manage information and skill overload. Thus, while the expansion of youth outcome studies and the emergence of EBTs clearly represent major advances in the field, the sheer number of "possibly efficacious," "probably efficacious," and "well-established" treatments presents a significant challenge for both therapists-in-training, as well as for seasoned practitioners.

Given the information and skill acquisition demands inherent in mastering multiple treatment manuals, it is not evident that improvement of youth treatment outcomes will follow from the proliferation of treatment manuals. Instead, it might be worth revisiting the role of treatment manuals in both clinical research and practice. Manuals were developed to homogenize treatment and reduce within-(treatment) condition variability across therapists, supervisors, and sites. Although most manuals lend themselves to flexible application, the aim of manualized therapy is to provide a consistent treatment at a "set" dose analogous to pharmacological therapy. Thus, manuals represent a means to an end. Specifically, they operationalize specific treatment principles (for example, principles of reinforcement, exposure, or cognitive restructuring) through a set of recommended activities or interactions—what might be called *implementation guidelines*. In brief, a manual is a means for bringing specific change principles to life.

We propose that what is critical for the improvement of child and adolescent therapy is less about mastery of manuals, and more about understanding

and applying core change principles inherent in manuals with known efficacy. To this end, it may be time to redirect attention to core principles that are captured in empirically supported protocols (see Barlow, Allen, & Choate, 2004 and Moses & Barlow, 2006). Recently, Woody and Ollendick (2006) summarized the core principles of effective treatments for anxiety disorders. In conducting evidence-based treatment for the anxiety disorders, they proposed that therapists should:

- Challenge misconceptions through discussion and explicitly question the evidence.
- Actively test the validity of erroneous and maladaptive beliefs through behavioral experiments.
- Use repeated exposure to the feared situation to reduce the intensity of the fear response.
- Eliminate avoidance of feared situations.
- Improve skills for handling feared situations.

Our review of EBTs across commonly occurring disorders reveals significant overlap in treatment principles, albeit significant variation in treatment protocols. As an initial effort to refocus attention on change principles, we highlight some of the common features and cross-cutting principles inherent in evidence-based protocols. This account is not intended to be exhaustive, but rather illustrative of emerging principles of change in youth treatment.

## Principle 1: Treatments Are Focused and Time-limited

Perhaps the most striking difference between EBTs and traditional child therapies involves level of structure. Traditionally, child therapy has been open-ended and guided by the principle of "following the lead of the child." To a great degree, the agenda was defined by whatever the child or family presented in a specific session. Thus, the content and focus of sessions could range widely over successive weeks of treatment. In contrast, EBTs provide a structure for the course of therapy. Although the client's concerns are elicited and incorporated into ongoing therapy, treatments are focused on specific treatment targets that are viewed as relevant for the reduction of a class of symptoms. For example, in the treatment of adolescent depression, the target could be the acquisition of effective coping strategies (typical of CBT) or the restructuring of problematic relationships (central to IPT). Once the treatment target has been identified, therapy remains focused on its modification.

Some years ago, Weisz, Donenberg, Han, and Kauneckis (1995) used a gardening metaphor to describe this important difference across therapies. To extend their metaphor, EBT therapists tend to "water their gardens" (conduct therapy) with the hose set to "stream," whereas traditional therapists set the nozzle to "spray." Evidence-based treatments target specific skills, processing deficits, or cognitive, emotional, or behavioral patterns, including interpersonal patterns, and attend to their modification sequentially, rather than simultaneously addressing multiple problems. Consequently, therapy is structured in a relatively orderly manner. Manuals undoubtedly enhance structure, but the core principle embodied in the manual involves systematic focus on single treatment targets and an orderly progression to new targets following improvement in the initial target. Although most EBTs involve multiple components, all involve a sequential approach to change.

Similarly, EBTs tend to be time-limited in duration. It is possible that this feature is an artifact of the constraints of conducting clinical trials, and very little evidence exists on dose–response relations in youth EBTs. However, it is also possible that a time-limited approach prevents therapist drift, sharpens treatment focus, and increases client participation. Based on this common feature of EBTs, it may be wise for therapists to structure treatment in time-limited segments rather than presenting it as an open-ended process. In turn, therapist and client can renegotiate additional segments based on treatment progress.

## Principle 2: Therapists Are Active

As noted earlier, traditional child and adolescent therapy is structured, in large part, by the youth's lead. To a great degree, then, therapists are in a *responsive* mode. In contrast, a review of EBT manuals indicates that therapists are cast in a very different role. Although therapists are expected to respond to concerns or situations presented by clients, therapists also are expected to actively guide patients through therapy tasks. In this respect, EBT therapists share a number of important characteristics with coaches. Like coaches, therapists are expected to form a good working relationship with their players, prepare them for the challenges of a game or performance, and help them develop the skill repertoire for, or overcome the impediments to, successful execution in a game or show (live-performance conditions). Therapy is not simply didactic. Good therapists identify the relevant skills, capacities, or patterns that are essential for successful performance and provide clients with relevant opportunities and motivation to practice or rehearse. In brief, therapists

don't just talk about the skills, just as a good dance instructor doesn't just describe a ballet. Evidence-based treatment therapists break down the "dance" into specific components, model "moves," provide ample opportunities for practice (e.g., in role-plays), and ultimately conduct "dress rehearsals" (e.g., in behavioral experiments, exposure trials, or prescribed interactions).

As Woody and Ollendick (2006) noted, effective EBT therapists do not just "direct" clients as to what to do, when to do it, where to do it, and how to do it. Rather, a collaborative process is enlisted in which the therapist draws upon clients' input to shape the content of sessions. This collaboration is most evident in such activities as constructing a hierarchy for exposure, planning homework assignments, or devising relevant role-plays. Importantly, in the context of skill training, effective EBT therapists attempt to integrate clients' immediate concerns or situations, often elicited at the beginning of sessions, into modeling or practicing relevant components. In this respect, therapists are actively responding to child or adolescent material while maintaining therapeutic focus.

A limited number of studies have compared EBTs to nondirective approaches. Perhaps the best evidence for the importance of therapist activity comes from a series of studies comparing trauma-focused CBT (TF-CBT) to nondirective supportive therapy for sexually abused children. Across four randomized controlled trials, results consistently showed greater improvements among children treated in TF-CBT compared to nondirective therapy (see Cohen, Mannarino, Murray, & Igleman, 2006 for a review). Similar findings have been obtained in the area of adolescent depression. Brent et al. (1997) found that CBT produced a lower rate of major depressive disorder at the end of treatment than nondirective supportive therapy, as well as a higher rate of remission. Of course, level of therapist activity and direction is only one dimension of difference between these two treatments, but clearly results favor treatments with a more active and directive therapist. Additional studies comparing EBTs to nondirective supportive therapy will strengthen the evidence base for EBTs and help isolate the contribution of specific factors to treatment outcomes.

## Principle 3: Clients Are Active Participants

Evidence-based treatment manuals consistently prescribe an active role for clients. Children and adolescents are not passive recipients of treatment, but rather they are active participants in therapy.

Treatment involves much more than exposure to the components in a manual; instead, EBTs call for active youth involvement in the activities, procedures, and interactions outlined by the manual. For example, skill acquisition is predicated on active practice of new skills in and between sessions. Exposure requires active encounters with actual or imagined anxiety-evoking situations. Reworking emotional reactions in IPT for adolescent depression hinges on the client's presentation of relevant emotional events in sessions. As these examples suggest, EBTs require both an active therapist and an active client.

As noted earlier, surprisingly few studies have examined the role of client involvement in EBTs. Research by Chu and Kendall (2004) yielded results that are consistent with this treatment principle. Higher levels of child participation produced better response to CBT for anxiety disorders. But, for the most part, this finding stands alone in the EBT literature. Despite the importance ascribed to active client participation in EBT manuals, very little has been done to evaluate this assumption or to identify what constitutes an adequate level of participation. Research on EBTs would be advanced by identifying how much participation is needed to which treatment components.

Given the importance of active participation in EBTs, the identification of therapist strategies or behaviors that promote or undermine treatment involvement is critical. A number of studies have examined therapist behaviors as predictors of working alliance in youth EBTs (Creed & Kendall, 2005; Russell, Shirk, & Jungbluth, 2008), but this line of research is in an early stage of development. It is likely that effective engagement strategies will vary as a function of client characteristics, for example, initial level of motivation or conversely hostility, and that one set of strategies will not fit all.

## Principle 4: Therapy Extends Beyond the Therapy "Hour" and Setting

In virtually all EBTs, the assignment of between-session activities (homework) is a common feature. Between session assignments provide opportunities for practicing newly acquired skills, for generalization of concepts and skills to new situations, for behavioral experimentation, and for potentially greater integration of therapy content with "live" emotional reactions than can be attained in session. Thus, therapy extends well beyond the office setting.

Again, despite the importance ascribed to homework in EBTs, evidence for the impact of homework completion by youth is virtually nonexistent.

Initial results with depressed adolescents are mixed. In fact, it has been suggested that homework completion might be less important with youth since noncompleted homework is typically completed in session (Clarke et al., 1992). Yet, given the putative functions of homework, completion of assignments in sessions barely approximates its presumed goals. As a core component of EBTs, the contribution of homework completion to treatment outcome is clearly in need of evaluation across child and adolescent disorders. If, for example, homework completion is unrelated to outcomes, or only related to outcomes for a subset of youth, then time allocated to homework assignment and review could be reallocated to other therapy components that may be more strongly related to beneficial effects.

The foregoing principles cut across widely divergent EBT protocols. It is likely that other principles will emerge with further scrutiny of diverse manuals. In many ways, the foregoing principles represent *formal* rather than *content* features of EBTs. It may be that core change principles will need to be anchored to specific classes of disorders, as enumerated by Woody and Ollendick (2007) for anxiety disorders. However, the identification of general principles may not be out of reach. To this end, we offer the following examples as potential core change principles in youth EBTs.

- *A significant portion of behavior is regulated by environmental consequences.* Contingent reinforcement of desired behavior is critical for change.
- *A significant portion of behavior, including maladaptive emotional reactions, is maintained by avoidance.* Graded exposure to challenging situations can reduce avoidance and improve behavior.
- *Stress is associated with many psychological disorders and can amplify symptoms.* Methods to reduce stress either through improved coping or environmental change (e.g., reduce family conflict) will decrease symptoms.
- *Cognitive processing problems or maladaptive beliefs often are associated with specific disorders.* An important focus of treatment is the identification and remediation of such cognitive features.

Admittedly, these examples are highly consistent with a cognitive-behavioral approach to treatment—and not by accident! Cognitive-behavioral therapy and behavior therapy have been the most commonly examined approaches in the EBT literature. A growing number of studies have examined interpersonal therapy and family-based approaches, and it is likely that accumulating evidence will point to additional change principles. An area that has received less attention in the youth treatment literature involves the role of emotion in therapeutic change. A comprehensive model of therapeutic change may ultimately include cognitive, behavioral, emotional, and relational principles derived from different therapeutic perspectives.

### Future Directions

As is evident, the field of child and adolescent psychotherapy has reemerged in recent years. Not that many years ago, the practice was in danger of becoming extinct and relegated to dinosaur status. Fortunately, advances in the study of developmental psychopathology have occurred that have been accompanied by exciting and far-reaching developments in evidence-based assessment and treatment practices. These advances have placed clinical child and adolescent interventions on more sure footing. However, our legs are not strong, and we cannot rest on our laurels. Much more remains to be accomplished in terms of developing well-established interventions for a variety of child and adolescent problems and disorders, and in identifying the core principles that underlie these interventions. We have our work cut out for us!

# Couple Therapy: Theoretical Perspectives and Empirical Findings

Donald H. Baucom, Norman B. Epstein, Jennifer S. Kirby, *and* Mariana K. Falconier

## Abstract

Whereas most couples enter into marriage or similar committed, romantic relationships with the full expectation that they will live their lives together in a happy and rewarding manner, the divorce rate in the United States and many Western countries continues to be alarmingly high—in the United States hovering around 50%. As a result, mental health practitioners have focused energy on ways to alleviate relationship distress. Many approaches for assisting distressed couples have been developed, yet few have been evaluated to demonstrate that they actually help couples. The current chapter provides an overview of the major models of couple therapy that have been evaluated in well-controlled research studies and have demonstrated that they benefit couples. The models included are: behavioral couple therapy, cognitive-behavioral couple therapy, integrative behavioral couple therapy, emotionally focused couple therapy, and insight-oriented couple therapy. For each model, the theoretical approach, overall interventions, and effectiveness are discussed.

**Key Words:** Cognitive-behavioral therapy, couple therapy, marriage, relationship distress

Most adults across cultures are involved in committed, intimate couple relationships at some point in their lives, whether it be in the form of marriage or cohabitation (Buss, 1995). Since 1970, marriage rates have declined in most Western countries, the average age at marriage is increasing, and the rate of cohabitation is growing. Even with these delays in committing to a relationship, intimate couple relationships continue to be viewed as the best forum for meeting individual needs for affection, companionship, loyalty, and emotional and sexual intimacy, even among those individuals who have experienced previous relationships as unsatisfactory (Halford, Kelley & Markman, 1997). And marriage continues to be the most common means of expressing commitment in a couple's relationship. Based on data from the 1990s, within 5 years of cohabitation, 82% of couples in the United States and between 50% and 66% of couples in most European countries have married (Kiernan, 2004). By the age

of 50, approximately 90% of the population in Western countries has been married at least once (McDonald, 1995); the great value placed on marriage also can be seen in widespread efforts among same-sex couples to enact legislation to legalize marriage for them.

As common as committed intimate relationships and marriage are, approximately 55% of American and 40%–45% of Australian, English, German, or Swiss first marriages end in divorce (Halford et al., 1997), and approximately 50% of the divorces occur early in the relationship, during the first 7 years of marriage. An additional 10%–25% of couples live in stable but unhappy relationships (Gallup, 1990; Hahlweg, 2004). And, as painful as the experience of divorce is for many people, approximately 75% of divorced men and 66% of divorced women remarry within 3 years. Unfortunately, the divorce rate in second marriages is even higher than in first marriages (Cherlin, 1992).

Given the alarming rate of both marital distress and dissolution, it is fortunate that clinicians and researchers have devoted considerable effort to developing and evaluating interventions for treating marital and relationship problems. In the current chapter, we provide an overview of the major models of couple therapy[1] that currently have accumulated empirical support demonstrating that the interventions are of help to couples when applied in well-controlled research studies, what the field refers to as "empirically supported interventions." This decision to include only approaches with empirical support is not intended to imply that other widely used approaches such as structural family therapy (Minuchin & Nichols, 1998), narrative therapy (Freedman & Combs, 2002), and brief strategic therapy (Shoham & Rohrbaugh, 2001) are not useful for couples. In fact, investigators interested in some other couple therapy approaches such as solution-focused therapy (a brief approach centered on finding solutions with clients rather than discussing the history of their problems, Hoyt, 2008) have begun to conduct well-controlled treatment investigations to evaluate their efficacies, but at present such studies are limited. In addition, the field awaits evaluation of the efficacy of interventions for individuals who are in committed relationships but who are not married; thus, the research described throughout this chapter applies to legally married couples only.

In discussing the efficacy of various approaches to couple therapy, we have adopted criteria set forth by Chambless and Hollon (1998) for empirically supported interventions. Briefly, for a treatment to be evaluated as efficacious for a given population, these authors propose that the treatment needs to be superior to a waitlist condition (i.e., couples not receiving treatment) or equivalent to another efficacious treatment (i.e., as helpful to couples as another intervention that has already been shown to be of assistance to couples); all of these criteria must be met within the context of an otherwise well-conducted scientific investigation. Successful implementation of treatments by therapists other than the originators

of the treatment is another prerequisite for defining an intervention as efficacious; that is, persons other than those who developed the treatment must be able to conduct it successfully as well. Thus, Chambless and Hollon require that the efficacy of a treatment must be corroborated by at least two independent teams of investigators, and that the preponderance of the evidence must support the treatment's utility for distressed couples. If the type of treatment has been successful in only one study or in multiple studies by the same investigator, then it is described as "possibly efficacious" (see Chambless & Hollon, 1998 and the special issue of the *Journal of Consulting and Clinical Psychology* [Kendall & Chambless, 1998] for an in-depth discussion of the strengths and weaknesses of this approach to evaluating psychotherapy research). Whereas these criteria might seem highly technical, they are important in the current context because they serve as the basis for identifying the treatments that are discussed in this chapter, based on the research support for them. Based on these criteria, we will discuss three broad approaches to couple therapy with sufficient current empirical support: (a) behavioral couple therapy (BCT) and its variants, including cognitive-behavioral and integrative BCT; (b) emotionally focused couple therapy (EFCT); and (c) insight-oriented couple therapy (IOCT).

Just as different theoretical approaches to individual therapy vary in a wide variety of ways, different forms of couple therapy vary in numerous ways. However, many of these differences among couple therapy approaches can be captured by exploring three dimensions that characterize the treatment. First, theoretical approaches vary in the degree to which they focus on overt behavioral patterns versus on internal experiences such as cognitions and emotions. That is, some approaches emphasize how partners communicate or act toward each other, whereas other approaches give greater focus to a partner's internal experience of how safe it feels to be close to another person. Second, approaches vary in whether they focus on the roles that the individual members play in the development and functioning of the relationship (e.g., a good relationship requires two well-adjusted individuals) or on the couple's dyadic interaction patterns and other relationship characteristics (e.g., the couple's problem is that, as a unit, they cannot communicate well with each other). Third, approaches differ in the extent to which they focus on the present or more proximal factors (e.g., the couple spends little time together enjoying themselves) versus more

---

[1] The term "couple therapy" is employed in this chapter because it is the term commonly used in the field at present. However, the reader should be aware that in almost all of the empirical investigations to date, couples receiving intervention have been married; thus, the applicability of the findings to unmarried, committed couples is unclear.

historical or distal factors in addressing relationship distress (e.g., the husband has learned from early experiences in his family of origin that even caring relationships always end in pain; thus, he stays distant from his wife). Therefore, we will describe how each approach addresses each of these three dimensions. No approach focuses exclusively on one pole of these dimensions, but there are notable differences in their relative emphases that shape how a therapist understands a couple's difficulties and intervenes to be of assistance to them.

## Models Based on Behavioral Perspectives
### Behavioral Couple Therapy

As suggested by the title of the model, BCT takes a systematic approach to the assessment and modification of couples' *behaviors* (e.g., Jacobson & Margolin, 1979; Stuart, 1980). Behavioral couple therapy was developed in the 1960s and 1970s, from the theoretical models of social exchange theory (Thibaut & Kelley, 1959) and social learning theory (Bandura, 1977). Social exchange theory proposes that a person's level of relationship satisfaction depends on his or her ratio of positive to negative experiences in that relationship; that is, few people are likely to be satisfied in a relationship that has a high rate of negative interactions between the partners while few positive interactions occur. Social learning theory suggests that members of a couple shape each other's behavior by providing positive or negative consequences for each other's actions. Thus, whether intended or not, often partners teach each other how to behave within the relationship by what behaviors are rewarded or punished. For example, if a husband puts down the newspaper to talk only when his wife finally yells at him, he has inadvertently reinforced her yelling, which he greatly dislikes.

BASIC CONCEPTS
*Behavior*
Empirical investigations have supported the social exchange conceptualization of intimate relationships focusing on rates of positive and negative behaviors, such that self-reported relationship satisfaction is correlated (a) positively with the frequencies of partners' positive actions, and (b) negatively, to an even stronger degree, with the frequencies of the partners' negative actions (Weiss & Heyman, 1990). Thus, distressed couples are more likely to demonstrate a high rate of negative behaviors and a low rate of positive behaviors; conversely, non-distressed spouses are more likely to engage in more positive behaviors toward their partners than negative ones (Gottman, 1994). In accordance with social learning theory, other findings indicate that distressed married couples are more prone than non-distressed couples to aversive, destructive patterns of communication, such as a demand–withdraw pattern in which one partner pursues an issue while the other withdraws, often resulting in an escalation of these roles over time (Christensen & Heavey, 1990; Christensen & Shenk, 1991). Furthermore, distressed couples are more likely to engage in exchanges in which one person's hurtful comment is reciprocated with greater intensity by the receiving partner. Consequently, there are not only high rates of negative communication behaviors among distressed couples, but there are long continuous strings of negative behaviors between the two partners, with one person's negative behavior leading to the other person being negative as well.

*Cognition*
As will be discussed subsequently, BCT has evolved into cognitive-behavioral couple therapy, a therapeutic modality that places significant emphasis on partners' cognitions about each other and their relationship. Even from a more behavioral perspective, however, cognitions are important because of their relationship to behavior. First, the impact of a partner's behaviors as positive or negative depends, in part, on the recipient's subjective experience and evaluation of these behaviors (Baucom & Epstein, 1990). For example, a husband may buy his wife a new blouse as a gift for no particular occasion. The wife may either interpret this behavior as a loving and thoughtful act, based on her inference that he was thinking of her and thought the blouse would look good on her, or she may interpret his gesture as an indication of his dissatisfaction with her wardrobe and an attempt to improve her appearance. These different interpretations of the same behavior likely would have differing impacts on the wife's feelings and subsequent behavior toward her husband. Behavioral couple therapists also assume that people choose to engage in a particular behavior because of their expectancies about the rewards and punishments they will receive from their partners. Therefore, when partners think about their relationships in distorted or extreme ways, it is likely to influence their behavior.

*Affect*
In addition to cognition, behavioral couple therapists have noted that emotional responses or affect

has a great influence on couples' behaviors and relationship satisfaction. Studies of couples' conversations have shown that distressed partners are more likely to respond negatively to each other's expressions of negative affect than are members of nondistressed couples (negative reciprocity); furthermore, these expressions of negative affect are not as likely to be offset by high levels of positive affect as they are in nondistressed relationships (Gottman, 1994). Thus, the expression of emotion, both negative and positive, is an important form of communication between partners. At times, a couple experiences difficulties as a function of the degree and manner in which emotion is expressed. At one end of the continuum, some individuals express little emotion, which can contribute to a lack of understanding from the other partner and a lack of closeness between the partners in particular. At the other end of the spectrum, some individuals express a great deal of emotion, and particularly when the emotions expressed are negative, such expression can be overwhelming to the other partner, who will often withdraw in an attempt to stop or escape from the strong emotions.

## CONTRIBUTION OF THE COUPLE VERSUS THE INDIVIDUAL IN COUPLE DISTRESS

With a major focus on interactive processes as a primary source of couple distress, behavioral couple therapists place a strong emphasis on the contribution of the couple as a dyad, rather than the individual's unique characteristics. Although partners bring learned behaviors from the past into their current relationships, social learning theory emphasizes that a spouse's behavior is both learned and influenced by the other partner's behavior. Over time, spouses' influences on each other become a stronger predictor of current behavior than the influences of previous close relationships. The behavioral approach also is based on social exchange theory principles that link the couple's satisfaction to higher ratios of pleasing versus displeasing behaviors that the partners exchange. Thus, the behavioral model suggests that a couple's ability to maintain a satisfying relationship is based on their skills for providing each other with pleasing and effective behavioral exchanges. As a result, therapeutic interventions are focused primarily on altering behavioral exchanges between the partners and developing more effective communication skills. In early behavioral models, little attention was given to understanding the unique characteristics of each partner, and how individual factors, including both strengths and vulnerabilities, contribute to marital adjustment.

## PROXIMAL VERSUS DISTAL FACTORS IN UNDERSTANDING RELATIONSHIP DISCORD

Behavioral couple therapy places a strong emphasis on the present, exploring how partners interact with each other and communicate with each other. Historical perspectives are addressed primarily in terms of understanding how well entrenched a behavioral interaction pattern might be and the various contexts in which it has occurred over time.

## APPROACHES TO TREATMENT
### Behavior
Because a central tenet of the behavioral model is that distress is caused by a low ratio of positive to negative exchanges, behavioral couple therapists have used behavior-exchange procedures such as "love days" (Weiss, Hops, & Patterson, 1973) or "caring days" (Stuart, 1980) to alter this ratio. More precisely, these procedures involve each partner agreeing to enact certain positive behaviors requested by his or her partner in order to increase the percentage of positive exchanges. Similarly, couples have been taught to develop behavioral contracts in which each person agrees to behave in specific ways desired by the partner, and then receives reinforcement for these actions. Although behavioral contracting appears to be less emphasized in current behavioral approaches to assisting distressed couples, it served as a major intervention strategy in many of the treatment outcome investigations that have been conducted. In addition, to increase the likelihood that couples will experience more positive interactions, behavior therapists teach couples specific communication skills and guidelines for (a) expressing thoughts and feelings, (b) engaging in empathic listening, and (c) problem-solving or decision-making. It is assumed that, by developing these skills, couples will enhance their abilities to negotiate more satisfying solutions to conflicts, as well as their abilities to experience more intimacy through skillful expression of feelings. As a result, couples will decrease negative reciprocity and increase positive reciprocity in their communication and overall relationship.

### Cognition
In the early texts on BCT, Jacobson and Margolin (1979) recommended that therapists instruct couples to monitor and record their cognitions at home, and Stuart (1980) promoted the concept of *relabeling*, which involves challenging the partners to alter their negative interpretations of ambiguous actions on each other's part. Unfortunately, descriptions of cognitive restructuring in early behavioral texts were

quite brief, and they typically did not give therapists a great deal of guidance in how to accomplish this goal. It also should be noted that cognitive interventions were not systematically employed in the treatment outcome studies that were conducted, which we discuss subsequently. Thus, despite the theoretical recognition of the role of cognitions in influencing the behaviors of spouses, the original BCT interventions did not address cognitions directly.

*Affect*

Behavioral approaches to couple relationships have viewed emotions (e.g., joy, anger, sadness) as reactions to specific behavioral interactions. That is, distress is viewed as resulting from particular behavioral patterns that are repetitive, ingrained, and reciprocal, which then lead to negative emotions. Consequently, behaviorists' approaches to modifying emotion typically have depended on the behavioral interventions described previously; once the behaviors change, affect will follow as well. However, this approach of altering affect through changing behavior may be problematic for some distressed couples (Epstein & Baucom, 2002). Specific behavior changes may not be powerful enough to overcome existing negative feelings toward the partner due to "sentiment override," or overall negative feelings about the partner and relationship that have developed over time. Indeed, research findings indicate limited associations between partner behaviors and overall relationship satisfaction (e.g., Halford, Sanders, & Behrens, 1993; Iverson & Baucom, 1990), suggesting that the original behavioral model might be too limited to explain and intervene with the complexities of relationship distress.

Theoretical models of relationship distress and related interventions continue to evolve over time, and this has been the case with behavioral perspectives on relationship functioning. As a result, two noteworthy enhanced behaviorally oriented approaches have evolved: cognitive-behavioral couple therapy (CBCT) and integrative behavioral couple therapy (IBCT).

### Cognitive-Behavioral Couple Therapy

Cognitive-behavioral couple therapy evolved from BCT and is consistent with trends in the overall field of behavior therapy to incorporate cognitive factors into behavioral conceptualizations of maladaptive responses. Consequently, most of the BCT theoretical perspectives and interventions described previously have been incorporated into CBCT. The much greater emphasis on cognition in the original

formulation of CBCT (e.g., Baucom & Epstein, 1990) is its primary difference from BCT. Whereas BCT practitioners noted the importance of cognitions to behavior change without explicitly targeting cognitions in treatment, the CBCT model also proposes that cognitive change is important in its own right. That is, in many instances, a couple might *not* need to change their behavior to increase their relationship satisfaction; instead, if they develop more positive interpretations of each other's behavior, then positive relationship adjustment might result. For example, a woman who holds an extreme standard for her husband's behavior (e.g., that if he is committed to the family, he should want to spend of all his nonwork hours with them) might be dissatisfied if he does not meet this standard, perhaps interpreting his involvement in individual hobbies as indicating a lack of commitment to the family. Helping her to reevaluate and reduce the stringency of her standard might be the intervention of choice, rather than a behavior change on either person's part. Thus, CBCT builds on the behavioral model by proposing that increasing relationship satisfaction involves a balance of behavioral and cognitive changes, both of which hold the potential for important emotional change.

#### BASIC CONCEPTS

Overall, CBCT incorporates basic behavioral perspectives on the role of behavior and affect in relationship functioning. Its major contribution involves the development and elaboration of the role of cognitions in relationship distress. Thus, a brief description of the cognitive perspective is provided.

*Cognition*

CBCT researchers have identified five major types of cognitions involved in couple relationship functioning (Baucom, Epstein, Sayers, & Sher, 1989). Empirical studies suggest that these cognitions are associated with, or even lead to, partners' negative affective and behavioral responses to each other (Epstein & Baucom, 1993, 2002; Fincham, Bradbury, & Scott, 1990; Noller, Beach, & Osgarby, 1997). The first three cognitions involve partners' thoughts about specific events in their relationship. *Selective attention* involves how each member of a couple idiosyncratically notices, or fails to notice, particular aspects of relationship events. Selective attention contributes to distressed couples' low rates of agreement about the occurrence and quality of specific events, as well as to negative biases in perceptions of

each other's messages (Noller et al., 1997). Thus, if a husband does not notice his wife's attempts to be more caring, then her behaviors are unlikely to have an effect on him. *Attributions* are inferences that an individual makes about the determinants of a partner's positive and negative behaviors. The tendency of distressed partners to attribute each other's negative actions to global, stable traits has been referred to as making "distress-maintaining attributions" because they leave little room for future optimism that one's partner will behave in a more pleasing manner in other situations or in the future (Holtzworth-Munroe & Jacobson, 1985). For example, if a husband attributes his wife's difficulties in completing all of her tasks (while she serves as the major caregiver to their three children and pursues a graduate degree) to her lack of intelligence, then he is unlikely to believe that there is much hope for change in the future. Bradbury and Fincham (1990) reviewed and noted the empirical support for the importance of partners' attributions in relationship functioning, and a growing body of research (e.g., Sanford, 2006) has continued to demonstrate the significant impact of partners' attributions on their emotional responses and behavior toward each other. *Expectancies*, or predictions that each member of the couple makes about particular relationship events in the immediate or more distant future, are the last type of cognitions involving specific events. Negative relationship expectancies have been associated with lower satisfaction, stemming from pessimism about improving the relationship (Fincham & Bradbury, 1989; Pretzer, Epstein, & Fleming, 1991).

The fourth and fifth categories of cognition are forms of what cognitive therapists have referred to as basic or core beliefs shaping one's experience of the world. These include (a) *assumptions*, or beliefs that each individual holds about the characteristics of individuals and intimate relationships, and (b) *standards*, or each individual's personal beliefs about the characteristics that an intimate relationship and its members "should" have (Baucom & Epstein, 1990; Baucom et al., 1989). Couples' assumptions and standards are associated with current relationship distress, either when these beliefs are unrealistic or when the partners are not satisfied with how their personal standards are being met in their relationship (Baucom, Epstein, Rankin, & Burnett, 1996; Halford, Kelly & Markman, 1997). For example, if a wife has an assumption that men simply cannot deal with emotions, then she might be unlikely to share her feelings with her husband, which leads to a sense of distance and lack of

intimacy, something that is very important to her. In such a circumstance, her assumption led her to behave in ways that rob her of what she greatly desires.

## CONTRIBUTIONS OF THE COUPLE VERSUS THE INDIVIDUAL IN COUPLE DISTRESS

Cognitive-behavioral couple therapists see relationship problems as developing not only from behavioral excesses and deficits within the couple, but also from each individual's cognitions that either elicit distress or impede the resolution of conflicts (Epstein, Baucom, & Rankin, 1993). Thus, some of the problematic cognitions that the therapist identifies may have developed from each individual's history, including previous romantic relationships, a person's family of origin, and society at large, as well as from their current relationship. For example, depending on how a husband experienced his mother's domination and control over his father's daily activities, he might overgeneralize and predict that his wife will eventually try to control his every move, even if she presently exhibits no overt signs of making such attempts. He might then react defensively to any suggestions from his wife regarding how he might behave more effectively, even when her ideas have considerable merit. Thus, many of the problematic behavioral interactions between spouses may evolve from their relatively stable cognitions about the relationship. Unless these cognitions are taken into account, successful intervention with the couple's behavioral interactions is likely to be compromised. Therefore, cognitive behavioral couple therapists attend to how each person thinks about and experiences the relationship. In this way, the unique characteristics, learning histories, and current thoughts and cognitions of each partner are integrated into the couple's ongoing interactions.

## PROXIMAL VERSUS DISTAL FACTORS IN UNDERSTANDING RELATIONSHIP DISCORD

Given that CBCT derived from BCT, it also emphasizes the present relative to the past. However, to the degree that an individual's distorted cognitions are rooted in the past, such historical precedents are noted, so that an individual can learn to differentiate between what he or she learned in the past versus what is occurring in the present. It is important to identify instances in which a cognition may have been accurate regarding past experiences but does not fit the current relationship.

## APPROACHES TO TREATMENT

The various interventions described in BCT apply to CBCT as well, again with the major contribution of CBCT being an increased focus on interventions to directly alter cognitions.

### Cognition

The cognitive behavioral approach (Baucom & Epstein, 1990; Epstein & Baucom, 2002; Rathus & Sanderson, 1999) has integrated assessment and intervention procedures from cognitive therapies (Beck, Rush, Shaw, & Emery, 1979; Meichenbaum, 1985) with traditional skills-oriented behavioral strategies. CBCT teaches partners to monitor and test the appropriateness of their cognitions. It incorporates some standard cognitive restructuring strategies, such as: (a) considering alternative attributions or explanations for a partner's negative behavior; (b) asking for behavioral data to test a negative perception concerning a partner (e.g., that the partner never complies with requests); and (c) evaluating extreme standards by generating lists of the advantages and disadvantages of trying to live up to a highly stringent standard.

## Integrative Behavioral Couple Therapy

Christensen and Jacobson developed IBCT (Christensen, Jacobson, & Babcock, 1995; Jacobson & Christensen, 1996) to build on BCT by emphasizing acceptance of the characteristics of one's partner and the relationship. IBCT includes a core assumption that there are genuine incompatibilities in all couples that are not amenable to change and that partners' emotional reactions, based on a lack of acceptance of each other's behavior, are as problematic, or more so, than the behavior itself. Attempting to cajole or force one's partner to change often can lead to a resistance to change. Therefore, IBCT interventions focus on a balance between systematically changing partners' behavior and the achievement of acceptance between partners regarding behavior that is unlikely to change.

### BASIC CONCEPTS

IBCT incorporates many of the concepts from BCT and CBCT but places an increased focus on emotional reactions that partners have in response to the difficulties they encounter in their relationships. The importance of constructive behavioral interactions and cognitively viewing each other's behaviors in realistic ways remain central to IBCT. IBCT primarily differs from BCT in its emphasis on partners accepting incompatibilities that are unlikely to be

responsive to behavioral change efforts. Whereas Christensen and Jacobson describe acceptance as a largely emotional process, it is difficult to differentiate between the cognitive and affective changes that are necessary in the acceptance process. Unless such differentiations can be demonstrated empirically, it might be best to refer to an emphasis on an internal, subjective affective/cognitive shift that is critical for accepting one's partner.

### CONTRIBUTIONS OF THE COUPLE VERSUS THE INDIVIDUAL IN COUPLE DISTRESS

IBCT continues to incorporate the BCT emphasis on couples' maladaptive behavioral interaction patterns, and thus, places a significant focus on the couple as a unit. Although these couple-level interaction patterns might be a notable aspect of what needs to be accepted by both partners, acceptance itself is an internal, subjective experience that exists on an individual level. Thus, IBCT attempts to promote acceptance in each partner and the couple as a unit as a means for reducing maladaptive interaction patterns that have been caused by a lack of acceptance.

### PROXIMAL VERSUS DISTAL FACTORS IN UNDERSTANDING RELATIONSHIP DISCORD

Given its derivation from BCT, IBCT also emphasizes present circumstances in the couple's relationship. However, an individual's achievement of greater acceptance of a partner can involve being aware of the vulnerabilities that the partner developed in the past, perhaps prior to the current relationship.

### APPROACHES TO TREATMENT

#### Affect

In addition to the use of the typical behavioral interventions described earlier to promote behavior change, IBCT employs three major strategies to promote acceptance: empathic joining around the problem, unified detachment from the problem, and tolerance building (Christensen et al., 1995; Jacobson & Christensen, 1996). During empathic joining, the IBCT therapist elicits vulnerable feelings (such as sadness) that may underlie partners' observed negative emotional reactions (such as anger) about an area of concern, encourages expression and elaboration of these vulnerable feelings, and communicates empathy for these understandable reactions. As a result, the therapist attempts to build empathy between the partners for each other. During unified detachment from the problem, the therapist helps the couple step back from the problem and assume

a more descriptive and less evaluative stance toward the problem. The therapist may engage the couple in an effort to describe (without evaluating) the common sequences that they go through, to specify the triggers that activate each other and escalate negative emotions, to create a name for their problematic pattern, and to consider variations in their interaction pattern and factors that might account for these variations. The therapist then might encourage the couple to engage deliberately in the problematic sequence in the session or at home, so that they can become more aware of their pattern and take it less personally. In tolerance building, the therapist helps the couple remember the positive aspects and benefits of their individual differences, as well as the negative implications of their differences.

## Empirical Support for Behaviorally Oriented Interventions

### BEHAVIORAL COUPLE THERAPY

Behavioral couple therapy is the most widely evaluated couple treatment, having been a focus of approximately two-dozen well-controlled treatment outcome studies. Behavioral couple therapy has been reviewed in detail in several previous publications, including findings from specific investigations (e.g., Alexander, Holtzworth-Munroe, & Jameson, 1994; Baucom & Epstein, 1990; Baucom, Shoham, Mueser, Daiuto, & Stickle, 1998; Bray & Jouriles, 1995) as well as meta-analyses (Baucom, Hahlweg, & Kuschel, 2003; Dunn & Schwebel, 1995; Hahlweg & Markman, 1988; Shadish et al., 1993; Shadish & Baldwin, 2002, 2003). All of these reviews reach the same conclusion: BCT is an efficacious intervention for distressed couples.

A large number of investigations have satisfied efficacy criteria by comparing BCT to waitlist control conditions in which couples do not receive treatment, consistently finding that BCT is more efficacious than the absence of systematic treatment. Several early investigations of BCT also have compared it to nonspecific or placebo treatment conditions (in which couples were seen for treatment but the specific components focal to behavioral interventions were omitted), with BCT generally being more efficacious than nonspecific treatment conditions (Azrin et al., 1980; Crowe, 1978; Jacobson, 1978). Researchers also can conduct what are called *meta-analyses,* in which the findings across all investigations are placed on a common metric or unit of measurement, so that findings across studies can be averaged even when different measures are employed. The results of meta-analyses have confirmed the

previous findings that behaviorally oriented treatments are of help to distressed couples (Dunn & Schwebel, 1995; Hahlweg & Markman, 1988; Shadish et al., 1993; Shadish & Baldwin, 2002, 2003). Baucom et al. (2003) concluded that, compared to waiting list control groups, BCT has an average effect size[2] of 0.72 (which would generally be viewed as a moderate effect), and is consistent among studies conducted in several countries.

Another way in which the usefulness of psychotherapeutic interventions is assessed is to evaluate the frequency with which clients receiving treatment move from the distressed to the nondistressed range, in what is regarded as clinically significant change (Jacobson, Follette, & Revenstorf, 1984). Findings suggest that between one-third and two-thirds of couples will be in the nondistressed range of marital satisfaction after receiving BCT. Most couples appear to maintain these gains for short time periods (6–12 months); however, long-range follow-up results are not as encouraging. In a 2-year follow-up of BCT, for example, Jacobson, Schmaling, and Holtzworth-Munroe (1987) found that approximately 30% of couples who had recovered during therapy had relapsed subsequently. In addition, Snyder, Wills, and Grady-Fletcher (1991) reported that 38% of couples receiving BCT had divorced during a 4-year follow-up period. Thus, brief BCT improvements are not maintained for many couples over a number of years, although some couples maintain and even improve upon their gains.

### COGNITIVE-BEHAVIORAL COUPLES THERAPY

The efficacy of cognitive interventions has been explored in two ways—as the sole intervention, or as part of a broader set of therapeutic strategies to assist distressed couples. Huber and Milstein (1985) compared cognitive couple therapy with a waiting list control condition. Their cognitive couple therapy focused primarily on irrational relationship standards and assumptions that were highlighted by Epstein and Eidelson (1981), along with specific irrational marital beliefs noted by Ellis (1978).

---

[2] A between-group effect size is merely the difference in means between two treatment conditions expressed in standard score form; that is, it can be derived by calculating the difference between the means of the two interventions, divided by the standard deviation of the control group. Glass, McGraw, and Smith (1981) propose the following guidelines for different sizes of effect sizes: 0.2–0.49 = small; 0.5–0.79 = medium; 0.8 and above = large.

Six weeks of cognitive couple therapy was more effective in assisting couple than was the waiting list condition. Applying the Chambless and Hollon criteria (1998), conjoint cognitive therapy would be classified as a possibly efficacious treatment for marital distress.

In current practice, cognitive interventions are typically used with a variety of behavioral interventions, as well as with interventions focusing on couples' emotions. Based on the description of CBCT provided earlier, Baucom and colleagues (Baucom & Lester, 1986; Baucom, Sayers, & Sher, 1990) supplemented traditional BCT with cognitive restructuring interventions targeted at couples' marital attributions and their marital standards. In these two studies, both traditional BCT and CBCT were more effective than a waiting list condition in improving the couples' marital adjustment and communication. However, there were no significant differences between the two treatment conditions. These results were replicated in a similar investigation by Halford et al. (1993). Furthermore, the magnitude of change produced for various dependent measures appears to be consistent with what has been found in a number of BCT investigations. Compared to a waiting list control group, Baucom et al. (1990) found in their larger study that CBCT has an effect size of 0.52. They also found that approximately 43% of the couples had moved into the nondistressed range following treatment. Thus, the findings to date suggest that CBCT is as efficacious as BCT alone and shows more improvement than waitlist conditions, but it does not produce enhanced treatment outcomes. In interpreting these findings, it is important to note that couples were randomly assigned to treatment conditions. Some couples might benefit more from a central focus on cognitive change, whereas others may need extensive alterations in how they behave toward each other. At present, no reported investigations have addressed this matching issue.

### INTEGRATIVE BEHAVIORAL COUPLE THERAPY

Christensen et al. (2004) have completed the first large-scale randomized, controlled trial of IBCT, comparing it to BCT as described by Jacobson and Margolin (1979). This study, including 134 couples, is the largest trial of therapy to date for distressed couples and has adequate power to detect treatment differences, compared to the small sample sizes included in most other treatment studies. The findings indicated that, in terms of improving marital adjustment, both treatments resulted in gains from pre- to post-test, and there were no overall differences between the two conditions at post-test. However, couples in the two treatments demonstrated different patterns of change over the course of treatment. Couples in BCT improved more quickly than did couples in IBCT, but their level of improvement flattened out near the end of treatment. Meanwhile, IBCT couples showed slow but steady improvement during treatment, with no flattening out over time. The proportion of couples showing clinically significant improvement into the nondistressed range was not different for the two treatments (52% and 44% for IBCT and BCT, respectively) and was similar to what has been demonstrated for BCT in other investigations. Likewise, the within-group effect size of IBCT was $d = 0.86$, almost identical to the average within-group effect size of BCT ($d = 0.82$), seen across 17 investigations of BCT (Baucom et al., 2003). Thus, similarly to CBCT, IBCT appears to be of benefit to couples, and the magnitude of its effects is similar to those of BCT. At 5-year follow-up, separation/divorce rates for couples in the two treatment conditions were virtually identical at slightly over 25% (Christensen, personal communication, July, 2007).

### Emotionally Focused Couple Therapy

Emotionally focused couple therapy, developed by Johnson and Greenberg (1985; Greenberg & Johnson, 1988), has its roots in experiential therapies and emphasizes understanding individuals' subjective experiences, in particular their emotional responses, in their intimate relationships. Johnson and Denton (2002) have noted that EFCT represented an important shift away from the prevailing emphasis on behavior and cognition in the marital field. Emotionally focused couple therapy draws substantially from attachment theory (Bowlby, 1989), which describes how humans have an innate need for emotional attachment to nurturant others, beginning in infancy and continuing throughout life. Based on the degree to which an individual's early caretakers are physically and psychologically available, a child develops either a secure or an insecure attachment style. Empirical evidence has lent support to the concept that the attachment style or pattern that an individual develops during childhood tends to be stable into adulthood, although significant experiences in adult relationships are capable of altering an individual's attachment pattern (Berman, Marcus, & Berman, 1994; Davila, Burge, & Hammen, 1997; Rothbard & Shaver, 1994; Waters, Hamilton, & Weinfield, 2000). Instances in which an individual's partner was unavailable to

meet his or her attachment needs can result in what are labeled "attachment injuries." Memories of such experiences of abandonment can make the individual highly sensitive to feeling abandoned by the partner in future situations (Johnson, 1996; Johnson & Denton, 2002).

Theory and research have identified up to three types of insecure adult attachment: dismissing-avoidant, preoccupied (anxious-ambivalent), and fearful-avoidant (Ainsworth, Blehar, Waters, & Wall, 1978; Bartholomew & Horowitz, 1991; Hazan & Shaver, 1987), but all of them involve a cognitive component or "working model" in which the individual is sensitive to the likelihood that significant others will not meet his or her needs for emotional attachment. According to attachment theory, when an individual perceives that a significant other, such as a spouse, is not available, this elicits internal, vulnerable "primary" emotions such as anxiety but also may elicit "secondary" emotions such as anger expressed toward the spouse. Johnson and Greenberg (1985) developed EFCT as a means of helping partners to understand their own and each other's emotional responses due to attachment concerns, especially identifying the more vulnerable primary emotions underlying partners' expressed anger toward each other, and to find more constructive forms of behavior to increase intimacy and fulfill attachment needs.

## Basic Concepts

### BEHAVIOR

The EFCT model draws on family systems theory in positing that often a couple responds to one or both partners' attachment needs in a dysfunctional manner, which leads to a negative interaction pattern (Johnson, 1996; Johnson & Denton, 2002). On the one hand, each person attempts to elicit caring responses from the other in ways that backfire (e.g., nagging, clinging, criticism) or withdraws from the other in a self-protective manner to avoid hurt or rejection. On the other hand, the recipient of these maladaptive actions responds negatively (counterattacking, withdrawing) rather than providing nurturance. Emotionally focused couple therapy focuses on these negative interaction cycles between partners, as well as the two individuals' emotional experiences associated with attachment needs—how those needs are met or not met.

### COGNITION

Attachment theory, which forms a key part of the foundation of EFCT, describes fairly stable "working models" or cognitive schemas that individuals hold about themselves (as lovable or not) and about significant others (as available for nurturance or not). However, the proponents of EFCT (Johnson, 1996; Johnson & Denton, 2002; Johnson & Greenberg, 1985) emphasize that emotions organize partners' perceptions and attachment behaviors toward each other. Johnson and Denton (2002) state that change does not occur through insight but rather through new emotional experiences involving attachment interactions between partners. Thus, an individual comes to view a partner more as a secure source of nurturance based on interactions with the partner that elicit more positive emotions.

### AFFECT

In couples' relationships, insecure partners use a variety of strategies to cope with their primary emotions, such as fear or sadness concerning being neglected or abandoned. Some coping strategies involve the expression of anger or other secondary emotions (that cover up the primary emotions that, for some reason, seem too vulnerable or unacceptable) and attempts to coerce the partner to provide intimacy, whereas other strategies involve emotional states such as apathy or contempt and behavior such as distancing. It also is assumed that as long as individuals are experiencing strong fear of not having their attachment needs met, they will be unable to communicate constructively with each other. However, EFCT proposes that when partners have opportunities to feel emotionally soothed in interactions with each other, they will be less likely to respond with negative emotions and behavior toward each other. When an individual expresses primary attachment emotions such as sadness and anxiety, this communicates the individual's needs to the partner, who is the potential caregiver, which in turn should elicit comforting responses from the caregiver.

## Contributions of the Couple Versus the Individual in Couple Distress

The central role of attachment needs in the theoretical base of EFCT clearly identifies characteristics of the individual partners that contribute to marital distress. Kobak, Ruckdeschel, and Hazan (1994) note that when individuals' internal working models are secure, they expect that caregivers will attend to their attachment needs. Consequently, secure individuals are more likely to express their emotions so as to facilitate attachment (e.g., expressing anger

as a reflection of concern about distance in the relationship rather than as a personal attack on the caregiver). In contrast, individuals with insecure attachment working models commonly expect that direct expressions of attachment needs and emotions will lead to negative responses from a significant other, which results in a high level of anxiety about their ability to maintain the attachment. As described earlier, strategies for coping with attachment fears, such as detachment or hypervigilance and exaggerated expressions of emotion, are unlikely to elicit the desired nurturing responses, and the partner is unlikely to correctly interpret the vulnerable attachment needs underlying such behavior. The individual's insecure working model is reconfirmed when the caregiver does not respond in a comforting, nurturing manner.

Thus, the characteristics of the two individuals shape the couple's interactions, but the dyadic pattern that arises between partners also plays a crucial role in maintaining marital distress. Research studies have found that adults with insecure attachment patterns tend to use less constructive conflict-resolution tactics in intimate relationships, as well as more negative conflict management behavior, including psychological and physical abuse (Bookwala, 2002; Bookwala & Zdaniuk, 1998; Creasey, 2002; Dutton, Saunders, Starzomski, & Bartholomew, 1994; Roberts & Noller, 1998). Furthermore, EFCT's focus on dyadic couple interaction patterns is supported by studies indicating the combinations of two partners' attachment styles that are associated with levels of marital distress. For example, Fisher and Crandell (2000) found that clinic couples in which one partner had a preoccupied attachment style (anxious about losing the other's nurturance) and the other had a dismissing-avoidant style (more comfortable when distant) were characterized by conflict and a demand–withdraw interaction pattern.

## Proximal Versus Distal Factors in Understanding Relationship Discord

Emotionally focused couple therapy acknowledges that attachment concerns in the current relationship might be greatly influenced by historical factors and experiences that an individual had in earlier relationships, including family-of-origin interactions with parents, for example, and earlier romantic relationships. However, the focus within treatment is on the current relationship and attachment issues that are operating in the present.

## Approaches to Treatment
### BEHAVIOR

Emotionally focused couple therapy proponents suggest that adults' perception of threats to their attachment relationships elicits natural negative behavioral responses. To change such problematic responses, the therapist creates a safe setting in sessions for each person to explore, understand, and reveal his or her primary (insecure) emotions and gain empathy for the partner's attachment needs. The therapist assists individuals in developing more constructive interactions with their partners, such as direct, nonhostile communication, that increase the probability of receiving reassuring responses and greater intimacy (Johnson & Denton, 2002; Johnson & Greenberg, 1995). Although the therapist and couple may set general goals of improving communication and relationship functioning, they typically do not identify and focus on specific behavioral targets or skills-training. The therapist "reframes" negative behavior in terms of vulnerabilities and attachment needs and encourages further expressions of vulnerability. Presumably, understanding oneself and one's partner more clearly and experiencing an honest expression of emotion and needs for nurturance provide the context for adaptive behavior change.

### COGNITION

Emotionally focused therapists believe that relationship distress is caused by insecure attachment styles that include cognitive schemas in the form of "working models" of self in relation to a significant other, and that these schemas typically are formed in the individuals' earlier attachment relationships. However, in EFCT, little attention is paid to fostering insight about earlier origins of attachment responses; rather, the focus is on the partners understanding each other's adaptive needs for closeness and nurturance within the current relationship, so that they can seek and provide for these needs in more positive ways. Each person's expressions of vulnerability should foster empathy from the other partner. The empathic shift toward viewing the partner's negative behavior as arising from attempts to cope with vulnerable feelings, rather than from malicious motives, results in a significant cognitive change in the individual's attributions about the partner and potentially a greater willingness to provide comfort to that partner.

### AFFECT

A central goal of EFCT is to access the partners' insecure attachment styles through identifying the

secondary emotions typically expressed to each other and the underlying vulnerable primary emotions associated with attachment insecurity. The therapist not only reflects back an individual's expressions of emotion regarding the partner and relationship, but also probes for vulnerable feelings (Johnson & Denton, 2002). By increasing partners' mutual empathy for each other's attachment fears and understanding of the more benign reasons for each other's misguided and negative strategies that are intended to provide security, therapists help soothe the individuals and create opportunities for them to meet each other's attachment needs better (Johnson, 1996; Johnson & Denton, 2002; Kobak et al., 1994). Thus, affect is the therapist's window into the partners' attachment styles and the means for increasing more mutually satisfying interactions between partners.

### Empirical Support for Emotionally Focused Couple Therapy

Several investigations of EFCT have addressed its efficacy, and the findings to date indicate that it is of significant benefit to distressed couples (Baucom et al., 1998; Johnson, Hunsley, Greenberg, & Schindler, 1999). Approximately a half-dozen controlled studies have found EFCT to be superior to a waitlist control group (e.g., Denton, Burleson, Clark, Rodriguez, & Hobbs, 2000), with one study finding greater marital satisfaction for EFCT couples than BCT couples at post-treatment and at 8-week follow-up (Johnson & Greenberg, 1985). Johnson (2002) describes a meta-analysis of the four most methodologically rigorous outcome studies on EFCT and reports that EFCT produced recovery rates from relationship distress (into the nondistressed range) of 70%–73%, as well as an effect size of 1.3, all higher than has been found for BCT, CBCT, and ICBT (note that, as described below, Shadish and Baldwin [2003] concluded that there are no differences in the efficacy of behaviorally oriented couple interventions and EFCT). Also, most studies on EFCT have treated couples who range from nondistressed to moderately distressed, so further studies are needed to test the efficacy of EFCT with more highly distressed couples. In the one study with more distressed couples, Goldman and Greenberg (1992) found that the 14 couples in EFCT and 14 couples in systemic couple therapy were not different from each other at post-test, but at a 4-month follow-up the systemic therapy was superior to EFCT, due to the EFCT couples experiencing significant relapse during the follow-up period.

Goldman and Greenberg (1992) caution that, with severely distressed couples, a time-limited course of EFCT might not be sufficient to create a level of intimacy between partners necessary to maintain post-treatment gains. Considering the overall results from these empirical investigations, Baucom et al. (1998) classified EFCT as an efficacious treatment in assisting moderately distressed couples.

## Insight-Oriented Couple Therapy

Just as there is no singular behavioral approach to understanding relationship distress or conducting couple therapy, there is no one approach to understanding and treating relationship distress that focuses on the role of insight in fostering change. In general, these approaches are labeled psychodynamic and share a common emphasis on exploring the effects of relationship experiences early in an individual's life and their impact on current adult intimate relationships such as marriage (in contrast to EFCT, which emphasizes the couple's current relationship). Although psychodynamic approaches continue to be popular among couple therapists, little empirical research has been conducted on their efficacy, with one notable exception—Snyder's IOCT (Snyder & Wills, 1989). Insight-oriented couple therapy is based on the notion that current relationship problems result from partners' difficult or painful experiences in prior relationships. These negative experiences from the past intensify the effects of current challenging relationship interactions; within this context, partners react to current conflict by using defensive strategies that are designed to protect them from further hurt. In IOCT, individuals are helped to see how their negative emotional and behavioral responses within their current relationship are influenced by distressing experiences that they had in prior relationships, and that the coping strategies that were adaptive in those earlier relationships are inappropriate for achieving emotional intimacy and other personal needs in their current committed relationship. These interventions contribute to insight into one's interpersonal conflicts and coping patterns, including distortions and inappropriate solutions for achieving intimacy in one's relationship that are rooted in the past.

### Basic Concepts
#### BEHAVIOR
Insight-oriented couple therapy is based on the premise that adults' negative behavioral responses in their relationships are influenced by previous relationship experiences that compromise an individual's

ability to respond adaptively to the present relationship. As in other insight-oriented approaches, the individual's internalized views of relationships, or their relationship schemas, create a tendency to behave in particular ways to cope with perceived relationship conflict or dangers. Marital distress is increased by the partners' previously developed behavioral strategies for protecting themselves from relationship injuries, often in ways that do not fit the current relationship context. In essence, to a significant degree the individual is behaving as he or she did in the past, rather than responding to the present.

COGNITION

Insight-oriented couple therapy views individuals' cognitions regarding intimate relationships as a system of internalized representations that function as models of how relationships should and do work. These internalized representations are comprised of characteristics that the client either observed or experienced in early relationships with parents or similar significant caregiving figures; again, the experience of the present is seen as largely due to the past, particularly if there were earlier relationship difficulties or traumas that greatly impacted the individual. These representations from the past may be beyond awareness but are still influential in how the person interacts with his or her partner in the present and how the individual interprets current situations in the relationship. For example, a man whose parents devalued his artistic abilities because such behaviors were not perceived by the parents as masculine while he was growing up may subsequently develop limited self-esteem and believe that significant others view him as an inadequate male. Subsequently, he may perceive any disagreement from his wife as a devaluation of him as a male and respond with hurt feelings and withdrawal.

AFFECT

Insight-oriented couple therapists propose that emotions experienced within the context of interacting with a partner have a major impact on the overall relationship. The individual's developmental history presumably influences many of these emotional responses to one's mate. Although a couple's distress also may be due to current stressors in their life together and inadequate skills for coping with them, negative emotions tied to past relationship injuries tend to color present interactions and make them more difficult. In "affective reconstruction," these emotions and their origins must be identified, so that the partners can differentiate between past

and present relationship experiences and develop more constructive strategies for interacting with a partner in the present.

## Contributions of the Couple and the Individual in Couple Distress

Of all the models presented in this chapter, IOCT places the greatest emphasis on the *individual's* positive and negative contributions to the relationship. Although insight-oriented couple therapists pay considerable attention to the couple's interaction patterns, they largely focus on the personal histories that the individual partners bring to the relationship and how those histories influence the current interactions. A major goal of therapy is to make each partner's emotionally charged beliefs about relationships and their associated strategies for coping with significant others (typically developed during past relationships) clearer to both members of the couple. Through becoming aware of past injuries and hurts that have influenced an individual's view of relationships and how they behave currently, partners have the potential to develop empathy for each other as both partners struggle to correct these distorted schemas. Insight-oriented couple therapy capitalizes on the likelihood that each person's dysfunctional patterns of relating to significant others will be elicited in couple sessions more than in individual therapy, making them more apparent to the therapist and couple and available for therapeutic intervention.

## Proximal Versus Distal Factors in Understanding Relationship Discord

As noted earlier, IOCT assumes that current relationship difficulties often derive from earlier relationship traumas or difficulties. Thus, a major emphasis is placed on exploring and attempting to understand these earlier difficulties, consistent with the psychodynamic priority placed upon insight into the role of the past and how the past influences current functioning.

## Approaches to Treatment
### BEHAVIOR

In IOCT, the therapist identifies for the couple how their current negative affect and interaction patterns are emotional responses and coping strategies developed in response to emotional injuries in past relationships. The therapist reframes these negative responses as understandable based on those past events and encourages the partners to view them in a more benign manner and to self-disclose their

more vulnerable feelings within their relationship. A primary emphasis is placed on gaining insight into how previous relationship injuries contribute to current interaction patterns. Hopefully, this awareness of the past will allow the partner to behave differently in the present, recognizing that past hurts and injuries need not dictate how to interact with one's current mate.

## COGNITION

Insight-oriented couple therapists and other relatively psychodynamically oriented therapists believe that much of a couple's distress results from underlying processes and schemas that are generally accessible with effort, but often are beyond the individual's day-to-day awareness. Therefore, therapy focuses on identifying the content of these internalized representations derived from distressing experiences in past relationships and then interpreting them to clients in order to create insight into the effects of their relationship histories on their current maladaptive reactions to their partners. It is assumed that this insight then helps the individuals to modify their schemas and their continuing problematic relationship patterns in light of current awareness. The focus is on producing more realistic views of each other in the present relationship rather than focusing on resolving old issues with significant others, such as parents, from past relationships (Snyder & Schneider, 2002).

## AFFECT

Insight-oriented couple therapists consider clients' emotional responses to be a key source of information about partners' internal dynamics and views of relationships. Moments in which an individual experiences emotion toward the partner during therapy sessions are viewed as potential windows into unconscious material from earlier relationships. These earlier experiences are presumed to have contributed to the current distressing emotions and associated dysfunctional behavior toward a partner. When appropriate, the therapist attempts to identify and interpret the meaning of these emotional responses derived from the person's early history and encourages the individual to self-disclose vulnerable feelings. Each person is encouraged to identify relationship themes involving past disappointments and injuries. By helping the couple understand the significance of their negative emotional responses to each other and their developmental origins, the therapist helps the partners tolerate distress from the past without acting on it in the present. Furthermore, each partner becomes better able to provide for the other's personal needs because of their increased understanding of, and empathy for, each other.

### Empirical Support for Insight-Oriented Couple Therapy

Snyder and Wills (1989) compared the relative efficacy of IOCT and traditional BCT, both delivered for a mean of 19 sessions, and found both treatments to be efficacious relative to a waiting list condition at post-test. In terms of marital adjustment, the IOCT versus waiting list control comparison effect size was 1.15, and the BCT versus control group effect size was .85. There were no differences between IOCT and BCT, however, in altering marital adjustment. Furthermore, at post-test, the two therapies had similar percentages of couples who moved from the distressed range of relationship functioning to the nondistressed range (40% of IOCT couples and 55% of BCT couples, compared with only 5% of waiting-list couples). Whereas IOCT and BCT were comparable on marital adjustment at a 6-month follow-up, Snyder et al. (1991) recontacted 96% of the treated couples 4 years after the completion of therapy and found that significantly more of the BCT couples (38%) had experienced divorce relative to the IOCT couples (3%). In the longest follow-up period of any couple therapy intervention to date, IOCT couples also reported significantly higher levels of marital adjustment than BCT at the 4-year follow-up. Because finding meaningful differences between active treatment conditions is rare in the field of couple therapy, Snyder et al.'s findings call for replication to determine whether the long-term impact of IOCT is consistently superior to skills-based behavioral interventions. Based on the results from this one investigation, IOCT can be classified as possibly efficacious.

### The Overall Efficacy of Couple Therapy Across Theoretical Orientations

When the previously described approaches to couple therapy are compared, meta-analyses of couple therapy affirm that various approaches to treating couple distress produce statistically and clinically significant improvement for a substantial proportion of couples, with the average couple receiving therapy being better off at termination than 80% of couples not receiving treatment (Shadish & Baldwin, 2003). However, tempering enthusiasm from this overall conclusion are additional findings that in only 50% of treated couples do both partners show significant improvement in relationship satisfaction, and that

30%–60% of treated couples show significant deterioration at 2 years or longer after termination (Snyder, Castellani, & Whisman, 2006). Meta-analyses provide little evidence of differential efficacy across different theoretical orientations to couple therapy, particularly once other factors are controlled (Shadish & Baldwin, 2003). Thus, there appear to be several efficacious approaches to helping distressed couples with little data to suggest that, overall, one approach is more beneficial to couples than others. Of course, there is the possibility that specific couples might benefit most from a particular type of couple therapy, but so far no research has explored this important set of questions.

### Processes of Change

As discussed throughout the chapter to this point, each theoretical approach to couple therapy proposes that relationship distress results from specific factors and, therefore, that creating certain specific changes is necessary to improve the overall relationship adjustment or satisfaction for couples. However, there has been little research that confirms that these mechanisms proposed by each therapeutic approach are responsible for the overall therapeutic improvement that has been observed (Snyder et al., 2006). For example, investigations of BCT do result in improvement in communication and relationship satisfaction but fail to find an association between the magnitude of changes in communication behaviors and gains in relationship satisfaction. Similarly, although CBCT has been shown to produce positive change in targeted cognitions (e.g., expectancies and attributions), changes in these cognitions have not been linked to couples' gains in overall relationship satisfaction following CBCT (see Whisman & Snyder, 1997, for a summary of relevant studies).

More encouraging results have been reported by Doss and colleagues (Doss, Thum, Sevier, Atkins, & Christensen, 2005), who examined mechanisms of change in Christensen and colleagues' (2004) clinical trial comparing traditional BCT with IBCT. Both therapies were effective in increasing emotional acceptance and improving communication behaviors across the course of therapy; however, these changes differed by treatment in a manner that was consistent with their respective presumed change mechanisms. That is, as expected, acceptance increased significantly more for couples in IBCT than for couples in BCT, whereas couples in BCT showed larger initial gains in positive communication. Similarly, in an initial pilot study comparing IBCT with BCT, Cordova, Jacobson, and Christensen (1998) found that couples in IBCT showed relatively more unified detachment (a component of acceptance) over the course of therapy, and that these changes predicted couples' gains in relationship satisfaction.

### Effectiveness Investigations

All of the treatment research thus described has been conducted in university settings under highly controlled conditions with carefully selected couples and well-trained therapists working under close supervision. Whereas the findings from these types of investigations are promising and important, one cannot assume that similar treatment effects are obtained in real-world clinical settings, where a broader range of couples might be seen by therapists who have greater diversity of training and likely less supervision. Whereas treatments conducted in these highly controlled conditions are typically referred to as *efficacy* studies, intervention in less-controlled real-world settings are labelled as *effectiveness* investigations. The effectiveness of couple therapy in the field, outside of research settings, has not been researched sufficiently. In two uncontrolled prospective studies, Hahlweg and Klann (1998) and Klann (2002) investigated the effectiveness of marital counseling in Germany. In total, 139 counselors recruited 1,152 clients into the study. The interpretation of the results is difficult because the attrition rate was high: Only about 50% of the clients participated in the post-assessment 6 months later. Pre–post comparisons resulted in significant improvements in several scales. The effect size for overall marital adjustment was 0.45, a medium effect size. About 26% reported happy relationships after couple counseling—considerably less than in the efficacy study conducted by Christensen et al. (2006). Although much is still to be learned about the utility of couple therapy in typical clinical settings, the initial findings suggest it might be less effective than in the highly controlled contexts of efficacy studies.

## Conclusion
### Integrated Approaches

Considering the centrality that marriage holds in the lives of most adults and the high divorce rate, it is striking that controlled outcome studies have been conducted with only a few of the major theoretical approaches to treating relationship distress, as described in this chapter. The outcome evidence for behavioral (and its derivatives), emotionally focused, and insight-oriented approaches tends to be encouraging. The positive impacts demonstrated

in investigations of behavioral, cognitive, and affective interventions of BCT, CBCT, IBCT, EFCT, and IOCT need not be the basis for competition among approaches, but rather the grounds for seeking integration of models and procedures, to maximize our ability to be of help to couples who are struggling with the most significant relationships in their lives. At times, the concepts and terms used by different approaches seem to be incompatible, but our review suggests that the areas of overlap are substantial. The functioning of an intimate relationship includes behavioral interactions between the two individuals (including ingrained patterns), the often idiosyncratic cognitions that each person holds regarding the other, and a range of positive and negative emotional responses that influence cognitive appraisal, as well as types of behavior toward the partner. Consequently, all of the approaches reviewed here have much to offer the researcher who is attempting to understand couple functioning and the clinician whose goal is to alleviate conflict and distress, because they all address behavior, cognition, and emotion. Furthermore, they vary in their focus on the two individuals' characteristics versus influences of the couple as a dyad, but they all attend to both realms.

Some significant steps toward theoretical and procedural integration in couple therapy have been developed in recent years. Epstein and Baucom (2002) described an enhanced CBCT that incorporates a greater focus on containing or eliciting emotions and broadens the focus of assessment and intervention to include relatively equal attention to characteristics of the two individuals, their dyadic interaction patterns, and the interpersonal and physical environments that comprise the context within which the couple functions. The individual level includes each person's developmental history, personality characteristics, needs and motives, and any psychopathology that he or she brings to the relationship. At the dyadic level, the couple's communication and problem-solving skills, which have long been foci of BCT practitioners, still are staples of enhanced CBCT. Environmental factors, such as extended family members, jobs, and social institutions (e.g., schools), commonly present in close relationships have not previously been incorporated into the empirically supported couple interventions discussed here and require attention in future treatment research. Although environmental demands may challenge a couple's ability to adapt, they also may be vital sources of resources to help the couple cope with life stressors.

Similarly, Snyder and Schneider's (2002) recent pluralistic approach to affective reconstruction broadens Snyder's earlier IOCT and assumes that relationship problems are influenced by multiple factors and require a multidimensional conceptual model and varied interventions. This pluralistic approach combines insight into developmental processes with behavioral, cognitive, and structural interventions intended to improve couples' relationship skills, enhance intimacy, reduce stressors in the partners' lives, and eliminate negative defensive coping strategies. Snyder and Schneider describe a hierarchical model of intervention that includes the components of (a) developing a collaborative alliance with the couple; (b) containing disabling relationship crises; (c) strengthening the marital dyad through positive interactions and increased goodwill; (d) promoting relationship skills for expressiveness, empathic listening, conflict resolution, parenting, financial management, and time management; (e) challenging partners' cognitive distortions contributing to relationship distress; and (f) exploring the individuals' psychological injuries in past relationships that affect their current negative emotional and behavioral responses to each other. In-depth exploration of negative impacts that psychological injuries from earlier relationships have on current emotional and behavioral responses to a partner are combined with practical training in behavioral skills to reduce stress on the couple and enhance intimacy (which can reduce the effects of old emotional wounds). Emotionally focused therapy proponents have not pursued integration with other approaches to a significant extent, but there seems to be great potential for using concepts and methods from other theoretical approaches in the service of modifying problematic responses to insecure attachments.

Christensen (2009) proposes a set of common elements that cut across those various couple therapy approaches that have demonstrated efficacy. Building on the work of Barlow and colleagues (Allen, McHugh, & Barlow, 2008; Barlow, Allen, & Choate, 2004) related to general principles of therapeutic change for individual psychopathology, Christensen suggests that all of the empirically supported couple therapies have five common elements: (a) alteration of cognitive distortions regarding the bases for relationship distress; (b) decreases in negative, destructive behaviors between partners; (c) increases in positive behaviors and an emphasis on strengths; (d) encouragement for couples to address difficult issues that have been avoided; and (e) the teaching of effective communication to assist in these goals.

The employment of broad principles might contribute to an even more pervasive effect that cuts across different theoretical approaches. The listed principles might make couples more relationally attuned and aware, and provide them with novel ways to think about how to improve their relationship. Baucom and colleagues (Sullivan & Baucom, 2004, 2005) have addressed this issue from the perspective of *relationship schematic processing* (RSP), which refers to the degree to which an individual processes information in terms of relationship processes. An individual who is high on RSP thinks about his or her own behavior and its impact on the other person and the relationship, along with anticipating the other partner's needs and preferences and balancing the partner's needs with one's own needs. Sullivan and Baucom (2004; Sullivan & Baucom, 2005) proposed that increasing RSP might be a common mechanism of change that cuts across theoretical approaches, such that any effective couple therapy teaches individuals to think more appropriately in relationship terms. Consistent with this notion, they demonstrated (a) that CBCT does increase the quantity and quality of men's RSP and (b) that women's increases in marital satisfaction in response to CBCT were correlated with the degree to which their male partners increased in RSP. Stated differently, women became more satisfied with the marriage when men learned to process more effectively in relationship terms. Likewise, they demonstrated that couples receiving insight-oriented couple therapy in Snyder's outcome study (Sullivan, Baucom, & Snyder, 2002) increased in RSP as well. Whether the education of couples to think more effectively in relationship terms or the use of the principles suggested by Christensen (2009) turn out to be common mechanisms of change that are central to all efficacious forms of couple therapy is not known at present, but it will be important to continue to explore whether the specific interventions that therapists employ are the critical variables, or whether therapeutic change can be accounted for in other ways as well.

### Future Directions

The integrative efforts described here focus primarily on theoretical approaches that have received empirical support for their efficacy. In addition, a number of other couple therapy approaches have not yet been evaluated empirically, yet are widely practiced and have many elements in common with the approaches described in detail in this chapter. For example, as the name implies, de Shazer (1985, 1988) developed solution-focused couple therapy, a brief approach centered on finding solutions with clients rather than discussing the history of their problems. Central to this approach is the notion that language constructs people's reality; therefore, a heavy emphasis is placed in therapy on the content of clients' language and how their choices of terms influence their experiences. Solution-focused therapy emphasizes the here and now, focusing on the concerns that clients bring to therapy regarding issues currently existing in their relationship. To work toward solutions, practitioners of this approach emphasize setting goals with a couple that are important to the clients; clear; described in specific concrete behavioral terms; workable; and involve what needs to happen rather than what needs to be avoided (Hoyt, 2008), an approach similar in many ways to BCT in its emphasis on solutions for the here-and-now. Consistent with the focus on language in solution-focused therapy, narrative therapy involves the belief that our behavior, emotions, and perceptions are shaped by the way we "story" or conceptualize themes in our lives (White & Epston, 1990). The issues that couples bring to therapy involve narratives about their relationship that are limited, in the sense that they incorporate only some experiences from the partners' lives and also are influenced by broader cultural values about what constitute appropriate and healthy characteristics of individuals and relationships. It is assumed that distressed couples have developed "problem-saturated stories" about their relationship (e.g., that they cannot meet each other's basic emotional needs). The focus of narrative couple therapy is on uncovering alternative narratives about the couple and their relationship that open up new meanings and possible ways for the partners to relate to each other— stories with themes in which problems are overcome and in which the partners have more positive identities as individuals and as a couple. Narrative therapists help couples actively search for "unique outcomes" or evidence of exceptions to their negative story about their relationship and collaboratively develop a new narrative, strategies that are consistent with those in CBCT.

Whereas the preceding discussion of common elements of efficacious treatment highlights the issues that should be emphasized in couple therapy, this might not be all that is essential for efficacious treatment. In addition, the overall quality of the couple–therapist relationship (i.e., the therapeutic alliance) might be an important factor in efficacious treatment. Although the quality of the therapeutic

alliance in explaining treatment effects has not been investigated empirically in couple therapy, the therapeutic alliance has received considerable attention in psychotherapy research more generally. A recent meta-analysis of psychotherapy concluded that the therapeutic alliance explains between 38% and 77% of the variance in treatment outcome, whereas specific techniques account for only 0%–8% of the variance (Wampold, 2001). Furthermore, Fitzpatrick, Stalikas, and Iwakabe (2001) demonstrated that the impact of specific techniques was dependent on the quality of the therapeutic alliance. Thus, focusing on certain issues within the couple's relationship within the context of a positive, safe therapeutic relationship might provide an optimal context for couples to relate to each other in a more constructive manner.

# Interventions for Mental Health Problems in Later Life

Jason M. Holland *and* Dolores Gallagher-Thompson

## Abstract

Older adults are increasingly making up a larger segment of the worldwide population, which presents both challenges and opportunities for the clinical psychologist in the 21st century. In this chapter, we address some of the unique aspects of working with this population, focusing on general guidelines for tailoring interventions for older adults, specific treatments for particular problems commonly faced in later life, as well as issues of diversity and how they might impact psychotherapy with older clients. We also outline several areas in geropsychology that are in need of further investigation, namely the use of technology, post-traumatic stress, and family therapy, and offer some recommendations for future directions in this field of study.

**Key Words:** Age difference, diversity, geropsychology, interventions, older adults

*In the midst of a long-term caregiving relationship with her husband who was suffering from a terminal cancer, Rosa, a Latino woman of 67 years of age accompanied her husband during his final weeks in an inpatient hospice unit. Although her demeanor conveyed a profound sense of emotional fatigue and at times hopelessness, Rosa maintained that she was "managing," and night after night sat by her husband's side, often neglecting her own health by only sleeping a few hours each night, skipping meals, refusing staff assistance, and only allowing herself sporadic 5- to 10-minute breaks during the day. Despite efforts on the part of staff to persuade Rosa to take better care of herself and rest more frequently, she maintained that she must stay with her husband around the clock, as it was of the utmost importance to him that only she would assist with "private matters," such as helping him go to the bathroom. Likewise, both Rosa and her husband expressed a sense of mistrust of staff, at times noting that if she left the room no one will be monitoring him. These tensions were aggravated by the presence of Rosa's American-born children, who tended to grieve more expressively and were confused*

*by their mother's stoic presentation. At the time of her husband's death, however, Rosa exhibited clear signs of depression, complaining of fatigue, sleeplessness, lack of appetite, and a deep sense of being misunderstood.*

In many ways, this clinical vignette exemplifies the shifting demographics of our society and the new challenges and demands these changes will bring for clinical psychologists in the 21st century. Indeed, in 2006, an estimated 37 million people in the United States (12% of the population) were 65 and older, and this figure is anticipated to grow to approximately 71.5 million people (nearly 20% of the total U.S. population) by 2030. Far from being a homogenous group, racial and ethnic diversity is increasing among seniors as well—a trend that is literally and figuratively changing the face of geropsychology (see www.aging-stats.gov, for additional U.S. aging statistics). Notably, with improving health-care interventions and longer life expectancies, these U.S. figures also parallel a larger pattern worldwide, in which older adults are progressively representing a larger and larger segment of the population (Kinsella & Velkoff, 2001).

Inextricably linked to these demographic trends are a host of unique biological, psychological, and social issues faced by older adults that might often call for specialized skills, knowledge, and sensitivity on the part of clinical psychologists (American Psychological Association, 2004). Although most older adults are resilient and lead active/productive lives even in the face of developmental challenges, such as increasing health problems and interpersonal losses (Bonanno et al., 2002; Davis, Zautra, Johnson, Murray, & Okvat, 2007), the combination of these factors can make for a complex clinical picture when an older adult presents for treatment. Notably, many clinicians may feel somewhat unprepared for work with these clients, as few doctoral programs in clinical psychology offer specialized training in gerontology (DeVries, 2005). As illustrated by Rosa and her struggle to cope with the increasing demands of caregiving, clinicians who are working with older adults must often attend to issues related to bereavement, physical health, and cultural diversity, as well as generational differences—all of which are interwoven within a long and rich personal history.

Given these unique issues and increasing demand for geriatric services, it is the purpose of the present chapter to: (a) orient the reader to important differences between older adults and younger adults and provide general recommendations on how psychologists might appropriately modify their assessments and interventions with older clients, (b) outline some of the most common problems faced by this population and describe specific treatments and assessment strategies that have been shown to have strong empirical support, (c) discuss issues of diversity as applied to psychotherapeutic work with older adults, and (d) describe some promising new directions in geropsychology and propose areas for future work.

## Tailoring Assessments and Interventions for Older Adults

Although older adult clients pose unique challenges to clinicians, we propose that most psychological interventions need not be significantly "adapted" for this population, which would imply that psychotherapies in their current forms are somehow insufficient and require alterations at a fundamental level. Indeed, studies have consistently shown that treatments, such as cognitive-behavioral therapy (CBT), are applicable and efficacious with older clients even when few substantive changes are made to the basic protocol (Gatz et al., 1998; Laidlaw, 2001; Scogin & McElreath, 1994). Rather than reinventing one's

therapeutic approach, Laidlaw and colleagues (2003) suggest that clinicians would do well to simply consider how existing approaches might be "modified" for older adults by attending to client-specific variables and making subtle changes in the delivery, timing, or pace of interventions to maximize efficacy. Of course, we believe that these modifications work best when tailored to the individual client as closely as possible and when they take into account the tremendous heterogeneity among older adults (Nelson & Dannefer, 1992). For example, many often consider anyone over the age of 65 years to be an older adult. However, this broad definition encompasses individuals who might differ in age by 20 to 30 years, have diverse experiences as members of a unique generational cohort (e.g., World War II, the Great Depression), and face vastly different developmental challenges. As a way of partially addressing this issue, distinctions have been made between the *young-old* (65–74 years), *old-old* (75–84 years), and *oldest old* (85 years and over).

### General Assessment Issues

Notwithstanding the diversity among older adults, some general guidelines can be applied to work with this population, starting with the initial assessment (Edelstein et al., 2008). Because of the stigma associated with mental illness for earlier-born cohorts, older persons might often come into contact with a psychologist only after being referred by a family member or other health-care providers, such as a primary care physician (Heath, Grant, Kamps, & Margolin, 1991). In these cases, the initial stages of an assessment with an older adult would ideally involve communicating with the referring provider, in order to gain a full understanding of the reason for the referral and gather other relevant information about the client's history from the medical records (La Rue, 1992; Storandt, 1994). Likewise, it also becomes important to include family members as part of the assessment to gain collateral information about their understanding of the presenting problem(s) and how their perceptions align with (or differ from) the client's own self-report (La Rue & Watson, 1998).

Assessment with an older client should also involve some evaluation of his or her cognitive functioning, as the cognitive changes associated with aging will vary from client to client. Memory impairments in older adults can signal different problems, such as mild cognitive impairment, dementia, or depression, and neuropsychological testing can often help provide a clearer diagnostic picture (Kaszniak & Christenson, 1994).

In many cases, a cognitive assessment might simply take the form of a brief screening instrument, such as the Mini Mental Status Examination (MMSE; Folstein, Folstein, & McHugh, 1975) or the Cognistat Evaluation (Kiernan, Mueller, Langston, & Van Dyke, 1987). However, because these brief assessments are often not sensitive enough to accurately and reliably diagnose problems such as Alzheimer disease (Galasko et al., 1990), a more refined and thorough neuropsychological assessment would likely be necessary if the goal were to arrive at a differential diagnosis (see Morris, Worsley, & Matthews, 2000; Storandt & Vandenbos, 1994, for reviews).

The assessment of psychological symptomatology might also take a different course when working with older adults. Although many common assessment instruments, like the Minnesota Multiphasic Personality Inventory (MMPI; Butcher et al., 1991), have been shown to yield similar results with different age groups, clinicians would do well to be cognizant of potential differences in the way symptoms might manifest themselves among older and younger adults and tailor their assessments accordingly (Jeste, Blazer, & First, 2005). For example, depressed older adults are less likely to endorse cardinal symptoms of depression, such as feelings of sadness, and instead often report a variety of somatic complaints (e.g., sleep disturbance, weight loss, and/or fatigue) unrelated to any medical problem (Gallo, Anthony, & Muthén, 1994). As a result, primary care clinics often miss elevated depressive symptoms among older adults (Lebowitz et al., 1997). Thus, when available, clinicians might prefer to rely on assessments that take into account the unique clinical presentation of older adults (Edelstein et al., 2008). In the case of depressive symptoms, instruments like the Geriatric Depression Scale (GDS) have been devised that specifically target those symptoms of depression more typically endorsed by older adults (Yesavage et al., 1983).

Clinicians working with older adults should also be aware that the elderly are at heightened risk for suicide, and about one-fifth of all completed suicides are carried out by people over the age of 65 (Florio, Hendryx, Jensen, & Rockwood, 1997; Hall, Platt, & Hall, 1999; Hirschfeld & Russell, 1997). Indeed, older clients' suicide attempts, particularly those of elderly men, are more likely to be lethal, as these individuals are less likely to make suicidal gestures as a cry for help, often have access to lethal doses of medications, and frequently use more lethal methods (e.g., shooting) (Hall et al.,

1999; NIH Consensus Conference; 1992). Risk factors for suicide among older adults include mental health problems (e.g., depression, anxiety), physical health problems (e.g., cancer, renal failure, congestive heart failure), and moderate to heavy alcohol use (Adams, 1999; Fiske, O'Riley, & Widoe, 2008; Grabbe et al., 1997; Heisel & Flett, 2008; Moore & Bona, 2001).

Given these alarming trends, at a minimum, assessment should involve some screening for suicidal ideation and intent. This assessment would ideally include collateral contact with family, given that the majority of older adults who commit suicide do not divulge this information to a health professional but do make suicidal ideations known to their spouse (Moore & Bona, 2001). The topic of suicide should also be raised directly with the older client, to gauge suicidal ideation/intent and also express openness to discussing difficult topics of this sort. Such conversations might also be supplemented with more formal assessments such as the Geriatric Suicide Ideation Scale, which has been validated with older adult samples and includes age-appropriate items dealing with reactions to loss of physical functioning, social relationships, and status (Heisel & Flett, 2006).

### General Intervention Issues

Beyond the initial assessment, researchers and practitioners have also proposed models to help clinicians make decisions about how to modify their interventions for work with this population. One model that has remarkable practical value is the Contextual, Cohort-Based, Maturity, Specific Challenge (CCMSC) model (Knight & McCallum, 1998). This model applies knowledge from scientific gerontology to a psychotherapy context and takes into account the fact that older adults are in many ways more mature than younger adults but are often facing some of life's most arduous challenges (e.g., bereavement, caregiving, chronic illness, and disability). The CCMSC model also considers the unique social context of older adults as a population of individuals who were raised within a different sociocultural environment (as members of an earlier-born cohort) and are potentially immersed within age-specific communities (e.g., assisted living communities, senior centers).

From a maturational standpoint, the CCMSC model emphasizes that older adults bring a variety of valuable strengths to the table when presenting for psychotherapy. In particular, older adults have a vast storehouse of knowledge about how things are

and how things work, based on years of work, family, and other interpersonal experiences. Thus, existing problems that become a focus of clinical intervention will often share some similarities with past experiences an older adult has already encountered, which might serve as important parallels to enhance understanding and possibly reframe current challenges. For instance, in the case of Rosa presented in the opening vignette, treatment involved discussing past experiences with loss and how these experiences might relate to her present circumstances. Through this exploration, Rosa was able to normalize some of her reactions to the loss of her husband after considering her father's death, nearly 30 years prior, and how she and her mother had grieved intensely at first but later recovered and even came to value life more as a result of the experience.

Despite misconceptions that memory impairment is a normal part of aging, the memory performance of older adults has been found to be comparable to that of younger adults in most domains, especially when the material is relevant and motivation is high (Hultsch & Dixon, 1990). However, the aging process is typically associated with declines in some specific areas of cognition, such as processing speed (i.e., timed tasks) and working memory, which is where memories are temporarily held and processed before being stored within long-term memory (Light, 1990; Salthouse, 1985). Given these cognitive changes, the CCMSC model suggests that therapy might be appropriately modified by slowing the pace of speech, simplifying sentences, and breaking down complex information into smaller parts (Knight & McCallum, 1998). Growing older is also often associated with decrements in sensory perception (i.e., hearing and vision), and this might require adjustments in terms of providing written materials and questionnaires in large print, decreasing excess noise, or respecting clients' preferred modes of communication (e.g., speaking into one's "good ear") (Desai, Pratt, Lentzner, & Robinson, 2001; Hays, 1996). Clinicians would do well to apply these general guidelines flexibly, though, as cognitive and sensory changes could be rather subtle, particularly among the young-old.

Beyond the effects of maturation, the CCMSC model also proposes that older adults' experiences as members of a particular generational cohort, as well as their unique social context, has an influence on the process of psychotherapy, perhaps more so than aging itself (Knight & McCallum, 1998). Having matured within a different period of time, earlier-born cohorts have different skills, viewpoints (e.g., about marriage, divorce, or gender roles), and life experiences compared to later-born cohorts—all of which come to bear on the psychotherapeutic endeavor. For instance, members of earlier-born cohorts, on average, tend to have less formalized education compared to later-born cohorts (Stoops, 2004), which could translate into less reliance on abstract thinking, unfamiliarity with complex terms, and less psychological-mindedness. The particular settings where seniors live, socialize, and receive services—which may or may not be age-specific—can also operate as distinctive subcultures that shape older adults' experiences and potentially put parameters around what is possible in terms of resources, support, and opportunities for growth. Thus, in many ways, psychotherapy with an older client is analogous to working with individuals from another culture, in that the therapist will ideally gain knowledge of the idioms, values, and mores unique to this population and, at a minimum, be appropriately sensitive to differences and willing to ask questions and learn.

As an example of how a specific therapeutic approach might be modified for older adults, Laidlaw and colleagues (2004) have developed a comprehensive conceptualization of CBT for late-life depression (Figure 36.1). Consistent with Knight and McCallum's (1998) CCMSC model, this conceptualization considers cohort effects, maturation, physical health, and the unique sociocultural context of older adults. However, in keeping with the principles of CBT, this conceptual framework primarily emphasizes how these factors might work in combination to influence core beliefs and potentially lead to automatic negative thoughts that would become the focus of a cognitive-behavioral intervention. For instance, *cohort beliefs* that one should be strong and independent may impact one's reaction to a change in physical health (e.g., "I should not be a burden on my family") and may also affect an older adult's *sociocultural beliefs* (internalized societal beliefs) about the aging process (e.g., "Growing old equals frailty and weakness") (Laidlaw, Thompson, & Gallagher-Thompson, 2004).

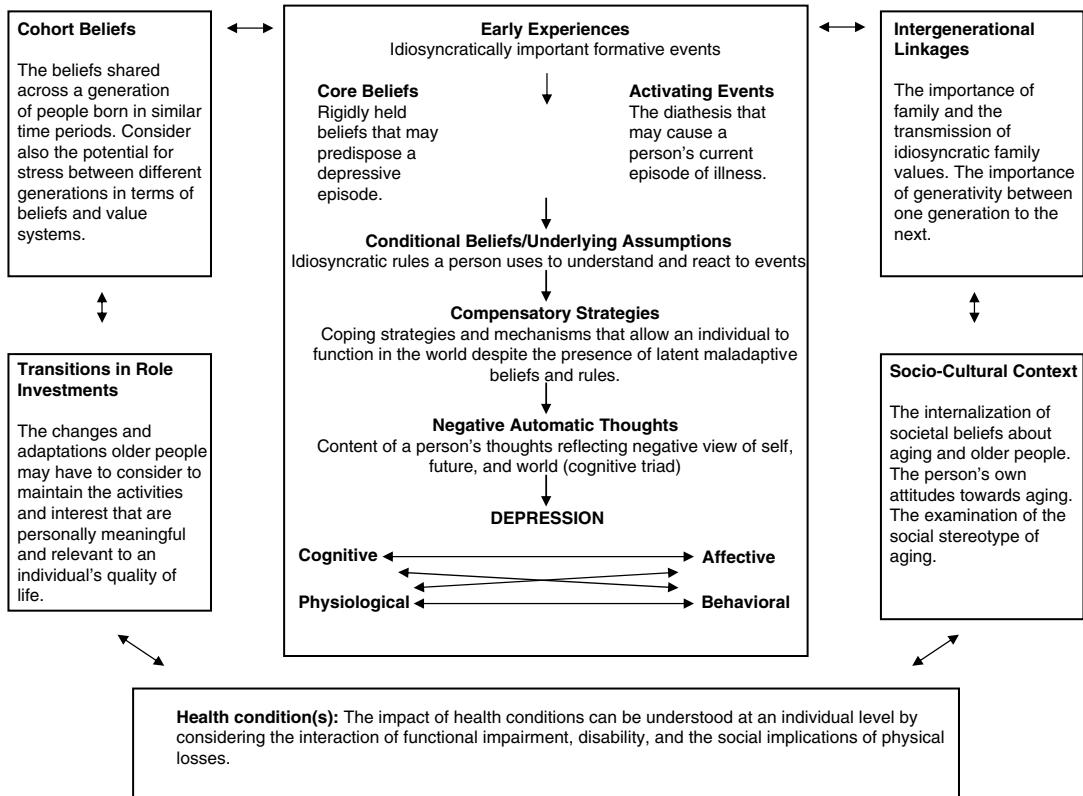
Laidlaw and colleagues' (2004) also encourage CBT therapists working with older adults to be mindful of *transitions in role investments* and the challenges many older adults face to remain invested in meaningful roles after life transitions like retirement. In addition, this model emphasizes *intergenerational linkages* and the importance that older generations place on the continuity and transmission


**Figure 36.1** Cognitive-behavioral conceptual framework for older adults. Adapted from Laidlaw, K., Thompson, L. W., & Gallagher-Thompson, D. (2004). Comprehensive conceptualization of cognitive behaviour therapy for late life depression. *Behavioural and Cognitive Psychotherapy, 32,* 389–399. of values within the family. Notably, intergenerational relationships with younger generations, who may tend to place more value on autonomy/independence, may become a source of distress and confusion for older adults, and it is not uncommon for older adults to report strained relations with their adult children as the source of a depressive episode (Bengtson et al., 2000; Floyd & Scogin, 1998; Thompson, 1996). Given the universality of these themes for many older adults, clinicians working with geriatric clients should be mindful of disruptions in role transitions and intergenerational relationships when conducting their initial assessments.

## Empirically Supported Interventions for Specific Problems

Beyond these general guidelines for how the process of psychotherapy might be tailored for older adults, specific psychosocial interventions that aim to target particular problems or symptoms experienced by older adults have been developed and tested. It is to these specific treatments that we now turn our attention. Before doing so, however, it should be

noted that many of these psychological interventions for older adults are used in tandem with psychotropic medications. Although our primary focus is on psychologically based treatments in later life, clinical psychologists would do well to have some base knowledge of psychopharmacology with older adults and be able to play an active role in coordinating care with providers from different disciplines.

Notably, the psychopharmacology of younger adults does not necessarily apply to older adults and having this specialized knowledge puts clinicians in a better position to offer informed recommendations and act as an additional safeguard against dangerous drug interactions and other medication problems. For example, although benzodiazepines are often used as antianxiety medications, this class of drugs has been known to have paradoxical effects when used with older adults and could actually increase elderly clients' agitation (Kyomen & Whitfield, 2008). Additional information about geriatric psychopharmacology has been comprehensively reviewed in previous works (e.g., Jacobson, Pies, & Katz, 2007).

Notwithstanding the important role of psychopharmacology in later life, in this section, we focus on specific psychosocial treatments that have been shown to have empirical support with older adults for a number of problems often faced by this population, namely depression, anxiety, alcohol and drug misuse, insomnia, behavior problems associated with dementia, caregiver stress, and complications in the grieving process.

## Depression

Depression is one of the most commonly occurring psychological problems in late life. In particular, the prevalence of major depressive disorder (MDD) ranges from 1% to 4% among community-dwelling elders, from 5% to 10% among primary care patients, from 10% to 12% among older adults hospitalized for medical and surgical services, and to about 13% among home health-care patients (Blazer, 2003; Bruce et al., 2002). Of course, these figures likely underestimate the impact of depression among older adults, as 8%–16% of community-dwelling elders tend to report elevated levels of depressive symptoms, which may or may not meet criteria for MDD (Blazer, 2003).

Elevated levels of depression are a serious concern for older adults and have been shown to hasten the progression of a number of health conditions and also increase the likelihood of hospital admission and nursing home placement (Harris & Cooper, 2006; Rumsfeld et al., 2005; van Gool et al., 2005). Thus, assessment and screening for these symptoms becomes all the more important, and several instruments have been shown to have validity with older samples, including the Geriatric Depression Scale (Yesavage et al., 1983), the Beck Depression Inventory (Beck, Steer, & Brown, 1996), and the Center for Epidemiological Studies Depression Scale (Radloff, 1977). As mentioned previously, clinicians should be aware that depression can manifest differently among older adults compared to younger individuals, in that depressed elders might be less likely to endorse affective symptoms, such as depressed mood, and instead exhibit more somatic complaints, anxiety, memory loss, or cognitive impairments (Gottfries, 1998).

Fortunately, clinicians have a range of treatments for geriatric depression to select from that have been shown to have strong empirical support. Generally speaking, meta-analyses of outcome studies for depression among older adults have revealed substantial treatment effects, with those in a treatment condition being between .61 and .78 of a standard deviation better off than controls on measures of depression (Cuijpers, van Straten, & Smit, 2006; Engels & Vermey, 1997; Scogin & McElreath, 1994). More specifically, Scogin and colleagues (2005) have identified several evidence-based psychological treatments (EBTs) for geriatric depression (Scogin, Welsh, Hanson, Stump, & Coates, 2005). In this evidence-based review, a treatment was regarded as an EBT if at least two methodologically strong studies (e.g., randomized controlled trials) were identified with a minimum of 30 participants across studies (60 years or older) that showed a given treatment to be "(a) better than the control or comparison groups or (b) equivalent to an existing EBT" for the same targeted problem, in this case geriatric depression (Scogin et al., 2005, p. 225).

Using this set of criteria, six different treatments were identified as EBTs, namely behavioral therapy, CBT, cognitive bibliotherapy, problem-solving therapy, brief psychodynamic therapy, and reminiscence therapy (Scogin et al., 2005). Behavioral therapy typically views depressed mood as stemming from a lack of pleasant events and/or an overload of unpleasant events, and hence treatment involves helping clients to incorporate more pleasant activities into their daily lives, in order to improve mood (Lewinsohn, 1974). Cognitive-behavioral theory, whether applied in a psychotherapy or bibliotherapy context, tends to emphasize the role of unhelpful, negative thoughts in maintaining depressive symptoms and aims to gently challenge these cognitions in an effort to promote more rational thinking and improved mood (Gallagher-Thompson, Steffan, & Thompson, 2008). Notably, CBT treatments also tend to incorporate behavioral strategies (e.g., increasing pleasant activities, relaxation), and protocols have been developed that are specifically designed for older adults (Laidlaw, Thompson, Dick-Siskin, & Gallagher-Thompson, 2003).

In contrast to these approaches, problem-solving therapy typically teaches skills for adaptively approaching problems and encourages older adults to view problem-solving as a coping strategy for dealing with situations that promote a depressed mood (Nezu, Nezu, & Perri, 1989). Brief psychodynamic approaches to treating geriatric depression emphasize the role of internal conflicts and unresolved issues, particularly around issues of independence and dependence, and focus on how these processes play out in the therapeutic relationship, which is often viewed as a driving mechanism of change (Rose & DelMaestro, 1990). Finally, reminiscence therapy involves having depressed older

adults review their life histories, concentrating on the significant positive and negative life events, in an effort to promote an enhanced understanding of these events and a greater sense of acceptance about life accomplishments and disappointments (Birren & Deutchman, 1991).

### Anxiety

Although anxiety disorders are common in later life, the prevalence has been shown to be somewhat lower than that of younger age groups (Sheikh & Salzman, 1995). In a review of epidemiological research examining anxiety disorders among the elderly, Flint (1994) found prevalence rates of diagnosable anxiety disorders among older adults spanning from 0.7% to 18.6%. In terms of specific disorders, prevalence rates ranged from 0% to 10% for phobic disorder, 0.7% to 7.1% for generalized anxiety disorder (GAD), 0% to 1.5% for obsessive-compulsive disorder, and 0.1% to 1.0% for panic disorder.

However, these figures likely do not provide a complete picture of the role of anxiety in later life, and clinicians would be well advised to use caution and flexibility when applying present diagnostic criteria for anxiety disorders with older adults (Jeste et al., 2005). For example, older adults are less likely than their younger counterparts to report their own symptoms of anxiety and, interestingly, less likely to report symptoms of anxiety in others as well (Levy, Conway, Brommelhoff, & Merikengas, 2003). Hence, it is not uncommon for older adults to experience considerable distress even when reporting subthreshold levels of anxiety (Wetherell, Le Roux, & Gatz, 2003). Current diagnostic criteria might also fail to distinguish between true anxiety symptoms and anxiety secondary to physical illness and/or loss of function (e.g., fears about being out at night that coincide with the onset of visual problems) (Jeste et al., 2005).

It is also notable that anxiety symptoms might manifest differently in older adults. In particular, some research suggests that the anxiety disorders are more likely to co-occur with depression (and vice versa) among older adults compared to younger adults (Palmer, Jeste, & Sheikh, 1997; Parmelee, Katz, & Lawton, 1993). It has also been suggested that the content of phobias could differ as a function of age, with older adults possibly being more likely to fear inanimate objects, such as heights or lightning, and younger adults being more likely to have fears related to tangible entities like animals (Jeste et al., 2005).

Given the potentially unique presentation of anxiety among older adults, clinicians working with elder clients would do well to rely on assessment instruments that have been tested with this population when assessing for these symptoms. Fortunately, a broad range of clinician-administered and self-report measures of anxiety symptoms have demonstrated adequate reliability and validity with older samples, including the Anxiety Disorders Interview Schedule (DiNardo, Brown, & Barlow, 1994), the State Trait Anxiety Inventory (Spielberger, Gorsuch, Lushene, Vagg, & Jacobs, 1983), and the Beck Anxiety Inventory (Beck, Epstein, Brown, & Steer, 1988), just to name a few. The Worry Scale, in particular, deserves mention as it was specifically designed to gauge worries that are often salient to older adults (e.g., worries about finances, physical health, and social matters; Wisocki, Handen, & Morse, 1986).

Recent reviews of the psychotherapy outcome literature on late-life anxiety have also revealed that several treatment approaches appear to be effective at ameliorating anxiety symptoms with this population. Overall, psychosocial treatments for late-life anxiety have been shown to reduce anxiety symptoms by .55 of a standard deviation unit compared to controls (Nordhus & Pallesen, 2003). However, a more recent review of the current empirical literature supported four treatment approaches as EBTs, using criteria similar to that of Scogin and colleagues (2005; see Yon & Scogin, 2007, for the updated criteria). In particular, this review found support for CBT, cognitive therapy, relaxation training, and supportive therapy (Ayers, Sorrell, Thorp, & Wetherell, 2007). Cognitive-behavioral therapy for late-life anxiety involved many of the same treatment components as CBT for depression (e.g., cognitive restructuring, relaxation techniques) but often also included exposure interventions designed to habituate clients to feared stimuli. Interestingly, cognitive therapy (e.g., cognitive restructuring) and relaxation training (e.g., progressive muscle relaxation, meditation) were also found to be effective stand-alone strategies for addressing late-life anxiety. In addition to these treatments, supportive therapy was also found to be efficacious and involved reflective listening, empathic communication, and support.

### Alcohol and Drug Misuse

Alcohol and drug misuse among older adults is often unrecognized by health providers, as older adults are often hesitant to acknowledge these difficulties due to concerns about the social stigma attached to such problems (e.g., being labeled an "alcoholic") (Substance Abuse and Mental Health Services Administration [SAMHSA], 1998). In addition,

obvious markers for substance abuse/dependence among younger adults (e.g., impairments at work or school, concerns of a spouse) might not apply for older adults, who could be retired and/or widowed (Dupree, Schonfeld, Dearborn-Harshman, & Lynn, 2008; Oslin, 2005). Yet, the best evidence suggests that alcohol and drug misuse is a problem faced by many older adults. For example, among participant 65 years or older who completed SAMHSA's (2004) annual survey, 6.9% reported binge drinking (i.e., five or more drinks on the same occasion) in the last month, and 1.8% reported heavy drinking (i.e., binge drinking for 5 or more days during the last 30 days). Other studies have also found that 2%–15% of older adults exhibit symptoms consistent with alcoholism (Adams, Barry, & Fleming, 1996; Gomberg, 1992).

Notably, depending on the specific clinical population and setting, these figures could vary. For example, it has been estimated that 10%–15% of primary care patients meet criteria for problem drinking (i.e., drinking levels leading to social, emotional, or health difficulties) (Callahan & Tierney, 1995; Oslin, 2004). Also, among veterans with substance abuse diagnoses being treated in Veterans Affairs (VA) hospitals, 23% are over the age of 55 (Moos, Mertens, & Brennan, 1993). Schonfeld and colleagues (2000) also reported fairly high rates (38%) of recent illicit substance use in a VA substance abuse treatment program for older adults. Consistent with these findings, it appears that substance abuse problems are generally more prevalent among older men compared to older women. One study found that 2.75% of elderly men met criteria for alcohol abuse or dependence; whereas, only .51% of women of the same age met these diagnostic criteria (Grant et al., 2004). The Epidemiologic Catchment Area Study also revealed that the lifetime prevalence of drug abuse and dependence among older men was .12% compared to .06% for elderly women (Anthony & Helzer, 1991).

Because substance abuse problems are often overlooked in older adults, psychologists and other health-care providers would do well to regularly screen older adults for these problems. In particular, markers that might prompt an alcohol and/or drug screening include recently experiencing a major psychosocial transition (e.g., loss of a spouse, retirement), the presence of physical symptoms often associated with substance use (e.g., sleep complaints, cognitive impairments), abnormality in liver functioning, and/or slurred speech (Dupree et al., 2008). Three brief screening instruments have been recommended

by the Center for Substance Abuse Treatment (2006). In particular, the older adult–specific measure, the Short-Michigan Alcoholism Screening Test – Geriatric (Blow et al., 1992), has been recommended, as well as the Alcohol Use Disorders Identification Test (AUDIT; Babor, de la Fuenta, Saunders, & Grant, 1992) and the CAGE screening instrument (Mayfield, McLeod, & Hall, 1974)—both of which have shown adequate sensitivity and specificity with older samples (O'Connell et al., 2004).

In general, older adults who have been identified as having problems with substance abuse/dependence are amenable to treatment but tend to prefer interventions that are nonconfrontive, supportive, and focus broadly on coping with depression, loneliness, and loss (SAMHSA, 1998). Although some studies have suggested that older adults do best in age-specific substance use treatment programs (Kashner, Rodell, Ogden, & Guggenheim, 1992; Kofoed, Tolson, Atkinson, & Toth, 1987), more recent findings indicate that older adults can have good outcomes in mixed-age programs when the treatment itself is compatible with older adults' needs and preferences (Oslin, Pettinati, & Volpicelli, 2005).

With regard to specific interventions, SAMHSA (1998) recommends that the least intensive treatment choices be considered first with older substance abusers. In keeping with this guideline, two randomized clinical trials have been conducted with older problem drinkers that tested the efficacy of brief interventions in primary care settings, which for the most part consisted of an expression of concern, feedback regarding the implications of their drinking, and an explicit recommendation to reduce alcohol consumption (Copeland, Blow, & Barry, 2003; Fleming, Manwell, Barry, Adams, & Stauffacher, 1999). The collective outcomes of these trials revealed that brief counseling is an acceptable strategy for this population and might reduce alcohol use and increase service utilization among at-risk drinkers who received treatment, compared to those in the control conditions.

Preliminary evidence also suggests that, when appropriate, more intensive interventions, such as motivational interviewing (MI) and CBT, are effective with older adults dealing with substance-related problems. For example, in one drug trial comparing naltrexone (used to prevent cravings for alcohol) to a placebo medication among older adult alcohol abusers, participants in both conditions received a 3-month motivational counseling intervention, which involved exploring ambivalent feelings about change and meeting the client where they were in

terms of their readiness for change (Oslin et al., 2005). Notably, compared to the younger adults in this study, older adults attended more therapy sessions, had greater medication adherence, and experienced less relapse—providing preliminary support for the utility of an MI approach with this population. In another investigation, problem drinkers were randomly assigned to one of three conditions, namely CBT, relationship enhancement, or relationship enhancement plus vocational enhancement (Rice, Longabaugh, Beattie, & Noel, 1993). Among the older adults in this sample, CBT proved to be the most beneficial treatment option and consisted of standard CBT interventions that particularly emphasized cultivating skills for dealing with personal problems. Other CBT interventions for alcohol abuse, specifically tailored for older adults, have also been used with success (see Dupree et al., 2008, for a full description).

### Insomnia

Older adults tend to experience insomnia more frequently and more intensely compared to younger adults (Lichstein, Durrence, Riedel, Taylor, & Bush, 2004). Indeed, somewhere between 20% and 40% of older adults experience clinical levels of insomnia, which is the most prevalent sleep disorder among individuals of this population (Ancoli-Israel, Pat-Horenczyk, & Martin, 2001; Foley, Monjan, Brown, & Simonsick, 1995; Mellinger, Balter, & Uhlenhuth, 1985). The increased susceptibility of older adults to insomnia has been attributed to factors such as an increase in stressors, environmental changes, and physical and emotional difficulties—all of which can prompt and/or exacerbate sleep problems (Stone, Booth, & Lichstein, 2008). However, it is notable that normal aging by itself is associated with some changes in sleeping patterns and might results in decreased sleep efficiency, variable and earlier sleep time, less deep sleep, and waking up more frequently during the night (Nau, McCrae, Cook, & Lichstein, 2005). Thus, clinicians might often have difficulty distinguishing between normal developmental sleep changes and insomnia, highlighting the importance of assessment with this population.

Assessment might take the form of sleep diaries or psychometrically sound questionnaires, such as the Pittsburgh Sleep Quality Index (PSQI; Buysse, Reynolds, Monk, Berman, & Kupfer, 1989), which provide cutoff scores that can aid in differential diagnosis. Objective measures are also available that do not rely on self-report and are often preferable, particularly if memory impairments are suspected. For example, a device known as an *actigraph* can be worn on the wrist to measure movement, in order to make inferences about whether or not a person is asleep or awake (Ancoli-Israel et al., 2003). More sophisticated and comprehensive objective measures are also available, such as polysomnography, which might provide more accurate data with older adults and help to differentiate between the overlapping symptoms of many sleep, mental, and physical disorders (Sivertsen et al., 2006).

Once an older adult has been identified as experiencing elevated symptoms of insomnia, clinicians have several empirically supported psychological treatments to choose from that have been shown to significantly enhance the sleep quality of older adults (McCurry, Logsdon, Teri, & Vitiello, 2007). In particular, using the criteria for identifying EBT's for older adults (Yon & Scogin, 2007), McCurry and colleagues (2007) concluded that both sleep restriction-sleep compression interventions as well as multicomponent CBT treatments are efficacious for this population. Sleep restriction therapy is based on the notion that a discrepancy often exists between *perceptions* of the amount of sleep needed and *actual* sleep need, and this discrepancy can be dealt with by encouraging clients to spend time in bed based on actual sleep needs instead of desired sleep (Spielman, Saskin, & Thorpy, 1987). Specifically, in this treatment, clients are instructed to limit the time spent in bed to match the amount of time they actually spend sleeping (gauged by sleep diaries or other assessments), and clients can gradually increase the time spent in bed by 15–20 minutes until an optimal sleep duration is attained. Sleep compression therapy is based on the same psychological principles but instead gradually decreases time in bed (Riedel, Lichstein, & Dwyer, 1995).

Multicomponent CBT interventions include a variety of strategies, most often education about sleep hygiene, relaxation, sleep restriction, and stimulus control. Sleep hygiene education involves discussion about the contribution of a variety of factors—sleep schedule, diet, physical environment, and activity—that often contribute to and maintain sleep difficulties (Stepanski & Wyatt, 2003). Relaxation techniques, such as diaphragmatic breathing and progressive muscle relaxation, are also frequently used to lessen physiological arousal and increase the likelihood of getting to sleep (Manber & Kuo, 2002).

Stimulus control interventions typically involve providing a list of instructions that aim to establish bed as a prompt for sleep, avoid pairing time in bed

with activities inconsistent with sleep (e.g., watching television, reading), and help individuals acquire a consistent sleep pattern (Bootzin, 1977). These instructions typically involve advising clients to only use the bed for sleep (or sex); go to bed only when sleepy; leave the bed and bedroom after 20 minutes of sleeplessness and only return after feeling sleepy (to be repeated as many times as necessary); regardless of sleep quantity, wake up at the same time each morning; and avoid daytime napping (Bootzin & Epstein, 2000). With older adults, this intervention should be applied flexibly, as it potentially involves getting in and out of bed repeatedly, which could be challenging in the presence of physical limitations. In these cases, clients could instead sit up in bed and initiate a relaxing or soothing activity (e.g., listening to music) until they get tired, as a way to avoid further tossing and turning (Stone et al., 2008).

### Behavior Problems Associated with Dementia

Epidemiological studies suggest that roughly 6% of community-dwelling older adults over the age of 70 suffer from some form of dementia, and this figure rises to about 50% for individuals over the age of 85 (Evans et al., 1989; Kukull et al., 2002). Likewise, in long-term care settings (e.g., nursing homes), about half of the residents carry a dementia diagnosis (Magaziner et al., 2000). As dementia progresses, it is often associated with a variety of behavioral problems, such as verbal and physical aggression, wandering, and opposition to care (Cohen-Mansfield & Billig, 1986; Mega, Cummings, Fiorella, & Gornbein, 1996). Notably, these behaviors increase the risk of caregiver stress, falls, or other accidents, and ultimately they are often the primary reason for institutionalization (Yaffe et al., 2002).

Because of the potential emotional, physical, and financial costs of dementia-related behavioral problems, behavioral management of these symptoms becomes an important part of a care recipient's treatment plan. However, before intervening, it is important to conduct a comprehensive assessment. This assessment is often done idiographically and involves interviewing the caregiver or residential staff members to generate hypotheses about what antecedents (e.g., boredom, hunger, having to go the bathroom) could be triggering problematic behaviors and what consequences of the behavior (e.g., increased attention) might be reinforcing its reoccurrence. Other more formal assessments include the Behavioral Pathology in Alzheimer's Disease Rating Scale (Reisberg et al., 1989), which

asks caregivers to rate their level of distress related to 25 possible problem behaviors, and the Pittsburgh Agitation Scale (Rosen, Burgio, Kollar, & Cain, 1994), which measures aggression and agitation based on 1–8 hours of direct observation. Since depressive symptoms can also contribute to behavioral disturbances, an assessment of these symptoms might also be warranted using the Cornell Scale for Depression in Dementia. This 19-item instrument gauges behavioral symptoms of depression through interview and observational methods and collects information from both the patient and a family caregiver or nursing staff member (Alexopoulos, Abrams, Young, & Shamoian, 1988).

Intervention for behavior problems related to dementia often involves pharmacological treatment in the form of antipsychotic, antidepressant, and/or anticonvulsant medication (see Bharani & Snowden, 2005, for a review of specific medications). However, treatment would ideally involve some combination of pharmacology and behavioral management. Medications for the management of these behaviors are not without risk (e.g., fatigue, sedation, increased disorientation/confusion) and a behavioral approach represents a safe and effective supplement (or in some cases perhaps an alternative) to these interventions. Notably, a recent empirically based review concluded that two approaches to behavioral management of these symptoms have strong empirical support (Logsdon, McCurry, & Teri, 2007), namely treatments based on the progressively lowered stress threshold (PLST; Hall & Buckwalter, 1987) and behavioral problem-solving (Teri et al., 1998) theoretical models. Generally speaking, both of these treatment approaches involve training family caregivers or nursing staff members to identify targeted behaviors, generate hypotheses about possible antecedents, make appropriate changes to the care recipient's physical environment or schedule, and/or modify interpersonal interactions to reduce the occurrence of these behaviors.

### Caregiver Stress

There are an estimated 44.4 million caregivers in the United States (roughly 21% of the adult population) who offer unpaid care to another adult suffering from a physical or mental disability. Although the typical caregiver in the United States is a Caucasian woman in her mid-forties, it is notable that 39% of caregivers are men, 43% are 50 years of age or older, and 27% represent ethnic minorities (12% African American, 10% Hispanic/Latino, 4% Asian American)—highlighting the rich diversity

among these individuals (National Alliance for Caregiving & AARP, 2004). Caregiving of any kind can be a source of stress that affects physical and psychological functioning; however, evidence suggests that caring for a loved one with Alzheimer disease or other form of dementia presents unique challenges and often results in higher levels of stress compared to other caregiving circumstances (Ory, Hoffman, Yee, Tennstedt, & Schulz, 1999). Indeed, caring for a loved one with dementia has been associated with higher levels of depression as well as physiological outcomes, such as high blood pressure and heart problems (Gallagher, Rose, Rivera, Lovett, & Thompson, 1989; Schulz & Martire, 2004; Vitaliano, Scanlan, Zhang, Savage, & Hirsch, 2002; Vitaliano, Young, & Zhang, 2004).

Given the prevalence of depression among dementia caregivers (estimated at roughly 20%; Cuijpers, 2005), the assessment of a caregiver presenting for treatment would ideally include an evaluation of current depressive symptoms. Notably, the instruments recommended for depressed older adults would also be applicable for caregivers. Two caregiving-specific measures also deserve mention and provide useful information beyond an assessment of depression. The Revised Memory and Behavior Problem Checklist gauges the frequency of disruptive behaviors and memory-related behaviors, such as asking questions repeatedly, on the part of the care recipient and asks caregivers to indicate the amount of stress experienced as a result of these behaviors (Teri et al., 1992). Another useful instrument is the 22-item self-report measure, the Zarit Burden Interview, which assesses the total physical, emotional, and financial tolls of caregiving (Zarit, Todd, & Zarit, 1986).

The last 10 years have seen tremendous growth in the number of high-quality treatment outcome studies for distressed caregivers. For example, in Gatz and colleagues' (1998) review of psychological treatments for older adults, only four caregiver intervention studies met EBT criteria. In contrast, in an updated review of this literature using similar inclusion criteria (Yon & Scogin, 2007), 19 studies were identified that supported the efficacy of a variety of caregiver interventions, including psychoeducational skill building programs, psychotherapy and counseling, and multicomponent interventions (Gallagher-Thompson & Coon, 2007).

With regard to psychoeducational skill building programs, four approaches were found to warrant EBT status (Gallagher-Thompson & Coon, 2007). They include behavioral management skills training

(e.g., Bourgeois, Schulz, Burgio, & Beach, 2002), depression management (e.g., Coon, Thompson, Steffen, Sorocco, Gallagher-Thompson, 2003), anger management skill training (e.g., Steffen, 2000), and the PLST model (e.g., Huang, Shyu, Chen, Chen, & Lin, 2003). Behavioral, depression, and anger management programs typically adhere to CBT principles and involve interventions such as training individuals to increase pleasant activities, challenge automatic thoughts, and identify triggers for anger and frustration. Rather than directly targeting caregiver symptoms, programs based on the PLST model typically focus on teaching skills to manage stressors, such as changes in routine or multiple and competing stimuli, that might interact with the care recipient's physical condition to exacerbate problem behaviors (Hall & Buckwalter, 1987).

This empirically based review also supported the use of psychotherapy as well as multicomponent interventions (Gallagher-Thompson & Coon, 2007). Of the three studies that tested formal psychotherapy or counseling and met EBT criteria, all used CBT or were strongly CBT based. Two studies that tested a multicomponent intervention (made up of two or more distinct theoretical perspectives) were labeled as EBTs. These studies included one treatment that involved individual and family counseling sessions, participation in support groups, and ad hoc follow-up counseling (Mittelman, Ferris, Shulman, & Steinberg, 1995), and another treatment that incorporated family therapy with a computerized phone system, which allowed for support group participation, as well as access to information about caregiving and community resources (Eisdorfer et al., 2003).

## Prolonged Grief

The loss of loved ones is perhaps one of the most challenging psychosocial transitions in later life (Thompson, Tang, DiMario, Cusing, & Gallagher-Thompson, 2007). Notably, by the age of 65, one half of all women and 10% of all men experience the loss of a spouse, and these figures rise to 80% and 40%, respectively, by age 85 (Rosenzweig, Prigerson, Miller, & Reynolds, 1997). Of course, the cumulative losses experienced by older adults dramatically surpass these figures, as the loss of siblings and friends exceed spousal bereavement by factors of 3:1 and 9:1, respectively (Hays, Gold, & Peiper, 1997). Despite the ubiquity of loss in later life, recent evidence suggests that most successfully adjust to these trying circumstances. In particular, the Changing Lives of Older Couples (CLOC)

project, a prospective study of spousal bereavement among older couples, found that about 40% of widows and widowers were resilient in the face of loss and 6 months afterward exhibited minimal depressive and grief symptomatology (Bonanno et al., 2002).

For a subset of 10%–15% of bereaved older adults, however, the loss of a loved one prompts a prolonged grief reaction—a chronic and severe form of grieving lasting longer than 6 months that is characterized by intense separation distress, intrusive thoughts about the deceased, a sense of purposelessness and meaninglessness about life, and impairments in everyday functioning (Bonanno et al., 2002; Prigerson, Bierhals, Kasl, & Reynolds, 1997; Prigerson & Maciejewski, 2006). The proposed diagnostic criteria for Prolonged Grief Disorder (PGD) are presented in Table 36.1. Although PGD is still being considered for inclusion in the *Diagnostic and Statistical Manual of Mental Disorders*, this cluster of symptoms has been shown to uniquely predict a variety of detrimental outcomes (after accounting for the impact of depressive and anxiety symptoms), such as heart problems, cancer, hypertension, and changes in eating and smoking habits (Prigerson et al., 1997).

Given the potential impact of PGD, clinicians would do well to screen for the presence of these symptoms using validated self-report and/or clinician-administered instruments, such as the Inventory of Complicated Grief (Prigerson & Jacobs, 2001). Importantly, this type of assessment could identify bereaved older adults who are most likely to benefit from treatment. For example, in a recent meta-analysis of bereavement intervention research, it was found that interventions generally did not promote improvements on measures of depression, grief, and other relevant outcomes, and this trend held across all age groups (Currier, Neimeyer, & Berman, 2008). However, when efforts were made to specifically include only bereaved individuals who were particularly distressed, the effects of treatment were substantial, underscoring the importance of assessing for complications in the grieving process (Currier et al., 2008).

Tests of psychosocial treatments for PGD are just beginning to emerge; however, several recent studies support the efficacy of CBT-based interventions. Generally speaking, these interventions often involve gently challenging negative grief-related beliefs (e.g., "Life will never hold meaning again") and facilitating gradual exposure to the painful details of the loss experience in order to promote less avoidance and new understandings of the loss that allow for a more hopeful future. For example, a 6-week therapy, complicated grief treatment (CGT), was recently tested against interpersonal psychotherapy (IPT) in a randomized clinical trial with

**Table 36.1  Criteria for prolonged grief disorder proposed for DSM-5**

**Criterion A.** Chronic and disruptive yearning, pining, longing for the deceased

**Criteria B.** The person must have four of the following eight remaining symptoms at least several times a day or to a degree intense enough to be distressing and disruptive:

1. Trouble accepting the death

2. Inability to trust others

3. Excessive bitterness or anger related to the death

4. Uneasiness about moving on (e.g., making new friends, pursuing new interests)

5. Numbness/detachment (e.g., feeling disconnected from others)

6. Feeling that life is empty or meaningless without deceased

7. Feeling bleak about the future

8. Agitation (e.g., jumpiness or edginess)

**Criterion C.** The above symptom disturbance causes marked and persistent dysfunction in social, occupational, or other important domains.

**Criterion D.** The above symptom disturbance must last at least 6 months.

Adapted from Prigerson, H. G., & Maciejewski, P. K. (2005–2006). A call for sound empirical testing and evaluation of criteria for complicated grief proposed for DSM-5. *Omega: Journal of Death and Dying, 52*(1), 9–19. Reprinted with permission of the publisher, Baywood Publishing.

95 participants who met criteria for PGD (Shear, Frank, Houck, & Reynolds, 2005), many of whom were older adults. The CGT condition included therapeutic procedures such as *revisiting*, in which participants retold, recorded, and reviewed their stories of loss, and *imaginal conversations*, which facilitated a renewed bond to the deceased through imaginary dialogue. In this study, CGT was shown to be better than IPT at ameliorating symptoms of PGD and improving participants' work and social adjustment. Complicated grief treatment also yielded a more rapid rate of recovery with regard to PGD symptoms, although the two treatments generated similar outcomes on measures of depression and anxiety. Notably, other recent studies that have tested the efficacy of CBT-based interventions for PGD have also produced favorable results (Boelen, de Keijser, van den Hout, & van den Bout, 2007; Wagner, Knaevelsrud, & Maercker, 2006).

## Diversity Among Older Adults

Recent years have shown an increase in the ethnic and racial diversity among older adults in the United States, and this trend is expected to continue over the next several decades. In particular, in 1990, ethnic minorities made up 13% of individuals over the age of 65 years. Notably, this figure rose to 16% in 2000, and is anticipated to grow to 23% by 2020, and to 36% by 2050 (U.S. Census Bureau, 2003). These demographic shifts are likely to have an impact on the health-care system as a whole, and for psychologists working with older clients, in particular, signal the importance of culturally sensitive clinical practice. Thus, beyond having a general understanding of how interventions might be tailored for older adults and knowledge about the specific empirically based treatments for this population, geropsychologists of the 21st century will increasingly need to have an understanding of cultural differences and be able to respond to older clients' varying needs. Given the relevance of these issues to older adults, in this section we will explore important ethnic/racial differences in later life and discuss how these relate to (a) the clinical presentation of emotional distress and its assessment, as well as (b) treatment usage, treatment preferences, and treatment outcome.

### *Clinical Presentation of Emotional Distress*

In many ways, mental illness itself represents a culturally created construct. Notwithstanding tremendous within-culture variation, the signs and symptoms of emotional disruption are undoubtedly influenced by the collective expectations and beliefs of a culture about the etiology of psychological problems and the appropriateness of different ways of expressing these problems. Indeed, it is interesting to note that psychological difficulties like eating disorders that are prevalent in Westernized, technologically advanced societies are virtually nonexistent in less industrialized cultures, highlighting the crucial role of culture in defining mental illness (Horwitz, 2002).

Not surprisingly, culture and ethnicity seem to operate in a similar fashion with older adults and have a palpable effect on the ways in which emotional distress is manifested in this population. Although some investigations have failed to find substantial differences in the symptom profiles of older adults on the basis of ethnicity or race (Blazer, Landerman, Hays, Simonsick, & Saunders, 1998; Mouton, 1997), other studies have revealed subtle variations and provide clinicians with a roadmap (albeit an incomplete one) for understanding how culture might intersect with psychological problems in later life. For example, with regard to ethnic differences in geriatric depressive symptoms (which have been researched most extensively), depressed African American elders have been found to be less likely to report symptoms of dysphoria (Gallo, Cooper-Patrick, Lesikar, 1998), as well as feelings of helplessness or worthlessness (Karel & Moye, 2002), compared to Caucasian older adults. Other studies have also suggested that older African Americans might be more likely than Caucasians to endorse having thoughts about death (Gallo et al., 1998) and fatigue-like symptoms (i.e., reporting that "everything was an effort") (Mills, Alea, & Cheong, 2004, p. 224).

In studies with adults of mixed age groups, possible differences in the expression of depressive symptoms have also been noted among individuals of Latino and Asian cultures. For example, some studies suggest that depressed individuals from Asian cultures might be less likely to endorse symptoms from the psychological realm, such as sadness, irritability, or rumination, and more likely to report somatic complaints like headaches, insomnia, or fatigue (Cheung, 1980; Kleinman, 1982; Lin & Cheung, 1999). These global trends should be considered cautiously, however, especially in light of the fact that other studies have failed to identify elevated levels of somatization among Asian participants (Mackinnon, McCallum, Andrews, & Anderson, 1998). Beyond these findings pertaining to Asian cultures, one investigation of Latino and Caucasian individuals found that Latinos were more likely than Caucasians

to endorse items related to tearfulness and punishment and less likely to endorse an inability to work (Azocar, Areán, Miranda, Muñoz, 2001).

These potential differences in symptom presentation are likely due to a variety of culturally influenced factors, such as the degree of stigmatization placed on mental illness, as well as to beliefs about aging and the cause of psychological problems. For example, studies of African American and Caucasian elders have found that African Americans tend to be more likely to view depression as a sign of personal weakness (Mills et al., 2004) and are more likely to hold negative beliefs about aging (Foos, Clark, & Terrell, 2006). It is also notable that ethnic minority older adults vary in their degree of identification with traditional cultural norms, and the extent to which someone has adopted the folkways of the dominant culture appears to have an impact on their expression of emotional distress. Specifically, one study of Mexican American elders found that acculturation was associated with pervasive differences in the way items were endorsed on the Center for Epidemiological Studies – Depression (CES-D) scale (Chiriboga, Jang, Banks, & Kim, 2007). Another study of more than 1,500 elderly Chinese-Canadian immigrants revealed that higher levels of identification with traditional Chinese cultural values resulted in a greater likelihood of being depressed (Lai, 2004).

Cultural differences are also likely to influence the prevalence of psychological problems. Although less is known about the relative incidence of mental disorders among older adults of different ethnicities, studies of adults in general have shown some differences. For example, one large multisite epidemiological study suggested that, after accounting for socioeconomic status, African Americans were less likely than Caucasians to meet diagnostic criteria for major depression, obsessive-compulsive disorder, drug and alcohol abuse or dependence but were more likely to experience phobias and somatization (Zhang & Snowden, 1999). Another investigation specific to older adults found the prevalence rate of suicide among Caucasian elders to be greater than that of African American elders by a factor of more than three (15.8 suicides per 100,000 compared to 5). Notably, Asians and Hispanic/Latino older adults were also shown to be less likely to commit suicide than Caucasians (with 10.6 and 7.9 suicides per 100,000, respectively; National Institute of Mental Health, 2007).

There are, of course, a multitude of possible explanations for these differences in prevalence rate.

In the case of suicide, it is notable that, compared to Caucasians, African American elders tend to have higher levels of religiosity, which often plays an important role in coping with depressive symptoms and also likely strengthens cultural prohibitions against suicide (Consedine, Magai, & Conway, 2004; Jang, Borenstein, Chiriboga, & Mortimer, 2005). Beyond the possibility that ethnic differences in prevalence are due to true variation in the expression of psychological distress, it has also been noted that practitioners may be influenced by cultural biases when diagnosing older adults of ethnic minority groups. For example, one study found that African American and Hispanic/Latino individuals with bipolar disorder were more likely to be misdiagnosed with schizophrenia (Mukherjee, Shukla, Woodle, Rosen, & Olarte, 1983). Notwithstanding these worrisome findings, it is notable that many of these studies have yielded mixed results, and two recent investigations using a case vignette design (where participants of a different ethnicity/gender portray the exact same clinical presentation) suggest that psychiatrists and primary care physicians diagnose geriatric depression similarly regardless of race and gender (Kales, Neighbors, Blow et al., 2005; Kales Neighbors, Valenstein et al., 2005).

Given these cultural differences in clinical presentation and prevalence, as well as the possibility of clinician bias in diagnostic practices, it is imperative that clinical psychologists be mindful of culturally sensitive practices when assessing and conceptualizing cases involving diverse older adults. Hays (1996) suggests that one helpful model for conducting a culturally responsive assessment with older adults is the ADRESSING framework, which takes into account the influences of Age, Disability, Religion, Ethnicity, Social status, Sexual orientation, Indigenous heritage, National origin, and Gender. Notably, such an approach acknowledges the rich heterogeneity within cultural groups and discourages inaccurate generalizations, in that within any given ethnic group (or other ADRESSING factor) individuals are represented as varying across all other factors proposed by the ADRESSING paradigm. When clinicians have knowledge and interest in the unique experience of diverse older adults, and apply it to their therapeutic work, treatment and assessment will likely be improved by enhancing rapport and fostering greater understanding of clients' identity and heritage, as well as by improving the assessment of clients' circumstances, needs, and unique strengths (Hays, 1996).

Beyond these general guidelines, culturally sensitive assessment can also be supplemented with standardized

instruments that have been translated into different languages and shown to be reliable and valid with diverse groups of older adults. For example, the CES-D is available in English and Spanish and has been shown to be a useful tool for assessing geriatric depression among diverse older adults, although norms and factor structures might vary across different groups (Mui, Burnette, & Chen, 2001). Clinicians can also make use of the GDS, which is also available in 28 different languages at http://www.stanford.edu/~yesavage/GDS.html. Likewise, the commonly administered cognitive screening instrument, the MMSE, is available in 57 different languages at www.minimental.com, and has generally been shown to be a fair test of mental status with older adults of different ethnicities, although some ethnic groups might be more likely to have errors for certain items (Escobar et al., 1986; Espino, Lichtenstein, Palmer, Hazuda, 2001). Other measures have also been devised that specifically tap into culturally relevant factors, such as level of acculturation and cultural mistrust, and could provide a useful supplement to traditional measures of psychopathology (see Sabnani & Ponterotto, 1992, for a review).

### Treatment Usage, Preferences, and Outcome

The collective experiences, beliefs, and attitudes of different cultural groups about psychotherapy and other health services undeniably has an impact on the way in which these services are utilized and, in some cases, might influence treatment adherence and outcome. Generally speaking, minority populations tend to underuse mental health services, regardless of age or insurance status (Pingatore, Snowden, Sansone, & Klinkman, 2001; Yeo & Gallagher-Thompson, 2006). After accounting for confounding factors, such as socioeconomic status, older African Americans have also been shown to visit a physician less frequently, which statistically accounts for the higher mortality rates observed among this population compared to Caucasians (Sherkat et al., 2007). Thus, these service utilization patterns are certainly reason for concern and can potentially have fatal implications.

A variety of reasons have been proposed for these disparities among ethnic minority older adults, including lack of financial resources, knowledge deficits, perceived insensitivity of practitioners, and/or fear of unnecessary hospitalization or other intrusive interventions (Alvidrez, Areán, & Stewart, 2005; Mills & Edwards, 2002; Unützer, Katon,

Sullivan, & Miranda, 1999). With regard to knowledge deficits, studies have shown that ethnic minority older adults tend to possess less knowledge about Alzheimer disease and perhaps depression too, which could partially explain why services addressing these issues might be underutilized (Ayalon & Areán, 2004; Zylstra & Steitz, 1999). Another investigation points to an additional contributing factor and showed that African American elders were more likely than Caucasians to believe that doctors do not display enough compassion or respect toward older adults (Jackson & George, 1998). Similarly, Strakowski and colleagues (1995) found that African Americans were in fact more likely to be hospitalized than Caucasians when presenting for emergency psychiatric services, irrespective of insurance coverage or suicidal/homicidal ideation—likely adding to a general sense of mistrust held by many African Americans.

Another culturally influenced factor that has been found to impact the utilization of mental health services among older adults is treatment preference. In particular, African Americans and Hispanics/Latinos have been found to be less likely to view depression as being biologically-based and often indicate a preference for psychotherapy over antidepressant medications (Cooper et al., 2003; Givens, Houston, Van Voorhees, Ford, & Cooper, 2007). Numerous studies have shown that older ethnic minorities are less likely than Caucasians to receive an adequate trial of antidepressants (Blazer, Hybels, Simonsick, & Hanlon, 2000; Fyffe, Sirey, Heo, & Bruce, 2004; Strothers et al., 2005), and it seems likely that this association is at least partially explained by differences in treatment preference. Indirect evidence for such a claim is offered from a handful of studies that have shown that ethnic minorities are just as likely as Caucasians (or in some cases more likely) to receive an adequate trial of psychotherapy, contrasting with the literature on antidepressants (Brown, Schulberg, Sacco, Perel, & Houck, 1999; Harman, Edlund, & Fortney, 2004).

One simple tactic for handling issues of preference would, of course, be to offer the preferred treatment if it is available and has been shown to be effective. However, in some cases, treatment options may be limited, due to financial constraints, insurance, or lack of resources. In addition, the empirical evidence in support of the preferred treatment might be insufficient. Encouragingly, one study suggests that the preferences of older adults for counseling or antidepressants do not appear to predict subsequent satisfaction with treatment or outcome, regardless

of whether or not the preferred treatment was received (Gum et al., 2006).

Given the lack of association between treatment preference and outcome, clinicians may opt to provide psychoeducation to older ethnic minority clients to enhance adherence and reduce treatment dropouts when a preferred treatment is not available or indicated. For example, one study found that older African Americans who received a brief psychoeducational meeting attended significantly more psychotherapy sessions compared to those in the control group (Alvidrez et al., 2005). Notably, this psychoeducational intervention involved addressing issues, such as (a) how a medical-model conceptualization of mental illness could reduce stigma, (b) the specific circumstances that would prompt an involuntary hospitalization, (c) the importance of the patients' input and feedback in the process of therapy, and (d) the receptivity of the therapist to discussing issues of spirituality or religion, just to name a few. These preliminary results are encouraging, and provide clinicians with some direction on how issues of treatment preference and nonadherence might be addressed with older ethnic minority clients. Although Alvidrez and colleagues' (2005) psychoeducational intervention was specifically tailored to increase adherence to a psychotherapeutic intervention, it could likely be altered to address concerns about antidepressant or other psychotropic medications. Of course, more work is needed in this area before any definitive claims can be made.

Notwithstanding the importance of attending to cultural differences among older adults and making appropriate treatment modifications, several studies suggest that psychotherapeutic approaches that are effective with older adults generally appear to be applicable to ethnic minority elders as well. For instance, one randomized controlled trial tested the efficacy of a combined antidepressant and/or problem-solving treatment with 1,801 older adults experiencing symptoms of depression, many of whom were African American and Latino (Areán et al., 2005). This study found that those in the intervention condition exhibited significantly less depressive symptoms than controls, regardless of their ethnicity. Notably, minimal efforts were made to tailor this intervention to ethnic minority groups, highlighting the efficacy of this treatment approach even in a virtually unmodified form (Areán et al., 2005). In another randomized clinical trial, the efficacy of a home-based CBT intervention was tested with a sample of 134 diverse rural older adults, predominantly African American, and those who received CBT exhibited significantly greater improvements in quality of life and reductions in psychological symptoms (Scogin et al., 2007). Taken together, these studies provide preliminary evidence supporting the use of CBT and problem-solving techniques with diverse groups of older adults.

The Resources for Enhancing Alzheimer Caregiver Health (REACH) projects also incorporated a large proportion of ethnic minority groups and in many ways represent a model for culturally sensitive intervention. The first phase of the REACH project included 1,222 caregivers at seven different sites, many of whom were African American or Hispanic/Latino (Schulz et al., 2003). Although the specific treatments varied across each location, most included psychoeducation/skill building interventions, often combined with efforts intended to improve caregiver social support. Despite differences across sites, overall findings demonstrated that active interventions were superior to control conditions at ameliorating symptoms of caregiver burden. Notably, these improvements were most prominent for women and those with lower levels of education. With regard to depressive symptoms, Hispanic caregivers, nonspouses, and individuals with less education exhibited the most treatment-induced gains. These different effects observed for subgroups of REACH I participants underscore the varying needs of diverse caregivers as well as the potential benefit of an intervention that could flexibly attend to the distinctive combinations of problems faced by individual caregivers (Gallagher-Thompson et al., 2003).

In an attempt to better handle these varying needs, a second phase (REACH II) administered a structured, yet customized, multicomponent intervention (mostly based on CBT principles) to 642 Hispanic/Latino, Caucasian, and African American caregivers across five sites (REACH II Investigators, 2006). Depending on a caregiver's level of symptomatology on baseline measures, the actual intervention that a caregiver received could be molded to concentrate on five potential target areas; depression, burden, self-care, social support, and problem behaviors. For most participants, these interventions decreased symptomatology (as assessed by measures that corresponded to each of the five target areas) compared to controls, particularly among Caucasian and Hispanic/Latino caregivers and African American spousal caregivers. In both REACH projects, all interventions and assessment materials were offered in Spanish, bilingual/bicultural staff were hired, and substantial efforts were made to individualize the interventions to make them more amenable to varying

cultural views of dementia and caregiving (Gallagher-Thompson et al., 2003).

## Future Directions in Geropsychology

Although a wealth of information is now available about psychological problems among diverse groups of older adults and the efficacy of interventions for this population, some gaps in the empirical literature are still in need of further investigation. It is, of course, not feasible to cover all of these topics. However, in this section we will discuss several "high-priority" areas for further research and offer some recommendations for what this future work might look like.

### Technology

Recent years have seen vast improvements in elder care through the advancement of a variety of technologies. One of the most prominent advances has been the advent of the Internet and its use with older adults to improve mental and physical health. Indeed, a recent survey of more than 2,000 adults in the United States found that 22% of individuals over the age of 65 reported having access to the Internet and were as enthusiastic about online resources as younger users (Fox, 2004). This trend is encouraging, given the salutary effects of Internet use among older adults. For instance, one study of 293 bereaved older adults found that Internet use predicted lower levels of prolonged grief and post-traumatic stress symptomatology after a loss (Vanderwerker & Prigerson, 2004). Other investigations have revealed that Internet use among older adults is associated with lower levels of social loneliness and higher levels of global psychological well-being (Chen & Persson, 2002; Sum, Mathews, Hughes, & Campbell, 2008).

Given these encouraging trends, clinicians and researchers have increasingly looked to the Internet as a potential modality for intervention. Although there are certainly drawbacks to this mode of delivery (e.g., lack of face-to-fact contact), Internet-administered interventions might overcome many barriers to treatment faced by older adults, such as lack of transportation and/or physical disability. One of the most successful and promising advancements in this area has been the online adaptation of Lorig and colleagues' (2006) self-management program for chronic diseases, such as arthritis, diabetes, and heart disease. The core of this intervention involves enhancing self-efficacy, which is viewed as a crucial mechanism for improving coping, communication, and control in the context of chronic illness (Marks, Allegrante, & Lorig, 2005). Encouragingly, a recent

randomized clinical trial that tested the efficacy of the online adaptation of this brief intervention revealed that those receiving the self-management program had significantly improved health statuses at a 1-year follow-up compared to controls. The proposed mechanism of change for this intervention was also supported by a significant positive association between improved self-efficacy at 6 months and improved health status at 1 year (Lorig, Ritter, Laurent, & Plant, 2006).

With the success of this Internet-administered self-management program for chronic illness, interventionists have sought to adapt it to other contexts, such as caregiving. Specifically, the Powerful Tools for Caregivers program is based on similar self-management concepts and aims to provide caregivers with tools for managing self-care, coping with common stressors, and improving communication. This program is available as an Internet-administered intervention, in addition to an in-person group format, and preliminary evidence from an uncontrolled pilot study suggests that it increases caregivers' level of confidence, reduces depressive symptoms, and improves reactions to care recipients' memory and behavior problems (see www.matherlifeways.com; www.rosalynncarter.org/ptchistory, for additional information).

Randomized clinical trials are beginning to emerge that demonstrate the utility of computer-mediated interventions for caregivers (e.g., Marziali & Donahue, 2006). However, more methodologically sound interventions studies of this kind are needed to investigate the efficacy of these treatments in the context of caregiving, as well as other problems commonly faced by older adults. Notably, improved quality control of Internet resources for older adults is sorely needed, as one investigation of Internet geriatric health information found that much of the publicly available materials are of suboptimal quality with regard to credibility and educational value (Hajjar, Gable, Jenkinson, Kane, & Riley, 2005). Future studies would also do well to consider visual presentation of these Web-based materials and whether or not age-specific modifications (e.g., in layout, organization, or font size) enhance participation or outcome (Echt, 2002).

Beyond the Internet, technologies such as artificial intelligence (AI) and robotics will also likely play a larger role in improving elder care in the future (Marling, 2007; Roy & Pineau, 2007). For instance, repetitive and mechanical tasks, such as medication reminding, walking assistance, and monitoring, can likely be performed with technological assistance,

which could free caregivers to focus on more demanding tasks and potentially reduce burnout (Roy & Pineau, 2007). Importantly, assistive technology already appears to be having a substantial impact on elder care, and one study found that the use of assistive technologies dramatically increased in the 1990s, which accounted for the observed declines in personal care needs of older adults during this time (Freedman, Agree, Martin, & Cornman, 2006). Of particular relevance to clinical psychologists, future work that examines the psychological benefits of this kind of assistance in terms of reducing caregiver burnout or improving the quality of life of physically impaired older adults would certainly enhance our knowledge about the total impact of these technological changes.

### Post-traumatic Stress

Post-traumatic stress reactions (i.e., characterized by hyperarousal, avoidance, and reexperiencing symptoms following a negative life event) among older adults have increasingly become a focus of concern over recent years. Indeed, older adults may possess unique risk factors for post-traumatic stress, as the transitions associated with growing older (e.g., bereavement, caregiving, and retirement) combined with cognitive, physical, and functional declines could aggravate the stress related to a traumatic event (Bonwick & Morris, 1996; Schnurr, 1996). In addition, in one of the largest studies of Vietnam veterans, 30% of male veterans met criteria for lifetime post-traumatic stress disorder (PTSD), and 15% met criteria for current PTSD (Kulka et al., 1990). Notably, this cohort of veterans are approaching old age, underscoring the need for more work in the area of PTSD and aging.

The best available evidence suggests that older adults have a 6-month prevalence rate of 0.9% for PTSD. However, it appears that a larger subset of older adults (13.1%) experiences elevated levels of post-traumatic stress that do not necessarily meet all of the criteria for a full PTSD diagnosis, emphasizing the importance of not focusing on diagnostic criteria too narrowly when working with this population (Van Zelst, de Beurs, Beekman, Deeg, & van Dyck, 2003). Although more work is clearly still needed, the existing literature also suggests that PTSD in older adults might manifest differently compared to younger or middle-aged adults. For example, compared to younger male veterans with PTSD, older male veterans with PTSD have been found to be less likely to have a comorbid major depression episode or current substance abuse

diagnosis (Frueh et al., 2004). Furthermore, other research has shown that older adults who experience a traumatic life event during later life tend to experience more avoidance, sleep problems, crying spells, and hyperarousal compared to middle-aged or younger adults who experienced similar traumas (Goenjian, Najarian, Pynoos, & Steinberg, 1994; Hagström, 1995).

Studies like these that point to potential differences in the expression of PTSD among older and younger adults highlight the need for age-appropriate assessment instruments. Several investigations of older adult veterans have demonstrated the reliability and validity of some of the more widely used measures of post-traumatic stress, such as the Clinician-Administered PTSD Scale (Hyer, Summers, Boyd, Litaker, & Boudewyns, 1996), the Mississippi Scale for Combat-Related PTSD (Hyer, Walker, Swanson, & Sperr, 1992), and the Impact of Events Scale (Summers, Hyer, Boyd, & Boudewyns, 1996). However, two of these studies recommended using lower cutoff scores for older veterans (Hyer et al., 1992; Summers et al., 1996). Future studies would do well to further examine the sensitivity and specificity of existing PTSD instruments and consider the usefulness of age-specific measurement as more is learned about the unique presentation of PTSD among older adults.

With regard to treatment, it is sobering to note that, to the best of our knowledge, there have been no randomized controlled intervention studies for the treatment of PTSD among older adults. However, several case studies and single-subject investigations have provided researchers with some promising directions for future studies. In particular, these preliminary reports describe the potential usefulness of a variety of approaches, namely anger management therapy, eye movement desensitization reprocessing (Hyer & Woods, 1998), and life-review techniques (Maercker, 2002), as well as exposure-based treatments (Russo, Hersen, & Van Hasselt, 2001). Nevertheless, randomized controlled trials that test the efficacy of these interventions for the treatment of PTSD in later life are badly needed to establish the relative effectiveness of different treatment approaches with this population.

### Marital and Family Therapy

In many ways, marital and family therapy represents an ideal framework for approaching older adults, in that the family is often the most important social context for these individuals (Qualls, 1999, 2000). Although it is not without its drawbacks (e.g., Qualls,

1996; potentially increasing concerns about stigma and privacy), a family-focused approach makes sense, given that multiple family members of different generations are often impacted by the life transitions faced by an older adult (Doka, 1997; Kriegsman, Penninx, & van Eijk, 1994; Ronch & Crispi, 1997). Indeed, transitions such as illness, disability, or retirement can disrupt traditional family and martial roles, often shifting the balance of responsibility and independence (Qualls, 1993).

In spite of the applicability of such an approach, only 8.9% of marriage and family therapy (MFT) programs have reported incorporating topics relevant to gerontology (Barber & Lyness, 2001). Likewise, as of 1996, only 2.3% of conference sessions and 3.2% of articles in the MFT literature were found to focus on issues specific to aging. This content analysis of the MFT literature also revealed a dearth of empirical studies and theoretical papers related to retirement, widowhood, and sexual dysfunction in later life (Van Amburg, Barber, & Zimmerman, 1996).

Although this disparity in coverage of late-life topics in MFT training programs and scholarly works is likely due to a number of factors, one possible explanation might stem from biases of practitioners about their own self-efficacy in changing such longstanding and ingrained family patterns. In particular, one survey of doctors', nurses', and social workers' attitudes toward family therapy for older adults revealed that, although these professionals were open to the possibility of family therapy with this population, many had concerns about the potential for change in older families (Gilleard, Lieberman, & Peeler, 1992).

Despite these possible concerns, there is growing awareness that enhanced communication and functioning within the family of an older adult can have a reciprocal effect. Notably, it seems that improved relationships positively impact the physical and mental health status of elderly clients dealing with difficult life transitions and, in turn, often also lead to better adjustment of the family as a whole—further supporting the potential utility of family therapy for this population. In particular, one recent study found that higher levels of caregiver burden experienced by a spouse or adult child negatively impacted an older adult's response to antidepressant treatment for geriatric depression (Martire et al., 2008). Other investigations have also shown that a high degree of support from family and friends can have a profound impact on health outcomes and improve adjustment to disability and chronic illness (McIlvane & Reinhardt, 2001; Seeman, 2000).

It appears that the effects of positive relationships within the family work both ways and can also serve to buffer the impact of a difficult late-life transition on the family unit. For example, in their review of the impact of chronic illness on elderly patients' families, Kriegsman and colleagues (1994) found that these medical problems generally had a significant negative impact on both spouses and adult children. However, based on their review of this literature, it was concluded that the most salient factor affecting the health of the family members appeared to be the strength of the patient's marriage and the degree of social support the patient was able to provide to his or her spouse (Kriegsman et al., 1994).

Considering the impact of familial relationships in the context of older adults' medical and mental health problems, future studies would do well to focus on the potential benefits of marital and family therapy for older adults. Given the longstanding relationships within families of older adults, core family therapy strategies and techniques, like genograms, transmission of family histories, and exploration of cyclical patterns of interacting would likely have great relevance for this population (Tisher & Dean, 2000). Theorists and practitioners have also proposed other techniques, such as narrative therapy and expressive arts (Caldwell, 2005), life validation, and life review (Hargrave & Anderson, 1997), as well as solution-focused and behavioral interventions (Bonjean, 1997).

Despite the promise of many of these treatments, the present empirical evidence does not appear to be strong enough to support any of these interventions as an EBT. With regard to randomized clinical trials, several multicomponent caregiver stress interventions have successfully implemented a family therapy module, offering some preliminary support for this approach (Eisdorfer et al., 2003; Mittelman et al., 1995; Schulz et al., 2003). However, more studies are needed to shed light on the unique impact of family therapy and provide information about the relative efficacy of different approaches.

## Conclusion

We believe this is an exciting time to be working in the area of clinical geropsychology. Medical advances and increased knowledge about healthy life practices (e.g., diet, exercise, emotional health) have increased the adult life span and, as a result, older adults are making up an increasingly larger proportion of the worldwide population. As clinical psychologists, we are in a unique position to improve the lives of these individuals, and a wealth of resources is now available

to aid clinicians in conducting empirically based practice with older adults. In this chapter, we relied on the best available evidence to provide both general and specific recommendations for handling a variety of problems often encountered in later life, including depression, anxiety, substance abuse, insomnia, dementia, caregiver stress, and prolonged grief. Although more work is, of course, still needed—particularly in the areas of cultural diversity, technology, post-traumatic stress, and family therapy—we have offered a preliminary roadmap for approaching older adults in a psychotherapeutic context and hopefully have demystified some of the idiosyncrasies of working with this population.

# Working with Sexual-Minority Individuals

Lisa M. Diamond, Molly R. Butterworth, *and* Ritch C. Savin-Williams

**Abstract**

The present chapter provides a review of some of the primary psychological issues confronting sexual minorities (i.e., individuals with same-sex attractions and relationships). Our goal is to provide a flexible set of preliminary questions that can be used to help sexual-minority clients to articulate their own idiosyncratic experiences and give voice to their own unique needs. We begin by addressing two of the most common and important clinical issues faced by sexual minorities: generalized "minority stress" and acceptance and validation from the family of origin. We then turn attention to the vast—and vastly underinvestigated—population of individuals with bisexual attractions and behavior, who actually constitute the majority of the sexual-minority population, despite having been systematically excluded from most prior research. We review the increasing body of research suggesting that individuals with bisexual patterns of attraction and behavior actually face greater mental health risks than those with exclusive same-sex attractions and behavior, and we explore potential processes and mechanisms underlying this phenomenon, focusing particular attention on issues of identity development and transition over the life span. We conclude by outlining a number of areas for future clinically oriented research.

**Key Words:** Bisexuality, identity development, minority stress, sexual orientation, stigmatization

One of the most notable developments in clinical psychology over the past 20 years has been the explosion of attention to the lives of men and women with same-sex attractions and relationships—which we collectively denote *sexual minorities*. After a long history of denigration and stigmatization, during which such individuals were viewed as fundamentally and necessarily maladjusted (for example Krafft-Ebing, 1882; Socarides, 1996), psychologists now generally adopt a balanced and thoughtful approach to these populations, attending to their unique and ordinary strengths, as well as to their unique and ordinary challenges. This has not only improved our basic understanding of the sexual-minority life course, but has also contributed to mainstream research on mental health by highlighting how individuals' private experiences of love and desire, and their resulting sexual self-concepts, profoundly shape their day-to-day and long-term well-being.

Perhaps the single most important recent change in our understanding of sexual-minority populations concerns their size and composition. A decade ago, a chapter such as this would have probably been called "Working with Lesbian and Gay Individuals," and would have focused exclusively on men and women who were exclusively attracted to the same sex and who openly claimed a lesbian or gay identity. These characteristics were presumed prototypical of individuals with same-sex attractions and relationships. Although there were clearly some men and women who identified as bisexual or who rejected sexual identity labels, these individuals were typically considered exceptional and were often suspected to be struggling with confusion, denial, and/or internalized homophobia.

We now know that these assumptions were woefully inaccurate. Studies using random, representative samples have demonstrated that the most common type of individual with same-sex attractions is actually *not* an openly identified lesbian or gay man, but someone who considers himself or herself to be heterosexual *despite* same-sex desires and/or behaviors. The most common type of individual with same-sex attractions actually experiences attractions to *both* sexes and not just the same sex; the most common type of individual with same-sex attractions does *not* report tidy correspondences among his or her desires, fantasies, love relationships, and sexual behaviors, but instead experiences mild to moderate discrepancies among these domains (i.e., desires that are never acted upon; same-sex sexual liaisons in the absence of lesbian-gay-bisexual identification). The most common type of individual with same-sex attractions has *not* been unambiguously certain of these attractions since early childhood, but has experienced discontinuities—sometimes slight, sometimes drastic—between childhood, adolescent, midlife, and late-life experiences of love, desire, fantasy, behavior, and identification.

Unfortunately, psychological research has been slow to match this expanded picture. Practically all scientific knowledge regarding clinical issues facing individuals with same-sex attractions is based on fairly narrow samples of openly identified lesbians and gay men (and historically, far more men than women). Compounding the problem, studies have long underrepresented bisexual, ethic-minority, rural, and working-class individuals. As a result, we face significant obstacles in providing accurate guidelines to clinical psychologists on the needs and experiences of individuals with same-sex attractions and behaviors. Our state of knowledge regarding their needs and experiences is currently being revolutionized as psychologists increasingly come to terms with the startling breadth and diversity of sexual minorities.

How, then, to proceed? We could certainly adhere closely to the published literature on lesbians and gay men, acknowledging its limitations but nonetheless using it as the basis for extrapolation to other sexual minorities. Yet, the usefulness and validity of such a strategy is dubious—now that we realize just how much of the iceberg lies beneath the surface, it is difficult to justify focusing only on the tip. Accordingly, our review proceeds as follows. We begin by providing an overview of sexual-minority populations and two of the most common and important clinical issues they face: generalized

"minority stress," and acceptance and validation from the family of origin. We then turn attention to the vast—and vastly underinvestigated—population of individuals with *bisexual* attractions and behavior, who actually constitute somewhere between 75% and 90% of the sexual-minority population, despite having been systematically excluded from the majority of research on sexual minorities over the past several decades. We address the increasing body of research suggesting that individuals with bisexual patterns of attraction and behavior actually face *greater* mental health risks than those with exclusive same-sex attractions and behavior, and we explore potential processes and mechanisms underlying this phenomenon, focusing particular attention on issues of identity development and transition over the lifespan. We conclude by outlining a number of areas for future research. The goal is to provide clinicians not with a static model of "lesbian-gay-bisexual concerns" but a flexible set of preliminary questions that they can use to help their sexual-minority clients to articulate their own idiosyncratic experiences and give voice to their own unique needs.

## Defining the Population

First, foundational and definitional issues deserve attention. Most notably, what exactly does it mean to talk about sexual minorities? Who is included in this population, and what is the rationale for considering them a distinct subgroup? The term *sexual minority* refers to all men and women with same-sex attractions and/or experiences. It is used here instead of "lesbian-gay-bisexual" because research has resoundingly demonstrated that not all individuals with same-sex attractions and experiences identify as lesbian, gay, or bisexual. In fact, very few of them do. A random, representative survey of American adults found that the number of individuals with same-sex attractions or experiences was more than double the number of individuals who actually identified as lesbian-gay-bisexual (Laumann, Gagnon, Michael, & Michaels, 1994). Similar findings have emerged from surveys conducted in other countries (Wichstrom & Hegna, 2003) and in studies of adolescents (reviewed later). Despite the diversity of these individuals' experiences, one thing they undeniably share is that their same-sex attractions and/or experiences place them squarely outside conventional norms prescribing uniform and universal heterosexuality, potentially exposing them to multiple personal and social ramifications, such as self-stigmatization, denigration by others, harassment or victimization, lack of social support, and lack of public acknowledgment

of their relationships. This is why they are considered sexual *minorities*.

Unfortunately, many of our observations about the experiences of this broad group are hampered by the fact that the majority of psychological research on same-sex sexuality has adopted a much narrower focus, recruiting participants on the basis of their open identification as lesbian or gay. Hence, the inevitable result is that practically everything psychologists currently know about the sexual-minority life course is based on an extremely small and arguably unrepresentative subset of sexual-minority populations as a whole. This, of course, raises the larger question, exactly *why* are the lives of sexual minorities distinctive to begin with? After all, there has certainly been plenty of psychological research conducted during the past 20 years focused on demonstrating just how "normal" (i.e., similar to heterosexuals) sexual minorities are, in a variety of psychological and social domains. Hence, in contrast to historical notions of homosexuals as psychologically sick and therefore fundamentally different from heterosexuals, the trend over the past several decades has been for psychologists to emphasize that lesbian-gay-bisexual individuals are healthy individuals who are actually quite similar to heterosexuals in practically all domains of psychological health and functioning (Kitzinger, 1987).

The key difference, of course, is their desire for and participation in same-sex intimate relationships, despite the widespread cultural condemnation of such relationships. This exposes such individuals to a range of unique psychosocial challenges from early childhood through adulthood, potentially including confusion and self-doubt, denigration and stigmatization from peers, rejection from family members, social stereotyping, employment and housing discrimination, difficulties accessing health care, and outright physical violence. A national survey by the Kaiser Foundation found that three-fourths of lesbian-gay-bisexual adults reported some form of prejudice or discrimination as a result of their sexuality, one-third of gay men and one-half of lesbians reported experiencing rejection by a friend or family member, and one-third said that they had actually suffered violence against them or their property (Kaiser Foundation, 2001, November). Attitudes can be particularly pernicious in rural, suburban, and other more isolated environments. Lynch (1992) found that, compared to sexual minorities living in urban centers with large and visible lesbian-gay-bisexual populations, suburban sexual minorities were more circumspect, more fearful of exposure,

and anticipated more intolerance and discrimination. The same is true for some ethnic communities (reviewed in Greene, 1997, 1998).

Although attitudes toward same-sex marriage have become increasingly positive over the past decade, about half of American adults oppose legal recognition for same-sex marriages (Polling Report. com, 2008). Reflecting this view, in 1996, Congress passed the Defense of Marriage Act, allowing the Federal government to override any state legal recognition of same-sex marriage. Opposition to same-sex marriage is mainstream, endorsed by all major candidates for president in the 2000, 2004, and 2008 elections—although some candidates support non-marriage alternatives, such as civil unions or domestic partnerships. Six months after Massachusetts began issuing marriage licenses to same-sex couples in November 2004, 11 states passed ballot measures denying any formal recognition of same-sex marriages. That trend continued in 2006, when seven more states passed same-sex marriage bans. Currently, 45 states have either a constitutional amendment or a state law restricting marriage to one man and one woman.

## Minority Stress and Mental Health

The end result of the social stigmatization, rejection, and legal disenfranchisement that some sexual minorities face is "minority stress," defined as the unique strain experienced as a result of occupying a socially marginalized category (Meyer, 2003). As comprehensively reviewed by Meyer, the fundamental tenet underlying the conceptualization of minority stress is that individuals learn about themselves and develop their self-concepts partly on the basis of how they are treated and perceived by others (Allport, 1954; Crocker, Major, & Steele, 1998; Goffman, 1963; Pettigrew, 1967). Hence, chronic negative evaluations, at the level of both concrete interpersonal interactions and broad-based cultural norms, have detrimental effects on sexual minorities' self-evaluations and, accordingly, their mental well-being. Meyer (2003) discussed four key mechanisms through which minority stress operates. The first and perhaps most obvious includes objective, external stressors, which may be either chronic or acute. Examples include harassment and victimization (Balsam, Rothblum, & Beauchaine, 2005; D'Augelli, Pilkinton, & Hershberger, 2002), workplace discrimination (Badgett, 1998; Waldo, 1999), the lack of institutional resources such as marriage (Brewer & Wilcox, 2005; Lannutti & Lloyd, 2005; Rothblum, Balsam, & Solomon, 2008), and experiences such

as chronic neglect or rude treatment at restaurants, hotels, and shops (D. A. Jones, 1996; A. S. Walters & Curran, 1996). The second includes *expectations* of such events and hence might include phenomena such as personal discomfort in certain settings, such as family events, where disapproval and poor treatment is expected (Caron & Ulin, 1997; Oswald, 2002). The third includes the internalization of negative social attitudes toward same-sex sexuality, often called "internalized homophobia" (Igartua, Gill, & Montoro, 2003; Meyer & Dean, 1998), and the fourth includes active and vigilant concealment of one's same-sex sexuality in an attempt to avoid external stressors (DiPlacido, 1998; Herek & Capitanio, 1996; McKenna & Bargh, 1998).

Minority stress has been advanced as an explanation for the fact that, on the whole, both adolescents and adults reporting same-sex attractions and/or identifying as lesbian-gay-bisexual tend to show disproportionately high rates of anxiety, depression, suicidality, self-injurious behavior (including eating problems), substance use, and use of mental health services. These findings are based on studies using large, nationally representative populations (Austin et al., 2004; Case et al., 2004; Cochran, Sullivan, & Mays, 2003; Jorm, Korten, Rodgers, Jacomb, & Christensen, 2002; Paul et al., 2002; Ziyadeh et al., 2007), as well as on studies using heterosexual siblings as a comparison group to control for potential confounds of family background and even the heritability of psychological distress (Balsam, Beauchaine, Mickey, & Rothblum, 2005). The notion that minority stress may account for the link between same-sex sexuality and mental health is supported by the fact that studies have found that sexual-minority youth with the highest mental health risks are those who have been exposed to the greatest levels of stigmatization and victimization (Balsam, Rothblum, & Beauchaine, 2005; Bontempo & D'Augelli, 2002; D'Augelli, Grossman, & Starks, 2006; Russell & Joyner, 2001).

These data, however, highlight a critical point: Stigma, discrimination, and minority stress are *not* uniform experiences. Not only do sexual-minority individuals face vastly different exposure to minority stress, depending on their individual family background, social class, geographic environment, etc., but they are also equipped with vastly different coping resources, due to personality characteristics, social support resources, and institutional protections from harassment and discrimination. This helps to explain why some studies have not found significantly greater mental health problems among sexual-minority individuals than among their heterosexual counterparts. Because different studies capture different subgroups of sexual-minority men and women, with different psychosocial risk factors, different degrees of exposure to prejudice and discrimination, different sets of family issues, and different coping mechanisms, such variability in the findings is to be expected (Anderson, 1998; Fitzpatrick, Euton, Jones, & Schmidt, 2005; Konik & Stewart, 2004; Meyer, 2003; Rutter & Soucar, 2002; Savin-Williams, 2001c).

Furthermore, social attitudes toward same-sex sexuality have been gradually changing over the years (reviewed in Loftus, 2001; Savin-Williams, 2005; S. D. Walters, 2001), thus reducing some sexual-minority individuals' exposure to minority stress. For example, the proportion of Americans who think homosexuality is an "acceptable alternative lifestyle" has steadily increased from 34% in the early 1980s to 57% in 2008 (Polling Report.com, 2008). Nearly all Fortune 500 companies include sexual orientation in their nondiscrimination policies, and about half offer same-sex domestic partner benefits to their employees (Graham, 2005; Gunther, 2006; Weinstein, 2007). This pattern of increased acceptance appears to be linked to increased familiarity with sexual-minority individuals in day-to-day life. Approximately four in ten Americans report having a close friend or a family member who is lesbian, gay, or bisexual (Neidorf & Morin, 2007), and those who befriend sexual minorities tend to have more positive perceptions of them. Among adolescents and young adults, attitudes toward sexual minorities are especially positive (Savin-Williams, 2005). For example, two-thirds of high school seniors supported the right of same-sex couples to adopt, and a recent study found that more than three-fourths of high school seniors favored legalized same-sex marriage or civil unions (Broverman, 2006; Buchanan, 2008). Such historically high levels of acceptance can be attributed in part to the growing visibility of same-sex sexuality in the national media. As one cultural observer noted, "During the course of the '90s homosexuality went from being largely invisible to shockingly visible to fairly pedestrian" (Doig, 2007). As a result of such changes, we can expect increased variability in sexual-minority individuals' exposure to minority stress. Although some gay/lesbian/bisexual individuals continue to face unrelenting stigma in their local communities as a result of their same-sex sexuality, others are able to live lives that are relatively free of harassment, shame, and denigration, and may enjoy full support, validation,

and acceptance from friends, family members, and co-workers. Clearly, the task for clinicians is to sensitively attend to the unique constellation of risk and resiliency factors characterizing each of their sexual-minority clients. Critical factors to assess include their overall exposure to the four forms of minority stress outlined earlier *and* to the combination of individual and cultural factors (coping mechanisms, access to social support, cultural norms that permit or forbid open discussion of personal problems, etc.) that moderate their responses to such stressors. This approach will yield more effective clinical interventions than an approach that presumes that an individual's sexual-minority status automatically confers a relatively automatic and uniform degree of psychological strain.

## Sexual-Minority Youth

The same factors that introduce mental health risks for sexual-minority adults—stigmatization, internalized homophobia, victimization, and minority stress—may be particularly problematic for sexual-minority adolescents. Studies documenting the specific effects of these phenomena on sexual-minority youth have been beset by the same methodological problems that have plagued research on adults, namely misspecification of the target population and over-reliance on small, nonrepresentative samples. With respect to specifying the target population, one chronic limitation of previous research has been that investigators often discount same-sex sexuality when it occurs during the adolescent years, presuming that youth who engage in same-sex contact are simply experimenting and will eventually identify as heterosexual. For example, Maccoby (1998, p. 191) asserted that "a substantial number of people experiment with same-sex sexuality at some point in their lives, and a small minority settle into a life-long pattern of homosexuality." Maccoby is certainly correct in that adolescent same-sex contact is not a reliable predictor of future same-sex sexuality, but the problem is that there is no definitive way at the time to differentiate between youth who will "settle into a lifelong pattern" of same-sex sexuality and those who will not. Longitudinal research on adolescent and young adult sexual-minority women (Diamond, 2000b, 2003a, 2005b) has found that factors such as age of first same-sex attractions, age at first sexual questioning, and age of first same-sex contact failed to distinguish women who ended up, by their mid 30s, maintaining lesbian-bisexual versus heterosexual identities. The only significant predictor of future identity was a woman's

initial ratio of same-sex to other-sex attractions, which remained relatively stable over time (Diamond, 2008b). In the absence of such information, *all* same-sex sexuality during the adolescent years deserves careful attention. Even for youth who end up identifying as heterosexual, adolescent expressions of same-sex sexuality might prove to be developmentally significant, and hence have implications for their adjustment and well-being (both positive and negative).

Just how common is adolescent same-sex sexuality? The National Longitudinal Study of Adolescent Health found that 13% of American girls and 6% of American boys reported same-sex attractions, a same-sex relationship, or a nonheterosexual identity (Savin-Williams, 2005). For comparison, Laumann et al.'s (1994) similarly random, representative survey of American adults found that nearly 9% of women and 10% of men reported same-sex attractions or behaviors. Focusing specifically on same-sex behavior, a recent representative survey found that 5% of male teenagers and 11% of female teenagers reported same-sex sexual contact (Mosher et al., 2005). Notably, estimates of adolescent same-sex sexual contact increase dramatically when one restricts the sample to youth who have also pursued heterosexual sexual contact (DuRant, Krowchuk, & Sinal, 1998), demonstrating that most adolescents pursue same-sex contact in addition to—rather than instead of—other sexual contact. Also, youth reporting same-sex attractions or same-sex contact overwhelmingly identify as heterosexual (Garofalo, Wolf, Wissow, Woods, & Goodman, 1999; Mosher, Chandra, & Jones, 2005; Remafedi, Resnick, Blum, & Harris, 1992).

Do youth with same-sex attractions, behaviors, or identities show greater mental health problems than their heterosexual counterparts, similar to the findings regarding sexual-minority adults? The answer is *perhaps*—it depends on which populations are being sampled. Numerous studies have found that sexual-minority youth, lumped together as a unitary unit, often report heightened feelings of stress, loneliness, anxiety, and depression, and heightened use of drugs and alcohol (Consolacion, Russell, & Sue, 2004; French, Story, Remafedi, Resnick, & Blum, 1996; Garofalo et al., 1999; Remafedi, 1999; Remafedi, French, Story, Resnick, & Blum, 1998; Rosario, Schrimshaw, & Hunter, 2004b, 2006; Russell & Consolacion, 2003; Russell, Franz, & Driscoll, 2001; Russell & Seif, 2002; Savin-Williams, 2001c). As with adults, stigmatization and victimization play a critical role in these problems (Balsam, Rothblum et al., 2005; Bontempo & D'Augelli,

2002; D'Augelli et al., 2006; D'Augelli, Pilkington, & Hershberger, 2002; Horn & Nucci, 2006; Mallon, 2001; Rivers & D'Augelli, 2001; Safe Schools Coalition of Washington, 1999; T. Williams, Connolly, Pepler, & Craig, 2003, 2005).

Perhaps the greatest amount of research and popular attention has focused on sexual-minority youths' risks for suicidality. Numerous studies over the past 20 years have provided ample evidence for elevated suicide attempts and suicidal thoughts among lesbian-gay-bisexual-identified youth sampled from community support groups, university groups, Internet respondents, and high schools across the United States (Garofalo et al., 1999; Halpert, 2002; Kulkin, Chauvin, & Percle, 2000; McDaniel, Purcell, & D'Augelli, 2001; Morrison & L'Heureux, 2001; Remafedi et al., 1998; Russell & Joyner, 2001; Saulnier, 1998). This conclusion has been articulated in major clinical, medical, and public health journals, and is based on research with numerous adolescent populations using a variety of research designs and conducted across time and various cultures (Faulkner & Cranston, 1998; Fergusson, Horwood, & Beautrais, 1999; Fergusson, Horwood, Ridder, & Beautrais, 2005; Garofalo, Wolf, Kessel, Palfrey, & DuRant, 1998; Garofalo et al., 1999; Jorm et al., 2002; Pinhey & Millman, 2004; Ploderl & Fartacek, 2005; Remafedi et al., 1998; Russell & Joyner, 2001; Silenzio, Pena, Duberstein, Cerel, & Knox, 2007). The proportion of such youth reporting suicide attempts ranges from slightly elevated upward to 70%, considerably above the attempt rates of youth who do not identify as gay.

## Rethinking Sexual-Minority Youth Suicidality

There are, however, exceptions to this blanket conclusion, and the research on sexual-minority youth suicide actually provides an important cautionary lesson in making inferences about the mental health "consequences" of sexual-minority status. Specifically, a number of empirical studies over the years have failed to find sexual orientation differences in suicide risk between young adult heterosexuals and non-heterosexuals (Eskin, Kaynak-Demir, & Demir, 2005; Fitzpatrick et al., 2005; Jorm et al., 2002; Norlev, Davidsen, Sundaram, & Kjoller, 2005; Robin et al., 2002; Rutter & Soucar, 2002; Savin-Williams, 2001c; Skegg, Nada-Raja, Dickson, Paul, & Williams, 2003; van Heeringen & Vincke, 2000; Whitbeck, Chen, Hoyt, Tyler, & Johnson, 2004; Yoder, Hoyt, & Whitbeck, 1998). In trying to explain these

discrepancies, investigators have focused on the different subpopulations that have been represented in different studies (Muehrer, 1995; Savin-Williams, 2001a). For example, some studies have sampled youth almost exclusively from "nonrepresentative settings such as crisis centers, runaway shelters, or support groups" (Muehrer, 1995, p. 75), which tend to over-represent a specific, help-seeking fraction of the sexual-minority youth population that is most likely to suffer from pronounced physical, psychological, and social problems.

Furthermore, research on sexual-minority youth suicide—like research on sexual minorities more generally—rarely includes individuals with same-sex attractions or experiences who do not identify as lesbian/gay/bisexual. One study that did include these "unidentified" sexual-minority youth found relatively lower rates of suicide attempts during the past year than have been found in other studies: 5% among young men and 11% among young women (Russell & Joyner, 2001). This raises the possibility that elevated rates of suicide attempts may be specifically linked to lesbian-gay-bisexual identification rather than to same-sex sexuality in and of itself. Importantly, the link between identification and increased suicidality could operate in a number of ways. Perhaps for some youth, identification increases their exposure to victimization and harassment; for other youth, being targeted and teased by other kids (perhaps because of gender nonconformity) might prompt them to question their sexuality and identify as lesbian, gay, or bisexual at a relatively early age.

Thus, it is more accurate to conclude that *certain subsets* of sexual-minority youth face increased risks for suicide than to conclude that all sexual-minority adolescents face increased risks. Of course, some might argue that the distinction is functionally irrelevant: What does it matter if the suicide risk applies to only a subset of the sexual-minority youth population? After all, any elevated risk certainly deserves serious attention. The problem, however, is that, in order to intervene effectively with the most troubled youth, clinicians must understand exactly *who* is at greatest risk, and why. Does it have to do with prior adjustment problems? Gender nonconformity? Family strife? The lack of social support? Research has not yet provided definitive answers to these questions. There is, however, sufficient evidence to indicate that certain factors should be treated as "red flags": dysregulated impulse control and a propensity for intense psychological pain (Joiner, Brown, & Wingate, 2005); persistent social stigmatization and victimization; feelings of self-loathing and

rejection by either peers or family (Garofalo et al., 1999; Hershberger, Pilkington, & D'Augelli, 1997; Remafedi et al., 1998); and a history of depression or anxiety, substance use, victimization, impulsivity, delinquency, homelessness, and previous suicide of friends or family members (Brent, 1995, 2001; Joiner et al., 2005; Kisch, Leino, & Silverman, 2005; Miller & Taylor, 2005; Norlev et al., 2005; Silenzio et al., 2007; Weissman et al., 1999; Yip et al., 2004).

It bears noting that one of the inadvertent "downsides" of focusing so much attention on the potential for suicidality among sexual-minority youth is that the large but generally invisible population of well-adjusted sexual-minority youth is routinely ignored in much contemporary research. In trying to identify and help the most troubled youth, we have generally failed to make use of the indispensable information afforded by the "success stories" in this population: What accounts for their resilience? Why do some youth escape a "risk" trajectory while others do not? From a clinical perspective, it is important to remember that many of the most pressing psychosocial problems facing sexual-minority youth have little to do with their sexual identity. Rather, they may be struggling with routine adolescent concerns regarding maturity, schoolwork, relationships with parents, resisting peer pressure, and dating.

Finally, it is important to note that the persistent focus on suicidality risks may become a self-fulfilling prophecy. Sexual-minority youth may come to internalize the widely disseminated image of the long-suffering, suicidal gay adolescent (Savin-Williams, 1990). For example, one youth told an interviewer that he did not believe he was truly gay because he had not yet attempted suicide (Savin-Williams, 1998). Clearly, clinicians need to remain mindful of the potential for suicidality among sexual-minority youth, yet still take full account of each individual youth's particular mix of risk and resiliency, challenges and strengths.

## Family Ties

Another of the most common topics of clinically oriented research on sexual minorities concerns family relationships. It is commonly assumed that sexual minorities are uniformly alienated or ostracized from their families of origin, yet this is not the case. Rather, research has demonstrated incredible diversity in sexual minorities' family ties. These relationships can provide support *or* shame; acceptance *or* rejection, joy *or* distress, comfort *or* alienation.

Perhaps the only generalization that can safely be made is that the family relationships of sexual minorities pose a unique set of challenges for all members. Unfortunately, rigorous empirical research in this area has lagged behind other topics in sexual-minority psychology. For example, although many studies of sexual-minority youth have investigated their ties to parents (reviewed in Crosbie Burnett, Foster, Murray, & Bowen, 1996; Savin-Williams, 2001b), this is less so for studies of sexual-minority adults. This leaves us with an incomplete picture of sexual-minority individuals' socioemotional development, given that immediate and extended family members clearly have powerful influences on one another's opinions, feelings, choices, and well-being across the entire life course, as reviewed later.

### Initial Disclosure

How many sexual minorities are completely open about their sexuality to family members? How long does it typically take for them to come out? Reliable answers to these questions are practically impossible to obtain, and estimates vary dramatically depending on how samples are recruited (Green, 2000). For example, sexual minorities recruited from lesbian-gay-bisexual social activities and organizations tend to report relatively higher rates of family disclosure than do individuals recruited from support groups. Overall, however, studies suggest that about 80% of self-identified lesbian-gay-bisexual individuals have disclosed their sexuality to one or more family member (Kaiser Foundation, 2001, November), with about 60%–77% of respondents reporting that they are "out" to their parents (Bryant & Demian, 1994).

Disclosure of one's sexuality to some family members, but not others, is fairly common (reviewed in Green, 2000). In general, mothers and sisters are told more often—and earlier—than are other family members, largely because they are perceived as being more potentially accepting (reviewed in Savin-Williams, 2001b). Other factors that shape the timing and breadth of sexual minorities' disclosure to family members include the degree of predisclosure intimacy, openness, support, contact, and conflict in these relationships; issues of economic dependence; the family's cultural background and religious values; and overall appraisals of the costs and benefits, for both continued secrecy versus the inevitable disruption brought about by disclosure (Bryant & Demian, 1994; Green, 2000).

Of course, simply revealing one's same-sex sexuality to family members is not the same as establishing an open and honest dialogue about it. Surveys indicate

that even among lesbian-gay-bisexual individuals who are "out" to their parents, many do not discuss the issue directly (Kaiser Foundation, 2001). In some cases, parents may know and quietly tolerate the situation (Brown, 1989; D'Augelli, Grossman, & Starks, 2005; Herdt & Beeler, 1998), and yet make their disapproval subtly known, for example by refusing to acknowledge or validate the sexual-minority individual's romantic relationships. Much remains unknown about the long-term process through which families—and particularly parents—gradually progress from initial disapproval of a family member's same-sex sexuality to increasing acceptance and tolerance, and how issues of disclosure and openness are managed over time in the course of ongoing day-to-day interactions. The dynamics introduced by selective disclosure also warrant greater attention. When sexual minorities choose to reveal their sexuality to some family members, but not others, they inadvertently create "ingroups" and "outgroups" within the family who maintain starkly different perceptions and expectations of the sexual-minority family member (Crosbie Burnett et al., 1996). Over time, these differences may hinder family cohesion.

### Is Openness Beneficial?

Some families never accept a family member's same-sex sexuality, which raises an important question: *Why disclose at all*? It is easy to assume that openness is preferable to secrecy, and that sexual minorities who choose never to share their identity, their community, and their romantic lives with family members are less well-adjusted and less psychologically connected to family members.

Yet, researchers have increasingly called this assumption into question (Green, 2000; Green & Mitchell, 2002; Laird, 2003; LaSala, 2000b). It is certainly true that many sexual-minority individuals derive distinct benefits from being open about their sexuality with family members, including increased intimacy and communication, heightened connectedness and support, and feelings of validation and legitimacy of one's identity and relationships (Herdt & Beeler, 1998; LaSala, 2000a, 2000b; Weston, 1991).

However, these effects are largely dependent on the type of family relationships that existed prior to the disclosure. If a sexual-minority individual has a history of conflict and poor communication with family members and anticipates that they will sharply disapprove of his or her same-sex sexuality, then secrecy might make more sense than disclosure

(Green & Mitchell, 2002). In such cases, secrecy might actually prove psychologically adaptive because it allows the individual to protect and cherish his or her own personal truth and integrity (Laird, 1993, 1998; Ponse, 1978). Hence, instead of uniformly encouraging full disclosure, it may be preferable for friends, activists, and clinicians to encourage sexual-minority individuals to carefully evaluate their goals and expectations regarding disclosure and to realistically assess whether—given their own particular family dynamics—these expectations are likely to be met (Green, 2000).

Issues of disclosure also take on a different meaning for sexual minorities at later stages of the life course. As Herdt and Beeler (1998) indicated, when young adults disclose their same-sex sexuality to parents and other family members, family reactions often revolve around thoughts of the future, sometimes involving grieving for lost expectations and fantasies, as well as fears about their loved one's risk for harassment and victimization. Yet, when the family member making the disclosure is in his or her 50s or early 60s, many of these concerns about the future are largely moot. The sexual-minority family member has already traversed major milestones involving career, intimate relationships, and, potentially, even children. Hence, disclosure to family members raises more issues about the past than the future. Family members may have to substantially revise and reconsider their narratives of family history (Beeler & DiProva, 1999). Was *everything* involving this person a fabrication? What else might be unknown—not only about this particular individual, but all other family members? How can something so important go unnoticed? As Herdt and Beeler (1998) pointed out, reckoning with and undoing decades of duplicity may prove to be a more pressing issue in such cases than wrestling with the fact of same-sex sexuality itself.

### Unique Issues for Ethnic-Minority Families

Culture and ethnicity play important roles in structuring sexual minorities' family-of-origin relationships. As noted earlier, reliable estimates are difficult to obtain, but extant research suggests that ethnic minorities are often less likely to disclose their sexuality to family members, largely because they expect more negative responses (reviewed in Green, 2000). Same-sex sexuality obviously has drastically different meanings in different cultures (Blackwood, 2000; Murray, 2000; W. L. Williams, 1998), and families with highly traditional or religious backgrounds might have more negative conceptions of same-sex

sexuality—or less knowledge about it altogether—than more mainstream Western families (Chan, 1992; Collins, 1990; Espin, 1984; Greene, 1998; Hidalgo, 1984; Icard, 1986; Morales, 1992). For example, some languages do not have positive or neutral terms for "lesbian," "gay," or "bisexual" (Espin, 1997).

Importantly, the nature, parameters, and underlying reasons for the stigmatization of same-sex sexuality vary considerably across different ethnic groups, and these differences have correspondingly distinct implications for sexual-minority individuals' experiences, both in terms of initial decisions to disclose and also with respect to long-term adjustment. For example, Latino, African American, Asian-Pacific Islander, and South Asian communities typically place considerable emphasis on family ties, and same-sex sexuality is often construed as a violation and betrayal of familial cohesion and loyalty (Amaro, 1978; Chan, 1992; Espin, 1984, 1987; Hidalgo, 1984; Jayakar, 1994; Smith, 1997; Tremble, Schneider, & Appathurai, 1989; Vasquez, 1979; Wooden, Kawasaki, & Mayeda, 1983).

In addition, many South Asian families continue to arrange their children's marriages (Jayakar, 1994), and the social ties created by these marriages may have important implications for the family's integration into other social networks. Men and women whose same-sex sexuality leads them to withdraw from this tradition may be viewed by their parents as making a selfish choice that impacts negatively upon the family's entire social system. Within African American communities, same-sex sexuality is often associated with longstanding cultural stereotypes of African Americans as hypersexual and morally bankrupt (Clarke, 1983; Collins, 1990; Greene, 1986; Icard, 1986). Thus, sexual minorities often feel pressured to hide their same-sex sexuality in order present an image of normalcy to larger Anglo society and contradict these racist stereotypes (Clarke, 1983; De Monteflores, 1986; Gomez & Smith, 1990; Mays & Cochran, 1988).

For these reasons, ethnic-minority men and women may express their sexuality in distinctive ways that run counter to common conceptions of "the lesbian-gay-bisexual experience." For example, some ethnic-minority men might pursue exclusively sexual same-sex behavior with strangers to avoid identifying as gay, and maintain their most important romantic ties to women (Carballo-Dieguez, 1989; Carballo-Dieguez & Dolezal, 1994; Vasquez, 1979). Others might identify as lesbian or gay and regularly pursue same-sex behavior, but might resist larger participation in gay culture, choosing to

emphasize the cultural component of their identity in order to maintain their strong cultural and family ties (Icard, 1986; Mays & Cochran, 1988; Mays, Cochran, & Rhue, 1993). These factors must be carefully considered by researchers investigating how sexual minorities from different ethnic groups manage their sexual-minority identity in the context of broader family and community ties.

### *From the Family's Point of View*

In considering how sexual minorities maintain functioning relationships with their families of origin, it is important not to lose sight of the fact that adjustment to a family member's disclosure of same-sex sexuality may be experienced quite differently from the family's point of view than from the point of view of the sexual-minority individual. Overall, there has been far more research from the latter than the former perspective (Crosbie Burnett et al., 1996). Yet, we know from the small amount of qualitative, clinically oriented accounts available (Beeler & DiProva, 1999; Griffin, Wirth, & Wirth, 1986; C. Jones, 1978; Oswald, 2000; Strommen, 1989; Walsh, 2003) that many of the psychological hurdles faced by sexual minorities—feelings of invisibility, fears of marginalization and social stigmatization, uncertainty and confusion about the future, and feelings of loss for the old, ostensibly "normal" self—are shared by their parents, siblings, aunts, uncles, and grandparents. Family members also face many of the same practical decisions: Should they hide this information from colleagues? Can anyone "tell?" Which friends of the family are likely to be supportive, and which are likely to be judgmental and rejecting? Will people think that it is the family's "fault" and that they somehow provided a dysfunctional childhood environment that "caused" this to happen? It is also not uncommon for some family members—especially siblings—to question their *own* sexuality. Especially given the public visibility of scientific findings about the potential genetic underpinnings of same-sex sexuality, it is perhaps natural for siblings and even parents to wonder if they are carrying the much-touted "gay gene," and what that might mean for them.

Overall, then, one way to summarize these issues is to note that such families face an extended period of vulnerability during which they gradually reconstruct a new sense of themselves as a unit and during which they must revise their own individual relationships with the sexual-minority family member (Beeler & DiProva, 1999; Walsh, 2003). This vulnerability, as noted earlier, need not be interpreted

as necessarily dramatic or negative. Some families experience these transitions as positive events that bring them together, whereas others wrestle with significant feelings of anger, resentment, and betrayal (Crosbie Burnett et al., 1996; Savin-Williams, 2001b; Strommen, 1989). Perhaps the only reliable predictions that can be made are that families with high-quality ties before the disclosure, characterized by mutual intimacy, support, cohesion, and warmth, generally fare better (Patterson, 2000; Savin-Williams, 2001b), and that the family's adjustment must be considered in light of contextual factors such as their local community, their values, religious background, economic status, and cultural beliefs (Crosbie Burnett et al., 1996; Rostosky et al., 2004; Savin-Williams, 2001b; Strommen, 1989).

## Stepping Back: Whose Experiences Are We Missing?

As the foregoing review attests, both adolescents and adults with same-sex attractions and behaviors face a number of psychosocial challenges stemming from their minority status with respect to the culture at large. Yet, moving from this broad-based view to a more specific, process-oriented strategy for addressing the clinical needs of this population is exceedingly difficult because our present knowledge—improved as it may be compared to a decade ago—remains incomplete. Quite simply, nearly all extant research on the well-being of sexual minorities under-represents the largest subset of sexual minorities—those with same-sex *and* other-sex attractions and behavior. Some of these individuals may identify as bisexual, others as "mostly heterosexual," and still others may attach no label to their sexuality whatsoever (Diamond, 2008b). All of these individuals are overlooked when researchers specifically recruit only lesbian- and gay-identified participants.

With respect to individuals who actually identify as bisexual, some researchers have deleted such respondents from their research samples on the basis that it was impossible to know whether they were "actually" confused heterosexuals versus closeted lesbian-gay individuals (reviewed in Rust, 2000d). Even researchers willing to study bisexual individuals have faced definitional problems. If one broadly conceives of bisexuality as a pattern of erotic responsiveness to both sexes (Rust, 2002), then just how *much* erotic responsiveness to each sex is necessary to qualify one as bisexual rather than either heterosexual or lesbian-gay? One attraction? Several fantasies? What about individuals who claim that they do

not currently experience attractions to both sexes but have so in the past, or expect that they might have the potential to do so in the future?

Rather than wrestling directly with these questions, researchers have tended to take the easy route of simply excluding bisexuals or, more frequently, lumping them with gays and lesbians. The end result is a literature on sexual minorities that implicitly posits lesbian and gay experiences as prototypical. For example, between 1975 and 1985, only 3% of the journal articles published on same-sex sexuality specifically included the word "bisexual" or "bisexuality" in the title, abstract, or subject headings. Between 1985 and 1995, this figure increased to 16%, reflecting the emerging acknowledgment of bisexuality as a legitimate sexual identity. In the past 10 years, however, that percentage has climbed only 3 more percentage points, demonstrating that the empirical under-representation of bisexuality persists (with some notable exceptions, such as Firestein, 1996, 2007; Paul, 1985, 1996; Rust, 1992, 1993, 2000c).

The implications of this systematic omission would not be so dire if bisexuals constituted only a small subgroup of sexual minorities, but this is not the case, as a number of representative studies have demonstrated (Bailey, Dunne, & Martin, 2000; Garofalo et al., 1999; Kirk, Bailey, Dunne, & Martin, 2000; Laumann et al., 1994; Mosher et al., 2005; Remafedi et al., 1992; Savin-Williams & Ream, 2006). Not only do bisexuals constitute a rather large group, but they are in fact the largest subset of individuals with same-sex attractions and experiences. For example, Laumann's research team (1994) found that approximately 4% of American men and 4% of American women described themselves as attracted to both men and women, whereas only 2.4% of men and .3% of women described themselves as exclusively attracted to the same sex. Another large-scale representative study of American adults (Mosher et al., 2005), conducted more than a decade later, found that 5.6% of American men and nearly 13% of American women were attracted to both sexes, whereas only 1.5% of men and .8% of women were exclusively attracted to the same sex. Similar results have been found internationally. Analyses of the self-reported sexual attractions of 3,000 twins in the Australian Twin Registry (Bailey et al., 2000) found that 8% of men and women reported same-sex attractions and, of these individuals, 75% of men and over 90% of women also reported experiencing other-sex attractions. A random representative sample of New Zealanders (Dickson,

Paul, & Herbison, 2003) found that approximately 6.8% of men and 18% of women reported some degree of attraction to the same sex, but only 1.2% of men and .8% of women were exclusively attracted to the same sex. Hence, directly contrary to the conventional wisdom that lesbian and gay men and women represent the prototypical "types" of sexual minorities and that bisexuals are unusual exceptions, the data clearly show that bisexuals are the prototypical sexual minorities, and lesbian-gay individuals represent the exceptions.

The specific distribution of attractions to both sexes also warrants attention. In every large-scale representative study, the single largest group of individuals with same-sex attractions are predominantly—but not exclusively—attracted to the other sex. We might think of these individuals as "Kinsey 1's" or the "mostly heterosexuals." On the Kinsey scale, zero represents exclusive heterosexuality and 6 represents exclusive same-sex sexuality. What is particularly interesting about this finding—and its consistency across different studies conducted in different countries—is that this group of "mostly-heterosexual" men and women has historically been treated with the *most* skepticism and denigration from scientists and laypeople alike. When it comes time to eliminate questionable cases from research samples, Kinsey 1's are the first to go (e.g., Bos, Sandfort, de Bruyn, & Hakvoort, 2008; Rahman & Hull, 2005; Tiggemann, Martins, & Kirkbride, 2007). Most researchers would not consider them sexual minorities at all. Yet, this has the unintended result of eliminating the vast majority of individuals with some degree of same-sex sexuality. Our failure to examine their experiences has important implications, as recent research suggests that they may vary in several key outcomes from heterosexuals *and* from gays/lesbian individuals (Austin et al., 2004; Busseri, Willoughby, Chalmers, & Bogaert, 2008; Busseri, Willoughby, Chalmers, & Bogaert, 2006; Diamond, 2008b; Ellis, Robb, & Burke, 2005; Thompson & Morgan, 2008). For example, in terms of commitment to a sexual identity, "mostly heterosexual" women have been found to be more likely to explore their sexual identity than are heterosexual women (Thompson & Morgan, 2008), manifested through their increased interest in same-sex romantic and sexual relationships and their openness in the future to these endeavors. Thompson and Morgan argued that these were not women on their way to "becoming something else"; rather, they occupied a behaviorally unique space and did not aspire to being heterosexual, bisexual, or lesbian.

In other domains, the research findings are conflicting, underscoring the need for future research. For example, some studies find that "mostly heterosexual" individuals score higher than all other groups on mental health problems (Austin et al., 2004), whereas other studies find that they score lower, or show no significant differences (Austin et al., 2004; Busseri et al., 2008; Busseri et al., 2006).

The underinvestigation of bisexual, "nonidentified," and "mostly-heterosexual" youth has begun to change in recent years. Investigators have increasingly adopted broader inclusion criteria for studying sexual minorities and have attempted to understand the unique experiences of men and women with attractions to both sexes (Dickson et al., 2003; Hoburg, Konik, Williams, & Crawford, 2004; Kinnish, Strassberg, & Turner, 2005; Savin-Williams, 2005). One troubling result of these efforts has been a growing number of studies suggesting that individuals with bisexual patterns of attraction and behavior may actually have *higher* mental and physical health risks than lesbian, gay, mostly heterosexual, or heterosexual individuals (Marla Eisenberg & Wechsler, 2003; Galliher, Rostosky, & Hughes, 2004; Jorm et al., 2002; Moon, Fornili, & O'Briant, 2007; Robin et al., 2002; Russell, Seif, & Truong, 2001; Udry & Chantala, 2002). The mechanisms underlying these greater risks have not been specified, although extant findings support the possibility that bisexual individuals simply face more extreme and prolonged versions of the stressors that are common to all sexual minorities, due to the invisibility and stigmatization of bisexuality and the lack of social support resources targeted specifically to bisexuals.

Hence, in the next section, we focus specifically on what is currently known about the mental health of bisexual men and women. Following the practice of most studies reviewed, we use the descriptor "bisexual" to describe individuals who report sexual attractions and/or behavior with both men and women, regardless of whether they openly identify as bisexual. We take a broader review of the collected findings, adopting a process-oriented approach to discern reasons as to why bisexual individuals face distinct risks and what their experiences can tell us about the clinical concerns of sexual minorities more generally.

## Anxiety, Depression, and Generalized Mental Health

Comparing bisexuals to other sexual identity groups on anxiety, depression, or general mental health, bisexuals typically score significantly worse (Jorm

et al., 2002; Rothblum & Factor, 2001; Savin-Williams & Joyner, 2007) than gay men and lesbians, who may or may not score significantly worse than heterosexuals. Some studies find no statistically significant differences between groups, but nonetheless report that bisexuals typically have the most elevated scores on these measures (Balsam, Beauchaine et al., 2005; Tjepkma, 2008). For example, in a representative sample of Canadian adults, including hundreds of self-identified bisexual men and women, Tejpkema (2008) found that, in comparison with heterosexuals, all four sexual-minority groups (bisexual men, gay men, bisexual women, lesbians) reported significantly more mood and anxiety disorders. Although they did not specifically compare bisexuals to lesbians and gay men, the data clearly indicate higher rates among both male and female bisexuals, especially bisexual women. For example, 25% of bisexual women reported being diagnosed with a mood disorder, compared with 11% of lesbian women and 8% of heterosexual women. Similarly, in a nationally representative sample of youth, Udry and Chantala (2002) found that girls who had both male and female sexual partners were more than twice as likely to be depressed as were those who had exclusively male partners; boys with both male and female partners were also at significantly greater risk. In contrast, girls and boys with exclusively same-sex partners were not at increased risk. Thus, with few exceptions (Sandfort, Bakker, Schellevis, & Vanwesenbeeck, 2006), bisexual women are consistently found to be at greater risk than women with exclusively same-sex or exclusively other-sex attractions and behavior; among males, the only difference is that, in some studies, males with exclusively same-sex attractions and behaviors have mental health risks equal to or greater than those of bisexual men.

## Substance Use

Consistent with findings for anxiety and depression, studies directly comparing bisexuals with heterosexuals and with lesbians and gay men have generally found that bisexuals report significantly greater use of alcohol and drugs, although findings are often moderated by age of the sample. Among adolescents, those with both same-sex and other-sex sexual partners consistently report greater use of alcohol and illegal drugs than do adolescents with exclusively other-sex partners (Robin et al., 2002; Udry & Chantala, 2002), and they are also at greater risk for binge drinking (Robin et al., 2002). In large population-based studies of high school students

conducted by Robin and colleagues (2002), approximately 45% of bisexually behaving adolescents had tried cocaine, compared with approximately 20% of youth with same-sex partners and approximately 13% of youth with other-sex partners. Similar findings have emerged from studies using convenience samples of youth recruited from sexual-minority youth centers. One recent study found that bisexually behaving youth were significantly more likely to be current smokers and to report having currently or previously used hard alcohol, marijuana, crack, and heroin (Moon et al., 2007).

Among adults, findings have been more mixed. Jorm and colleagues (2002) found that self-identified bisexuals had the highest rates of alcohol use, followed by gay and lesbian individuals. Consistent with this, the Dutch population-based survey conducted by Sandfort and colleagues (2006) found that bisexually attracted adults were more likely than heterosexuals to have ever used marijuana or hashish, although they did not differ regarding alcohol or hard drugs. As with the research on anxiety and depression, there is some evidence for sex differences, with bisexual women demonstrating increased risk more consistently than bisexual men. For example, in a study using a national random sample of college students on 119 college campuses, Eisenberg and Wechsler (2003) reported that bisexually behaving women were approximately twice as likely to smoke, binge drink, and use marijuana in comparison to women with exclusively other-sex partners. Yet, bisexually behaving men were actually less likely to binge drink than were men with exclusively other-sex partners, similar to other findings regarding alcohol and drug use among bisexual versus gay men (Warner et al., 2004).

## Suicidality

Bisexual individuals frequently have the highest rates of suicidal ideation and suicide attempts when compared to heterosexuals and to men and women with exclusively same-sex patterns of attraction and behavior, both during adolescence and adulthood (Jorm et al., 2002; Ploderl & Fartacek, 2005; Robin et al., 2002; Savin-Williams & Joyner, 2007). For example, in Robin et al.'s population-based study, approximately 45% of youth with both male and female sexual partners reported suicide attempts, compared to approximately 17% of those with exclusively same-sex partners and 12% of those with exclusively other-sex partners. Moon et al.'s (2007) study of youth center participants found that bisexually behaving adolescents were more than four

times as likely to have attempted suicide than were lesbian and gay youth, and bisexual youth were less likely to endorse the statement, "I am a good person worthy of being alive" (Moon et al., 2007). Again, however, findings are moderated by sex differences, with bisexual females showing particularly high risk, reporting, in some cases, twice as many suicidal thoughts as heterosexual girls (Udry & Chantala, 2002), and exclusively gay young men showing risks that are sometimes equal to and sometimes greater than young bisexual men.

## Making Sense of the Findings: Sexual-Minority "Subtypes?"

Taken together, findings have been so striking that it is somewhat surprising that there has not been more open and explicit discussion of the potential mechanisms underlying the apparent risks associated with bisexuality. Some scholars have interpreted these findings to suggest that bisexuals, particularly youth, are disproportionately likely to engage in a wide range of risk-taking behavior and that their pursuit of sexual behavior with both male and female partners reflects a generalized tendency toward experimentation and risk-taking (Moon et al., 2007; Robin et al., 2002). This interpretation is consistent with Eisenberg's (2001) data that women with both same-sex and other-sex sexual partners were disproportionately likely to report having multiple sexual partners in the past 30 days. Although this at first appears to confirm the negative stereotype of bisexuals as sexually unrestrained, it is important to remember that Eisenberg's study—as is the case with many others—operationally defined the "bisexual" category so that it only included individuals who had pursued recent sexual contact with *both* male and female partners. Bisexually attracted individuals who had no recent sexual partners, or only one sexual partner, were not considered "bisexual." Hence, in such cases, bisexuality is confounded with having multiple sexual partners. Such sampling considerations must be carefully considered when interpreting all aforementioned findings.

Another common explanation offered for the mental health risks associated with bisexuality is that men and women with bisexual patterns of attraction and behavior are generally mired in the process of transitioning from a heterosexual to a gay or lesbian identity, and that the attendant confusion and ambiguity accounts for their greater mental health problems. Certainly, some bisexual individuals, particularly youth, report confusion and self-doubt about their identities (Hillier, Dempsey, Harrison,

Beale, & Matthews, 1998), describing reasons for bisexual identification such as, "Confused because I'm in love with my best friend, but I've only had sex with boys," "How do I explain the fact that I just got drunk and kissed a boy/girl at a party?," and "What if it's only this girl/boy and not any others?" However, Hillier and colleagues also noted that many bisexually identified youth "were quite comfortably assuming this label, did not appear at all confused, and described supportive and progressive family and friendship networks" (p. 29). Among adults, some studies have found greater identity confusion among bisexuals than among lesbians and gay men, but associations between identity confusion and mental health typically disappear after controlling for "outness" and connection to lesbian-gay-bisexual communities (Balsam & Mohr, 2007). Hence, in these cases, it is not "identity confusion" that places bisexuals at greater risk but the fact that bisexuals who are doubtful about their sexual identity tend to be more secretive and to have less access to social support. It also bears emphasizing that the global characterization of bisexuals as "in transition" or "confused" is increasingly dubious, especially as the phenomenon of bisexuality gains greater cultural legitimacy and visibility as a distinct sexual-minority identity unto itself (reviewed in Diamond, 2008a; Rust, 2000e). Certainly, some bisexuals have been observed to transition to gay or lesbian identity labels (Kinnish et al., 2005; Rosario et al., 1996; Rosario, Schrimshaw, Hunter, & Braun, 2006), and often report improved psychological health thereafter (Paul et al., 2002; Stokes, Damon, & McKirnan, 1997). Yet, recent long-term longitudinal research suggests that, over long stretches of time, sexual-minority women are actually more likely to switch to bisexual from lesbian labels than vice versa (Diamond, 2008b).

A third possible explanation for the greater mental health risks reported by bisexuals centers on the aforementioned minority stress model (Herek, 2007; Meyer, 2003), which maintains that bisexual men and women are more detrimentally affected by chronic and acute stressors associated with their sexual-minority status than are gays and lesbians. Is there evidence to suggest that this is the case? Some research suggests that there is. Bisexuals not only face many of the same forms of stigma and discrimination as do gay and lesbian individuals, but they are often subjected to additional prejudice—specifically targeted to bisexuals—from both the heterosexual and gay-lesbian communities (Hillier et al., 1998; Morris & Rothblum, 1999). This additional

stigma, commonly denoted *biphobia,* may contribute to the elevated mental health problems observed in bisexual individuals. Indeed, Herek (2002) found that bisexuals elicited more negative responses from heterosexual individuals than *any other minority group*, with the exception of injecting drug users. Other surveys have found that bisexuals are significantly more likely than gay and lesbian individuals to be judged "unacceptable" (Eliason, 1997), and are perceived as being likely to cheat on their relationship partners, potentially infecting them with sexually transmitted infections as a result (Spalding & Peplau, 1997).

A particular form of minority stress unique to bisexuality is the fact that many individuals—scientists and laypeople alike—believe that bisexuality does not really exist (Ochs, 1996; Rieger, Bailey, & Chivers, 2005; Rust, 2002). As a result, many bisexual individuals lack support and validation not only from the mainstream heterosexual community, but also from the lesbian-gay community. Even in purportedly inclusive sexual-minority groups and organizations, bisexuals may be distinctly excluded. Similarly, sexual-minority youth with bisexual patterns of attraction and behavior often report feeling isolated within gay and lesbian communities (Ault, 1996; Ochs, 1996), noting that their sexual-minority peers think they are just going through a phase, or a temporary state of confusion or denial (Hillier et al., 1998). For youth who find their identities invalidated by sexual-minority peers, forming connections with such peers may not provide the same psychological benefits that have been observed among conventionally identified lesbian and gay youth. For example, one young bisexual woman noted that, after joining a gay and lesbian support group, she was criticized for not being a "real lesbian," and therefore failed to find the support and acceptance that she was seeking (Hillier et al., 1998). Rothblum and Factor (2001) suggested that because bisexuals are often denigrated by both heterosexuals and gay and lesbian individuals, they end up being "doubly oppressed," and as a result may be more likely to remain closeted and to feel disconnected from lesbian and gay communities (Balsam & Mohr, 2007). Prolonged secrecy and isolation among bisexual individuals may keep them from accessing forms of social support and solidarity that have been observed to buffer sexual-minority individuals from the negative effects of minority stress (Lewis, Derlega, Griffin, & Krowinski, 2003; Luhtanen, 2003). The end result is that bisexual individuals have fewer opportunities and resources for replacing negative

and stigmatizing self-concepts with positive affirmations of their sexual selfhood (Morris, Waldo, & Rothblum, 2001).

## Bisexual Subtypes?

Given the diverse mechanisms that may account for various mental health risks facing bisexual individuals, one potential interpretation of the extant data is that there is no global "type" of bisexual individual who faces heightened psychosocial challenges, but rather a number of different "subtypes" of bisexual men and women who face either greater or lesser risks, and that the key to understanding a particular bisexual individual's mental health status is to figure out the subtype to which he or she belongs.

For example, it bears noting that, in contrast to the relatively dire portrait painted by some of the large-scale studies comparing bisexual to lesbian, gay, and heterosexual individuals, some studies have found that there are undoubtedly many bisexual men and women who proudly embrace their enduring patterns of attraction to both sexes and take steps to affiliate with other bisexuals and bolster their social support (Firestein, 2007). These are arguably the "healthiest" bisexual individuals possible, and they stand in sharp contrast to bisexual men and women who may "actually" be gay or lesbian but are identifying as bisexual as an irrational defense against acknowledging their same-sex sexuality to themselves and others (Paul et al., 2002; Stokes et al., 1997). Presumably, such individuals should be at risk for higher levels of self-loathing, have little access to social support, and be persistently fearful of victimization and stigmatization. One might further imagine that there is a group of bisexuals who are most accurately described as "curious heterosexuals," dabbling in bisexual attractions or relationships because it has become relatively "cool" in the current cultural context (Diamond, 2005a; Hegna & Larsen, 2007).

The notion of "subtypes" is a tempting one. After all, psychologists have long gravitated toward categorizing sexual-minority individuals with respect to their specific degrees of same-sex and other-sex attractions and behavior, the triggers and contexts for these attractions and behaviors, expressions of masculinity versus femininity, and preferences for social contact with men versus women (Blumstein & Schwartz, 1977; Klein, 1993; MacDonald, 1981; Stokes, Miller, & Mundhenk, 1998; Taywaditep & Stokes, 1998; Weinberg, Williams, & Pryor, 1994). Importantly, there is no empirical evidence that such sexual-minority types *actually exist*—they are

fundamentally human creations, born of our own attempts to impart order and coherence on a vast and complex phenomenon. On one hand, subtypes might prove to be useful heuristics, assisting clinicians in quickly grasping a client's key issues. An individual who reports only one instance of "experimental" same-sex behavior obviously does not face the same risks of social stigmatization as an individual with a long-term pattern of bisexual behavior. On the other hand, such heuristics risk drawing attention away from a particular client's unique and fundamentally individual concerns and risks reifying distinctions that end up doing more harm than good.

In particular, typologies that distinguish between presumably enduring versus transient forms of bisexuality are problematic, as they set up an implied hierarchy of authenticity that deems some individuals' same-sex sexuality more legitimate than others. Such hierarchies have a long history in the psychological literature. Researchers have historically contrasted "constitutional" same-sex sexuality, attributed to an intrinsic predisposition for the same sex, with "facultative" or "opportunistic" same-sex sexuality, attributed to reduced opportunities for other-sex contact or prolonged sex-segregation (Bell, Weinberg, & Hammersmith, 1981; Klein, 1993; Money, 1988; Rust, 2000a; Zinik, 1985). Individuals with "constitutional" same-sex sexuality have been expected to periodically seek same-sex partners even when other-sex partners are available, whereas those with "facultative" same-sex sexuality are expected to seek same-sex partners only when other-sex partners are unavailable. An example of facultative same-sex sexuality might be adolescent boys at same-sex boarding schools, who have been found to engage in more same-sex behavior than those at mixed-sex schools, but to return to other-sex behavior on leaving such environments (Wellings, Field, Johnson, & Wadsworth, 1994). The same phenomenon at all-female colleges has been jokingly called "LUG," or "lesbian until graduation" (Davis, 1999; Kyrakanos, 1998; Rimer, 1993).

Are such distinctions meaningful? It depends on their use. Certainly, the clinical issues facing individuals who have consistently pursued bisexual behavior from adolescence through adulthood are different from the clinical issues facing individuals whose expression of same-sex sexuality is more dependent on situational factors. Yet, the problem with sorting sexual minorities into "constitutional/ facultative" categories or other, similar, categories, such as "born/primary lesbians" versus "elective/political lesbians" (Golden, 1996), is that such distinctions,

once invoked, tend to take on a life of their own. They also presume that we understand much more about the etiology of different expressions of same-sex sexuality than is actually the case. For example, despite the widespread assumption that self-identified lesbians with stable and enduring patterns of same-sex sexuality probably express those attractions at an early age (theoretically reflecting the essential, "constitutional" origin of those attractions), whereas bisexuals with more variable, situationally based expressions of same-sex sexuality probably express their attractions much later, this does not appear to be the case (Diamond, 1998, 2005b). Hence, invoking such distinctions in the absence of solid data regarding the factors that do and do not differentiate between diverse experiences and expressions of same-sex sexuality may be more misleading than helpful.

In the end, researchers have come to view all same-sex and other-sex behavior as governed by varying degrees of constitutional and situational components (Kirkpatrick, 2000, p. 390). Instead of implicitly dismissing any individual's same-sex sexuality as "transient" or "opportunistic" on the basis of certain surface features such as its duration, its age of onset, or its situational context, we should focus on asking relevant questions about the ways in which *all* individuals' sexual desires, motives, and self-concepts have unfolded in diverse ways, across diverse contexts, and according to diverse timetables, and should probe the implications of such variability for current and future behavior, self-concept, and well-being.

### Taking a Process-oriented Approach

For this reason, it is preferable to parse the complex phenomenon of same-sex sexuality, especially bisexuality, in terms of underlying processes and mechanisms that shape individual experience and adjustment, rather than shoehorning individuals into predefined categories. This approach guards against reifying inaccurate typologies, highlights important sources of diversity within sexual-minority populations, and prevents exaggerating differences between heterosexuals and sexual minorities. This last point is particularly important from a clinical perspective. Historically, when researchers describe distinctive or salient characteristics of sexual minorities, the implicit presumption is that such characteristics are attributable to their sexual-minority status. In other words, despite the voluminous psychological literature detailing hundreds of individual difference dimensions that moderate social, sexual, emotional,

cognitive, and moral development, researchers frequently frame investigations of sexual-minority men and women as studies of "the impact of sexual orientation" or "the consequence of a stigmatized sexual identity" without testing or even questioning whether something other than the individual's same-sex sexuality might be responsible for the phenomenon of interest.

The critical point is that clinicians should not presume that sexual-minority status is the most important influence on a client's well-being, simply because it might be the most salient and distinctive. Even when sexual-minority status *is* a critical issue for an individual's mental health, clinicians must remain mindful of the many different processes and mechanisms through which it potentially exerts its effects. For one person, sexual-minority status might prove significant because it introduces chronic self-doubt and anxiety; another might be completely confident and well-adjusted on an individual level but find that his or her sexual-minority status introduces a chronic source of tension and distrust within the family of origin. One study (Diamond & Lucas, 2002) of adolescent peer relationships found that sexual-minority adolescents had significantly higher levels of anxiety, depression, and loneliness than their heterosexual counterparts, but mediational analyses found that these differences were entirely attributable to the fact that sexual-minority adolescents had significantly more pessimistic expectations when it came to future romantic relationships. The majority of these youth—even those who had successfully managed to date a number of same-sex partners—reported fearing that they would never find the type of romantic relationship that they wanted. Hence, in this case, it was not prejudice, stigmatization, bullying, or self-loathing that was responsible for these youth' psychological difficulties. It was, instead, a particularly acute version of a relatively common adolescent worry: Will I find someone to really and truly love me?

Similarly, studies of same-sex couples have repeatedly found that their most characteristic features often have less to do with being sexual minorities than with distinctive interpersonal dynamics that arise when two women or two men are combined in a romantic relationship, providing a "double dose" of conventionally socialized patterns of gender-specific interpersonal behavior. For example, Kurdek (1998) detected a small but significant tendency for lesbian couples to report greater intimacy with their partners, assessed by self-reported factors such as shared time and the degree to which

partners maintained a "couple" identity (see also Roisman, Clausell, Holland, Fortuna, & Elieff, 2008). Yet, the degree to which such heightened intimacy is beneficial to the relationship is unclear. For example, it does not necessarily promote relationship longevity (Kurdek, 1998), and some clinicians have argued that it might actually prove detrimental to same-sex female couples by promoting excessive psychological "fusion" or "merger" (Biaggio, Coan, & Adams, 2002; Nichols, 1987). This psychological fusion might play a role in the finding that long-term female couples show sharper declines in sexual frequency over time than either heterosexual or male couples (Iasenza, 2002; Peplau, Fingerhut, & Beals, 2004), along with the tendency for women to to desist from taking the lead in initiating sexual activity as a result of conventional female socialization (Blumstein & Schwartz, 1983; Nichols, 1988, 1990). These examples demonstrate the fundamental importance of taking a process-oriented approach to unearthing both *whether* and *why* sexual-minority individuals might present a distinctive range of issues to clinicians.

With this in mind, we now adopt a process-oriented approach to one particular issue that is psychologically significant for all sexual minorities, but which has particular and enduring relevance for those with bisexual patterns of attraction and behavior—identity development and transition over the lifespan. In addition to the general issue of minority stress discussed earlier, issues of identity transition remain among the most preeminent clinical issues facing sexual minorities. Furthermore, our understanding of these issues has arguably undergone more dramatic transformation in the past decade than any other aspect of sexual-minority psychology, especially in light of the accumulating evidence for stark gender differences in same-sex sexuality and in the phenomenon of sexual fluidity. This latter is particularly fundamental to our understanding of the antecedents and implications of bisexuality. For this reason, issues of identity development and transition merit particularly close attention.

## Identity Development and Transition

The process by which same-sex attracted individuals come to acknowledge those attractions, question their meaning, and potentially adopt a gay, lesbian, or bisexual identity has received extensive attention by social scientists over the past three decades. Initially, researchers were primarily concerned with charting a normative timetable of sexual identity "milestones" through which all sexual minorities

were presumed to progress from uncertainty and confusion to self-knowledge and self-acceptance (Diamond, 2005c; Savin-Williams, 2005). Although diverse in conceptual underpinnings, sexual identity models are nearly universal in their linear stage sequences (Cohen & Savin-Williams, 1996; Sophie, 1986). For example, most models mark the onset of sexual identity development as the individual's first awareness of same-sex attractions, presumed to occur in late childhood or early adolescence. This is followed some years later by a period of testing and exploration, during which youth seek information about gay, lesbian, and bisexual individuals and communities and/or engage in experimentation with same-sex sexual contact. Succeeding stages of identity development entail adopting a sexual-minority label, disclosing this sexual identity to others, becoming involved in a same-sex romantic relationship, celebrating one's sexual identity within a larger social context (e.g., the political arena), and, finally, integrating sexuality within a personal identity.

Although such a linear progression is intuitively appealing, extant research suggests it is simply inaccurate. Rather, considerable diversity exists among sexual-minority youth of different backgrounds, cohorts, and ethnicities regarding the paths taken to sexual-minority identification, particularly regarding the relative ordering of first same-sex sexual contact and self-labeling among young gay and bisexual males (Dubé, 2000; Rosario, Hunter, Maguen, Gwadz, & Smith, 2001; Rosario, Schrimshaw, Hunter et al., 2006; Savin-Williams & Diamond, 2000). Perhaps, the most notable deviations from the standard model have been documented among lesbians and bisexual women (Diamond, 1998, 2000b, 2003a, 2005b, 2008a, 2008b; Golden, 1996; Rust, 1992, 1993). This is perhaps to be expected, given that most sexual identity models were originally derived from exclusively male samples. Not only do women typically initiate sexual identity development at later ages than men, but they appear to do so for different reasons, often referencing emotional rather than sexual feelings for women. In some cases, the order in which they complete stages of sexual identity development is reversed (Diamond, 1998). For example, whereas same-sex activity typically occurs 1 to 2 years prior to a gay or bisexual identification among males (Herdt & Boxer, 1993; Rosario et al., 1996; Savin-Williams & Diamond, 2000), sexual-minority females often have their first same-sex contact after identifying as lesbian or bisexual (Diamond, 1998; Savin-Williams & Diamond, 2000), perhaps reflecting the fact that interpersonal and situational factors exert a greater press on women's than men's psychosexual development more generally (Baumeister, 2000; Diamond, 2008b; Udry & Billy, 1987; Udry, Talbert, & Morris, 1986).

In critiquing traditional sexual models, numerous researchers (Cass, 1990; Eliason, 1996, 1997; Morris, 1997; Rust, 2000b) have called for a more nuanced approach that examines the multiple antecedents and implications of sexual identity transitions across the entire life course, and not simply when an individual *first* comes to grips with same-sex sexuality. One of the primary weaknesses of previous sexual identity research is its longstanding reliance on retrospective data, which (by default) defines the outcome of sexual identity development to be whatever identity an individual claims when he or she happens to be surveyed. This has led to the widespread supposition that sexual identity development is a "one-time-only" event that begins in early adolescence and finishes in early adulthood. Yet, numerous studies suggest that individuals may begin, suspend, and revisit the process at multiple points in the life course, particularly as their social environments, developmental tasks, and intimate relationships undergo change (Diamond, 2007; Peplau, 2001; Peplau, Garnets, Spalding, Conley, & Veniegas, 1998; Rosario, Schrimshaw, Hunter et al., 2006). Longitudinal studies have found that continued questioning and change in sexual identity is particularly common among individuals with bisexual patterns of attraction and behavior (Diamond, 2008b; Stokes et al., 1997; Weinberg et al., 1994), due to the fact that bisexual attractions create, ipso facto, a broader range of possibilities for individuals' sexual and romantic experiences over time (Weinberg et al., 1994).

Overall, this phenomenon has received little substantive attention because it has been viewed the same way that bisexuality has been defined—exceptional rather than normative. Furthermore, because individuals are highly motivated to construct coherent and consistent life histories (Boxer & Cohler, 1989; Cass, 1990), those who periodically re-question their sexual identities are likely to edit these experiences from the retrospective identity narratives they tell to researchers, or to dismiss them as artifacts of protracted denial of their true sexual orientation (Blumstein & Schwartz, 1977). Yet, research increasingly suggests that multiple transitions in identity are not indicative of psychological dysfunction or denial; they may simply reflect an individual's honest and straightforward reckoning with a continually changing landscape of intimate relationships whose

meaning is fundamentally context specific. Particularly for individuals with bisexual patterns of attraction and behavior, a single, fixed identity label may never completely succeed in representing the complicated, situation-specific, and sometimes relationship-specific nature of their sexual self-concepts. Given the complexities of their desires, the healthiest identity outcome might not be a stable identity—even if it is a bisexual identity—but rather openness to multiple identities in different contexts.

## A Case Study of Multiple Identity Transitions

In the only long-term longitudinal study of sexual-minority women's sexual identity development, approximately one-third of women changed their sexual identity labels in the 2 years between the first and second waves of data collection (Diamond, 2000b). Some of these changes involved women in the "questioning-unlabeled" category deciding to adopt lesbian or bisexual labels, which was certainly consistent with traditional coming-out models. Yet, there were numerous additional "switches" between lesbian and bisexual labels and, perhaps most unexpectedly, five women actually *gave up* their lesbian or bisexual labels in favor of "unlabeled" identities, and an additional five women gave up their lesbian-bisexual labels in favor of a *heterosexual* label! Yet, all of these women continued to acknowledge attractions to women. The women who switched to heterosexual typically reported that their same-sex attractions simply were not sufficiently strong or frequent enough to justify identifying as lesbian or bisexual.

In the ensuing 2 years, an additional one-quarter of women switched labels (Diamond, 2003a). This time, three lesbians switched to bisexual labels, one bisexual and one unlabeled woman switched to a lesbian label, three lesbian and three bisexual women "unlabeled" themselves, six bisexuals now identified as heterosexual, and three of the women who had adopted heterosexual labels at the previous interview changed their minds and now considered themselves nonheterosexual, but unlabeled. The next two assessments brought more of the same (Diamond, 2005b, 2008a): about one-third of women changed identities between the third and fourth interviews, and another third changed identities between the fourth and fifth assessments. Furthermore, it was not the same subset of women who changed each time. Although some women changed their label more than once over the decade, most changes were "one-time-only" transitions. By the 10-year point, *over two-thirds* of the women had changed their identity label at least once after the first interview. Whereas traditional sexual-developmental models (based on *men's* memories of their pasts) presume that it is fairly atypical for individuals to undergo any additional identity questioning after they first come out, this study found exactly the opposite. The women who kept the same label for the whole decade turned out to be the smallest and most atypical group.

The specific patterns of change observed were also telling. The majority of identity changes undertaken during the 10 years of the study (over 80%) accommodated other-sex attractions and relationships. That is, women switched *to* a bisexual, unlabeled, or heterosexual label. Thus, when women reconsidered and changed their identities, they typically did so in a way that broadened rather than narrowed their potential range of attractions and relationships. Notably, this pattern corresponded to observations made in the 1960s, in which women's sexual experiences were viewed as "broadening" as they aged, whereas men's tended to become narrow and more specialized (McIntosh, 1968). In the final analysis, two groups could be identified. The first included self-identified lesbians who had been fairly exclusively attracted to and involved with women throughout the study, and who were least likely to change their identities. The second group included everyone else: They reported consistently bisexual patterns of attraction and behavior over time, and they were the most likely to change their identities. Their experiences demonstrate just how much researchers have been missing by failing to include bisexual women in previous studies of identity development. Clearly, individuals who are drawn to both men and women face a more complex set of issues when adopting an identity label—and maintaining that label over time—than do individuals with exclusive same-sex attractions and relationships. In order to settle on the "right" identity, individuals with nonexclusive attractions must go beyond acknowledging their same-sex attractions and must consider exactly how strongly they lean toward women versus men, whether sexual and emotional feelings are equally important, whether behavior trumps fantasy or vice versa, and whether social networks and ideological beliefs should play a role.

Importantly, the undertaking of multiple identity transitions introduces its own set of complexities and challenges. Individuals who undertake such changes may face confusion, disdain, and anger from friends and family members, perhaps even from gay and lesbian friends, many of whom may have internalized negative stereotypes about bisexuals and may

interpret the change in terms of betrayal and/or abandonment. Thus, individuals with bisexual attractions often find, ironically, that participating in a "socially desirable" heterosexual romance suddenly garners more scorn and anger than did their previous same-sex relationships. Their gay and lesbian friends might accuse them of "selling out" and trying to pass as heterosexual. Family members may claim that their other-sex attractions prove that their same-sex attractions were a phase, or that they can "give up" their same-sex interests if they so desire. Hence, even when undertaken thoughtfully, and with sound reasons, post–sexual identity transitions can introduce a number of psychosocial hurdles for sexual minorities.

It also bears noting that the aforementioned findings regarding women's long-term patterns of identity change clearly demonstrate that bisexuality is not a transitional stage for most women. Few women adopt bisexuality "on the way" to lesbian identification; neither is it common for heterosexual women to adopt bisexuality as an experimental phase (Diamond, 2008a). Although women who entered the study with bisexual or unlabeled identities were significantly more likely to subsequently change their identities than were lesbians, most of these changes were between bisexual and unlabeled identities, and there was no evidence for large-scale shifts toward either lesbianism or heterosexuality. By the 10-year point, only one of the women who had initially identified as bisexual, and only five of the women who had initially been unlabeled, had identified as lesbian. A similarly small number of women who had initially identified as bisexual eventually settled on a heterosexual label by the 10-year point. Furthermore, none of these women showed evidence of progressive changes in their ratio of same-sex to other-sex attractions over the 10 years of the study. They were—and remained—sexually attracted to both men and women consistently over time.

Additional evidence against the "transitional stage" model of bisexuality comes from the fact that the overall number of women adopting bisexual or unlabeled identities did not decline over the course of the study. If bisexuality were a temporary stage or phase, one would expect that, as women moved into adulthood, fewer and fewer would maintain these identities. Yet, to the contrary, the percentage of women claiming a bisexual or unlabeled identity hovered between 50% and 60% at each study wave. By the 10-year point, more than 75% of participants had spent at least some time identifying as

bisexual or unlabeled. These results do not rule out the possibility that some women adopt "bisexual" as a temporary, transitional label, but they do suggest that this appears to be an exceptional rather than a normative pattern, especially as "bisexual" gains increasing cultural visibility as a legitimate sexual orientation in and of itself (Rust, 2000e).

## Rejecting All Identities

Another notable finding from the longitudinal research on women's identity development was the large number of women who consciously rejected lesbian or bisexual labels in favor of "unlabeled" identities. This pattern flies in the face of traditional sexual identity models, which presume that the process of sexual questioning inevitably and uniformly culminates in the adoption of a lesbian, gay, or bisexual label. Yet, an increasing number of studies report that some individuals conclude, or temporarily suspend, the questioning process without claiming *any* identity label, sometimes as a thoughtful challenge to the notion of sexual categorization and sometimes because they simply find that none of the existing identity labels aptly describes the way in which they experience their sexuality (Diamond, 2008b; Golden, 1987; Savin-Williams, 2005). For example, many of these individuals claim that they "fall in love with the person, not the gender," and that current sexual identity labels fail to adequately describe such a phenomenon (Blumstein & Schwartz, 1990; Diamond, 2008b).

According to conventional sexual identity models, "unlabeled" identities are necessarily dysfunctional. All existing sexual identity models posit a final stage involving the synthesis, resolution, integration, and consolidation of a clearly defined lesbian, gay, or bisexual identity (Cass, 1979; Coleman, 1981/1982; Lee, 1977; Minton & McDonald, 1983; Mohr & Fassinger, 2000; Troiden, 1979), and this final stage is presumed to be critical for future healthy development. Ambivalence or uncertainty about claiming a lesbian, gay, or bisexual label is typically taken as a sign that the individual continues to suffer from internalized homophobia and self-stigmatization. To be sure, studies conducted in the 1980s and 1990s have reliably found that sexual-minority individuals with positive, well-defined lesbian, gay, or bisexual identities had greater ego strength, self-esteem, general adjustment, and overall well-being compared to those who did not claim positive lesbian-gay-bisexual self-concepts (Brady & Busse, 1994; Levine, 1997; Miranda & Storms, 1989; K. L. Walters & Simoni, 1983; Wells & Kline, 1987).

Yet, much of this research failed to tease out whether such benefits were attributable to the acceptance and integration of a sexual *identity* or to the acceptance and integration of one's *same-sex sexuality*, labeled or not. For example, one of the items that Mohr and Fassinger (2000) used to assess identity synthesis among lesbians was, "I am at the point where I feel a deep contentment about my love for other women." Mohr and Fassinger implicitly suggest that any woman agreeing with this statement would identify as lesbian or bisexual, yet the present research shows that this is not necessarily the case. Another problem in interpreting previous research is that there has been considerable historical change in attitudes toward sexual self-identification. A growing number of sexual-minority youth are intentionally challenging notions of sexual categorization and adopting alternative self-concept such as "queer," "questioning," and "none of the above" (Savin-Williams, 2005). For this newest cohort, being "unlabeled" means something drastically different than for a sexual minority 20 years ago.

For all of these reasons, clinicians should avoid making assumptions about the meaning of identity rejection or relinquishment without carefully attending to the individual's reasons and reasoning. There is no single pathway for healthy sexual identity development and no prototypical outcome. Men and women with different peer environments, different families, different ethnic and cultural backgrounds, and different personalities face markedly different options and constraints in crafting healthy identities and relationships. The goal should be to help them weigh these multiple options rather than prescribing one particular goal.

## Are Women Distinctive?

The findings reviewed here regarding the phenomenon of identity change and the adoption of "unlabeled" identities concern women. Although similar phenomena have been observed among men (Rosario, Schrimshaw, Hunter et al., 2006; Savin-Williams, 2005), they appear to be less common. Why is this the case? Over the years, researchers have begun to gravitate toward the notion that female same-sex sexuality is intrinsically more flexible and variable than male same-sex sexuality (Baumeister, 2000; Diamond, 2003b, 2005b; Peplau, 2001), perhaps best reflected in the fact that bisexual patterns of attraction appear more common in women than in men (Baumeister, 2000; French et al., 1996; Laumann et al., 1994; Russell & Consolacion, 2003; Russell & Seif, 2002). Notably, this phenomenon

has recently been validated using physiological, as well as self-report measures (Chivers, Rieger, Latty, & Bailey, 2005; Rieger et al., 2005). Specifically, researchers found that, although self-identified bisexual men reported sexual attractions to both women and men, they tended to become physiologically aroused by either one or the other (Rieger et al., 2005). In direct contrast, the majority of lesbian and heterosexual women showed physiological arousal to *both* male and female sexual stimuli, regardless of sexual orientation (Chivers et al., 2005).

There is also evidence that women's attractions—whether bisexual or "monosexual"—show a greater capacity for change over time and across situations (Diamond, 2003a, 2005b; Weinberg et al., 1994). Perhaps for this reason, women are more likely than men to ascribe a role for choice, circumstance, chance, and change in their sexual orientation and identity (Golden, 1996; Whisman, 1996), not only during adolescence but also well into adulthood. Thus, whereas many gay- or bisexual-identified men recall experiencing their first same-sex attractions a few years prior to puberty (similar to the age at which most heterosexual children recall their first other-sex desires, as pointed out by McClintock & Herdt, 1996), many women report that they did not experience same-sex attractions until adulthood, often as a result of encountering gay, lesbian, or bisexual individuals, ideas, or opportunities for same-sex contact (Cass, 1990; Diamond, 1998; Golden, 1987, 1994; Kitzinger & Wilkinson, 1995; Silber, 1990). This is often the case for "political lesbians," who typically report that they chose to orient their lives around women for social and political reasons, and then found their sexual desires following suit (Ettore, 1980; Golden, 1987, 1994; Kitzinger & Wilkinson, 1995; Silber, 1990; Whisman, 1993, 1996). Women are also more likely than men to pursue sexual behavior that runs counter to their avowed attractions and identities—that is, women with predominantly heterosexual attractions pursuing sex with women and women with nearly exclusive same-sex attractions engaging in sex with men (Bell et al., 1981; Diamond, 2003a, 2005b; Rust, 1992; Weinberg et al., 1994).

In many such cases, the impetus for these "atypical" encounters is an intense emotional bond (reviewed in Diamond, 2003b), and in fact, numerous sexual-minority women have reported that their feelings for women are predominantly emotional, or that their sexual desires are triggered or enhanced by feelings of emotional connection (Blumstein & Schwartz, 1990; Esterberg, 1994; Gramick, 1984;

Hedblom, 1973; Nichols, 1987; Ponse, 1978; Savin-Williams, 1998; Vance & Green, 1984; Weinberg et al., 1994). In extreme examples of this phenomenon, some women report having fallen in love with one—and only one—woman, and experiencing same-sex desires exclusively in this context (Blumstein & Schwartz, 1990; Cass, 1990; Cassingham & O'Neil, 1993; Diamond, 2000a). Women also appear more likely than men to report that their desires are not so much directed toward *women* at all, but rather to "the person" they happen to fall in love with (Blumstein & Schwartz, 1990; Cassingham & O'Neil, 1993; Diamond, 2002, 2008b; Golden, 1987).

This is consistent with the fact that the aforementioned 10-year study of women's sexual identity development found that self-identified lesbians who *fell in love* with a man over the course of the study found it far more difficult to continue identifying as lesbian than did women who simply engaged in periodic sexual contact with men (Diamond, 2008b). In fact, all of the women who had initially identified as lesbian, but who developed full-blown romantic relationships with men (which amounted to 30% of the lesbians) eventually switched to bisexual or unlabeled identities. Most notably, they undertook these changes even if they felt that their true orientation was still lesbian. Taken altogether, then, the accumulated evidence suggests that variable patterns of same-sex and other-sex desire and behavior may emerge in any woman over time, and this might simply be more pronounced among the subset of women who consciously identify as bisexual. Accordingly, the distinction between lesbianism and bisexuality may be a matter of degree rather than kind, and a woman's adoption of a bisexual or lesbian identity may have more to do with her self-concept, ideology, and intimate relationships than with her sexual "essence" (Golden, 1996; Rust, 1993, 1995, 2001).

What about men? Importantly, we simply lack sufficient data to determine the specific degree of sexual fluidity among men largely because there have been no long-term longitudinal studies of sexual variability in men. Evidence suggests some degree of fluidity (Rosario, Schrimshaw, Hunter et al., 2006; Stokes et al., 1997; Weinberg et al., 1994), although not as much as has been documented in women. Hence, although clinicians might find the concept of sexual fluidity more broadly applicable to female than male clients, it proves useful in guarding against reductionistic assumptions regarding same-sex behavior in *both*

men and women. Quite simply, the phenomenon of sexual fluidity reminds us that not all individuals who experience same-sex desires or relationships at any one point in time, within any particular relationship, will continue to do so in the future. Of course, this fact creates somewhat of a quandary for clinicians. On one hand, individuals who describe their same-sex experiences as uncharacteristic, "one-time-only" events, attributable to the unusual features of a particular same-sex relationship, might be making a truthful and accurate assessment, or they might be attempting to discount and deny their own capacity for same-sex sexuality. Although it is important for clinicians to avoid prematurely categorizing their clients' sexual identities, it is also important to prompt individuals to honestly reflect on the nature of their same-sex feelings and determine their personal relevance. Because there is no bona fide way, at a single moment in time, to differentiate an enduring pattern of same-sex sexuality from a highly circumscribed, relationship-specific experience triggered by sexual fluidity, the best strategy is to remain open and nonjudgmental, so that individuals can reflect openly and honestly about the quality and personal relevance of their same-sex *and* other-sex experiences in a safe, pressure-free environment. Clinicians might remind clients struggling with these issues that no single sexual or romantic experience can "prove" one's true sexual identity or place a definitive end to the sexual questioning process. Given that individuals with ambiguous, fluid, or bisexual attractions often feel abnormal by heterosexual, gay, and lesbian standards, such individuals need to be reassured that such inconsistencies and ambiguities are actually far more common than they realize.

## Conclusion
### Future Directions
In considering directions for future research on sexual-minority individuals, it is important to remain mindful of the weaknesses that have plagued previous research, particularly failures to represent the full range of individuals with same-sex attractions, behaviors, identities, and relationships. In addition to the underrepresentation of bisexuals, "mostly heterosexuals," and unlabeled individuals, studies have also underrepresented ethnic minorities, rural and working-class individuals, and those in the later stages of the life course. Greater research on these underrepresented subpopulations is critical for accurately understanding how the unique strengths and challenges of sexual-minority individuals interact with various

individual and contextual factors to shape their life trajectories. Contextual influences are also likely to be particularly important in understanding the unique experiences of individuals with bisexual patterns of attraction and behavior. A growing body of research has demonstrated that issues of ethnicity, culture, and social class influence the meaning that such individuals ascribe to their experiences, and their decisions about behavior, disclosure, and identification (Chung & Katayama, 1999; Greene, 1997; Grov, Bimbi, NanÁn, & Parsons, 2006; Jayakar, 1994; McLean, 2003; Nazario, 2003; Rosario, Schrimshaw, & Hunter, 2004a; Savin-Williams, 1996). The clinical implications of these decisions bear close attention.

Another important direction for future research concerns intersections between sexual identity and *gender* identity (the latter referring to an individual's psychological sense of being female or male, whereas the former refers to one's sense of being heterosexual, lesbian-gay, or bisexual). Research has found that a subset of sexual-minority adolescents and adults report significantly more gender-atypical (i.e., violating conventional cultural standards for appropriate masculinity or femininity) ideation and/or behavior— both in childhood and in adulthood—than do heterosexuals (Bailey, Nothnagel, & Wolfe, 1995; Bailey & Zucker, 1995; Lippa, 2000; Phillips & Over, 1992, 1995). Hence, although gender identity and sexual identity are fundamentally distinct constructs, many individuals wrestle with questions about both domains simultaneously, largely owing to the fact that they have absorbed cultural stereotypes suggesting that all sexual-minority individuals are "inverted" with respect to gender. As a result of these pervasive cultural stereotypes, gender-atypical men and women are not only frequently suspected of being lesbian, gay, or bisexual, but often wonder themselves whether this is the case, even in the absence of same-sex attractions (Hunter, 1993; McGann, 1999). This reflects the fact that there is more cultural "space" for a notion of gender-*typical* sexual minorities than gender-atypical *heterosexuals* (Hunter, 1993). In other words, although people may no longer unilaterally presume that all gay men are hyperfeminine, it is still commonly presumed that any man who *is* hyperfeminine is necessarily gay. Thus, in addition to confronting the same risks for stigmatization, isolation, and harassment that are confronted by sexual-minority youths, gender-atypical men and women also face the problem of having their sexual identity defined for them, often before they have even had a chance to reflect upon it, and often erroneously.

We know little about the internal psychological sequelae of gender atypicality over the life course and how it may differ for individuals with different patterns of same-sex and other-sex attractions. Some individuals, notably, may face greater stigma for gender-atypicality than for same-sex sexuality. Hence, in considering the phenomenon of "minority stress," the unique experiences of gender-atypical men and women must be borne in mind. Even individuals who do not face explicit condemnation for their gender atypical interests or behavior may wrestle with ongoing concerns about the nature of their gender and sexual identity. Women may be wrestling with painful realizations of the pervasive social constraints that continue to be placed upon them in contemporary society, and which limit their interpersonal and occupational aspirations. Men may wrestle with the realization that, to maintain status as appropriately masculine men, they must adopt behaviors and attitudes that some find intrinsically distasteful, such as aggressiveness, dominance, and often outright misogyny. Some have argued, in fact, that one reason "sissy" behavior is so virulently denigrated is that conventional masculinity is so restrictive, distasteful, and difficult to attain that boys could not be counted on to fully adopt it unless the penalties for *not* adopting it were severe (Gilmore, 1990; Hart & Richardson, 1981; Herek, 1986; Hunter, 1993).

Given how little is known about the etiology and ontology of gender atypicality, it is important to avoid making assumptions about the motives for and long-term implications of a particular individual's gendered ideation, appearance, or behavior. On this point, it is important to acknowledge that there has long been considerable debate over whether extreme forms of gender atypicality, including actual cross-gender identification, should be treated as correctable psychological problems or natural forms of human variation (Bradley & Zucker, 1997; Corbett, 1998, 1999; Halderman, 2000). At present, there is no uniform answer to this question, and most researchers and clinicians have taken a case-by-case approach to this issue. Certainly, there has been growing awareness and appreciation of the unique experiences of individuals with fluid, ambiguous, changing notions of their own gender, just as there has been growing appreciation of individuals with fluid, ambiguous, changing notions of their own sexuality (Diamond & Butterworth, 2008). The important point is to recognize the unique *and diverse* developmental experiences of gender-atypical men and women, to appropriately assess the relevance

(or lack of relevance) of sexual orientation to different individual's cases, and to take active steps to promote their physical and psychological well-being.

Finally, it is important that future studies counteract the negative cast of most prior research on sexual minorities by closely investigating the positive attributes, strengths, and skills of individuals with same-sex attractions and behaviors (Savin-Williams, 2005). One unexplored possibility, for example, is that individuals who actively wrestle with questions about their sexuality end up developing a healthier sense of sexual agency, better able "to know their sexuality as feelings as well as actions, feelings to which they are entitled" (Tolman, 1994, p. 268). Even individuals who experiment with same-sex sexuality, but end up identifying as heterosexual, might benefit from temporarily broadening their definitions and conceptualizations of sexuality. In particular, participation in same-sex activity necessarily disrupts widespread cultural assumptions about the "naturalness" of heterosexuality, as well as the "naturalness" of female and male gender roles. Participation in same-sex relationships and consideration of same-sex attractions might prompt all individuals to ask themselves important, useful questions about how they conceive of their sexuality, and what types of relationships they desire in the future. This has the potential to create altogether new and healthy trajectories of sexual and gender development.

Perhaps the most important recommendation for clinicians serving sexual-minority men and women is to take seriously the incredible diversity of these individuals' sexual profiles. This entails acknowledging and communicating to sexual-minority men and women that the categories "heterosexual," "gay/lesbian," "bisexual," and even "female" and "male" do not represent the full range of feelings, fantasies, and relationships they may find themselves experiencing throughout the life span. Clinicians can play a critically important role in sexual-minority individuals' well-being by simply providing them with a safe and supportive context within which they can consider the personal meaning of same-sex sexuality for their current and future relationships and identity. In contrast to early research on sexual minorities, which emphasized commonalities in their experiences due to their shared experience of stigmatization, we are now faced with the task of charting the multiple, interacting factors producing diversity in their developmental pathways. A fuller understanding of such diversity will clearly advance our capacity to foster sexual minorities' well-being over the life span.

# Interventions with Culturally Diverse Populations

Lillian Comas-Díaz

**Abstract**

This chapter addresses the need for cultural competence in the delivery of clinical psychological services. It advocates for cultural integrity in the adaptation of mainstream psychological practice. The role of cultural mirrors in the psychotherapeutic process is examined, namely, how worldviews, the therapeutic relationship, and communication affect therapy. The centrality of a sociocentric worldview in the delivery of psychological interventions for culturally diverse individuals is emphasized. The chapter discusses the role of cross-cultural therapeutic relationships, including racial identity developmental theories and ethnoracial bias, in addition to communication styles and their impact on clinical practice. The author advocates for the incorporation of ethnic specific therapies into psychological practice, and concludes with a discussion of ethnocultural psychological practice, an approach developed to integrate culture and ethnicity into the delivery of interventions with culturally diverse individuals.

**Key Words:** Cultural competence, liberation, sociocentric worldview, resilience

Treating culturally diverse populations can be a challenge and an opportunity. Many multicultural scholars and practitioners have questioned the cross-cultural effectiveness of mainstream psychological practice (Hall, 2001; Sue, Bingham, Porche-Burke, & Vasquez, 1999; Zane, Hall, Sue, Young, & Nunez, 2004). Some clinicians have examined the need to maintain cultural integrity within diverse psychological interventions. For instance, several psychoanalysts have incorporated clients' social, communal, and spiritual orientations into their practices (Foster, Moskowitz, & Javier, 1996). To illustrate, Altman (1995) modified an object relations framework to examine his clients' progress by their ability to use relationships to grow, rather than by the insights gained. Such adaptation appears to be consistent with the relational orientation of culturally diverse individuals. Likewise, Kakar (1985) adapted his psychoanalytic approach by educating, empathizing, and actively expressing interest and warmth toward

his East Indian clients. Moreover, several multicultural clinicians have recommended adapting evidence-based practice (EBP) to culturally diverse populations (Muñoz & Mendelson, 1995). Certainly, EBP contains elements congruent with culturally diverse individual' values, such as the importance of education in healing, the role of thoughts in maintaining health, the mind and body connection, and the relevance of making meaning out of adversity.

The gap between mainstream psychotherapists and culturally diverse individuals is beginning to narrow as the understanding between these two groups improves. A promise of an efficacious and ethical application of psychological services to culturally diverse individuals is on the horizon. In this chapter, I discuss psychological interventions with culturally diverse individuals. First, I advocate for cultural integrity in the delivery of psychological practice. Then, I examine the cultural adaptations of EBP practice.

Afterward, I discuss cultural variables that affect the therapeutic process with culturally diverse individuals. Furthermore, I examine the application of ethnic therapies and indigenous healing to multicultural individuals. I conclude with a discussion of an ethnocultural approach to delivery of psychological services. Finally, I offer recommendations for future research.

## Cultural Competence in Clinical Practice

Cultural competence is a process that provides the clinical skills needed to work effectively with culturally diverse individuals and communities (Cross, Bazron, Dennis, & Isaacs, 1989). This development enables practitioners to work effectively in a cross-cultural or multicultural situation. Since every therapeutic encounter is cross-cultural in nature (Comas-Díaz & Griffith, 1988), culturally competent psychotherapists enhance their clinical effectiveness. Likewise, clients who perceive their clinicians as being culturally competent tend to complete treatment and be satisfied with it. A set of congruent behaviors, attitudes, and policies, cultural competence reflects an understanding of how cultural and sociopolitical influences shape individuals' worldviews and related health behaviors, and how such factors interact at multiple levels of psychological practice (Betancourt, Green, Carrillo, & Ananch-Firempong, 2003). Culturally competent clinicians are specially trained in specific behaviors, attitudes, and policies that recognize, respect, and value the cultural uniqueness of individuals and groups (Hansen, Pepitone-Arreola-Rockwell, & Greene, 2000). These therapists develop the clinical skills needed to work effectively with culturally diverse populations and have the capacity to value diversity, manage dynamics of difference, acquire and incorporate cultural knowledge into their interventions and interactions, develop multicultural skills, conduct self- reflection and assessment, and adapt to diversity and to the cultural contexts of their clients. Needless to say, cultural competence enhances clients' treatment engagement, adherence, and completion.

However, cultural competence extends beyond clinical skills. In addition to practitioners' self-assessment, cultural competence requires an understanding of the historical and sociopolitical contexts of individuals and groups. Many culturally diverse individuals view mainstream psychotherapy as being monocultural, ethnocentric, and insensitive to their cultural and spiritual experiences (Hall, 2001; Sue, Bingham, et al., 1999). As such, dominant psychotherapy tends to support mainstream cultural values and consequently, neglects multicultural worldviews. In its extreme form, dominant psychotherapy can promote cultural imperialism by dismissing indigenous and spiritual beliefs. According to Young (1990), cultural imperialism universalizes and establishes as a norm the dominant group's experience and culture while ignoring multicultural perspectives. Furthermore, the history of service delivery to under-represented populations has been fraught with obstacles and missed opportunities. In particular, people of color in the United States have been subjected to neglect, discrimination, and even exploitation. For example, a medical apartheid— the history of medical experimentation on African Americans—offers a dark lens into the delivery of health services to this population (Washington, 2007). Also referred as America's Nuremberg, the history of gross injustices through medical research imparted upon African Americans has reduced their likelihood of seeking help for many treatable conditions, as well as their participation in clinical research (Caldwell-Colbert, Daniel, & Dudley-Grant, 2003). The Tuskegee project is a case in point. To illustrate, African American men were given a placebo, but were led to believe that they were receiving curative medication (penicillin), despite the fact that a cure for syphilis was found during the course of the research and administered to white men (Washington, 2007).

The legacy of the medical apartheid and America's Nuremberg has caused a psychopolitical reaction among many African Americans. Consequently, many African Americans tend to distrust clinical research protocols and established treatment facilities. Other people of color share a similar distrust or psychopolitical paranoia. Moreover, some researchers have used flawed and fraudulent methodologies and interventions with Native American individuals to the detriment of the community's well-being (Duran, 2006). Likewise, many Puerto Rican women were involuntarily sterilized when they received medical treatment (Comas-Díaz, 2008). Called *la operacion* (the operation), this medical procedure was a consequence of the U.S. policy to decrease overpopulation and unemployment among Puerto Ricans (Garcia, 1982). Such an oppressive medical legacy is relevant to psychological practice because many people of color seek treatment for emotional distress via their primary care practitioner. Thus, these clients frequently transfer their psychopolitical paranoia to psychological practitioners.

Interestingly, an empirical study showed that African Americans who endorsed positive expectations about seeking mental health services found

treatment less positive than their European American counterparts after utilizing such services (Diala et al., 2000). Moreover, when people of color seek mental health care, many receive poor psychopharmacological treatment. Clinicians' lack of recognition of racial and ethnic differences in drug metabolism and responses has resulted in psychopharmacological mistreatment of many people of color (Melfi, Croghan, Hanna, & Robinson, 2000). For example, although African Americans with affective disorders are often inappropriately treated with antipsychotic medications (Lawson, 1996; Strickland, Ranganeth, & Lin, 1991), many Latinos are treated inappropriately with other psychopharmacology, party due to their variable rate of drug metabolism (Jacobsen & Comas-Díaz, 1999; Mendoza & Smith, 2000). Moreover, due to ethnoracial differences in drug metabolism, Asian clients require lower doses of haloperidol than do whites to produce similar clinical effects (Pi & Gray, 2000). As a result, clinicians unaware of people of color's ethnopharmacological needs further add to their clients' mistreatment.

Another source of distrust among numerous people of color is what Duran (2006) called the "soul wound." According to these authors, many Native people need to heal the wound that is product of historical trauma, ungrieved losses, internalized oppression, suffering, and learned helplessness. Furthermore, many people of color's discomfort with mental health treatment may be strengthened by their suspicion that dominant psychotherapy is an instrument of acculturation (Ramirez, 1991) and of cultural imperialism. As a result, several mental health organizations examined impediments to the delivery of cultural competent services. The need for cultural competence emerged out of such examination.

## Cultural Competence in Mental Health Practice: Responses from Mental Health Organizations

In this section, I examine how two professional associations, namely the American Psychiatric Association and the American Psychological Association, addressed the need to infuse cultural competence into the delivery of psychological services to culturally diverse populations. The American Psychiatric Association (1994, 2000) developed the *cultural formulation*, a process-oriented assessment that grounds diagnosis in a cultural context. As a clinical tool, the cultural formulation examines (a) an individual's cultural identity, (b) cultural explanations for individual illnesses, (c) cultural factors related to the psychosocial

environment and levels of functioning, (d) cultural elements of the therapist–patient relationship, and (e) overall cultural assessment for diagnosis and treatment (APA, 1994). It also acknowledges the expression of distress through a glossary of culture-bound syndromes (APA, 1994). Such culture-bound syndromes are not restricted to unsophisticated, unacculturated individuals. I have witnessed several educated, intelligent, and achieving clients exhibit culture-bound syndromes in my clinical practice. As many of these clients suffer from anxiety and disconnection, an element of their treatment is to help them reconnect with their cultural and ethnic roots. Although the development of the cultural formulation is an impressive initial step, it is limited in its scope. Anchored in a medical model, the cultural formulation tends to emphasize individual pathology rather than strengths. Notwithstanding this limitation, the cultural formulation can be used as a model to increase the practitioner's cultural competence (Comas-Díaz, 2001; Lewis-Fernandez, & Díaz, 2002).

The development of the cultural formulation provided the impetus for the incorporation of *cultural analysis* into treatment. Based on ethnographic and anthropological research, cultural analysis aims to uncover the cultural knowledge people use to organize their behaviors and interpret their experiences (Spradley, 1990). When used in clinical practice, a cultural analysis relies on an object-relation model, with an emphasis on the importance of self and its relationships with others and with the environment. Lo and Fung (2003) identified the self, relations, and treatment as the three domains of the cultural analysis. The self domain entails the cultural influences on the self that may be relevant in psychological practice. These include affect, cognition, behavior, body, and self-concept, plus individual goals and motivations. The relations domain examines the cultural influence on clients' relationships with family, groups, others, society, possessions, environment, spirituality, and time. Finally, the treatment domain highlights therapy elements influenced by culture, such as communication (both verbal and nonverbal), problem–solution models, and the clinician–client relationship.

### American Psychological Association

The American Psychological Association formulated its *Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Clients* (APA, 1990) to guide culturally sensitive treatment. In essence, these guidelines exhorted practitioners

to recognize cultural diversity; understand the central role culture, ethnicity, and race play in culturally diverse individuals; appreciate the significant impact of socioeconomic and political factors on mental health; and help clients understand their cultural identification (APA, 1990). Following this development, the American Psychological Association (2003) published its *Guidelines on Multicultural Education, Training, Research, Practice and Organizational Change*. Both documents highlight the importance of psychologists' commitment to cultural competence. In brief, the multicultural guidelines encourage psychologists to recognize that we are cultural beings; value cultural sensitivity and awareness; use multicultural constructs in education; conduct culture-centered and ethical psychological research with culturally diverse individuals; use culturally appropriate skills in applied psychological practices; and implement organizational change processes to support culturally informed organizational practices and policy (APA, 2003).

## Cultural Adaptation of Evidence-based Psychological Practice

A challenge in the delivery of effective psychotherapy to clients from other cultures is to balance clinical expertise with the use of treatments that are informed by science in a culturally appropriate manner (Comas-Díaz, 2006a). Unfortunately, there is a lack of cultural and ecological validity in empirically supported treatment (EST) studies (Chambless at al, 1996; Hall, 2001; Roselló & Bernal, 1999; Sue et al., 2006). To address these concerns, practitioners and researchers have suggested adapting EST to multicultural populations (Bernal & Scharron del Rio, 2001). Such cultural adaptation has been proposed through the development of generic cross-cultural skills or the integration of culture-specific skills. *Generic cultural competence* refers to knowledge and skills required to work effectively in any cross-cultural psychotherapy (Lo & Fung, 2003). As every therapeutic encounter is cross-cultural in nature, the development of generic cultural competences is just plain good clinical practice. On the other hand, specific cultural competence enables therapists to work with particular ethnocultural groups. Nonetheless, EST tends to emphasize decontextualized manualized treatments (Carter, 2006; Wampold, 2007) and to restrict access to treatments of choice (Norcross, Koocher, & Garofalo, 2006; Rupert & Baird, 2004). In response to these concerns, the American Psychological Association established a Presidential Task Force on Evidence-based Practice (2006) to develop complementary frameworks for the integration of research evidence into practice. In turn, the task force members extended the definition of EBP to include contextual factors. More specifically, they defined EBP as the integration of the best available research, clinical expertise, and clients' culture, characteristics, and preferences (APA, 2006).

Therapeutic gains are reported in the application of EBP to culturally diverse populations (Voss Horrell, 2008). Researchers of color found that cognitive-behavioral therapy (CBT) was effective in treating depression among Latinos (Comas-Díaz, 1981; Organista, Munoz, & Gonzales, 1994) and African Americans (Kohn, Oden, Muñoz, Robinson, & Leavitt, 2002). Research also found efficacious results in the application of EBP to clients of color suffering from anxiety (Sanderson, Rue, & Wetzler, 1998) and obsessive disorder (Hatch, Friedman, & Paradis, 1996). Furthermore, Huey and Polo (2008) reported research findings providing evidence of EBP success with youth of color in the areas of attention-deficit hyperactivity disorder (ADHD), depression, conduct disorder, substance use, trauma-related disorders, and other clinical problems. The caveat of these research findings is that, to be effective, EBP needs to be culturally adapted to clients' contexts. To illustrate, Bernal and Scharron del Rio (2001) recommended the addition of multicultural awareness and culture-specific strategies, not only to cognitive-behavioral treatment, but also to other types of psychotherapy. Similarly, Comas-Díaz and Duncan (1985) provided an example of a successful cultural adaptation of an assertiveness training. Their empirical findings suggested that the intervention helped Latinas to express their assertiveness in a culturally relevant manner, while exploring the cultural consequences of their actions.

Notwithstanding these accomplishments, many clients of color tend to drop out of CBT as compared to European American counterparts (Miranda, et al., 2005; Organista et al., 1994). This finding seems to reaffirm the need to culturally adapt EBP for diverse populations. As Bigfoot (2008, March 13) stated, EBP is different from practice-based evidence. Thus, treating culturally diverse clients implies that cultural evidence needs to inform practice. For example, Lopez and his associates (2002) explored when and how to culturally adapt CBT. Bernal, Bonilla, and Bellido (1995) examined this issue and identified eight dimensions to increase cultural sensitivity and ecological validity in treatment outcome research. Moreover, they stated that these dimensions—language, persons, metaphors,

content, concepts, goals, method, and context—additionally serve as a guide for culturally adapting existing treatments. According to Bernal and his associates, the *language* used in therapy needs to be culturally appropriate to the client's worldview and life experiences. The dimension of *persons* refers to the therapeutic relationship. The *metaphors* dimension involves symbols and concepts shared by members of a cultural group. Moreover, the dimension of *content* comprises the therapist's cultural knowledge (i.e., does the client feel understood by the therapist?). The role of the *concepts* dimension is to examine whether the treatment concepts are consonant with the client's culture. *Goals* inquire whether therapeutic objectives are congruent clients' adaptive cultural values. *Methods* refer to the cultural adaptation and validation of methodology and instruments. Last, *context* considers the clients' environment, including sociopolitical and historical circumstances.

Evidence-based practice has not fully incorporated all of these dimensions. In particular, it has not taken into consideration the sociopolitical context. Moreover, mainstream psychotherapy has been silent regarding the role of history and sociopolitical contexts in people's lives (Brown, 1997). More specifically, EST modalities have underemphasized the role of cultural and social contexts in the delivery of clinical care to people of color (Rogers, 2004). The omission of sociocultural and political contexts is particularly detrimental for people of color, whose history of trauma and oppression differs from the experience of most majority group members (Vasquez, 1998). Dominant psychotherapy tends to overlook the effects of *racial microaggressions* on clients of color. Defined as the assaults inflicted upon individuals on a regular and acute basis solely due to their race, color, and/or ethnicity (Pierce, 1995) racial microaggressions also occur within therapeutic encounters in the form of color blindness, denial of individual racism, the myth of meritocracy, and pathologizing multicultural values and styles, among others (Sue et al., 2007). Moreover, fame and privilege do not protect people of color from microaggressions (Rivera, 1999). Indeed, racial microaggressions can lead to *ethnocultural allodynia*, a disturbance in individuals' ability to judge perceived ethnic and racial insults, and subsequently, discern defiant and maladaptive responses from adaptive and resilient ones (Comas-Díaz & Jacobsen, 2001). Since a decontextualized and ahistorical psychotherapy may lead marginalized people to internalize their oppression, such internalization compromises their agency (Freire, 1973) and mastery. As a result, clinicians

need to consider the sociopolitical context and examine oppression when working with culturally diverse clients.

Muñoz (1996) highlighted the sociopolitical context in his cultural adaptation of CBT by targeting both internal and external realities in Latinos' lives. Muñoz's recommendations included (a) the involvement of culturally diverse people in the development of psychological interventions, (b) inclusion of sociocentric worldview values, (c) consideration of religion/spirituality, (d) relevance of acculturation, and (e) acknowledgment of the effects of oppression on mental health (Muñoz & Mendelson, 2005). However, Muñoz's cultural adaptations need to be tailored to specific ethnic groups. For example, Muñoz identified the development of a positive meaning in life under adversity as a core belief within his CBT cultural adaptation. Such recommendation may need to be modified when working with some African Americans. Partly due to their history of trauma, slavery, and oppression, many African Americans are distrustful of "too much" positive thinking, in that they believe that this type of outlook may be unrealistic (hooks, 1993). A potential strategy to counteract this belief is to foster the development of resistance against oppression. For instance, in my clinical practice with African Americans, I culturally translate "positive thinking" into hope. When appropriate, I use my clients' spiritual and ideological beliefs to cognitively reframe their distrust of positive thinking. Indeed, I have found that hope—along with other positive values—is culturally contextualized. As an example, I associate hope with resilience. In short, the limitations of the adaptations of empirically supported practice point out to the influence of culture on the psychotherapeutic process.

## Cultural Mirrors in the Therapeutic Process

Culture reflects the psychological and spiritual factors that affect people's lives. Consequently, these "cultural mirrors" are reflected in the clinical practice. Indeed, cultural mirrors influence assessment and treatment, as well as the psychotherapeutic process. To illustrate, cultural mirrors reflect factors such as client's expectations, perception of clinician credibility, self-disclosure, trust, engagement, and development of therapeutic alliance. Whaley and Davis (2007) reviewed the empirical literature on EBP with people of color and concluded that culture affects the psychotherapeutic process more than it affects psychotherapeutic outcome. Therefore, the

examination of cultural mirrors can enhance clinicians' cultural competence and treatment effectiveness. For the purpose of this discussion, I concentrate on three cultural mirrors that affect the therapeutic process. They are worldview, therapeutic relationship, and communication.

## Worldview

Worldview informs behavior. The term *worldview* refers to the total system of ideas and beliefs that an individual holds of the universe and how it is constructed (Maduro, 1982). To illustrate, many people of color's interpersonal styles reflect the interactive influence of race, culture, ethnicity, gender, socioeconomic class, amount of acculturation to the mainstream, and sociopolitical factors. Within this context, the American Psychological Association Multicultural Guideline 1 endorses a commitment to a cultural understanding of the worldview of self and other. Furthermore, it encourages psychologists to appreciate how, as cultural beings, our worldviews (both clients' and psychologists') affect psychotherapy. This is necessary since client and therapist's differences in worldview can limit collaboration in treatment.

Many culturally diverse individuals adhere to a sociocentric or collectivistic worldview (Comas-Díaz, 2006b). Within a collectivistic orientation, members tend to endorse affiliation; understand themselves through others; emphasize family, social, emotional, and spiritual bonds; and prefer communal goals above individual ones (Triandis, 1995). Furthermore, they favor relational values such as interdependence, holism, and balance (Shweder & Bourne, 1982). Practitioners unaware of their clients' sociocentric worldview can violate personal and family norms by asking clients to prematurely disclose intimate information, soliciting the expression of emotion and affect, and requesting them to air family disputes—all before achieving credibility and earning their trust (Varma, 1988). Next, I discuss three sociocentric values, namely *familismo*, saving face, and contextualism.

### SOCIOCENTRIC WORLDVIEW VALUES:
#### FAMILISMO

An example of a sociocentric worldview, *familismo* extends family relations beyond bloodlines. *Familismo* is a Latino cultural mandate that designates as family members those individuals who have a significant role in the person's life. For example, people adhering to *familismo* often consider godparents, friends, mentors, teachers, close co-workers, and even neighbors as family members. Within this context, therapists and other health providers fit into the role of extended family members (Comas-Díaz, 1989). Moreover, clients endorsing *familismo* tend to translate individual treatment into family therapy with one person. For example, many Latinos frequently bring their relatives to therapy sessions. This means that clinicians need to be knowledgeable of family and group dynamics. Moreover, due to *familismo*, many clients are likely to share therapeutic knowledge and even medications with significant others (Jacobsen & Comas-Díaz, 1999). Along these lines, Roselló and Bernal (1999) identified the need to incorporate sociocentric values into psychological practice. Their empirical investigation found both CBT and interpersonal psychotherapy (IPT) to alleviate depression among Latinos. However, these researchers reported that participants in the IPT condition had an added advantage because the clients improved their self-concept and social adaptation. Rossello and Bernal noted that IPT is culturally congruent with *familismo*, since IPT can be culturally sensitive for collectivistic clients who experience losses, relational difficulties, and cultural role transitions. Interestingly, in a similar study published in 2008, Roselló, Bernal, and Rivera-Medina found CBT to be significantly superior to IPT. The researchers explained their contradictory 1999 and 2008 findings as a result of methodological flaws. The discrepancy in the two studies suggests the need for further research in the cultural adaptation of EBP.

Latinos who adhere to *familismo* tend to value relationships that bear mutuality. Within the mutuality context, some Latino clients may express gratitude toward their therapist by giving a gift. Indeed, gift-giving is an expression of sociocentric relations. Moreover, this practice has indigenous roots. As individual survival is linked to a communal survival, gift-giving solidifies gratitude within an interdependent context. Adherence to *familismo* can lead clients to present their therapist with small gifts such as folkloric expressions, souvenirs, food, beverage, art, and other small tokens of appreciation. *Familismo* gifts can be facilitated by the information available through the Internet. For example, clients can search their therapist's personal information through Google (Zur, 2008), LinkedIn, and others. Therefore, clients can find out the therapist's birthday and give a card (or small gift) for the occasion. Nonetheless, therapists' management of gift-giving requires a blend of cultural skills with cultural sensitivity.

## SOCIOCENTRIC WORLDVIEW VALUES: SAVING FACE

The concept of saving or losing "face" is central to a traditional Asian interpersonal orientation. Among many Asians, *face* refers to an interpersonal orientation within relationships and thus, represents social position gained through behavior that is recognized by others. According to Zane (2008, March 13), face entails the person's social presentation of values, attitudes, and traits that comprise his or her character. When behavior seems to reify this set of attributions, others recognize the person's face. *Saving face* is a motivator in behavior, not only socially, but also during therapy. Zane (2008) reported research that found loss of face among Asian clients as affecting self-disclosure in treatment. Based on this research, Zane identified the prevention of the threat to face as (a) direct avoidance of certain relationships, (b) use of intermediaries, (c) monitoring of conversation, (d) self-restraint in expression, and (e) modesty and self-effacing to reduce the possibility of being discredited. These recommendations can also be extended to Latinos coping with *verguenza*. As a cultural concept, *verguenza* is a type of socioemotional shame and/or absence of pride that is elicited when individuals lose face. The relevance of the cultural values of face and *verguenza* can be exemplified by Confucius' maxim: "Without shame you are not human" (Ji Xuesong, personal communication, 2007). A person's *verguenza* extends from the individual to the family and even to the ethnic community. Indeed, "being a credit to your ethnic group" entails pride and thus, is the opposite of *verguenza*. Moreover, *verguenza* can act as self-censorship in therapy. Zane suggested that to manage face (and I add *verguenza*) clinicians can (a) use protective maneuvers (such as respect and politeness), (b) depersonalize face-threatening incidents through the provision of warnings and explanations, (c) minimize the face-threatening episode, and (d) conceal or hide the incident when the client has lost control of his or her emotions.

## SOCIOCENTRIC WORLDVIEW VALUES: TRANSPERSONALITY

Transpersonality is a sociocentric way of relating. The term *transpersonal* refers to the development of identity beyond personal and individual levels (Scotton, 1996). Therefore, transpersonality involves people's ability to transcend their individual self into a self-other-environment identity to foster the interpenetration of cosmic influences in people's lives. As an illustration, many people of color endorse a transpersonal agency in which they see themselves as co-creators of their reality (Comas-Díaz, 2006b). That is, they share their agency with a transpersonal entity—a spiritual, religious, material, and or cosmic force (fate, destiny, fortune). Indeed, transpersonality can help people of color to enhance their cultural resilience and deepen their sense of meaning and purpose in life. For example, Ricardo Muñoz identified (1996) the development of a positive meaning in life under difficult circumstances as a core belief within his CBT cultural adaptation. Likewise, practitioners can explore clients' meaning-making and how they learn from adversity. Assigning meaning to a painful situation can cognitively reframe the event as a transformative experience. Along these lines, research has found that an ideological understanding of discriminatory events coupled with social activism facilitates recovery from oppressive trauma (Landrine & Klonoff, 1994).

## SOCIOCENTRIC WORLDVIEW VALUES: CONTEXTUALISM

Many culturally diverse individuals are immersed in their contexts. Consequently, they tend to take into consideration contextual factors in their behavior. Such style has been named *contextualism*, or the tendency to describe the self and other using more contextual references and fewer dispositional references (Choi, Nisbett, & Norenzayan, 1999). Individuals with a contextual cognitive style tend to process information while paying attention to their surrounding context, as opposed to individuals with a context-independent style, who tend to process stimuli as if they were unaffected by the context (Kuhner, Hannover, & Shubert, 2001). Berry (1991) empirically found that persons with individualistic worldviews on average score higher on context independence, whereas collectivistic persons tend to score higher on context dependence. For many people of color, contextualism is accompanied by a combined locus of control—a blend of internal and external locus of control, in which the context determines which locus of control will prevail (Comas-Díaz, 2006b).

Life experiences, history, and sociopolitical factors nurture people of color's contextualism. As discussed previously, African Americans' history of medical establishment abuses may result in a mistrust of treatment. Consequently, such mistrust hinders the development of the psychotherapeutic alliance among African American clients. Thus, practitioners need to expect, recognize, and address

this mistrust as a healthy paranoia. In response, clinicians need to prove credibility beyond their professional credentials, in order to earn their clients' trust. When working with clients of color, therapists need to exercise clinical acumen. Similarly, when compared to novice clinicians, experienced therapists tend to have better alliances with clients who are not comfortable with intimacy (Kivlighan, Patton, & Foote, 1998). Therefore, therapists working with people of color need to actively earn their trust. A way to accomplish this goal is to facilitate a therapeutic environment in which clients feel comfortable addressing contextual factors such as racism, sexism, and oppression. To initiate a therapeutic dialogue, clinicians can assess individuals' worldviews.

### ASSESSING WORLDVIEWS

Clients' worldviews and life experiences affect how they perceive, interpret, and present their problems to their practitioners. Moreover, worldviews shape the meaning that clients attribute to their illness, their help-seeking behavior, identification of their of social support, and their behavior in treatment (Anderson, 1995). The explanatory model is an effective clinical tool to elicit clients' expectations and perspectives on their illness (Kleinman, 1980). Clinicians can use this culture-centered assessment based on an anthropological method to begin unfolding their clients' worldviews. They can ask the following questions (Callan & Littlewood, 1998; Kleinman, 1980):

- What do you call your problem (distress or illness)?
- What do you think your problem (illness) does?
- What do you think the natural course of your illness is?
- What do you fear?
- Why do you think this illness or problem has occurred?
- How do you think the distress should be treated?
- How do want me to help you?
- Who do you turn to for help?
- Who should be involved in decision-making?

As many culturally diverse individuals endorse a sociocentric worldview, they require relational approaches to assessment and treatment. As examples of relational interventions, family and group therapy are particularly central to individuals' sense of well-being. Indeed, genealogical trees or genograms (McGoldrick, Gerson, & Shellenberger, 1999) and

cultural genograms (Hardy & Laszloffy, 1995) are congruent with a sociocentric worldview. In addition to family dynamics, cultural genograms map information such as cultural translocation, adaptation, acculturation, ethnic/racial identity development, historical and current trauma, racial socialization, oppressive experiences, in-group/out-group member dynamics, relations with members of dominant society, geopolitics, and many other contextual factors. When working with immigrant families, clinicians can use a culturagram to assess specific immigration issues and stages, such as reasons for relocation, legal status, languages spoken both at home and at the community, time in community, health beliefs, crisis events, holidays and special events, contact with cultural spiritual and religious organizations, values about education and work, and values about family structure power, hierarchy, rules, subsystems, and boundaries (Congress, 2002). Moreover, therapists can use these tools to chart their own cultural locations, as well as examine similarities and differences vis-a-vis their clients' contexts. Effective management of the therapeutic relationship is a significant way for clinicians to earn credibility, enhance trust, and cement a therapeutic alliance.

## Therapeutic Relationship

If the therapeutic relationship carries the treatment (Norcross & Lambert, 2005), culture is the steering wheel. Like other interpersonal relationships, therapists and clients negotiate psychotherapy not merely in terms of theoretical frameworks, but also in terms of cultural meanings. Successful clinical work with ethnic minorities depends on the therapist's skill in establishing and managing the therapeutic relationship (Jenkins, 1985). It also depends on the therapist's self-awareness and understanding of how ethnocultural and racial factors affect both therapist and client. The development of a therapeutic alliance, therefore, acquires inordinate importance within multicultural encounters. The strength of the early therapeutic relationship has been associated with positive therapeutic outcomes (Horvath, 2001). However, therapists need to obtain clients' *permission* to develop a multicultural alliance (Duran, 2006). In other words, the therapeutic alliance cannot emerge until the client feels comfortable with the clinician's trustworthiness, credibility, and cultural competence. Culture's influence ranges from treatment expectations, trust, credibility, and rapport, to the development of a therapeutic alliance. However, expectations about a therapeutic relationship vary cross-culturally (Portela, 1971). For instance, many Native American

clients expect their therapist to exemplify empathy, genuineness, availability, respect, warmth, congruence, and connectedness (Trimble et al., 1996). Traditional Asian clients may be overly deferential and inhibited (Sakauye, 1996), and lose face when revealing certain information. Likewise, many Latinos expect their therapist to act as a member of their extended family. Furthermore, some African Americans may wonder if their clinician is racist until proven otherwise.

Research suggests that many clients of color expect their practitioner to be active by giving advice, teaching, and guiding, as well as helping them to explore their lives and to grow emotionally (Comas-Díaz, Geller, Melgoza, & Baker, 1982). These complex expectations seem consistent with Atkinson, Thompson, and Grant's (1993) recommendations. Atkinson and his colleagues advised clinicians to integrate the intersecting roles of advisor, advocate, facilitator, and change agent into their function of psychotherapist when working with culturally diverse clients. Within this framework, acculturation levels and sources of the client's problem are less rigidly defined. For instance, a highly acculturated client may require the therapist's involvement as an advisor, advocate, and facilitator.

Similarly, a directive therapeutic style can facilitate the development of trust during the initial stages of therapy (Comas-Díaz 2006a). Many sociocentric clients interpret this therapeutic method as a sign of caring. Such an approach may be crucial for clients of color who expect instrumental help from their clinician. For instance, the term *ethno-underclass* describes low-income African Americans, American Indians, and Latinos who are chronically isolated from the mainstream (Fuchs, 1990). During psychotherapy, they may present ethno-underclass issues such as inadequate employment, housing, and food, as well as issues of personal safety, violence, and physical health. Therapists who acknowledge and respond to these concerns validate the client's reality and help to establish and cement the therapeutic relationship. The client's presentation of environmental issues should not be perceived as resistance to treatment. Furthermore, instrumental help can be broadly translated, as in modeling and psychoeducation. To illustrate, I often add the function of mentor to my psychotherapist's role when working with high-achieving women of color. Most of my therapeutic mentoring aims to facilitate clients' successful navigation of racism and sexism. Similarly, Seeley (2000) suggested flexibility in the therapist's role when working with culturally diverse individuals.

Likewise, Kakar (1985) modified his psychoanalytic approach with Southeast Indians by being active and didactical, as well as feeling and expressing pity, interest, and warmth. Flexibility in a clinician's role is also prevalent among mainstream psychotherapists. For example, therapists act as a combination of philosopher, teacher, and scientist in rational emotive therapies (Prochaska & Norcross, 1994).

## Racial Identity Development

Racial and ethnic identity development is salient in multicultural psychotherapy and relevant for the cross-cultural therapeutic relationship. The racial identity developmental theories offer a lens for understanding how clients of color process, as well as how they present to treatment, and even how they select their practitioner. Like levels of acculturation, racial identity stages speak about people of color's relationship with the dominant society. Racial identity theories propose that members of racial and ethnic minority groups initially value the dominant group and devalue their own group, then move to value their own group while devaluing the dominant group, and, in a final stage, integrate a value for both groups (Cross, 1991). According to Atkinson, Morten, and Sue (1998), the different minority identity development stages include (a) conformity (clients aspire to assimilate as they choose values and role models from the dominant group), (b) dissonance (individuals' begin to question and suspect the dominant group's cultural values), (c) resistance-immersion (individuals endorse minority-held views and reject the dominant culture's values), (d) introspection (individuals establish their racial ethnic identity without following all cultural norms), and (e) synergistic (individuals experience a sense of self-fulfillment towards their racial/ethnic/cultural identity without having to categorically accept their minority group's values). Other groups have proposed diverse cultural identity development theories. For example, mixed-race individuals develop their identity from personal identity, choice of group categorization, enmeshment/denial, appreciation, and integration (Poston, 1990).

Moreover, an European American identity developmental model also exists. According to Helms (1995), the white identity developmental stages include (a) contact (unaware of their own racial identity; white Americans tend to believe that the system in the United States is fair when considering race), (b) disintegration (individuals begin to acknowledge their white identity), (c) reintegration (individuals tend to idealize their racial group and

minimize the qualities and conditions of other racial groups), (d) pseudo-independence (individuals tend to intellectualize the acceptance of their own and others' race), (e) immersion-emersion (individuals question their racial status and privileges), and (f) autonomy (individuals develop flexible standards and internalize a multicultural identity without racism).

Racial identity formation is an active process; it does not necessarily follow a course of linear stages. Indeed, minority development is a fluid process that may change according to one's context, the emergence of new challenges, adult developmental stages, ego statuses, and sociopolitical circumstances. Clients' racial identity development can have a direct effect on the therapeutic relationship. For instance, individuals at the conformity stage may prefer a clinician from the dominant group, as opposed to a therapist from their own cultural group. Conversely, clients at the synergistic stage may not be overly concerned about their practitioner's ethnic or racial group. Racial identity developmental stages potentially interact with client and therapist ethnoracial match. Some research suggests that clients working with clinicians of similar ethnoracial backgrounds and languages tend to remain in treatment longer than those clients whose practitioners are not ethnically or linguistically matched (Sue, 1998). Furthermore, an empirical study showed that clients of color in race-similar therapeutic dyads participate more in their care than do those in race-dissimilar dyads (Cooper-Patrick et al., 1999).

Nevertheless, ethnic and racial client–practitioner matching is not always realistic. Additionally, some culturally diverse clients are concerned about confidentiality and stigma associated with psychological treatment. These individuals may prefer a therapist who is not a member of their ethnocultural group. Moreover, there are contradictory results regarding provider–client ethnic matching (Hall, 2001). A review of the research on ethnic matching between psychotherapists and clients found inconclusive results and low validity for ethnic matching (Karlsson, 2005). Furthermore, research on the effects of ethnic matching on treatment satisfaction among Mediterranean migrant patients showed that they did not value ethnic matching as relevant, and considered clinical competence, compassion, and sharing their worldview as important (Knipscheer & Kleber, 2004). These findings can potentially be extended to other ethnic groups. Regardless of ethnicity, race, gender, sexual orientation, class, physical ability, or other diversity variables, therapists who are culturally competent enhance their clients' satisfaction with treatment. As an illustration, Fuertes and Brobst (2002) empirically examined European American and ethnic minority (Asian American, African American, Hispanic/Latinos, and American Indian) respondents' perceptions of the impact of cultural competency in psychotherapy. Their findings suggested that the participants' perceptions of a clinician's cultural competence correlated significantly with their perceptions of a therapist's trustworthiness and expertise. The researchers concluded that counselor cultural competence increased client satisfaction in therapy.

### Ethnocultural Transference and Countertransference

The contradictory results in the client–therapist ethnic match may reflect the effects of racial, ethnic, and cultural identification and disidentification. Indeed, clients and clinicians often bring their imprinting of cultural, ethnic, and racial experiences into treatment. Such imprinting plays a significant role in the therapeutic relationship, since the reactions based on ethnocultural factors offer a roadmap for the relationship between self and other. Regardless of theoretical orientation, therapists working with culturally diverse individuals need to understand transference and countertransference, including the ethnocultural determinants of these phenomena (Zaphiropoulos, 1982). Racial and ethnic factors are easy and available targets for projection in therapy, which may be manifested in transference and countertransference. For example, Comas-Díaz and Jacobsen (1991) discussed ethnocultural transference and countertransference in both inter-ethnocultural dyads as well as in intra-ethnocultural dyads. These authors identified inter-ethnocultural transference as overcompliance and friendliness (predominant under a therapist–client societal power differential); denial (denial of ethnicity and/or culture); mistrust, suspiciousness, and hostility; and ambivalence.

The intra-ethnocultural transferential reactions include omnipotence (idealization of the therapist frequently promoted by the ethnic similarity), treason (client exhibits resentment and envy at therapist's successes), autoracism (client projects the strong negative feelings about him- or herself onto the ethnically similar therapist, and ambivalence. Some countertransferential reactions within the inter-ethnic dyad include denial of cultural differences, the clinical anthropologist's syndrome (excessive curiosity about clients' ethnocultural backgrounds at the expense of

their psychological needs, guilt (around working with lower societal-status clients, pity (expression of political impotence within the therapeutic hour), aggression, and ambivalence (toward the client's culture as well as toward the therapist's own culture). The intra-ethnocultural countertransferential manifestations include overidentification, *Us and Them* mentality (shared victimization due to racial discrimination), distancing, survivor's guilt (surviving harsh circumstance can impede professional growth and may lead to denying their clients' psychological needs), cultural myopia (inability to see clearly due to cultural factors that obscure therapy), ambivalence (working through the therapist's own ethnic ambivalence), and anger (being too ethnoculturally close to a client may uncover painful, unresolved emotions). Ethnocultural transference and countertransference tend to serve as catalysts for major therapeutic issues, such as trust, ambivalence, anger, identity, and others. As an initial step to initiate a discussion of ethnocultural transference and countertransference, Comas-Díaz (2001) suggested asking clients: "How do you feel about my being from a different culture from yours?" or conversely, "How do you feel about our being from similar cultures?" This type of examination can help to unfold the existence of unconscious racial bias.

## Therapist's Bias

Clinical work provides a fertile ground for the manifestation of ethnocultural and racial factors in the therapeutic process (Comas-Díaz & Griffith, 1988). These manifestations involve the conscious and/or unconscious acknowledgment of clients' and therapists' feelings and attitudes about their own ethnic and cultural identities, as well as their conscious and unconscious messages about racial, ethnic, and cultural differences in the therapeutic dyad (Comas-Díaz & Jacobsen, 1987). Indeed, empirical research has documented the existence of therapists' bias toward culturally different clients. To illustrate, Wampold and his associates (1981) studied the attitudes of psychotherapists toward African Americans, Chinese Americans, Japanese Americans, Jews, and Mexican Americans. They found that over 79 % of the sample of therapists' responses demonstrated the presence of subtle stereotypic attitudes, whereas 22.6% indicated highly blatant stereotypic attitudes. Therefore, as part of being culturally competent, therapists may want to examine their own biases. According to Laura Brown (1997), European Americans who grow up as members of a majority group are likely to be either covertly or overtly racist to some degree.

Cognitive psychology research has confirmed Brown's observation. Through the use of a response latency measure of bias, research has shown individuals who appear as nonprejudiced in self-report measures generally have negative attitudes toward African Americans (Dovidio & Gaertner, 1998). Moreover, in addition to the existence of unconscious and aversive negative racial feelings and beliefs toward people of color, studies have documented a widespread dissociation between implicit and explicit social stereotyping. (Dovidio, Gaertner, Kawakami, & Hodson, 2002). Research suggests that once stereotypic impressions are formed, these notions are often resistant to change (Gilbert, 1998). Therapists who do not examine their implicit and unconscious biases contribute to the development of pernicious effects on their clients (Vasquez, 2007). Self-reflection can help clinicians to recognize their attitudes toward others, and examine their impressions by unlearning and relearning information that has been socially taught about self and others (i.e., cultural, racial, and ethnic stereotypes, white privilege, internalized oppression, and other factors; Comas-Díaz & Caldwell-Colbert, 2006). This approach can allow for a deeper understanding of self and other.

Indeed, the American Psychological Association's Multicultural Guideline 2 encourages psychologists to understand how minority groups' history of oppression influences people of color's worldviews. In addition to recognizing historical factors, this understanding includes becoming aware of the effects of ongoing discrimination within the interaction of racism, sexism, elitism, xenophobia, and other forms of discrimination. Therapists can examine their biases through self-reflection, genograms, and power analysis. A power analysis compares the client's cultural group's social status with the practitioner's. This comparison entails the identification and challenge of internalized privilege and oppression. While conducting a power analysis, therapists examine their own areas of privilege and oppression, and compare their findings with their client's. According to Worrell and Remer (2003), clinicians can write down under a column headed by the letter "O" their areas of oppression. Next, they write their areas of privilege in a column under the letter "P" for privilege. After following the same procedure for their client's areas of oppression and privilege, therapists can compare their own results with those of their client's. In completing a power analysis, clinicians may want to include areas of historical oppression and privilege. Power analysis can help to unfold

areas of similarities and differences between clinicians and their clients. This process can help psychologists to take the perspective of their clients. When therapists are able to take the perspective of the "other," they can reduce their stereotypic and ethnocentric attitudes (Galinsky & Moskowitz, 2000). This process facilitates the development of empathy (Finlay & Stephan, 2000). Nonetheless, clinicians working with culturally diverse clients have to go beyond developing cognitive and affective empathy; furthermore, they need to engage in cultural empathy. A process of perspective taking by using a cultural framework as a guide for understanding the client from the outside-in, cultural empathy (Ridley & Lingle, 1996) helps to recognize the self in the other. Therapists can use explanatory models of distress, cultural genograms, self-awareness, and power differential analysis, among other methods, to develop cultural empathy.

### Communication

Communication is an integral component of culture. Likewise, language and cultural nuances transform the psychotherapeutic process. However, worldview differences between therapist and client can result in the clinician "hearing" but not "listening to" the client's narrative. As indicated previously, differing worldviews interfere with communication, the development of a therapeutic alliance, and therapist–client collaboration in decision making. Thus, an integral part of the therapeutic work is the "translation" of worldviews into a communication bridge that connects client and therapist. Being understood by another person can be intrinsically therapeutic because it eases the distress of isolation. Clinical lore proclaims that communication is to the psychotherapist what the scalpel is to the surgeon. Hence, when working with culturally diverse individuals, therapists need to expand their communication repertoire. Regardless of their use of language, culturally diverse clients often communicate in a sociocentric style. In other words, sociocentric members tend to communicate implicitly and indirectly. Such style helps to maintain harmonious relationships, relies on a substantial amount of nonverbal communication, and pays high attention to contextual factors. Hall (1983) identified this style as context-rich, in which communication adheres to a rich web of cultural nuances and meaning. In a similar vein, many people of color raise racial, ethnic, gender, socioeconomic, ideological, and political issues as a means of evaluating their therapist's credibility. For example, many Latino clients might engage in

plática to check out their therapist (Comas-Díaz, 2006a). A social lubricant, plática is a light conversation used prior to the discussion of serious issues. As such, plática helps to address potential conflicts, desensitize painful reactions, and offers a safety net for delving into deeper issues in therapy. Consequently, effective interventions with culturally diverse individuals require an understanding of context-rich communication. Beyond words, a context-rich communication comprises nonverbal signs such as body language, voice pitch and intonation, and other kinesthetic messages. An example of a nonverbal process, intuition can illuminate cross-cultural encounters. As a way of communicating and understanding, intuition relies on internal cues, hunches, and vibes (Butler, 1985). In a similar vein, I adhere to cultural resonance, the ability to understand clients through intuition, clinical skill, and cultural competence (Comas-Díaz, 2006a). Cultural resonance can provide information beyond those messages that are communicated verbally, such as clients' internal emotional state.

Psychotherapy language is culturally constructed and thus reflects the power differential inherent in the therapeutic relationship. Indeed, clinicians need to avoid eliciting what Duran (2006) called historical transference. In other words, historical transference entails a power differential resulting from the replication of the colonizer and colonized dynamic. An example of this power differential is the therapist's attitude toward the client's language. With its English-only movement, the United States government does not value bilingualism (Comas-Díaz & Padilla, 1992). Likewise, psychotherapy has not paid proper attention to language issues (Claus, 1998). For example, monolingual therapists do not appreciate, nor fully understand, bilingual and polyglot clients' experiences (Santiago Rivera & Altarriba, 2002). Such an attitude underestimates the multiple layers of meaning that language and bilingualism provide to people's lives. Javier (1995) studied bilingual individuals and gave them the choice to express their thoughts in English or Spanish. Most of them preferred to switch languages, and the researcher followed the lead of the participants. Based on these findings, Javier recommended that researchers who work with bilingual participants should integrate both languages to provide more reliable and descriptive data. Similarly, Luna, Ringberg, and Peracchio (2008) empirically found that bilingual bicultural individuals have incorporated two cultures within themselves, and consequently, have distinct sets of culture-specific concepts and mental frameworks

that activate aspects of their identities. In brief, bilingual bicultural individuals may be different persons, according to the language they speak. Clinicians unaware of these processes may be addressing only one identity when they communicate with bicultural clients in English.

Furthermore, clinical practice does not frequently speak to the realities or special needs of linguistic minorities. To enhance client and clinician communication, the American Psychological Association's Multicultural Guideline 5 urges psychologists to respect clients' language preferences and ensure accurate translation of documents by providing informed consent about the language in which assessment, therapy, and other procedures will be conducted (APA, 2003). Multicultural Guideline 5 also encourages psychologists to respect clients' privacy by not using interpreters who are significant others, relatives, community authorities, and/or unskilled in the area of mental health. The unaddressed psychotherapeutic needs of culturally and linguistically diverse individuals have fomented the examination of ethnic-specific modalities.

### Ethnic-specific Psychological Practice

The common elements in a psychotherapeutic process include a shared worldview, the healing qualities of the therapist, the client's expectations, and an emerging sense of mastery (Torrey, 1986). However, these elements may be interpreted differently across cultures. Some multicultural scholars have asked if there is any role for the development of culture-specific approaches to psychotherapy (López, Kopelowicz, & Cañive, 2002). As a response, various clinicians looked into the ancient wisdom of their ethnic communities (Comas-Díaz, 2006a; Duran, 2006). Ethnic psychological practice offers a culturally relevant framework, validates racial and ethnic meanings, and recognizes the importance of historical and political contexts of oppression (Comas-Díaz, 2007). Indeed, many ethnic psychologies adhere to a social justice perspective that promotes the construction and transformation of a more egalitarian future. Moreover, ethnic psychologies are anchored in a liberation discourse because they provide resources for rescuing ancestry and archetypes by reaffirming and grounding ethnic identity into a collective self. Certainly, indigenous practices and ethnic psychologies can be a source of healing and liberation. The Surgeon General concluded that Western psychological interventions could benefit from incorporating the core assumptions and practices of indigenous healing (Surgeon General, 2000). Similarly, the American Psychological Association's Multicultural Guideline 5 encourages psychologists to recognize that culture-specific treatment may require ethnic and indigenous interventions. When suitable, this guideline encourages psychologists to acknowledge and solicit the assistance of recognized helpers (community leaders, clergy) and traditional healers (shamans, *santeros*, medicine women/men, *curandero(a)s*, astrologers, psychics, *espiritistas*, and others). Psychologists can learn about helping practices and healing traditions used in non-Western cultures that may be appropriately incorporated into psychological practice.

Many traditional healing practices are based on indigenous sources of knowledge such as intuition, spirituality, experience, observation, nature, balance, harmony, ancestors, history, humor, and others (Bigfoot, 2008). This knowledge is obtained through specific ways of being in the world. Hence, these ways of knowing include honoring, listening, respecting, being humble, accepting, revering, collaborating, teaching, and learning, among others. These meaning-making processes are used to create awareness, foster healing, encourage liberation, and promote development. For instance, the family structure among many people of color honors ancestors by including the deceased, since relationships don't necessarily end with death (Council of National Psychological Associations, 2003; Shapiro, 1994). Dominant psychological models seldom address the domain of relationships with the deceased in psychological assessment and/or treatment (Comas-Díaz & Caldwell-Colbert, 2006). In the next section, I present a few illustrations of ethnic psychological practices.

### Bicultural Approaches

Bicultural effectiveness training (BET) and family effectiveness training (FET) target intergenerational conflicts elicited by acculturation and adaptation problems among Latinos (Szapocznik, Santisteban, Kurtines, Perez-Vidal, & Hervis, 1984). The Strengthening of Intergenerational/Intercultural Ties in Immigrant Chinese American Families (SITICAF) is an example of addressing cultural adaptation issues among Chinese Americans (Ying, 1999).

### Dichos *therapy*

*Dichos* psychotherapy, an ethnic psychology, involves Spanish proverbs or idiomatic expressions that capture folk wisdom (Aviera, 1996; Zuñiga, 1991). Also known as *refranes*, these Spanish language proverbs are a type of flash therapy that offers the therapist a window into many Latinos' worldview

(Comas-Díaz, 2006b). Muñoz used *dichos* in his cultural adaptation of CBT. Likewise, de Rios (2001) recommended *dichos* as a cognitive restructuring tool to facilitate flexibility, manage anger, and address interpersonal conflicts.

### Family Constellation Therapy

Developed by Bert Hellinger, and based on Zulu cultural and spiritual beliefs, family constellation therapy views individual and family dynamics in a larger context (Hellinger, Weber, & Beaumont, 1998). A former Catholic priest and missionary in South Africa, Hellinger conceptualizes the family energy field or family soul as the principle for understanding and treatment. The family soul, according to Hellinger, includes ancestors and future generations. Specifically, family constellation treatment entails becoming conscious of unconscious loyalties toward ancestors and generational burdens. A classic example is a woman who rejects her cold and distant mother and cannot get pregnant. Through constellation work, the client becomes conscious that her mother's distance was a protection against the loss of her first child.

### Liberation Psychology

Psychology of liberation emerged in Latin America as a response to sociopolitical oppression (Aron & Corne, 1994). It is intimately linked to Paulo Freire's (1970) *concientization* or the critical consciousness that involves the process of personal and social transformation that oppressed Latin Americans experienced while they alphabetized themselves in a dialectic discourse with their world. Within this context, psychology of liberation integrates an indigenous psychological perspective within an emancipatory paradigm (Comas-Díaz, Lykes, & Alarcon, 1998). Thus, psychology of liberation attempts to work with people in their contexts to enhance their awareness of oppression and the inequalities that have kept them subjugated. Through these means, liberation practitioners collaborate with the oppressed in developing critical analysis and engaging in a transforming practice.

### Morita and Naikan therapies

Morita therapy (Morita, 1998) and Naikan therapy (Reynolds, 1980) are psychological interventions developed in Japan, which infuse Japanese and Asian values (such as face) into clinical practice. Both therapies are sociocentric in nature and use relationships, beliefs, and milieu approaches in healing. Chinese mental health practitioners are using Morita therapy to treat inpatient clients (Xin Ke, personal communication 2007).

### Network Therapy

Carolyn Attneave (Attneave, 1990) developed network therapy. Using Native American values, network therapy is an extended family/group psychotherapy approach that involves the client's network (Speck & Attneave, 1973). It entails recreating the clan's network to activate and mobilize a person's family, kin, and relationships in the healing process.

### TEMAS and Cuento therapy

Tell Me a Story (TEMAS) is a projective psychological test developed with culturally relevant stimuli (Costantino, Dana, & Malgady, 2007). Multicultural in nature, this test comprises two sets of structured stimulus cards with pictorial problem solving—one for minorities (African Americans and Latino/Hispanics) and the other for nonethnic minorities. As a narrative assessment tool, TEMAS evolved into *cuento* therapy. According to Costantino, Malgady, and Rogler (1994) *cuento* therapy uses folktales with ethnic and culturally relevant stimuli in a social learning approach. It is designed to present models of adaptive interpersonal behavior. Through storytelling, this therapy uses modeling to promote a new synthesis of bicultural symbols and foster adaptive personality growth among Latino youngsters who live in two cultures (Costantino, Malgady, & Rogler, 1986). In this approach, clients are asked to focus on a culturally relevant hero or heroine and to use them as idealized but achievable figures (Costantino, Malgady, & Rogler, 1988). *Cuento* therapy provides a strong psychoeducational component. Research found *cuento* therapy to be effective with Puerto Rican children (Costantino, Malgady, & Rogler, 1986).

### Testimonio

*Testimonio* or testimony is a Latin American way of bearing witness that chronicles one's traumatic experiences and how these have affected the individual, family, and community (Cienfuegos & Monelli, 1983). Due to many people of color's history of distress, *testimonio* has successfully been used in trauma therapy (Aron, 1992). This verbal healing journey to the past honors the historically situated reality of culturally diverse individuals and anchors healing in a sociopolitical context.

## Ethnocultural Psychological Practice

To address the needs of culturally diverse clients—particularly clients of color—I suggest an ethnocultural

psychological approach. This theoretical and practical orientation integrates ethnic, cultural, racial, class, and other diversity variables into clinical practice. An ethnocultural practice aims to incorporate cultural competence and cultural integrity into the delivery of services to culturally diverse people (Comas-Díaz & Jacobsen, 2004). It integrates ethnicity and culture into clinical practice by infusing mainstream practice with multicultural values, ethnic/indigenous practices, critical analysis, and empowering approaches. Ethnocultural practice facilitates a transcultural analysis that aims at critical consciousness, or the process of transformation that oppressed individuals experience while educating themselves in a dialectical conversation with the world. Through this process, clients learn to read their condition and author their reality. Within this approach, the therapeutic relationship encourages the dialogue that helps clients express their truth, assert their identity, heal, and achieve agency.

Ethnocultural psychotherapy proposes an extensive evaluation—the ethnocultural assessment (Jacobsen, 1988). The ethnocultural assessment stages are heritage, saga, niche, self-adjustment, and relationships (Comas-Díaz & Jacobsen, 2004). To explore clients' heritage, therapists look at clients' ethnocultural ancestry, genealogy, history, genetics, and sociopolitical contexts. During this stage, clinicians examine clients' cultural trauma, psychopolitical mistrust, and soul wounds. To explore clients' saga, clinicians examine clients' family, clan, and group story through the history of immigration and other significant transitions. Exploration of the niche stage reveals the post-transition analysis, in which clinicians pay attention to clients' cognitive and emotional interpretation of their family saga. Next, therapists evaluate clients' self-adjustment separate from their family adaptation. Of relevance to this stage is the examination of clients' cultural resilience and creativity. Finally, the last stage of the ethnocultural assessment explores clients' significant affiliations, including the therapeutic relationship.

An essential aspect of ethnocultural therapeutic approach is an ethnopolitical perspective. As indicated before, many people of color require emancipatory approaches since the pain of oppression can be unbearable for individuals residing in a society that prides itself on being classless and open. This psychopolitical lens promotes conscientization, decolonization, social justice, and global solidarity. Consequently, ethnocultural approaches facilitate people of color's identification, acceptance, and celebration of their ethnicity and culture, as they help

to rescue ancestry and cultural resources (Comas-Díaz, 2007). It facilitates the development of cultural consciousness—a critical awareness of ancestry that encourages a reconnection to cultural resources to empower, heal, and redeem (Comas-Díaz, 2007). One of these resources is resilient creativity. Many people of color have used creativity as a resilient and subversive mechanism against oppression. Examples range from flamenco (*canto hondo* music from the Gypsy or Roma people), Hip Hop music, to Spoken Word or the original Nuyorican Poets Café (Algarín. & Piñero, 1975). *Arpilleras*, a colorful weaving depicting the stories of oppressed and traumatized Latin Americans, is a subversive creative response (Agosin, 1996). Interestingly, Leung, Maddux, Galinsky, and Chiu (2008) empirically showed that the relationship between multicultural experiences and creativity is stronger when people adapt (i.e., are culturally resilient), are open to new experiences, and when the creative context emphasizes flexibility over rigidity. This ethnopolitical approach depathologizes, affirms cultural strengths, encourages cultural consciousness, and facilitates resilience. It clinically addresses issues such as ethnocultural allodynia and exposure to racial microaggressions. Additionally, it examines postcolonization stress disorder, soul wound, and postslavery trauma, among other kinds of historical oppression. A goal of the ethnopolitical approach is to promote liberation, enhance group solidarity, sustain collective continuity, and promote the development of a just society.

## Conclusion
### Collective Cultural Competence

Dominant psychological practice tends to endorse an individualistic worldview, frequently ignoring collective, systemic, and sociopolitical contexts. Therefore, to effectively work with culturally diverse individuals, clinicians need to expand their scope of interventions. Adding a sociocentric lens to their clinical practice can enhance therapists' cultural competence. The development of cultural competence is a life-long process. To help this process, clinicians need to extend their cultural competence into collective contexts. Therefore, cultural competence requires the inclusion of systemic, organizational, and communal strategies. Likewise, Cross, Bazron, Dennis, and Issacs (1989) identified cultural competence as the encouragement of organizational change and growth. They suggested that the development of organizational cultural competence evolves from (a) *cultural destructiveness* (characterized by attitudes, policies, and practices that are destructive

to individuals' cultures, such as the prohibition against speaking individuals' mother tongue); (b) *cultural incapacity* (characterized by attitudes, policies, and practices that support the racial dominance of the dominant group and assume a paternalistic mode toward the ethnic groups); (c) *cultural blindness* (characterized by attitudes, policies, and practices that support the belief that all people are the same and that members of minority groups have some cultural deficiency); (d) *cultural precompetence* (characterized by attitudes, policies, and practices that convey awareness of limitations in multicultural communication and desire to provide a culturally sensitive treatment, but that have a simplistic view of cultural competence, and believe that a single act fulfills any perceived obligation to all ethnic groups); and finally, to (e) *cultural competence* (characterized by attitudes, policies, and practices that value and respect cultural differences, support continuing self assessment regarding culture, pay attention to the dynamics of difference, and continue to expand their knowledge and resources).

Individuals need to promote cultural competence in their communities. Indeed, social progress emerges when communities appreciate diversity (Fuentes, 1992), and thus, develop cultural competence. Moreover, communal cultural competence enhances society's civic benefits. The development of communal cultural competence emerges through the following stages: (a) *exclusionary* (communities are monocultural and have a civic disengagement); (b) *oblivious* (communities are mostly monocultural and have a civic detachment); (c) *naïve* (communities have civic amnesia, are ahistorical and acultural; (d) *charitable* (communities are multicultural and have civic altruism, but the norm is the giver's perspective); (e) *reciprocal* (communities are multicultural, address the legacies of inequalities and value partnering and cultural competence, and focus on the present society), finally, (f) *generative* (communities are multicultural; value interconnectedness, multiple perspectives, and cultural competence; and focus on everyone in the present and in the future) (Bordewich, 2005; Musil, 2003). Although the generative stage may be aspirational at this time, collaboration between researchers, clinicians, clients, and community shareholders is an initial step toward the promotion of community cultural competence.

## Future Directions

As the development of cultural competence is a lifelong process, maintaining cultural integrity in the delivery of psychological interventions also requires a life-long commitment. Therefore, to increase cultural competence and preserve cultural integrity in the delivery of interventions to culturally diverse populations, clinical psychologists need to systematically examine the following areas:

• Operational definition of cultural competent behaviors
• Connection between cultural competence and improved mental health functioning
• Relevance of sociopolitical contexts to clinical practice
• Incorporation of indigenous and ethnic psychology into psychological practice
• Examination of the role of spirituality and faith
• Cross-cultural studies of language and nonverbal communication
• Studies on transculturation/borderland issues and their effects on mental health
• Examination of ethnobiological and neurohormonal factors in psychopharmacological and psychological treatment
• Combinations of qualitative and quantitative methods
• Studies of resilience and cultural strengths among culturally diverse populations

Furthermore, we continue to face the following outstanding questions:

• What is the effect of globalization on clinical psychological practice?
• How does transnational mobility impact on clinical practice?
• How does multiculturalism influence dominant psychological effect practice?
• How does language (bilingualism, being a polyglot, nonstandard English) affect delivery of psychological services?
• How do we develop creative resilience, and how can we teach it?

As clinical psychology continues to improve the services to culturally diverse individuals and communities, the whole field will enhance its competence and integrity.

# Conclusion and Future Directions

# The Future of Clinical Psychology: Promises, Perspectives, and Predictions

David H. Barlow *and* Jenna R. Carl

## Abstract

In this chapter, we speculate on near to immediate future trends in clinical psychology and make ten predictions in the broad areas of training, diagnosis and assessment, and treatment. These include: (1) an increased focus on competencies in training; (2) the implications of evidence-based practice as a new major focus of training; (3) changes in the accreditation of training programs; (4) a move to dimensional conceptions of diagnosis; (5) clinical outcomes assessment as an integral part of practice, as well as a more individual focus in clinical research; (6) the increasing recognition and dissemination of psychological treatments; (7) the end of single-diagnosis psychological treatment manuals; (8) the development of drugs that specifically enhance the mechanisms of action of psychological treatments; (9) an expanded role for technology in service delivery; and (10) a clearer delineation of the terms "psychological treatments," referring to interventions directed at psychopathology and pathophysiology in the context of our health-care delivery system, and, "psychotherapy," increasingly based on data from positive psychology, but directed at enhancing personal adjustment and growth.

**Key Words:** Assessment, clinical psychology, diagnosis, future trends, training, treatment

In the first chapter of this handbook, I (DHB) recount two 40-year odysseys in the profession of clinical psychology: The first is David Shakow's 1969 look back at the first 40 years of his career; and the second is my own 40-year odyssey that coincidently began in 1969. Chapter 1 examines Shakow's predictions made in 1969 for the coming years in clinical psychology, focusing on three broad areas: training, diagnosis and assessment, and treatment. My own 40-year odyssey has played out in the context of a realization of Shakow's vision in most of these areas, but with many surprises and unexpected twists along the way, as detailed in Chapter 1. In this chapter, I am joined by a young colleague (JRC) beginning her own odyssey in clinical psychology, and together we briefly outline likely trends and developments over the coming decades. Many of these trends and developments are articulated in some detail in other chapters of

this handbook, and, in that sense have already begun. Others represent predictions that are more implicit than explicit in the book, but seemed important enough to us to note. In a very arbitrary manner and reflecting a popular organizational scheme of the day, we have grouped our predictions in a "top ten" list and emulate Shakow in covering the areas of training, diagnosis and assessment, and intervention (see Table 39.1), but without any intent to suggest that one topic is more important than another. Of course, the list could have been much longer and some of the themes could have been grouped together or separated into more specific issues, but this seemed as reasonable a way as any to venture into the realm of visions for the future. It will remain for someone else (perhaps JRC) to reflect on the fate of these themes at some future time, much as we have done with Shakow's predictions presented in Chapter 1.

**Table 39.1 Top predictions in clinical psychology by area**

| Training | 1. A Focus on Competencies | Clinical training goals will be assessed and indexed by outcomes in applied settings. |
|---|---|---|
| | 2. Evidence-based Practice | Strategies of evidence-based practice will join psychopathology, assessment, and interventions as foundational foci in training. |
| | 3. Accreditation | The face of accreditation will change to reflect distinct competencies. |
| Diagnosis & Assessment | 4. Diagnoses as Dimensions | A theoretically based dimensional system of nosology for mental disorders will gradually replace the current prototypical, categorical classification system. |
| | 5. Clinical Outcomes Assessment | Clinicians will be evaluated and differentially compensated based on treatment outcomes, and clinicians and clinical scientists will return to a more individual, idiographic focus to guide future clinical research and practice. |
| Treatment | 6. The Growth of Psychological Treatments and a Focus on Dissemination and Implementation | As new psychological treatments are developed and existing treatments become more efficacious, the focus will shift to currently underdeveloped efforts on dissemination and implementation. |
| | 7. Moving Beyond Single-Diagnosis Treatment Manuals | Modular transdiagnostic interventions will replace treatment protocols applicable to only a single diagnostic category. |
| | 8. Drugs That Enhance Psychological Treatments | Pharmacological agents that specifically bolster the effectiveness of mechanisms of action of psychological interventions will become increasingly common. |
| | 9. Technology-based Service Delivery | Digital technologies will become increasingly integrated into service delivery systems and will lead to more personalized care. |
| | 10. Psychological Treatments or Psychotherapy? | Psychological treatments will be a term reserved for evidence-based practices appropriate for addressing pathology in the context of health care systems. Psychotherapy will be a term reserved for procedures directed at enhancing personal adjustment and growth, but administered outside of health care systems and based increasingly on data emerging from the field of positive psychology. |

## Training
### *A Focus on Competencies*
*Clinical training goals will be assessed and indexed by outcomes in applied settings.*

In Chapter 1, and also in Chapter 8 by Catherine Grus, we find that the long-desired goal of measuring competencies, eloquently articulated by Shakow 40 years ago, is beginning to be realized. As described by Grus, and based to a large extent on work by Nadine Kaslow and colleagues, these initiatives are currently developing along several fronts. First, much has been achieved recently in the definition of competencies. The American Psychological Association's Competency Benchmarks Document (American Psychological Association [APA], 2007) outlines a competency framework with two domains of core competencies—foundational and functional—that are defined in detail at specific levels of professional development, such as entry to practicum, internship, and practice. The foundational competencies put forth by the APA (2007) comprise 12 core competencies that are then further delineated by "essential components" (defining skills) and "behavioral anchors" (behavioral benchmarks for assessing readiness). Specific assessment methods are suggested for each set of behavioral anchors. For example, the foundational competency "Relationships" is defined as, "Capacity to relate effectively and meaningfully with individuals, groups, and/or communities," and has three subcategories: Interpersonal Relationships;

Affective Skills; and Intradisciplinary Relationships. At the entry to practicum level, Interpersonal Relationships has the essential component "interpersonal skills" and behavioral anchors such as "listens and is empathic with others" and "respects and shows interest in others' cultures, experiences, values, points of view, goals and desires, fears, etc." Assessment methods recommended include: "performance and behavior in course(s) or evaluation milestones" and "examination of performance in interviews." Whereas, at the entry to practice level for Interpersonal Relationships, the essential component is "to develop and maintain effective relationships with a wide range of clients, colleagues, organizations, and communities" and behavioral anchors are "negotiates conflictual, difficult, and complex relationships including those with individuals and groups that differ significantly from oneself" and "maintains satisfactory interpersonal relationships with clients, peers, faculty, allied professionals, and the public." Here assessment methods proffered are "360 evaluation" (which refers to an evaluation that includes feedback from all levels of co-workers, supervisors and supervisees, clients, and sometimes self-feedback) and "self-evaluation."(APA, 2007; for further discussion of competencies see Grus, Chapter 8, this volume).

Second, efforts are under way aimed at developing more rigorous methods to assess competence. In 2004, the APA Board of Educational Affairs formed a Task Force on Assessment of Competence in Professional Psychology charged with researching and developing competency assessment methods. In 2008, the Task Force released "The Competency Assessment Toolkit for Professional Psychology," which provides information on 15 different assessment practices to help educate and guide users (APA, 2009). These assessment methods are also listed in the Competency Benchmarks Document (APA, 2007) mentioned earlier, and they include practices such as Client/Patient Process and Outcome Data, Case Presentation Review, and Simulation/Role Plays. The toolkit includes a grid that displays ratings of the usefulness of each assessment method for particular competencies and a fact sheet that describes each method, how it can be used, and the challenges involved in implementation for practicing clinicians (APA, 2009).

Third, there are increasing efforts between education/training organizations and regulatory/credentialing bodies to collaborate on developing competencies and assessment methods. Historically, these groups have functioned fairly independently, but a mutual interest in developing consistent competencies has encouraged cooperation. As Grus notes, several national competency initiatives, like the Competencies Conference and the APA Benchmarks and Toolkit work groups, recently brought these groups together (Chapter 8, this volume), and there is evidence that this trajectory of cooperation will continue. The Association of State and Provincial Psychology Licensing Boards (ASPPB) has made a concerted effort to include education and training advocates in its work on competencies "to ensure that the proposed regulations used language and constructs consistent with models of professional psychology education and training" (Grus, Chapter 8, this volume). Both sides understand the advantages of having a competency framework that is integrated across the education, licensing, and practicing continuum, and is simultaneously reflective of the needs of each of these systems. With consistent competency requirements in place, these uniform measures of knowledge and skills can replace complicated one-off licensing systems, as in the example of Canada's pioneering Mutual Recognition Agreement (MRA). This agreement foreshadows future possibilities enabled by competencies; it establishes five core competencies (interpersonal relationships, assessment and diagnosis, intervention and consultation, research, and ethics and standards) as the basis for recognition of practitioner licenses across territories (see Grus, Chapter 8, this volume).

A future development will be extending these learning objectives and strategies for assessing competencies directly into applied settings. In other words, it is not enough to simply ascertain learning outcomes in training programs; we also need to understand whether these outcomes, in the form of competencies, can be applied in such a way that they make a measurable difference in outcomes in the setting in which they are implemented—with an individual patient, within a clinic, or more broadly in the context of a community intervention.

To take one example, in the United Kingdom, Roth and Pilling (2007) have developed a competency framework for the use of cognitive-behavioral therapy (CBT) in the treatment of depression and anxiety. They identified which competencies to include in the framework through retrospective analysis of clinical trials outcomes data. That is, they reviewed clinical trials that tested CBT for depression and anxiety; identified those treatments with the greatest efficacy; studied the CBT manuals of those successful treatments; and deduced the underlying competencies necessary for effectively applying these treatments. Examples include knowledge

of the common cognitive biases relevant to CBT, ability to explain and demonstrate rationale for CBT to client, ability to adhere to an agreed-upon agenda, ability to use thought records, capacity to adapt interventions in response to client feedback, and knowledge of up-to-date research on each anxiety disorder. Grounding clinical competencies in the evidence base of treatment outcomes data is a promising beginning for developing competencies relevant to an applied setting. In addition, it will be important to conduct regular assessments of the quality of services provided, and the effectiveness of such assessment procedures will be contingent on the development of appropriate outcomes measures in each setting (described later). Although we still have more work to do, it seems very clear that we are on the road to setting standards for competency that will be more than grades on an exam and will extend into actual measured performance in clinical settings. A new book series entitled "Specialty Competencies in Professional Psychology," edited by Art and Christine Nezu and published by Oxford University Press, will take up these themes.

### Evidence-based Practice

*Strategies of EBP will join psychopathology, assessment, and interventions as foundational foci in training.*

At the time of the writing of this chapter, every health-care profession has accepted the fundamental concept of EBP. Policies have been developed articulating the principles of EBP as they would be operative ideally in each health profession (e.g., APA, 2006). Despite the widespread recognition of the importance of EBP, there is continuing ambiguity and uncertainty on the specific directions training programs must take to prepare students to be fully competent in implementing EBP. To take one example, the mental health field clearly recognizes the existence of empirically supported psychological treatments, and, as detailed later, governments and health-care policy makers around the world have committed over $2 billion to government agencies to disseminate evidence-based psychological treatments throughout systems of health care as of 2009. These agencies include the Substance Abuse and Mental Health Services Administration (SAMHSA), particularly in its National Registry of Evidence-based Programs and Practices (NREPP), as well as the Veterans Health Administration (VHA) and various state departments of mental health. In the United Kingdom, the National Health Service, through its National Institute for Health and Clinical Excellence (NICE), is also promulgating evidence-based

psychological treatments. Each of these groups is developing its own strategies and dissemination program for identifying and disseminating these interventions. The end result is that a large number of groups are frequently updating EBP approaches after a thorough search and analysis of the evidence, as outlined in some detail in Chapter 7 (Spring & Neville, this volume), Chapter 9 (Zeiss & Karlin, this volume), and Chapter 11 (Chorpita, Bernstein, & Miranda, this volume).

But how can the interested clinician find this information? At present, one would be hard-pressed to find one clinical psychology doctoral program that incorporates training in identifying up-to-date evidence-based interventions for its clinicians. However, well-articulated strategies for navigating the network of existing evidence-base resources have begun to appear in recent books on EBP (e.g., Norcross, Hogan, & Koocher, 2008; Spring & Neville, Chapter 7, this volume). More importantly, the National Institutes of Health (NIH) is funding a Council for Training in Evidence-based Behavioral Practice (EBBP) whose sole mission is to develop learning modules to facilitate the development of evidence-based behavioral practice at the level of the individual clinician. The Council is working toward granting continuing education credits for completion of these modules, but a step in the near future will be to incorporate these training procedures, or very similar strategies, into the curricula of training programs in clinical psychology (Spring & Neville, Chapter 7, this volume).

Three training modules have been developed by the Council: the EBBP Process Module, the Search for Evidence Module, and the Systematic Review Module (EBBP, 2007). These modules describe the foundation of what EBBP is; why it is advantageous for practitioners, clients, and the community; and how it can be implemented. The first module explains the EBBP five-step process: Ask, Acquire, Appraise, Apply, Analyze & Adjust—and then provides two simulated case examples, one with an individual client and one as a community intervention, through which the user gains practice applying this technique. Each of the five steps is a cue to the practitioner. "Ask" reminds the practitioner to formulate pertinent questions about health status and relevant environmental or cultural factors. "Acquire" prompts the practitioner to gather the best evidence related to the question. "Appraise" cues the practitioner to critically assess the evidence for "validity and applicability to the problem at hand." "Apply" calls for the practitioner to integrate the "context,

values, and preferences of the recipient of the health intervention, as well as available resources, including [his or her own professional] expertise" and to collaborate with the client in selecting and implementing the treatment. "Analyze & Adjust" entreats the practitioner to assess the process and outcomes and to modify the practices as necessary to improve outcomes.

The final two training modules focus on describing the resources available for EBBP and how to use them. The second module offers guidelines on searching for evidence, including describing differences between types of evidence, sources, and search resources; it also suggests strategies for improving search results. The third module describes systematic reviews and explains how they differ from traditional reviews; it also provides instruction for how to evaluate and conduct systematic reviews. These modules are designed to provide both an efficient and effective training tool. Although the information is intended to be accessible to users with little or no research training, even those with advanced research experience will likely improve their search techniques and use of existing resources.

This effort is pioneering and fills a critical gap, given that many training programs have not yet fully and systematically incorporated training in EBP into their curricula. However, in consideration of the growing top-down emphasis on EBP, it will not be long before accreditation bodies put forth standardized EBP training requirements (which may be based on the EBBP system described earlier) that can then be more fully integrated into each institution's training curricula. In addition, navigating EBP treatment guidelines will undoubtedly become simpler as existing resources expand their coverage of EBP and improve the quality of treatment guidelines. Most likely, one or two resources will emerge as the standards for the field. This has already happened in certain areas of medicine. UpToDate, for example, is an online resource that provides the latest treatment recommendations for physicians in 14 medical specialties. The information provided is evidence-based, extensive (covering 7,700 clinical topics), frequently updated with relevant new findings from peer-reviewed journals, and easy to use and access (by hand-held devices or computer) (UpToDate, 2009). Probably for all of these reasons, this resource has become a leading secondary source of reference for physicians seeking recommendations on clinical care. Development of a similar resource for psychological treatments will allow training programs to focus more on teaching the principles and frameworks of EBP and less on the more technical skills of searching the evidence. Thus, immersion in the principles of EBP will be a foundational component of training in clinical psychology.

### Accreditation

*The face of accreditation will change to reflect distinct competencies.*

Accreditation systems for clinical psychology in the years to come will identify clinical psychologists with overlapping but also distinct training and competencies. One set of competencies will be appropriate to service delivery, and with EBP as a context, will reflect Shakow's (1969) vision of a Scientist-Practitioner model of training in which science is integrated into practice. The second set of competencies will reflect the geometrically increasing complexity of actually conducting clinical science, in contrast to applying it to clinical problems. Scientist-practitioner programs concerned mostly with applying scientific findings in a clinical or applied context will likely continue to be accredited by the longstanding and widely accepted Committee on Accreditation (CoA) of the APA, with its well-established procedures for evaluating doctoral training programs and internships in clinical psychology and closely related fields. However, CoA's accreditation criteria will undergo change. As agreement is reached upon guidelines for EBP training, CoA will develop requirements that reflect these objectives. But for those programs charged with instilling an additional set of competencies focused on actually conducting "big" science in the form of large clinical trials, brain imaging technology, clinical behavioral genetics, and the like, a different system of accreditation may be required. Of course, it is also possible that CoA could accommodate this new development.

But some psychologists think that a new accrediting agency is needed for research-focused programs. The Academy of Psychological Clinical Sciences ("the Academy") was formed in 1995 as a coalition of research-focused (primarily clinical scientist model) doctoral programs to advocate for their interests in the accreditation process and in the development of the field. By the early 2000s, this group concluded that CoA's all-encompassing accreditation system was hindering scientific training and research within clinical psychology programs. The major impediment was the proliferation of courses and other requirements stipulated by CoA that greatly diminished the amount of time available for conducting science, with its requisite time-intensive individual mentoring.

Another factor was the slow pace at which CoA was requiring the integration of EBP as a training requirement. To resolve this dilemma, in 2006, the Academy created the Psychological Clinical Science Accreditation System (PCSAS), designed specifically to meet the needs of clinical science doctoral programs (PCSAS, 2009). The PCSAS is charged with the two-fold goals of "promot[ing] high-quality science-oriented doctoral education and training" and "enhanc[ing] the knowledge base for disseminating and delivering the safest, most cost-effective mental and behavioral health services to the public" (2009). Only doctoral clinical psychology programs that sit within "nonprofit, research-intensive universities" and that profess a "primary mission" of providing "high-quality, science-centered education and training" are eligible to apply for accreditation with PCSAS. There are five general areas that programs are evaluated on for accreditation: conceptual foundations, design and resources, quality of the science, quality improvement, and outcomes. The PCSAS aims to foster training in the most scientifically advanced research techniques possible and to continue to push research to the cutting edge by instilling methods of "quality improvement," continuously examining feedback and program results, making ongoing changes to the program as needed, and assessing "outcomes"—valuations of training based on results rather than on checklists of criteria.

A debate is under way regarding the value of a new accreditation system for research-focused programs. PCSAS proponents argue that this new accreditation system will set a higher standard for clinical science research training, to distinguish these programs from those with decreased emphasis on science and research. However, this point is contested by scientifically oriented clinical psychologists who believe that the emphasis should be on a better integration of the principles of EBP into existing programs. They also argue that pursuit of high-quality scientific research in academic programs historically has not been dictated by accreditation requirements, citing examples in other areas of science, such as biology, sociology, and the like, and therefore that an accreditation system focused on advancing scientific research is unnecessary.

Assuming that the PCSAS continues to grow, questions that remain include the relative value placed on matriculating in programs accredited by one organization or the other among health-care agencies and state licensing boards. Given the initial response from major health-care agencies such as the VHA and the NIH, it is likely that trainees from programs accredited by either organization would be seen as competent to deliver services and work in one setting or the other. The reaction of state licensing boards remains to be seen.

Looking toward the future, we project that both accreditation systems will remain relevant. The CoA accreditation will continue to identify programs meeting all criteria for training clinicians with competency in the practice of clinical psychology. This information, of course, will continue to be very relevant to state licensing boards. But, as noted earlier, and consistent with the vision of Shakow and the rise of EBP, the true realization of the Scientist-Practitioner model of training, which is a clinician who integrates science into his or her practice, will likely occur in both types of programs, including those whose training goals primarily focus on producing competent practitioners. These practitioners will also be capable of participating in the production of new knowledge as part of practice-research networks (Borkovec, 2004; Borkovec, Echemendia, Ragusea, & Ruiz, 2001) or through using more idiographic methods of assessment and evaluation (see Section 5). The introduction of EBP and outcomes assessment will facilitate this change, a trend that may have been underestimated by the Academy.

Accreditation by the PCSAS, on the other hand, will signify training that will produce competent practitioners, albeit with a different set of skills. These clinical scientists will be focused primarily on producing new knowledge, utilizing the full range of scientific methods (developing new treatments or assessment procedures, or delving in depth into the nature of psychopathology or psychological problems). A rather different set of skills is required for this endeavor, including grant preparation and writing, training in the conduct of large clinical trials, brain imaging technology and increasingly sophisticated data analytic strategies that would go well beyond the Scientist-Practitioner model as heretofore envisioned (Barlow, Hayes, & Nelson, 1984; Hayes, Barlow, & Nelson-Gray, 1999; Shakow, 1969). We expect that the majority of clinical psychologists will come from CoA-accredited scientist-practitioner programs. These programs will include current professional schools as well as some university-based doctoral programs that traditionally have produced clinical psychologists who engage primarily in service delivery. But, in view of the full tuition remission and stipends traditionally accorded in

scientifically based PhD programs, we predict that fewer slots in the future will be available on this track and the competition will remain keen. Much as Craighead and Craighead (2006) envisioned, these individuals will be dually competent in clinical practice and "big science," but, given support in the form of tuition remissions and stipends from mostly government sources targeted for training new scientists, these individuals will be increasingly expected to play out their careers in the context of providing the basic scientific underpinnings of our health-care delivery systems.

## Diagnosis and Assessment
### Diagnoses as Dimensions

*A theoretically based dimensional system of nosology for mental disorders will gradually replace the current prototypical, categorical classification system.*

The classification and diagnosis of pathology has its origins in medicine dating back to the time of Hippocrates. Traditionally, the goal was to identify pathologies that were somehow distinctly and qualitatively different from normality and from each other, thereby forming non-overlapping categories (Barlow, 1991; Widiger & Edmundson, Chapter 13, this volume; Kendall, 1975; Millon, 1991). When dealing with certain kinds of pathophysiology, such as neoplasms or bacterial infection, this model fits well. But a consensus has now emerged that the application of categorical classification to mental disorders is unsatisfactory and, in fact, has not been followed since the publication of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders, Third Edition* (DSM III; American Psychiatric Association, 1980). At that time, the framers of the DSM III and subsequent editions, such as DSM III-R (American Psychiatric Association, 1987) and DSM-IV (American Psychiatric Association, 1994), adopted a modified categorical or "prototypical" model of classification in which it was recognized that clear-cut boundaries among the disorders did not exist, but that we could create "prototypes" and assess to what degree psychopathology in individuals approximates the prototype. Thus, diagnostic prototypes listing various symptoms and characteristics were created with the provision that individuals must present with some of the core features, as well as a certain subset of the remaining prototypical symptoms of a particular disorder. This led to a state of affairs in which two individuals diagnosed with, for example, major depressive disorder (MDD), might meet diagnostic criteria for the requisite five

of eight symptoms of MDD, but have only two of them in common, and thereby look very different from one another. One patient might have symptoms 1, 2, 3, 4, and 5, while the other has 1, 2, 6, 7, and 8.

Difficulties with this approach have been detailed elsewhere (e.g., Widiger & Edmundson, Chapter 13, this volume), but include such issues as extensive comorbidity among existing diagnoses, questionable reliability of some prototypical categories, and difficulties in ascertaining categorical thresholds for the number, severity, or duration of symptoms. In fact, it seems that this problem in discerning when someone has reached a threshold in diagnostic criteria may be one of the major causes of diagnostic unreliability (Brown, Di Nardo, Lehman, & Campbell, 2001). It is also the case that there are many individuals who are, for example, clearly depressed or anxious at a clinically severe level, but who do not happen to meet prototypical criteria for one or another of the existing disorders. These individuals must then fall into a category "not otherwise specified" (NOS). In eating disorders, individuals categorized as eating disorder NOS comprise a sizable portion of those presenting for treatment (Fairburn, Cooper, Shafran, & Wilson, 2008). Finally, imposing what are essentially categories, even if just prototypes, on dimensional phenomenon leads to a substantial loss of valuable clinical information.

A consensus has also developed that adopting the more traditional method of organizing psychopathology along dimensions on various psychopathological features will provide a more conceptually satisfying system of classification. This approach would also avoid many of the difficulties inherent in the prototypical system, which is, of course, an attempt at a compromise between a strictly categorical and a fully dimensional approach. The research underlying dimensional approaches to diagnosis draws on decades of research on temperaments and has now advanced to the point at which it can be more broadly integrated into systems of nosology. To take just one example, over 40 years ago, Achenbach (1966) produced data on classifying psychopathology in children that led to what are now widely accepted dimensions of internalizing disorders and externalizing disorders (Achenbach & Edelbrock, 1978). This system became widely used as a more practical and valid approach to dealing with psychopathology in children, but did not, over the previous decades, seriously impact the categorical or prototypical system of diagnosis present in the DSM.

The historical and conceptual development of systems of diagnosis are thoroughly reviewed in Chapter 13 of this volume by Widiger and Edmundson.

As briefly noted in Chapter 1, the DSM-5 working groups, with substantial input from psychological scientists, have begun to move more systematically away from a psychometrically unsatisfactory categorical (or prototypical) approach to a more dimensional approach (Brown & Barlow, 2009; Leyfer & Brown, Chapter 14, this volume; Widiger & Edmundson, Chapter 13, this volume). This progress is furthest along for the personality disorders, in which categorical approaches are the least satisfactory (South, Oltmanns, & Krueger, Chapter 24, this volume). It also seems clear that the fullest realization of a dimensional approach in any official system of nosology will not be complete in time for DSM-5, but that it does represent the future, and the future of nosology will rest on increasingly sophisticated, empirically based psychological approaches incorporating rapidly developing information on the nature of psychopathology.

As one example, we (Brown & Barlow, 2009) have recently proposed a dimensional classification system based on the shared features of the DSM-IV anxiety and mood disorders. This proposal is based on research that has demonstrated substantial cross-sectional covariation in DSM-IV emotional disorders (mood and anxiety disorders). Much of the covariation is accounted for by the common higher-order dimensions that we refer to as neuroticism/behavioral inhibition (N/BI) and behavioral activation/positive affect (BA/P). We argue that N/BI presents as trait anxiety or chronic generalized distress, and can be more accurately referred to as anxiety/neuroticism/ behavioral inhibition (A/N), which is a substantial component of all negative emotional disorders. This temperament, which is strongly associated with activation of the hypothalamic-pituitary-adrenocortical (HPA) axis, is characterized by perceptions of uncontrollability regarding future threatening events, low self-confidence or low self-efficacy over one's ability to cope with these events, and excessive vigilance. Low positive affect on the other hand, reflecting low enthusiasm, an overriding pessimistic sense, and relative lack of interest is more specifically associated with the DSM-IV disorders of MDD and social phobia (SOC). Thus, A/N contributes to all of the emotional disorders, but (low) BA/P makes particular contributions to only some of them (Brown, Chorpita, & Barlow, 1998).

In addition to these two temperaments, individuals with emotional disorders present with varying levels of depressive mood. Some also present with manic features representing a pathological excess of positive affect. Several other key features are found across the emotional disorders, mostly having to do with the specific focus of A/N. That is, A/N can be focused on somatic symptoms (as in hypochondriasis), panic attacks and related autonomic surges (as in panic disorder), intrusive cognitions (as in obsessive-compulsive disorder [OCD]), social evaluation (as in social anxiety disorder), or past traumatic experiences (as in post-traumatic stress disorder [PTSD]). Finally, each individual experiencing the temperament of high A/N displays a pattern of avoidance behaviors manifested in various behavioral and cognitive dimensions. In summary, all individuals presenting with emotional disorders present with patterns reflecting dimensions of higher-order temperaments, dysregulated affective state, avoidance behaviors, and various foci of anxiety.

An example of a case from our clinic with a principal diagnosis of PTSD organized according to this dimensional system of nosology is presented in Figure 39.1. As illustrated in the figure, this individual evidenced an elevated focus of anxiety on past trauma, but also on social evaluation and panic (flashbacks). Various manifestations of avoidance were also elevated (see Brown & Barlow, 2009 for a fuller explication).

Although the transition to a dimensional nosology has already begun, the fullest realization of this approach will be slow to develop, and some have pointed out new problems that will arise (First, 2005). Among these difficulties, the "user friendliness" for clinicians who are accustomed to categorical labels (e.g., "she is depressed" or "he suffers from hypochondriasis") is perhaps the most serious, and presents a barrier that must be overcome. It is also clearly the case that clinical scientists have not yet reached full consensus on optimal ways to organize dimensional approaches, or in some cases such as personality disorders, just what the principal dimensions should be (see South, Oltmanns, & Krueger, Chapter 24, this volume). Nevertheless, barring some unanticipated radical new discovery on the nature of psychopathology by clinical scientists, systems of nosology will become increasingly dimensional.

### Clinical Outcomes Assessment

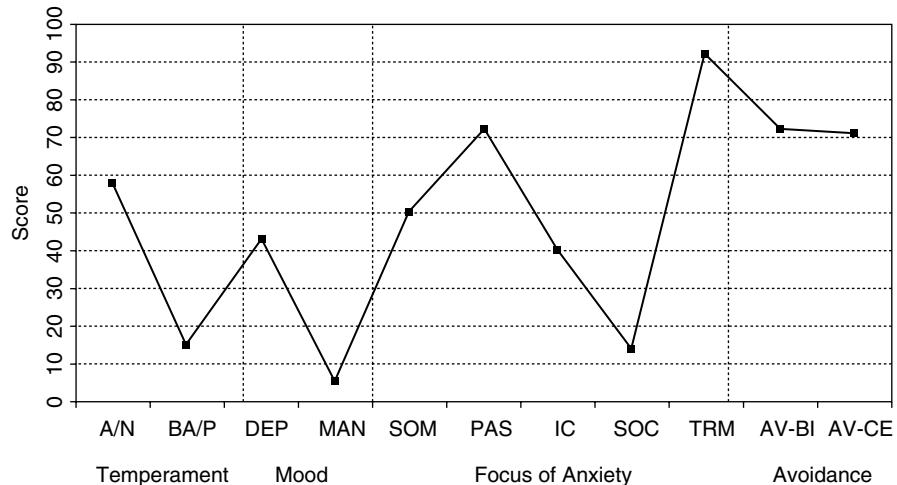
*Clinicians will be evaluated and differentially compensated based on treatment outcomes, and clinicians and clinical scientists will return to a more individual, idiographic focus to guide future clinical research and practice.*


**Figure 39.1** Example Patient Profile with a Dimensional Classification System.
A/N, anxiety/neuroticism/behavioral inhibition; BA/P, behavioral activation/positive affect; DEP, unipolar depression; MAN, mania; SOM, somatic anxiety; PAS, panic and related autonomic surges; IC, intrusive cognitions; SOC, social evaluation; TRM, past trauma; AV-BI, behavioral and interoceptive avoidance; AV-CE, cognitive and emotional avoidance. Higher scores on the *y*-axis (0–100) indicate higher levels of the *x*-axis dimension, but otherwise the *y*-axis metric is arbitrary and is used for illustrative purposes. From Brown, T. A., & Barlow, D. H. (2009). A proposal for a dimensional classification system based on the shared features of the DSM-IV anxiety and mood disorders: Implications for assessment and treatment. *Psychological Assessment, 21*(3), 256–271. Reprinted with permission of the publisher, American Psychological Association.

Clinical outcomes assessment, a strategy clearly anticipated and called for by David Shakow 40 years ago (see Chapter 1), is at the heart of EBP across all areas of applied psychology, but, as with most new initiatives, it is off to a rocky start. Although government agencies and policy makers are unanimous that we should be moving to outcomes assessment in almost every area of service provision, in many cases they have not settled on the best methods for accomplishing this. This is a process that will play itself out over the next several years, until consensus develops on the best ways to integrate outcome measurements in health and educational systems, and this consensus should and will be based on the full participation of all stake holders. This development will then get us past the problem of yet another unfunded mandate on practitioners. Nevertheless, outcomes measurement will ultimately highlight competence and quality among clinical psychologists.

Recent evidence of the promise of outcomes measurement has been eloquently highlighted in the field of cystic fibrosis (Gawande, 2004). This devastating medical condition is ordinarily treated in specialty clinics around the country. Policy makers and third-party payers persuaded these clinics several years ago to begin administering more uniform and valid outcomes measures under strict provisions of confidentiality (as requested by the clinics), such that individual clinics providing the services not

be identified. These confidentiality provisions were motivated, of course, by fear among clinicians of the possible fall-out of misinterpretation of data indicating less than optimal outcomes in a given clinic. As data were collected and shared among the clinics, it became clear that one clinic was doing far better than the others in terms of increasing quality of life and survival time. This was a considerable shock to the other clinics, all of which were under the impression that they were delivering state-of-the-art treatment in an effective manner. At this point, the remaining clinics (still operating under anonymity) requested that the identity of the leading clinic be revealed, so that they could ascertain why and how this clinic was achieving such superior results. A clinic in Minnesota was identified, and remaining clinics quickly arranged to compare notes, visit, and learn how current practices differed from other clinics, and how these differing procedures could be rapidly incorporated into clinics across the country. The result was improved patterns of care for all patients and closer collaboration and cooperation among the clinics on new advances.

A number of state psychological association officials in the United States have noted that outcomes measurement holds the promise of highlighting the superior services provided by doctoral-level clinical psychologists, since these findings are increasingly evident in research settings. Evidence has also begun

to appear that outcomes assessment changes the practice of mental health professionals. For example, Lambert and colleagues (2003) conducted a meta-analysis of three large treatment studies (each included over 1,000 clients) that showed that providing periodic feedback on patient progress to the clinician during the course of treatment, based on repeated ongoing objective assessment, improves treatment outcomes. Ideally, sophisticated outcomes assessment practices would be established, but in the meantime, therapists do not even know if their results are better or worse than average (see Hunsley & Mash, Chapter 5, this volume).

In view of various state and federal mandates on the implementation of EBP, there seems little question that outcomes assessment will become required and will lead, ultimately, to clinician profiling, as it has in some areas of medicine and surgery. This development, in turn, will facilitate the dissemination of evidence-based psychological (and drug) treatments as clinics and clinicians attempt to increase positive outcomes and meet developing "pay for performance" standards proposed for health-care systems. But, once again, developing a consensus of specific assessment procedures will prove difficult and contentious.

Clinical outcomes assessment focuses on change in the individual and, as we pointed out recently (Barlow & Nock, 2009), psychology has a long tradition of research that focuses on the individual rather than on the group average. These two emphases in establishing knowledge are referred to as *idiographic* and *nomothetic*. In 1962, Gordon Allport quoted Edward Tolman as saying "I know I should be more idiographic in my research, but I just don't know how to be." To which Allport replied "Let's learn" (Allport, 1962, p. 414). This longstanding aspiration reflects an understanding by most psychologists that the individual organism is the principal unit of analysis in psychology, whether the efforts be laboratory-based research with animals or the establishment of new interventions or assessments procedures with patients in the clinic. Indeed, some of the founders of experimental psychology, such as Wundt and Pavlov, focused their research on the study of individual organisms without sacrificing the scientific validity of their findings. When it came to establishing generality of results for their findings, they relied on replication in additional individuals (Barlow, Nock, & Hersen, 2009).

The funding of large randomized clinical trials (RCTs) to establish the efficacy of drug and psychological treatments, which began in earnest in the 1970s and 1980s, was one reason for a renewed emphasis on a more nomothetic approach to assessing change in clinical research. All psychologists, of course, whether working in the clinic or in a large clinical trial, are interested in the effects of treatment. But nomothetic and idiographic strategies approach the subject of variability among individuals and generality of findings across individuals in very different ways. Patients responding to a treatment in a clinical trial often show a range of outcomes from substantial improvement, to no improvement, or even deterioration. But the clinical trial, as with any nomothetic approach, assumes that much of this intersubject variability is intrinsic to the patient or due to uncontrollable external events. As a result, sophisticated data-analytic procedures are employed to look for treatment effects over and above this "error." If significant treatment effects are found, it is assumed that the results will be generalizable, at least to individuals similar to those patients included in the treatment group of the large clinical trial, if not to the population of all individuals presenting with the problem under study, such as depression. A more idiographic approach, on the other hand, would highlight why one individual differed from another after a given treatment by conducting some functional analyses in the context of a case formulation that might pinpoint reasons why one patient improved and the other did not. This information would be of considerable value to the clinician delivering services.

Randomized clinical trials are the gold standard for assessing the efficacy of our treatments (Kendall & Comer, Chapter 4, this volume). But it seems that a developing trend, which should be more fully realized in the years to come, is to enrich these methodologies with a complementary focus on the individual. We do have a good idea of how to be more idiographic in our research (e.g., Barlow & Nock, 2009; Barlow et al., 2009), and many of these more individualized strategies do not necessarily manipulate independent variables but rather are closer to the clinic. That is, assessment of a patient's progress over time is observed, and, based on the educated hypotheses of experienced clinicians, is functionally related to internal or external events that can then be addressed in therapy (McCullough, 2002; Shapiro, 1961). Furthermore, with the advent of outcomes assessment, these kinds of observations will be more common and our clinical science will be enriched.

Clinical replication is one example of a well-established idiographic assessment method that may

become more frequently utilized in applied settings in view of the growing emphasis on tracking treatment outcomes. Clinical replication is a form of field testing whereby a new treatment or treatment component is repeatedly administered by the same investigator or clinician within a specific setting across a series of patients with similar symptom presentations (Barlow & Hersen, 1984; Barlow et al., 2009; Hersen & Barlow, 1976). During treatment, and with the assistance of ongoing outcomes assessment, a clinician would carefully follow each individual's progress and document response, partial response, or nonresponse in patients. Since these clinicians are close to the situation, they are in the best position to formulate educated hypotheses on reasons for individual variation (success, partial success, or failure). These hypotheses could initially be evaluated by clinicians themselves and also fed back to clinical research centers for more systematic testing. Obviously, this information on generality of findings at the individual level would be extremely helpful both for future clinicians in selecting and applying similar treatments and for clinical scientists in investigating more systematically ways of improving treatments by making them more generally applicable. This strategy is eminently feasible and adds little, if any, cost. As mentioned earlier, the move toward instituting outcomes assessment will likely support an increase in data collected from clinical replication efforts, as will the rise of practice research networks (Borkovec, 2004; Borkovec et al., 2001). In these networks, as noted in Section 3, clinicians systematically collect data on individual patients, and do so in close collaboration with clinical research centers, with the goal of mutually explicating the individual outcomes of interventions across a large number of individuals and settings.

## Treatment
### The Growth of Psychological Treatments and a Focus on Dissemination and Implementation

*As new psychological treatments are developed and existing treatments become more efficacious, the focus will shift to currently underdeveloped efforts on dissemination and implementation.*

When it became clear over the past decade that psychological treatments targeting various presentations of psychopathology were at least the equal of pharmacological approaches, and in some cases superior (Barlow, 2004; Nathan & Gorman, 2007), health-care systems began to take action. Health-care policy makers and government agencies around the world committed several billion dollars to facilitate the dissemination of these treatments through a series of financial and regulatory incentives and mandates. For example, the VHA is the largest organized system of health care in the United States. In 2004, the VHA created a Mental Health Strategic Plan calling for the integration and improvement of mental health care (Zeiss & Karlin, Chapter 9, this volume). One of the principal goals of this plan was the dissemination and implementation of evidence-based psychological treatments throughout the system. Committees appointed by the VHA targeted a number of these treatments that seem most relevant to their mission, such as cognitive processing therapy (CPT) (Resick, Monson, & Chard, 2007) and prolonged exposure therapy (Foa, Hembree, & Rothbaum, 2007) for PTSD. Over a billion dollars has already been committed to initial efforts to roll out these treatments systemwide. Going forward, the intent is to identify additional treatments that would be particularly relevant to clinical care in the VHA, with the goal of making evidence-based psychological treatments available to all who need them.

Another major U.S. agency, SAMHSA has introduced the National Child Traumatic Stress Network (NCTSN), funded by the Center for Mental Health Services within SAMHSA. Congress has committed approximately $150 million thus far to the NCTSN to identify and disseminate evidence-based psychological treatments for traumatized children and adolescents. SAMHSA also supports 14 Addiction Technology Transfer Centers (ATTCs) across the United States to disseminate evidence-based assessments and treatments for substance use disorders.

Similar programs are ongoing at the level of state mental health systems in the United States, with a number of states actively implementing the dissemination of psychological treatments throughout their systems. For example, in the state of Hawaii, a task force entitled "The Empirical Bases to Services" was created by the Child and Adolescent Mental Health Division of the Hawaii Department of Mental Health. The purpose of this task force was to identify evidence-based psychological treatments for dissemination throughout their health-care system. Evidence-based family therapy programs for externalizing disorders in youth were seen as particularly relevant for the types of problems encountered by the state mental health system, and training ensued (Nakamura, Higa-McMillan, & Chorpita, in press).

In the United Kingdom, where health service delivery is nationalized, broader availability of evidence-based psychological interventions is now a matter of

health policy and has been mandated and funded (Clark, in press). This recognition has resulted in an unprecedented boom in the job market for clinical psychology in that country.

Given the enormous amount of clinical research on the efficacy and effectiveness of psychological treatments and procedures in the pipeline, it is likely that the number of these treatments will increase, as will their efficacy. But it is also likely that these interventions will undergo systematic modifications and developments, some of which are suggested in upcoming sections of this chapter. And an increasing emphasis will be placed on developing programs to prevent the onset of psychopathology and increase resilience as our knowledge of risk factors for various disorders grows. Preliminary efforts along these lines for depression, to take one example, look promising (Horowitz & Garber, 2006).

Yet, in the coming years, questions remain as to the implications of increased recognition of psychological treatments along with the pioneering but preliminary efforts at dissemination noted earlier. For example, in other health systems that are either less organized or less advanced than that in the United Kingdom, such as the U.S. health-care system, it is not clear that greater recognition of these treatments will be sufficient to translate into greater availability for the population in need. For example, Olfson and Marcus (2009) recently reported that, in the United States, the rate of treatment of depression with antidepressant medications approximately doubled over the most recent decade in which these data were collected, while the rate of "psychotherapy" diminished. Without more effective efforts at implementation and dissemination, it is not clear that greater recognition of psychological treatments will have a long-term impact. Thus, dissemination and implementation programs will become increasingly important.

Many of the dissemination programs in the United Kingdom and VHA were created with a distinct sense of urgency (McHugh & Barlow, 2010; McHugh & Barlow, in press). The difficulty is that this sense of urgency precluded the deliberate development of a consensus on how to best to implement the dissemination process. For example, dissemination science (Fixsen, Naoom, Blase, Friedman, & Wallace, 2005; Gladwell, 2000; Rogers, 2003) has long recognized a set of relatively consistent barriers to the adoption of innovations in almost any field of endeavor, such as agriculture, education, and communication. Some of these problems are eloquently detailed by Gawande (2007) in his discussions of

the difficulties in implementing consistent hand-washing procedures in hospitals, despite very clear empirical evidence on the health benefits of this approach and a "common sense" appreciation of the realistic nature of this policy.

So, for example, prior to successful implementation, several steps must be undertaken based on the wisdom of dissemination science. These steps include a comprehensive assessment of the nature of the stakeholders involved, a structured assessment of needs, and a plan for proceeding. Beyond that, potential outcomes of the implementation procedures, particularly training efforts in which individuals involved in service delivery acquire new skills, require close attention. Most dissemination projects recognize the need for didactic training, usually in the form of workshops, and more recently, in terms of Web-based interactive training. And most include some kind of assessment of the knowledge acquired from these efforts. But the evidence very clearly shows that these steps alone are inadequate to actually change the behavior of service delivery personnel (McHugh & Barlow, 2010; McHugh & Barlow, in press). In addition to didactic training, the necessity of training to a predefined level of competence and assessing the level of competence attained is crucial. The fact is that current efforts often stop there, assuming that, armed with this new knowledge and trained to a level of competence, evidence-based procedures will be successfully disseminated and implemented. But a number of additional issues must be considered in determining the success of a program of dissemination. For example, what percent of the clinicians who entered the program complete the training modules? What percent of the clinicians beginning the training program actually achieve a predefined level of competence, and what happens if they don't? After training efforts have been completed, how many patients are actually administered evidence-based procedures, and, most importantly, how many have benefited from the introduction of these new procedures, not only in terms of symptomatic reductions but also in increases in quality of life? Finally, and reflecting one of the most difficult issues in the dissemination of any innovation, has the implementation of EBPs been sustained over the long-term, and what procedures have been put in place to foster the sustainability of these innovations and to continue to assess outcomes?

Very few programs have considered the full range of barriers relevant to dissemination and implementation, and many often restrict their efforts to didactic information with an assessment of knowledge gain.

At present, it is an empirical question to decide which combination of procedures may prove to be the most useful to attain the kinds of outcomes desired. Obviously, it will be to the advantage of organizations to ascertain and adopt the minimum number of procedures necessary to achieve high levels of adoption, competence, and sustainability in the introduction of evidence-based psychological treatments into health delivery systems. Such an evaluation will need to include potential mediators of successful adoption, which could involve factors such as the length of supervision to achieve competence, as well as the best means to achieve long-term sustainability from among the several options currently available.

It seems clear that the demand for evidence-based psychological (and drug) treatments is increasing rapidly both at the level of individuals suffering from psychological problems as well as governments and public health authorities charged with improving the health of the population. But, at present, this demand has gotten ahead of our knowledge of the optimal ways to achieve the dissemination of these practices. An area of substantial growth for the immediate future will be addressing these pressing problems.

### Moving Beyond Single-diagnosis Treatment Manuals

*Modular transdiagnostic interventions will replace treatment protocols applicable to only a single diagnostic category.*

A number of significant limitations to current psychological treatments exist. Obviously, there are still a considerable number of patients who do not respond well to this type of remedy, and the reasons for their lack of response are not yet known. Thus, although treatment is effective for many people, there is plenty of room for improvement. Another problem that has become apparent with manualized treatments is that there are simply too many of them. Multiple manuals and protocols have been developed for most DSM-IV disorders, many of them with their own flavors or twists, but most of them reflecting the "copycat" phenomena present in pharmacological development in that they all rely on a core set of principles. For example, within the anxiety disorders, over 15 published manuals exist for panic disorder alone, most with simply trivial alterations and no empirical support justifying these alterations, and it is sometimes difficult to choose among them. Manuals for other disorders are proliferating as quickly, and it can take a significant amount of training to become adequately familiar

with even a few of the protocols. In addition, and as noted earlier, because the protocols require both didactic training and supervised training to competence, dissemination of even one treatment protocol to providers is an obstacle to the delivery of evidence-based treatment (Barlow, Levitt, & Bufka, 1999; McHugh & Barlow, 2010). Despite the allocation of billions of dollars to train and disseminate these protocols, when a clinician completes the required months of training, they are certified to treat only one diagnostic category (e.g., panic disorder, PTSD), with uncertain abilities to treat or even address common patterns of accompanying comorbidity (e.g., depression, OCD).

It is also clear that the presence of extensive comorbidity among various classes of disorders would clearly be better served through transdiagnostic unified treatment protocols that target several disorders simultaneously by focusing on common underlying factors. Considerable advances in understanding the nature of psychopathology have resulted in the identification of substantial overlap and common factors among disorders within a larger grouping. This overlap is evidenced through common patterns of neural activation, as well as through quantitative structural equation modeling, all of which suggest underlying factors in various classes of disorders that may be amenable to a single set of therapeutic principles. Within the anxiety and mood disorders, as we have detailed elsewhere (Fairholme, Boisseau, Ellard, Ehrenreich, & Barlow, 2010), some of these common factors include avoidance of emotional experience, pathological attributions and appraisals, the use of inappropriate emotion regulation skills, and the presence of emotion-driven behaviors or "action tendencies" associated with maladaptive and intense emotional experience.

Similar issues exist within other classes of disorders, such as the eating disorders (see Sysko & Wilson, Chapter 19, this volume). For example, and as noted earlier, Fairburn and colleagues (2008) have noted that as many as 40% of those presenting with eating disorders fall under the category of eating disorders not otherwise specified (NOS). Thus, whereas single-diagnosis protocols for eating disorders, such as bulimia and binge eating, are fully developed and have good evidence for efficacy, data on the efficacy of these protocols with eating disorder NOS patients has not been entirely clear. Fairburn et al.'s (2008) solution has also been to extract the core psychopathological principles present in all eating disorders and target them in a transdiagnostic protocol (Fairburn, Cooper, & Shafran, 2003).

In fact, it has become clear that existing treatment protocols for the full range of various classes of disorders, such as anxiety and eating disorders, contain a common set of therapeutic procedures. For anxiety disorders, this would include encouraging reappraisal and reattribution of perceived threat or danger both external and internal (interoceptive), the prevention of avoidance behavior, and exposure-based procedures that differ only in the situations, cognitions, and behaviors that provide the context for the application of the procedures (Allen, McHugh, & Barlow, 2008; Barlow, Allen, & Choate, 2004; Moses & Barlow, 2006). There is some evidence that these same fundamental therapeutic principles would be applicable to mood disorders, as well as to many of the somatoform and dissociative disorders that have anxiety, depression, and emotion dysregulation as key elements.

Other investigators are also working to identify evidence-based components of treatment that can be arranged in a modular fashion. For example, Chorpita and colleagues (Chapter 11, this volume), working closely with the State of Hawaii, have identified sets of psychological principles of change that comprise a menu of modules that can then be individually adapted for clients by trained providers in that state's mental health system. Mastering this set of principles and its implementation is a far more parsimonious and cost-effective method for reaching the largest number of people in need, when compared to mastering multiple single-diagnosis protocols.

### Drugs That Enhance Psychological Treatments

*Pharmacological agents that specifically bolster the effectiveness of mechanisms of action of psychological interventions will become increasingly common.*

What are the optimal ways of combining of psychological and pharmacological treatments for various mental disorders? Until recently, there has been a widespread belief that concurrent combinations of psychological treatments with pharmacological treatments produce a better outcome than either treatment alone. Of course, this has been true for psychotic disorders such as schizophrenia, in which psychological treatments directed at both positive and negative symptoms as well as social skill deficits may double the beneficial effects of medications. On the other hand, for the emotional disorders, data on the beneficial effects of concurrently combining treatments are surprisingly sparse. For the anxiety disorders specifically, most studies report no beneficial effects from combining treatments concurrently, although sequential strategies are proving effective in some cases (Barlow, 2008; Nathan & Gorman, 2007). In fact, some anxiolytic drugs, such as benzodiazepines, actually reduce or eliminate the beneficial effects of psychological treatments (Barlow, 2002).

To date, there has been no good theoretical reason why combining drugs and psychological treatments in the anxiety disorders would be effective. But now, based on exciting new translational research from neuroscience isolating brain circuits active in the learning and unlearning of fear and anxiety, new developments have occurred. To take one example, a drug called D-cycloserine (DCS), an old antibiotic, has been found to be synergistic with psychological procedures that enhance the extinction of fear and anxiety responses. Based on solid research from animal laboratories on neural circuitry involved in extinction learning (Hofmann, 2008; Myers & Davis, 2002), we now know this drug acts as a partial agonist of the glutamatergic N-methyl-D-aspartate (NMDA) neurotransmitter system that plays a major role in this type of learning. Unlike most anxiolytics, DCS is administered acutely, meaning that it is only taken just before the psychological treatment (exposure-based session) begins. Several clinical trials have demonstrated that DCS does enhance competently administered psychological exposure-based treatments for the anxiety disorders, such as social phobia (e.g., Hofmann et al., 2006) and OCD (Kushner et al., 2007; Wilhelm et al., 2008). Research is now rapidly expanding to other anxiety disorders. In view of the fact that this drug must be skillfully integrated with psychological treatments, a strong case can be made for prescription privileges for psychologists to best administer this combined treatment approach.

A more recent development is based on new neurobiological studies focused on understanding how fear memories are controlled. Gogolla, Caroni, Lüthi, and Herry (2009) noticed that, although extinction of fear memories was very difficult in adult rats, the extinction of fear acquired in young rats was much more successful in eliminating the fear memory. Since it is known that fear extinction involves neuronal circuits in the amygdala, the question became: What changes might occur during development of the amygdala that are responsible for making extinction of fear memories more difficult? Prior research had determined that maturation of a matrix of surrounding cells in the visual cortex occurred during development, and that eliminating

this matrix (which is composed of chondroitin sulfate proteoglycans [CSPGs]) from the cortex in the adult rat could enhance neuroplasticity to a level that is close to that found in a very young rat. This elimination can be accomplished by injecting the enzyme chondroitinase ABC. Building on this basic information from neuroscience, based on previous experiments on the visual cortex, Gogolla et al. (2009) demonstrated that acquired fear could also be eliminated in adult rats during extinction trials when these rats were injected with chondroitinase ABC. Although this has not been attempted in humans, it is representative of a trend that is almost certain to increase. That is, neurobiological research into brain function associated with psychopathology may lead to pharmacological agents that can augment the effects of psychological treatments, but that may have little or no effect in isolation from psychological treatments.

Other research has demonstrated that the neuropeptide oxytocin is fundamentally associated with trust and interpersonal closeness. The neural circuitry of trusting behavior seems to be associated with reduced activation of several brain structures, including the amygdala, the midbrain regions, and the dorsalstriatum. Now investigators are wondering whether this particular substance might augment psychological treatments for social anxiety and avoidance, as well as for autism. Thus, Guastella, Mitchell, and Mathews (2008) demonstrated that nasal administration of oxytocin enhanced the encoding of positive social information such that it was more memorable. The authors inferred that this could enhance the tendency to bond with other humans and experience greater intimacy and a stronger tendency to approach others. Another finding indicated that oxytocin acts specifically to increase gazing toward the eye region of human faces (Guastella, Mitchell, & Dadds, 2008). The authors speculate that this tendency may enhance emotional recognition and therefore interpersonal communication. All of these findings suggest that this substance could very well augment treatment for social difficulties. Now one preliminary study suggests that individuals with social anxiety disorder treated with a psychological intervention augmented by oxytocin evaluated their appearance more positively and performed somewhat better in a public speaking scenario than did those not receiving oxytocin (Guastella, Howard, Dadds, Mitchell, & Carson, 2009). Although this substance has not yet been demonstrated to be clinically useful in any definitive way, it is yet another example of where integrated research in neuroscience and psychological interventions is going.

## Technology-based Service Delivery

*Digital technologies will become increasingly integrated into service delivery systems and will lead to more personalized care.*

Advances in digital technologies have already enabled the development of many creative new approaches to mental health interventions, service delivery, and clinician training. These emerging practices include computerized training and interventions and service delivery via telephone, e-mail, text messages, instant messages, videoconferences, and the Internet. In Chapter 28 of this volume, Linda Dimeff and colleagues provide a thorough account of current technology-based interventions and highlight the wide range of application formats and their corresponding capabilities as interventions based on varying levels of interactivity, richness of media, social connectivity, and automation or live support. From a public health perspective these approaches potentially serve several objectives: they serve to increase dissemination of and access to high-quality, evidence-based treatments; and they serve to extend mental health care to rural and remote locations and to underserviced populations, including populations who either cannot access mental health facilities (due to disability or time constraints, for instance) or who choose not to access such care due to perceived stigma associated with mental health treatment. It is also anticipated that technology-based service delivery would have the secondary benefit of reducing overall treatment costs (although it is yet to be determined how cost savings would be distributed along the patient-provider-payer continuum).

Translating traditional training models for evidence-based treatments into high-quality computerized training programs may be the most feasible and cost-effective way to provide continuing education for clinicians. Dimeff and colleagues (2009) have demonstrated with their Panic Control Treatment Online Training (PCT OLT) for clinicians that Web-based interactive training can have better learning outcomes in terms of acquiring information on the principles of interventions than traditional didactic methods, and may also facilitate competence in the administration of an intervention. In addition, interactive computerized programs ensure a certain standardization of quality and may be easier to disseminate.

The computerization of psychological interventions extends evidence-based treatment a step further—into the hands of patients themselves. These interventions take many forms, utilizing different

psychological modalities, targeting different diagnoses, and comprising different media and sensory components (for additional information see Dimeff, Paves, Skutch, & Woodcock, Chapter 28, this volume). They can be accompanied by varying levels of clinician guidance and support, and administered in treatment settings or at home. To date, the most tested and efficacious computerized therapies have been CBTs, which also comprise the majority of leading evidence-based interventions and have the advantage of a structured format that translates easily into a computer program (Proudfoot, 2004). Several studies have found computerized CBTs for depression or anxiety disorders to be comparable to or even better than individualized CBT treatment with a therapist (Proudfoot, 2004; Reger & Gahm, 2009). However, there are limitations to these findings (Reger & Gahm, 2009), and these limitations are discussed later in the context of future directions.

One exciting example of the potential offered by computerized interventions is a treatment program developed by Craske and colleagues (2009) called Coordinated Anxiety Learning and Management (CALM). This interactive, computer-based CBT intervention aims to "singly address … the four most common anxiety disorders in primary-care settings: panic disorder (PD) with or without agoraphobia, generalized anxiety disorder (GAD), social anxiety disorder (SAD), and post-traumatic stress disorder (PTSD)" (Craske et al., 2009, p. 236). Customarily, in this setting, the primary care clinician refers patients to mental health professionals who are often not trained in evidence-based interventions, and, as a result, treatment outcomes are often unsatisfactory (Craske et al., 2009). Craske's program provides these mental health professionals with a tool to guide the patient through a structured evidence-based treatment modality while assisting the clinician in delivering the treatment with fidelity. This hybrid approach—that is, the combination of clinician assistance along with self-administered computer treatment—has been found to have higher rates of patient retention than computer-based treatment packages with no in-person support (Craske et al., 2009; Proudfoot, 2004). Preliminary data from an RCT for CALM indicate that clinicians have rated it positively and that patients have demonstrated understanding of the learning objectives, with concomitant reductions in clinical symptoms (Craske et al., 2009).

Another recent development is an expansion of service delivery mechanisms to include cell phones, e-mail, text messages, instant messages, videoconferences, and Internet applications. The telephone has made possible remote continuation of care for at least 50 years (Richardson, Frueh, Grubaugh, Egede, & Elhai, 2009), and for the most part, other new communication mechanisms are simply providing alternative and possibly enhanced options for the same treatment approach. An exception is the innovative use of remote sensing software and cell phones to monitor health signals and medication adherence, and to send updates to physicians via text messages (Koocher, 2009). Perhaps other novel treatment paradigms via these technologies await us. In the meantime, videoconferencing has significantly improved remote psychotherapy delivery by enhancing patient perception of the therapeutic alliance and allowing clinicians to observe some behavioral cues. Australia has widely implemented videoconferencing-based assessments and interventions and found that this type of service delivery may be as efficacious as face-to-face treatment as usual (TAU), although they are still grappling with how to best compare these methods (Richardson et al., 2009). Although each of these methods has limitations as a stand-alone therapy, if viewed as an extension of mental health service that can be applied and combined flexibly, depending on the patient's circumstances and preferences, there is considerable promise that these techniques will increase mental health-care coverage (Mohr, 2009).

A much-discussed area of research entails undertaking studies to target specific underserved populations with limited access to health-care providers, who may benefit significantly from computerized delivery of care (Mohr, 2009; Richardson et al., 2009). Policies will also be required to address the legal and ethical issues that will arise with wider dissemination of technology-based interventions and telemental health practices. For example, new standards of care will need to be determined, and a new governing body will likely be necessary to regulate interstate and international mental health care delivery (Koocher, 2009). Another area of future research involves the development of novel therapeutic modalities predicated on emerging digital technologies. As Mohr (2009) perceptively points out, most of the current technology-enabled treatments are merely traditional treatments applied via new technologies. He suggests that, in addition to optimizing current services, we should be asking how these technologies might enable new treatment paradigms.

In the future, continued improvement in the knowledge of individual predictors of treatment outcomes should allow the adaptive or "branching"

capabilities of computer programming to far more efficiently and accurately individualize treatments for specific patients. It is conceivable that computer-based assessment programs could at once triage, recommend personalized treatments, and where appropriate, provide part or all of a treatment package. Consider the following scenario: A treatment-seeker accesses an online or brick-and-mortar clinic where he or she completes a computerized, adaptive assessment module that poses questions regarding his or her areas of distress, symptomatology, health history, treatment preferences, demographic and psychosocial factors, behavioral tendencies, learning style, and other factors that may be deemed to have predictive value for treatment outcomes. With each response provided by the individual to a particular question, the computer adapts and refines the subsequent questions to increasingly hone in on the individual's specific needs and preferences. This assessment could even incorporate genetic information if the individual provided a DNA sample in advance of the assessment. Integrating all of this information into the assessment would allow the computer program to triage the case and recommend a treatment package with the most empirical support for that individual based on his or her predictive factors. For one individual, the prescribed treatment package could be purely self-administered, at-home, online treatment exercises; for another it could be a combination of medication, plus at-home online homework modules, plus bimonthly videoconference support with a specialty mental health provider. Obviously, for a more urgent case, the program would refer the individual for a live consultation with a clinician, but, even in this case, the individual could be immediately referred to the most appropriate clinical specialist rather than just any physician or mental health professional. This type of integrative computerized assessment process would support the National Institute of Mental Health (NIMH) priority of providing personalized care (Insel, 2009), as well as free up mental health professionals to provide other, perhaps more specialized services. Of course, there are still many details to be worked out, and rapidly emerging technologies will continue to change the format and capabilities of these interventions. No matter what form they take, it is clear that digital technologies will be increasingly integrated into the health-care delivery system.

### Psychological Treatments or Psychotherapy?

Psychological treatments *will be a term reserved for EBPs appropriate for addressing pathology in the context of health-care systems.* Psychotherapy *will be a term reserved for procedures directed at enhancing personal adjustment and growth, but administered outside of health-care systems and based increasingly on data emerging from the field of positive psychology.*

Thus far, we have outlined as likely future trends in clinical psychology the further development of outcomes measurement, psychological treatments, EBP, and the role of these developments in emerging health-care systems. An implication of these predictions is that clinical psychology is becoming ever more integrated into our health-care systems and is seen as having an increasingly important role to play in the remediation and prevention of both psychopathology and pathophysiology. In addition, the American Psychological Association has recently made it a matter of policy that psychology is a health-care profession (American Psychological Association, 2001; Johnson, 2001), and recent policy initiatives have focused on a greater integration of clinical psychology into primary care settings (Bray, 2009). Clearly, this is a very important initiative that is already coming to pass and that will have an impact on training programs and the way we practice. But one residual source of confusion going forward is an understanding by the lay public and health-care policy makers alike on the meaning of the term "psychotherapy." Elsewhere (Barlow, 2004; Barlow, 2006) it was noted that *psychotherapy* reflects such a heterogeneous set of activities that the term has lost its ability to communicate any precise meaning. Furthermore, the variety of procedures currently subsumed under the label of psychotherapy would be all but unrecognizable from one therapist to another (or one profession to another), encompassing such procedures as Web-based interactive behavior-change programs and long-term in-depth individual psychoanalysis. We have noted that this ambivalence and ambiguity can be resolved to some extent by delineating two different approaches to therapy that would be fundamentally identified by the problems addressed. The term "psychological treatments" and its synonyms, such as "psychological interventions," terms that are increasingly used today in health-care systems, would be reserved for those treatments that are part of health-related EBPs with a target of ameliorating psychopathology or pathophysiology; in other words, mental or physical disorders that would be eligible for treatment in organized health-care systems. Labeling these procedures as "psychological treatments" also identifies their origins in the psychological behavioral and cognitive science laboratories, and brands them in a manner that distinguishes

clinical psychologists as the most qualified profession to administer these procedures. Thus, clinical psychology would at last lay claim to its own set of procedures, a primary goal of any health-care profession. Of course, the debate over problems or disorders that are eligible for treatment, and therefore reimbursement by third-party payers within health-care systems, is a controversial one that is playing out both federally and state by state in the United States, with definitions tending to be relatively conservative. For example, despite parity legislation, even disorders widely accepted in diagnostic schemes of mental disorders (such as the DSM) are not necessarily gaining entrance into the health-care system if they are not somehow judged to be severe enough or "biologically based." But it is a reasonably good bet that, as parity legislation increases, most forms of psychopathology identifiable in accepted systems of nosology will likely gain coverage.

But remediation of pathology is not always the principal goal of psychotherapy. In fact, as pointed out previously (Barlow, 2006), psychotherapy has often been directed at problems in adjustment and growth. For thousands of years, this has been a very noble undertaking. In an Op-Ed contribution to the *New York Times* entitled "A Mind Is a Terrible Thing to Measure," Phillips (2006, February 26), addressing the current state of psychotherapy, notes that Western societies have been "divided between religious truth and scientific truth" as a basis for understanding human nature, and that perhaps psychotherapy should "inhabit the middle ground of arts in which truth and usefulness have traditionally been allowed certain latitude (nobody measures Shakespeare or tries to prove his values)." As Socrates noted thousands of years ago, "an unexamined life is not worth living" (Plato, 1996). And there are many people, perhaps most of us, who are searching generally for greater meaning in life, the resolution of problems in living, working out relationships, learning how to love and be loved, and personal growth. It is no accident that these goals are also addressed from an epistemological point of view by a variety of the humanities that do in fact occupy "the middle ground of the arts." But the fact of the matter is that these approaches will never be part of conservatively defined health-care systems and be reimbursed by health-care dollars, even if arguments are made noting the correlation of better adjustment with longevity and health. Health-care systems will always have difficulty paying for the direct treatment and prevention of pathology and are unlikely to fund the pursuit of happiness. Nevertheless, a very large market will continue to exist for these services, and psychologists may well continue to play a major role. However, these services will operate on a self-pay basis, and psychologists will not have a unique prerogative in the delivery of psychotherapy, as is now the case. Thus, psychological treatments or interventions will come to delineate those procedures with an accumulating evidence base as appropriate for treating pathology. The term "psychotherapy" would then refer to a heterogeneous set of approaches to personal growth and adjustment. Psychological treatments and psychotherapy would not necessarily be distinguished on the basis of theory, techniques, or even evidence, but rather on the types of problems addressed. But is an evidence-base for "psychotherapy" defined in this manner? The explosive growth in the field of positive psychology in recent years (Diener, 2000; Seligman, 2002) may well prove to be the emerging evidence base for psychotherapy that aims to facilitate personal growth and the pursuit of happiness. In this way, psychotherapy (as defined here) could become every bit as evidence-based as psychological treatments addressing psychopathology. And substantial confusion existing in the mind of the public on what we do would be clarified.

## Conclusion

In this chapter, we have speculated on ten themes or areas that are likely to reflect changes in the field of clinical psychology in the near to intermediate future. As noted at the beginning of the chapter, some of these changes have already begun, and we speculate more on how they will play out in the coming years. Other projected trends have not yet occurred, and time will tell whether our predictions come true or not. But the goal of this chapter is not necessarily to come out with the highest percentage of correct predictions among the large number of prognosticating psychologists willing to take these conceptual (and some would say foolish) leaps of faith. Rather, the overarching goal is to convey the current intellectual ferment, creativity, and vision that exist in clinical psychology today. To those who will be pursuing these goals and bearing witness to these changes, we can only say that we would be hard-pressed to think of a more exciting time to play out a career in clinical psychology. The longstanding potential of clinical psychology to relieve human suffering and enhance human functioning will become increasingly evident, and anyone participating in the realization of trends outlined in this chapter and other developments not yet envisioned will be very fortunate indeed to be a part of it.
