Foreword to the *Handbook of Child Psychology and Developmental Science*, Seventh Edition

WILLIAM DAMON

THE HANDBOOK'S DEVELOPING TRADITION

Development is one of life's optimistic ideas. It implies not just change but improvement, progress, forward movement, and some sense of positive direction. What constitutes improvement in any human capacity is an open, important, and fascinating question requiring astute theoretical analysis and sound empirical study. So, too, are questions of what accounts for improvement; what enhances it; and what prevents it when it fails to occur. One of the landmark achievements of this edition of the *Handbook of Child Psychology and Developmental Science* is that a full selection of top scholars in the field of human development have offered us state-of-the-science answers to these essential questions.

Compounding the interest of this edition, the concept of development applies to scholarly fields as well as to individuals, and the *Handbook's* distinguished history, from its inception more than 80 years ago to the present edition, richly reveals the development of a field. Within the field of human development, the *Handbook* has had a long and notable tradition as the field's leading beacon, organizer, and encyclopedia of what's known. This latest *Handbook* edition, overflowing with insights and information that go well beyond the scientific knowledge available in previous editions, is proof of the substantial progress made by the field of human development during its still-short (by scholarly standards) history.

Indeed, the history of developmental science has been inextricably intertwined with the history of the *Handbook*. Like many influential encyclopedias, the *Handbook* influences the field it reports on. Scholars—especially younger ones—look to it to guide their own work. It serves as an

indicator and as a generator, a pool of received findings, and a source for generating new insight.

It is impossible to imagine what the field would look like if Carl Murchison had not assembled a ground-breaking collection of essays on the then-almost-unknown topic of child study in his first *Handbook of Child Psychology*. That was 1931, at the dawn of a scholarly history that, like every developmental narrative, has proceeded with a combination of continuity and change. What does this history tell us about where the field of developmental science has been, what it has learned, and where it is going? What does it tell us about what's changed and what has remained the same in the questions that have been asked, in the methods used, and in the theoretical ideas that have been advanced to understand human development?

The First Two Editions

Carl Murchison was a star scholar/impresario who edited the *Psychological Register*, founded important psychological journals, and wrote books on social psychology, politics, and the criminal mind. He compiled an assortment of handbooks, psychology texts, and autobiographies of renowned psychologists, and even ventured a book on psychic phenomena (Sir Arthur Conan Doyle and Harry Houdini were among the contributors). Murchison's initial *Handbook of Child Psychology* was published by a small university press (Clark University) in 1931, when the field itself was still in its infancy. Murchison wrote:

Experimental psychology has had a much older scientific and academic status [than child psychology], but at the present time it is probable that much less money is being spent for pure

research in the field of experimental psychology than is being spent in the field of child psychology. In spite of this obvious fact, many experimental psychologists continue to look upon the field of child psychology as a proper field of research for women and for men whose experimental masculinity is not of the maximum. This attitude of patronage is based almost entirely upon a blissful ignorance of what is going on in the tremendously virile field of child behavior. (Murchison, 1931, p. ix)

Murchison's masculine allusion is from another era; it might supply good material for a social history of gender stereotyping. That aside, Murchison was prescient in the task that he undertook and the way that he went about it. At the time this passage was written, developmental psychology was known only in Europe and in a few forward-looking U.S. labs and universities. Nevertheless, Murchison predicted the field's impending ascent: "The time is not far distant, if it is not already here, when nearly all competent psychologists will recognize that one-half of the whole field of psychology is involved in the problem of how the infant becomes an adult psychologically" (Murchison, 1931, p. x).

For this first 1931 *Handbook*, Murchison looked to Europe and to a handful of American research centers for child study—most prominently, Iowa, Minnesota, University of California at Berkeley, Columbia, Stanford, Yale, and Clark—many of which were at the time called *field stations*. Murchison's Europeans included a young "genetic epistemologist" named Jean Piaget, who, in an essay on "Children's Philosophies," cited data from his interviews with 60 Genevan children between the ages of 4 and 12 years. Piaget's chapter would provide U.S. readers with an introduction to his soon-to-be seminal research program on children's conceptions of the world. Another European, Charlotte Bühler, wrote a chapter on young children's social behavior. In her chapter, which still is fresh today, Bühler described intricate play and communication patterns among toddlers—patterns that developmental scientists would not rediscover until the late 1970s. Bühler also anticipated critiques of Piaget that were to be again launched during the sociolinguistics heyday of the 1970s:

Piaget, in his studies on children's talk and reasoning, emphasizes that their talk is much more egocentric than social...that children from three to seven years accompany all their manipulations with talk which actually is not so much intercourse as monologue...[but] the special relationship of the child to each of the different members of the household is distinctly reflected in the respective conversations. (Bühler, 1931, p. 138)

Other Europeans include Anna Freud, who wrote on "The Psychoanalysis of the Child," and Kurt Lewin, who wrote on "Environmental Forces in Child Behavior and Development"—both would gain worldwide renown in coming years.

The Americans that Murchison chose were equally notable. Arnold Gesell wrote a nativistic account of his twin studies—an enterprise that remains familiar to us today—and Stanford's Lewis Terman wrote a comprehensive account of everything known about the "gifted child." Harold Jones described the developmental effects of birth order, Mary Cover Jones wrote about children's emotions, Florence Goodenough wrote about children's drawings, and Dorothea McCarthy wrote about language development. Vernon Jones's chapter on "children's morals" focused on the growth of *character*, a notion that was to become mostly lost to the field during the cognitive-developmental revolution, but that has reemerged in the past decade as a primary concern in the study of moral development.

Murchison's vision of child psychology included an examination of cultural differences as well. His *Handbook* presented to the scholarly world a young anthropologist named Margaret Mead, just back from her tours of Samoa and New Guinea. In this early essay, Mead wrote that her motivation in traveling to the South Seas was to discredit the claims that Piaget, Lévy-Bruhl, and other "structuralists" had made regarding what they called *animism* in young children's thinking. (Interestingly, about a third of Piaget's chapter in the same volume was dedicated to showing how Genevan children took years to outgrow their animism.) Mead reported data that she called "amazing": "In not one of the 32,000 drawings (by young 'primitive' children) was there a single case of personalization of animals, material phenomena, or inanimate objects" (Mead, 1931, p. 400). Mead parlayed these data into a tough-minded critique of Western psychology's ethnocentrism, making the point that animism and other beliefs are more likely to be culturally induced than intrinsic to early cognitive development. This is hardly an unfamiliar theme in contemporary psychology. Mead offered a research guide for developmental field workers in strange cultures, complete with methodological and practical advice, such as the following: (1) translate questions into native linguistic categories; (2) do not do controlled experiments; (3) do not try to do research that requires knowing the ages of subjects, which are usually unknowable; and (4) live next door to the children whom you are studying.

Despite the imposing roster of authors that Murchison had assembled for this original *Handbook of Child*

Psychology, his achievement did not satisfy him for long. Barely 2 years later, Murchison put out a second edition, of which he wrote: “Within a period of slightly more than 2 years, this first revision bears scarcely any resemblance to the original *Handbook of Child Psychology*. This is due chiefly to the great expansion in the field during the past 3 years and partly to the improved insight of the editor” (Murchison, 1933, p. vii). The tradition that Murchison had brought to life was already developing.

Murchison saw fit to provide the following warning in his second edition: “There has been no attempt to simplify, condense, or to appeal to the immature mind. This volume is prepared specifically for the scholar, and its form is for his maximum convenience” (Murchison, 1933, p. vii). It is clear that Murchison, despite his impresario urges, was willing to sacrifice accessibility and textbook-level sales for scientific value in this instance.

Murchison exaggerated when he wrote that his second edition bore little resemblance to the first. Almost half of the chapters were virtually the same, with minor additions and updating. (For the record, though, despite Murchison’s continued use of masculine phraseology, 10 of the 24 authors in the second edition were women.) Some of the authors whose original chapters were dropped were asked to write about new topics. So, for example, Goodenough wrote about mental testing rather than about children’s drawings, and Gesell wrote a general chapter on maturational theory that went well beyond his own twin studies.

But Murchison also made certain abrupt changes. He dropped Anna Freud entirely, prompting the marginalization of psychoanalysis within U.S. academic psychology. Leonard Carmichael, later to play a pivotal role in the *Handbook* tradition, made his appearance as author of a major chapter (by far, the longest in the book) on prenatal and perinatal growth. Three other physiologically oriented chapters were added as well: one on neonatal motor behavior, one on visual–manual functions during the first 2 years of life, and one on physiological “appetites” such as hunger, rest, and sex. Combined with the Goodenough and Gesell shifts in focus, these additions gave the 1933 *Handbook* a more biological thrust, in keeping with Murchison’s long-standing desire to display the hard-science backbone of the emerging field.

The Early Wiley Editions

Leonard Carmichael was president of Tufts University when he organized Wiley’s first edition of the *Handbook*. The switch from a university press to the long-established

commercial firm of John Wiley & Sons was commensurate with Carmichael’s well-known ambition; and indeed Carmichael’s effort was to become influential beyond anything that Murchison might have anticipated. (The switch to Wiley meant that what was to become known as Wiley’s first edition was actually the *Handbook*’s third edition—and that what is now called the seventh edition is really the *Handbook*’s ninth.) Carmichael renamed the volume the *Manual of Child Psychology*, in keeping with Carmichael’s intention of producing an “advanced scientific manual to bridge the gap between the excellent and varied elementary textbooks in this field and the scientific periodical literature” (Carmichael, 1946, p. vi).

Despite the small title change, there was significant continuity between the Murchison and Carmichael’s editions. Carmichael acknowledged this in the prefaces to both of his editions, the 1946 and 1954 *Manuals*:

Both as editor of the *Manual* and as the author of a special chapter, the writer is indebted . . . [for] extensive excerpts and the use of other materials previously published in the *Handbook of Child Psychology, Revised Edition*. (Carmichael, 1946, p. vi)

Both the *Handbook of Child Psychology* and the *Handbook of Child Psychology, Revised Edition*, were edited by Dr. Carl Murchison. I wish to express here my profound appreciation for the pioneer work done by Dr. Murchison in producing these handbooks and other advanced books in psychology. The *Manual* owes much in spirit and content to the foresight and editorial skill of Dr. Murchison. (Carmichael, 1954, p. v)

The first quote comes from Carmichael’s preface to the 1946 edition, the second from his preface to the 1954 edition. It is not known why Carmichael waited until the 1954 edition to add the personal tribute to Carl Murchison. Perhaps a careless typist dropped the laudatory passage from a handwritten version of the 1946 preface and its omission escaped Carmichael’s notice. Or perhaps 8 years of further development increased Carmichael’s generosity of spirit. It is also possible that Murchison or his family complained. In any case, Carmichael always acknowledged the roots of his *Manual*, if not always their original editor.

Leonard Carmichael took his 1946 *Manual* in the same direction established by Murchison back in 1931 and 1933. First, Carmichael appropriated five Murchison chapters on biological or experimental topics such as physiological growth, scientific methods, and mental testing. Second, he added three new biologically oriented chapters on animal infancy, on physical growth, and on motor and behavioral maturation (a tour de force by Myrtle McGraw that instantly made Gesell’s chapter in the same volume

obsolete). Third, he commissioned Wayne Dennis to write a chapter that focused exclusively on physiological changes associated with puberty. Fourth, Carmichael dropped Piaget and Bühler, who, like Anna Freud years earlier, were becoming out of step with then-current experimental trends in U.S. psychology.

The five Murchison chapters on social and cultural influences in development were the ones Carmichael retained: two chapters on environmental forces on the child (by Kurt Lewin and by Harold Jones), Dorothea McCarthy's chapter on children's language, Vernon Jones's chapter on children's morality (now entitled "Character Development—An Objective Approach"), and Margaret Mead's chapter on "primitive" children (now enhanced by several spectacular photos of mothers and children from exotic cultures around the world). Carmichael also stuck with three other psychologically oriented Murchison topics (emotional development, gifted children, and sex differences), but he selected new authors to cover them.

Carmichael's second and final *Manual* in 1954 was very close in structure and content to his 1946 *Manual*. Carmichael again retained the heart of Murchison's original vision, many of Murchison's original authors and chapter topics, and some of the same material that dated all the way back to the 1931 *Handbook*. Not surprisingly, the chapters that were closest to Carmichael's own interests received the most significant updating. As Murchison had done, Carmichael leaned toward the biological and physiological whenever possible. He clearly favored experimental treatments of psychological processes. Yet Carmichael still retained the social, cultural, and psychological analyses by Lewin, Mead, McCarthy, Terman, Harold Jones, and Vernon Jones, even going so far as to add a new chapter on social development by Harold and Gladys Anderson and a new chapter on emotional development by Arthur Jersild.

In 1946, when Carmichael had finished his first *Manual*, he had complained that "this book has been a difficult and expensive one to produce, especially under wartime conditions" (Carmichael, 1946, p. vii). But the project had been well worth the effort. The *Manual* quickly became the bible of graduate training and scholarly work in the field, available virtually everywhere that human development was studied. Eight years later, now head of the Smithsonian Institution, Carmichael wrote, in the preface to his 1954 edition: "The favorable reception that the first edition received not only in America but all over the world is indicative of the growing importance of the study of the phenomena of the growth and development of the child" (Carmichael, 1954, p. vii).

The Murchison and Carmichael volumes make fascinating reading, even today. The perennial themes of the field were always there: the nature/nurture debate; the generalizations of universalists opposed by the particularizations of contextualists; the alternating emphases on continuities and discontinuities during ontogenesis; and the standard categories of maturation, learning, locomotor activity, perception, cognition, language, emotion, conduct, morality, and culture—all separated for the sake of analysis, yet, as authors throughout each of the volumes acknowledged, all somehow joined in the dynamic mix of human development.

These things have not changed. Yet much in the early *Handbooks/Manuals* is now irrevocably dated. Long lists of children's dietary preferences, sleeping patterns, elimination habits, toys, and somatic types look quaint and pointless through today's lenses. The chapters on children's thought and language were done prior to the great contemporary breakthroughs in neurology and brain/behavior research, and they show it. The chapters on social and emotional development were ignorant of the processes of social influence and self-regulation that soon would be revealed through attribution research and other studies in social psychology. Terms such as *cognitive neuroscience*, *neuronal networks*, *behavior genetics*, *social cognition*, *dynamical systems*, *information processing*, and *developmental psychopathology* were unknown. Margaret Mead's rendition of the primitive child stands as a weak straw in comparison to the wealth of cross-cultural knowledge available in today's "cultural psychology."

Most tellingly, the assortments of odd facts and normative trends were tied together by very little theory throughout the Carmichael chapters. It was as if, in the exhilaration of discovery at the frontiers of a new field, all the facts looked interesting in and of themselves. That is what makes so much of the material seem odd and arbitrary. It is hard to know what to make of the lists of facts, where to place them, which ones were worth keeping track of and which ones are expendable. Not surprisingly, the bulk of the data presented in the Carmichael manuals seems not only outdated by today's standards but, worse, irrelevant.

Carmichael's second and final *Manual* had a long life: Not until 1970 did Wiley bring out a third edition. Carmichael was retired by then, but he still had a keen interest in the book. At his insistence, his own name became part of the title of Wiley's third edition: The edition was called, improbably, *Carmichael's Manual of Child Psychology*, even though it had a new editor and an entirely new cast of authors and advisors.

Mussen's Transformation

Paul Mussen was editor of the 1970 edition; once again the project flourished. Now a two-volume set, the 1970 third edition swept the social sciences, generating widespread interest in developmental psychology and its related disciplines. Rarely had a scholarly compendium become both so dominant in its own field and so familiar in related disciplines. The volumes became essential sources for graduate students and advanced scholars alike. Publishers referred to Mussen's 1970 *Carmichael's Manual* as the standard against which other scientific handbooks were compared.

By 1970, the importance of theory for understanding human development had become apparent. Looking back on Carmichael's last *Manual*, Mussen wrote: "The 1954 edition of this Manual had only one theoretical chapter, and that was concerned with Lewinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology" (Mussen, 1970, p. x). The intervening years had seen a turning away from the norm of psychological research once fondly referred to as "dust-bowl empiricism."

The 1970 handbook—still called, as noted above, *Carmichael's Manual*—had an entirely new look. The two-volume set carried only one chapter from the earlier books, Carmichael's updated version of his own long chapter on the "Onset and Early Development of Behavior," which had made its appearance under a different title way back in Murchison's 1933 edition. Otherwise, as Mussen wrote in his preface, "It should be clear from the outset...that the present volumes are not, in any sense, a *revision* of the earlier editions; this is a completely new *Manual*" (Mussen, 1970, p. x).

And it was. In comparison to Carmichael's last edition 16 years earlier, the scope, variety, and theoretical depth of the Mussen volumes were astonishing. The field had blossomed, and the new *Manual* showcased many of the new bouquets that were being produced. The biological perspective was still strong, grounded by chapters on physical growth (by J. M. Tanner) and physiological development (by Dorothy Eichorn), and by Carmichael's revised chapter (now made more elegant by some excerpts from Greek philosophy and modern poetry). But two other cousins of biology also were represented, in a chapter on ethology by Eckhard Hess and a chapter on behavior genetics by Gerald McClearn. These chapters were to define the major directions of biological research in the field for at least the next three decades.

As for theory, Mussen's *Handbook* was thoroughly permeated with it. Much of the theorizing was organized around the approaches that, in 1970, were known as the "three grand systems": (1) Piaget's cognitive-developmentalism, (2) psychoanalysis, and (3) learning theory. Piaget was given the most extensive treatment. He himself reappeared in this *Manual*, authoring a comprehensive (some say definitive) statement of his own theory, which now bore little resemblance to his 1931/1933 catalog of children's intriguing verbal expressions. In addition, chapters by John Flavell, by David Berlyne, by Martin Hoffman, and by William Kessen, Marshall Haith, and Philip Salapatek, all gave major treatments to one or another aspect of Piaget's body of work.

Several other theoretical approaches were represented in the 1970 *Manual* as well. Herbert and Anne Pick explicated Gibsonian theory in a chapter on sensation and perception, Jonas Langer wrote a chapter on Werner's organismic theory, David McNeill wrote a Chomskian account of language development, and Robert LeVine wrote an early version of what was to become "culture theory."

With its increased emphasis on theory, the 1970 *Manual* explored in depth a matter that had been all but neglected in the *Manual's* previous versions: the mechanisms of change that could account for, to use Murchison's old phrase, "the problem of how the infant becomes an adult psychologically." In the process, old questions such as the relative importance of nature versus nurture were revisited, but with far more sophisticated conceptual and methodological tools.

Beyond theory building, the 1970 *Manual* addressed an array of new topics and featured new contributors: peer interaction (Willard Hartup), attachment (Eleanor Maccoby and John Masters), aggression (Seymour Feshbach), individual differences (Jerome Kagan and Nathan Kogan), and creativity (Michael Wallach). All of these areas of interest are still very much with us.

Wiley's fourth edition, published in 1983, was redesigned to become once again the *Handbook of Child Psychology*. By then, Carmichael had passed away. The set of books, now expanded to four volumes, became widely referred to in the field as "the Mussen handbook."

If the 1970 *Manual* reflected a blossoming of the field's plantings, the 1983 *Handbook* reflected a field whose ground cover had spread beyond any boundaries that could have been previously anticipated. New growth had sprouted in literally dozens of separate locations. A French garden, with its overarching designs and tidy compartments, had turned into an English garden, unruly but often glorious in

its profusion. Mussen's two-volume *Carmichael's Manual* had now become the four-volume *Mussen Handbook*, with a page-count increase that came close to tripling the 1970 edition.

The grand old theories were breaking down. Piaget was still represented in 1983 by his 1970 piece, but his influence was on the wane throughout other chapters. Learning theory and psychoanalysis were scarcely mentioned. Yet the early theorizing had left its mark, in vestiges that were apparent in new approaches, and in the evident conceptual sophistication with which authors treated their material. There was no return to dust-bowl empiricism. Instead, a variety of classical and innovative ideas were coexisting: ethology, neurobiology, information processing, attribution theory, cultural approaches, communications theory, behavioral genetics, sensory-perception models, psycholinguistics, sociolinguistics, discontinuous stage theories, and continuous memory theories all took their places, with none quite on center stage. Research topics now ranged from children's play to brain lateralization, from children's family life to the influences of school, day care, and disadvantageous risk factors. There also was coverage of the burgeoning attempts to use developmental theory as a basis for clinical and educational interventions. The interventions usually were described at the end of chapters that had discussed the research relevant to the particular intervention efforts, rather than in whole chapters dedicated specifically to issues of practice.

The Fifth and Sixth Editions

There was a long hiatus between the fourth edition in 1983 and the fifth edition, which was not to appear until 1998. The fifth edition fell to me to organize, and this was not at my own initiative. Two Wiley editors—Herb Reich, a legendary figure in academic publishing, and Kelly Franklin, an up-and-coming innovative star—approached me about reviving the project, which they correctly believed had a vital tradition behind it, but that they also believed was in danger of falling by the wayside. I had been editing the Jossey-Bass series that I founded, *New Directions for Child and Adolescent Development*, and the two Wiley editors believed that if we could impart a “new directions” tone to a new *Handbook* edition, the project could regain its past appeal. I agreed, and I proposed that this next edition be organized in an intuitively simple four-volume design: a theory volume, a volume on cognitive and linguistic development, a volume on social and personality development, and a volume on child psychology in practice.

When Wiley accepted my proposal, my first action as general editor was to invite an incredibly talented group of volume editors—Nancy Eisenberg, Deanna Kuhn, Richard Lerner, Anne Renninger, Robert Siegler, and Irving Sigel—to collaborate on the selection and editing of chapters. The edition was to become the result of a partnership among all the editors; and the same team collaborated again to produce the sixth edition of the *Handbook* in 2006, with Richard Lerner assuming an added role as my co-editor-in-chief. The 2006 edition closely followed the model of the 1998 edition, with some important additions, such as chapters on the positive youth development approach, on artistic development, and on religiosity and faith in human development.

Our team approached the 1998 and 2006 editions with the same purpose that Murchison, Carmichael, and Mussen before us had shared: “to provide,” as Mussen wrote, “a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development” (Mussen, 1983, p. vii). We assumed that the *Handbook* should be aimed “specifically for the scholar,” as Murchison declared, and that it should have the character of an “advanced text,” as Carmichael defined it. We expected that our readership would be interdisciplinary, given the tendency of scholars in human development to do work across the fields of psychology, cognitive science, neuroscience, history, linguistics, sociology, anthropology, education, and psychiatry. In Volume 4, we hoped that research-oriented practitioners would be among the scholars for whom the *Handbook* had value.

By the time of the 1998 and 2006 editions of the *Handbook*, powerful theoretical models and approaches—not quite unified theories like the “three grand systems” that had marked earlier editions—were again organizing much of the field’s research. There was great variety in these models and approaches, and each was drawing together significant clusters of work. Among the powerful models and approaches prominent in the 1998 and 2006 *Handbooks* were the dynamic system theories, life-span and life-course approaches, cognitive science and neural models, the behavior genetics approach, person–context interaction theories, action theories, culture theory, ecological models, and neo-Piagetian and Vygotskian models. Although some of these models and approaches had been in the making for some time, by the end of the 20th century they had fully come into their own: Researchers were drawing on them more directly, taking their implied

assumptions and hypotheses seriously, using them with specificity and control, and exploiting all of their implications for practice.

The Present

The seventh Wiley edition of the *Handbook* continues and strengthens the trends toward specific theoretical analyses of multiple developmental processes, even highlighting this focus by including the term “processes” in three of the four volume’s titles, a designation new to the *Handbook*’s history. The volumes present a rich mix of classic and contemporary theoretical perspectives, but I believe it is fair to say that the dominant views throughout are marked by an emphasis on the dynamic interplay of all relational developmental systems that co-act across the life span, incorporating the range of biological, perceptual, cognitive, linguistic, emotional, social, cultural, and ecological levels of analysis. At the same time, the chapters together consider a vast array of topics and problems, ranging from sexuality and religiosity to law, medicine, war, poverty, and education. The emerging world of digital experience is also given a fuller treatment than in any previous *Handbook* edition, commensurate with our present-day technological revolution. All this gives this seventh edition of the *Handbook* a timely feel.

The present *Handbook*’s combination of theoretical and methodological sophistication and topical timeliness resolves an old tension evident in the *Handbook*’s prior cycling between theoretical-methodological and problem-centered approaches. My impression is that, rather than leaning in one direction or the other, this *Handbook* manages to be *both* more theoretical-methodological *and* more topical than the previous editions. As a developmental phenomenon, this puts the *Handbook* in a class of organisms that develop toward adaptive complexity rather than toward one or another contrasting polar dimension.

I wonder what Carl Murchison would think of the grown-up child that he spawned before the field of human development had become a mainstream endeavor in research and teaching around the world. Murchison’s idiosyncratic assortment of fascinating studies bears little resemblance to the imposing compendium of solidly grounded knowledge in the present *Handbook*. Yet each step along the 83-year way followed directly from what had gone before, with only occasional departures or additions that may have seemed more like gradual revisions at the time. Over the long haul, the change in the *Handbook* has been dramatic, but the change process itself has been marked by substantial continuities. If Murchison were to come back to life today, he may be astonished by the size and reach of his child, but I believe he would recognize it—and proudly so.

Preface

Across its editions, the title of this handbook has changed, now, five times: *A Handbook of Child Psychology*; *Manual of Child Psychology*; *Carmichael's Manual of Child Psychology*; *Handbook of Child Psychology*; and *Handbook of Child Psychology and Developmental Science*. As well, the field of scholarship represented in the *Handbook* has also been labeled differently: child psychology, child development, developmental psychology, and, today, developmental science. The rationales for the use of these labels involve historically changing ontological and epistemological assumptions.

During the latter years of the 19th century and for much of the past two thirds of the 20th century, and perhaps especially in the United States and Western Europe, the study of human development was a visible subfield of psychology (see Cairns & Cairns, 2006, for a review; see also Damon, in the Foreword to this edition of the *Handbook*). In this literature, and its antecedents in philosophy (see Baltes, 1983; Overton, 2006 for reviews), development was envisioned to be a life-span phenomenon (e.g., Erikson, 1959; Hall, 1904, 1922). However, the majority of the scholarship about human development in the United States and Western Europe was focused on the early years of life (infancy and childhood) (e.g., Binet & Simon, 1905a, 1905b; Gesell, 1929; Piaget, 1923; Preyer, 1882; Terman, 1925).

As a consequence, across this historical period, child psychology emerged as a specific subarea of psychology, spurred on by the research of scientists studying this age period; by the founding of several university centers and institutes devoted to the study of children (e.g., in Iowa, involving scholars such as Boyd R. McCandless; and in Minnesota, involving scholars such as Dale B. Harris); and by the work in the field of home economics, which was focused on children (and families), that was occurring within land-grant universities in the United States

(Cairns & Cairns, 2006; Lerner & Simon, 1998). At the same time, many of the contributors to child psychology also created a purportedly multidisciplinary instantiation of scholarship devoted to the study of children, that is, child *development*. In 1933, the Society for Research in Child Development (SRCD) was founded to promote such a multidisciplinary approach to the study of children (and to the application of child development research) but, in actuality, SRCD was from its outset and remains today dominated by scholars whose training is in psychology. It is not surprising, then, that, whether labeled child psychology or child development, the study of the early portion of the life span was approached in very similar ways by scholars studying children.

At its inception, the child development (or child psychology) field was framed by Cartesian-split conceptions of change across ontogeny and by reductionist accounts of the bases of human development (Overton, 2013a, 2013b; Overton & Müller, 2013). The core conceptual issues of child development were the nature-nurture, the continuity-discontinuity, and the stability-instability controversies (Lerner, 2002), and “solutions” to these debates involved, for instance, reducing development to being a phenomenon explained by either nature variables (genes or maturation; e.g., Hamburger, 1957) or by operant or respondent stimulus-response connections (e.g., Bijou & Baer, 1961). This split, reductionist ontology about development meant that the epistemological route to learning about the basis of development was to identify the essential (nature *or* nurture) explanatory variable(s). Accordingly, the study of development was also marked by variable-centered analyses, as exemplified by the tables of contents of the editions of this *Handbook* published during this period (e.g., Carmichael, 1946, 1954; Murchison, 1931, 1933; Mussen, 1970, 1983; see also Damon, in the

Foreword to this edition), as well as by the tables of contents of other major compendiums published during this period (e.g., Reese & Lipsitt, 1970; Stevenson, 1963).

However, as early as 1970, Mussen, the editor of the third edition of the *Handbook* published by Wiley, pointed to the potential meaning of a growing interest among some scientists to move away from a reductionist approach, involving descriptions of the variables purportedly accounting for ontogenetic structure and function, and toward an approach that viewed development as involving interrelations among variables (from multiple levels of organization). Mussen (1970) said that “the major contemporary empirical and theoretical emphases in the field of developmental psychology . . . seem to be on *explanations* of the psychological changes that occur, the mechanisms and processes accounting for growth and development” (p. vii). By pointing to the interest in change processes, Mussen was implying that we needed something more to explain the process of development, unless we believed that nature or nurture variables explained themselves in structure or function.

That “something more” was already emerging within the study of development—for instance, at a series of conferences held at the University of West Virginia in the late 1960s and early 1970s about the nature and implications of a life-span view of human development (e.g., Baltes & Schaie, 1974; Nesselroade & Reese, 1973; Schaie, 1970). These West Virginia University conferences, the edited books that derived from them, and the associated articles published in both theoretically oriented journals (e.g., *Human Development*, *Developmental Review*) and empirically oriented journals (e.g., *Child Development*, *Developmental Psychology*, *International Journal of Behavioral Development*, and *Journal of Research on Adolescence*) discussed the philosophical, theoretical, and methodological problems associated with split/reductionist accounts of development. In addition, they introduced ideas about the potential for plasticity (i.e., the potential for systematic change) in development across life, and pointed to the role of potentially mutually influential relations between individuals and their normative age- and history-graded experiences and, as well, their non-normative experiences, in instantiating this plasticity. Finally, they underscored the fundamental necessity of studying intraindividual changes (and interindividual differences in intraindividual changes) involved in these individual-context relations in order to describe, explain, and optimize the course of human development. These ideas would act synergistically with growing scholarship

in Europe that provided theory and data fostering a “reversal” of focus for developmental inquiry—from variable-centered to person-centered approaches to human development (e.g., Magnusson, 1999). These ideas were also synergistic with work in sociology that demonstrated that the course of life was shaped by historical events that one encountered at particular times and in particular places (Elder, 1974).

When taken together, the dimensions of human development scholarship that crystallized and coalesced between the 1970s and 1990s pointed to the vacuity of split/reductionist models (and their attendant methodologies). In turn, these ideas underscored the importance of time and place, person–context relations, plasticity, and the need for a focus on longitudinal (change-sensitive) methods to study intraindividual change across life and, as well, the diverse life paths of these intraindividual changes. These ideas, when considered together, presented a major challenge to the then-dominant metatheoretical and theoretical ideas in the field. Indeed, the new ideas about human development that found an impetus at the West Virginia University conferences grew in influence across the field and together, across the last three decades of the 20th century, created a Kuhn-like (Kuhn, 1962) paradigm shift (Overton, 2013a, 2013b; Overton & Lerner, 2012).

The shift in conceptual and empirical foci attendant to this paradigm shift was multifaceted. As I noted, Mussen (1970) observed that the field had been primarily descriptive and normative (Mussen, 1970), with the norms usually generated by studying only a small portion of humanity (i.e., European American middle-class children in the main; Hagen, Paul, Gibb, & Wolters, 1990). In addition, the “paradigm” framing this research was as likely (if not more likely) to use cross-sectional research to study development as it was to employ longitudinal methods. The use of cross-sectional designs (and data analysis methods, e.g., R-technique analyses; e.g., see Cattell, 1966, and for more current versions of these ideas see Molenaar & Nesselroade, 2014; Nesselroade & Molenaar, 2010) was predicated on the assumption of the applicability of the ergodic theorem (e.g., Molenaar, 2007; Molenaar & Nesselroade, 2014). The ergodic theorem holds that data sets are marked by: (a) homogeneity across individuals in a three-dimensional matrix that involves persons, variables, and time; and (b) stationarity of individuals’ scores on variables across time (Molenaar, 2007).

In contrast, the approach to the study of human development that was evidenced by the life-span and life-course perspectives involved research that documented the

presence of systematic variation in trajectories of intraindividual change, both within and across people. As such, the assumptions of homogeneity and stationarity of the ergodic theorem were rejected and developmental scientists placed greater importance on not only person-centered research but, as well, change-sensitive methodologies for both descriptive and explanatory efforts (Molenaar, 2007, 2010). What was distinctive about this research, however, was that it was both derived from and promoted diverse attempts to create theoretical models of human development associated with an emergent, relational paradigm (Overton, 2013a, 2013b; Overton & Müller, 2013), a conception that focused on the individual and on the course of his or her trajectories of reciprocal bidirectional relations with the multiple levels of the ecology of human development (represented as individual ↔ context relations). Examples were the bioecological model of Bronfenbrenner (e.g., 1979), the dialectical model of Riegel (e.g., 1975), the developmental contextual approach of Lerner (1982), the developmental systems concepts of Gottlieb (1997, 1998) and of Ford and Lerner (1992), the model of individual development proposed by Magnusson (1999), and the embodiment model presented by Overton (1994, 1997).

In short, these “strands” of theory merged in the 1970s, 1980s, and 1990s and shifted the predominant developmental “paradigm” away from reductionism, Cartesian-split conceptions, and methods predicated on ergodicity, and created a focus on models emphasizing the mutually influential relations between individuals and their contexts, on person ↔ context relations (Cairns & Cairns, 2006; Lerner, 2006). Such models involved the belief that time and place matter in regard to shaping the course of life (Bronfenbrenner, 2005; Elder, 1998; Elder & Shanahan, 2006), and emphasized that the scientific study of human development needed to study both the individual and the diversity of people in order to understand human development.

In sum, the relational paradigm that framed conceptions of the bases of human development was associated with the generation of several relational developmental systems models of human development (Lerner, 2006; Lerner & Overton, 2008; Overton, 2013a, 2013b; Overton & Müller, 2013), conceptions that were used to guide the study of individuals, contexts, and their dynamic interrelations across the life span. Table P.1 presents the defining features of such models.

This multilevel and multidisciplinary approach to studying human development was the basis of the view

that the field was best represented by the term developmental science. In turn, given this synergistic history of the links among theory, method, and research, it is not surprising that, at this writing, relational developmental systems theories are at the forefront of the study of human development (e.g., Lerner, 2012; Lerner & Benson, 2013a, 2013b; Overton & Lerner, 2012). Indeed, the fifth edition of the Wiley *Handbook* (Damon, 1998) had pointed to the growing prominence of such approaches to the study of human development and, in turn, the sixth edition (Damon & Lerner, 2006) noted that models derived from relational developmental systems thinking, and from a relational meta-model more generally, had become the predominant conceptual lens for the cutting-edge theory and methodological innovations guiding research in human development across the life span.

In the present seventh edition of the Wiley *Handbook*, this pathway of scholarly progression is continued. Key examples of relational developmental systems models are found across all four volumes of this seventh edition of the *Handbook*. Moreover, accompanying the use of these models are new methodologies to study individuals, to therefore capture the nonergodic character of human development and, as well, to study the developmental system within which individual ↔ context relations are embedded. Examples of these methods are also a prominent contribution of chapters in this edition of the *Handbook*.

Another key feature of the chapters in this edition of the *Handbook* is the applied use of relational developmental systems theoretical models. Based on ideas about the relative plasticity of individual ↔ context relations, this use of theory overcomes yet another traditional split within the study of human development—between theory-predicated explanations of human development and applications aimed at enhancing human development (Baltes, Reese, & Nesselroade, 1977; Lerner, 2002, 2012). For instance, to test explanations of developmental change, scholars need to institute or evaluate actions that are aimed at altering the bidirectional relations theoretically expected to produce changes in behavior and development. These actions must necessarily be embedded in the actual ecology of human development in order to have generalizability to the lived experiences of individuals (Lerner & Callina, 2014) and, as such, they constitute intervention (applied) research; at the same time, such research tests basic explanatory processes of human development. As such, in contemporary developmental science any splits between basic and applied research are regarded as anachronistic representations of the reductionist, Cartesian approaches of earlier eras.

TABLE P.1 Defining Features of the Relational Developmental Systems Paradigm**Relational Metatheory**

Predicated on a philosophical perspective that transcends Cartesian dualism and atomism, theories derived from the relational developmental systems paradigm are framed by a relational metatheory for human development. This focus includes an emphasis on process and a rejection of all splits between components of the ecology of human development (e.g., between nature- and nurture-based variables, between continuity and discontinuity, and between stability and instability). Holistic syntheses replace dichotomies, as well as reductionist partitions of the developing relational system, through the integration of three relational moments of analysis: the identity of opposites, the opposites of identity, and the syntheses of wholes. Deriving from the relational metatheory, relational developmental systems posit the organism as an inherently active, self-creating, self-organizing, and self-regulating nonlinear complex adaptive system, which develops through embodied activities and actions, as they co-act with a lived world of physical and sociocultural objects.

The Integration of Levels of Organization

Relational thinking, with the rejection of Cartesian splits, is associated with the idea that all levels of organization within the ecology of human development are integrated or fused. These levels range from the biological and physiological through the cultural and historical.

Developmental Regulation Across Ontogeny Involves Mutually Influential Individual ↔ Context Relations

As a consequence of the integration of levels, the regulation of development occurs through mutually influential connections among all levels of the developing relational system, ranging from genes and cell physiology through individual mental and behavioral functioning to society, culture, the designed and natural ecology, and, ultimately, history. These mutually influential relations may be represented generically as Level 1 ↔ Level 2 (e.g., Family ↔ Community), and in the case of ontogeny may be represented as individual ↔ context.

Integrated Actions, Individual ↔ Context Relations, Are the Basic Unit of Analysis Within Human Development

The character of developmental regulation means that the integration of actions—of the individual on the context and of the multiple levels of the context on the individual (individual ↔ context)—constitute the fundamental unit of analysis in the study of the basic process of human development.

Temporality and Plasticity in Human Development

As a consequence of the fusion of the historical level of analysis—and therefore temporality—in the levels of organization comprising the ecology of human development, the developing relational system is characterized by the potential for systematic change, by plasticity. Observed trajectories of intraindividual change may vary across time and place as a consequence of such plasticity.

Relative Plasticity

Developmental regulation may both facilitate and constrain opportunities for change. Thus, change in individual ↔ context relations is not limitless, and the magnitude of plasticity (the probability of change in a developmental trajectory occurring in relation to variation in contextual conditions) may vary across the life span and history. Nevertheless, the potential for plasticity at both individual and contextual levels constitutes a fundamental strength of all human development.

Intraindividual Change, Interindividual Differences in Intraindividual Change, and the Fundamental Substantive Significance of Diversity

The combinations of variables across the integrated levels of organization within the developmental system that provide the basis of the developmental process will vary at least in part across individuals and groups. This diversity is systematic and lawfully produced by idiographic, group differential, and generic (nomothetic) phenomena. The range of interindividual differences in intraindividual change observed at any point in time is evidence of the plasticity of the developmental system, and gives the study of diversity fundamental substantive significance for the description, explanation, and optimization of human development.

Interdisciplinarity and the Need for Change-Sensitive Methodologies

The integrated levels of organization comprising the developmental system require collaborative analyses by scholars from multiple disciplines. Interdisciplinary knowledge is a central goal. The temporal embeddedness and resulting plasticity of the developing system requires that research designs, methods of observation and measurement, and procedures for data analysis be change- and process-sensitive and able to integrate trajectories of change at multiple levels of analysis.

Optimism, the Application of Developmental Science, and the Promotion of Positive Human Development

The potential for and instantiations of plasticity legitimate an optimistic and proactive search for characteristics of individuals and of their ecologies that, together, can be arrayed to promote positive human development across life. Through the application of developmental science in planned attempts (interventions) to enhance (e.g., through social policies or community-based programs) the character of humans' developmental trajectories, the promotion of positive human development may be achieved by aligning the strengths (operationalized as the potentials for positive change) of individuals and contexts.

Source: Based on Lerner (2006) and Overton (2013a, 2013b).

In short, the application of developmental science (optimization) is a co-equal partner with description and explanation within developmental science as it now exists.

Once again, the chapters in this edition of the *Handbook* provide rich illustrations of the integrated foci of

developmental scholarship on the description, explanation, and optimization of human development across the life span.

Together, the metatheoretical, theoretical, methodological, and applied features of contemporary developmental

science that are represented across the four volumes of this seventh edition of the *Handbook* allow this reference work to continue its history of marking the best scholarship in our field and of specifying the key directions for scientific progress. These contributions of the *Handbook* emerge from the intellectual abilities and wisdom of the volume editors and the authors of the chapters involved in this edition. I am enormously indebted to Willis F. Overton and Peter C. M. Molenaar, editors of Volume 1, Lynn S. Liben and Ulrich Müller, editors of Volume 2, Michael E. Lamb, editor of Volume 3, and Marc H. Bornstein and Tama Leventhal, editors of Volume 4, for their broad and deeply erudite scholarship, vision, and leadership. Their knowledge and skills created and shaped the volumes they edited.

The volume editors and I are also profoundly grateful to the authors of the chapters in this edition. Their singular levels of expertise and mastery of their areas of scholarship are richly and compellingly conveyed in this edition. The work of these colleagues represents the best scholarship in developmental science, and we are deeply grateful for their truly field-defining contributions to this edition.

I wish to express particular gratitude to William Damon, for his thoughtful, illuminating, and generous Foreword to this edition of the *Handbook*. Professor Damon was the editor of the fifth and sixth editions of the *Handbook* and, as well, for five decades he has been a visionary intellectual leader of the field that we now term developmental science. He stands as a model of scholarly excellence, erudition, and wisdom, and I am deeply grateful to have his ideas frame the volumes in this edition.

In addition, as scholars contributing to reference works of the scope of the *Handbook* realize, their work cannot be crystallized, completed, or disseminated without the efforts of the professional editors and publishers who work with them. The editors and authors of the seventh edition have been exceedingly fortunate to have had superb support and, as well, collegial guidance, from our editors in the Institute for Applied Research in Youth Development at Tufts and at John Wiley & Sons.

Jarrett M. Lerner, the managing editor in the Institute at Tufts, was involved with the seventh edition since its inception. He has organized and advanced every facet of the editorial and production process. His professionalism, knowledge, organizational capacities, efficiency, commitment, and indefatigable, positive spirit were vital to the existence, and to any archival contributions, of this edition.

In addition, Patricia A. Rossi, the executive editor for psychology at Wiley, was a masterful and wise guide and

catalyst for the seventh edition, again from its inception. Her deep knowledge of the scholarly qualities that are required to produce a reference work that will set the standard of excellence for its field, and her enthusiasm and unflagging commitment to enabling editors and authors to attain this standard, were essential contributions to the development and completion of this edition. She and her colleagues at Wiley, who enacted a superbly organized, efficient, and invariantly high-quality production process, have enabled the scholarship of the authors and editors to be superbly presented to our readership.

Across the several years that I have worked on this edition of the *Handbook*, I have been blessed by having support, stimulation, and feedback from my colleagues in the Eliot-Pearson Department of Child Study and Human Development, and from my colleagues, staff, and students at the Institute for Applied Research in Youth Development, both at Tufts University. I am grateful for their inspiration and collaboration. I am also extremely fortunate to have had support for my scholarly work provided by the John Templeton Foundation, the Thrive Foundation for Youth, the Poses Family Foundation, the National 4-H Council, the Altria Group, Inc., the Bertelsmann Foundation, the National Science Foundation, the Gary and Joan Bergstrom family, and several individuals who have made private donations to the Institute to support its research. I thank them for their faith in me and for honoring me with their support. My family has been a vital resource of emotional and intellectual support—encouraging me when things seemed overwhelming and grounding me when, on rare occasions, things seemed to be going exceedingly well. My wife, Jacqueline Lerner, merits special recognition—as my life partner, as my chief scholarly collaborator, and my muse. I would have accomplished nothing in my career or my life without her.

Finally, the volume editors and I want to thank the colleagues and students who will read the chapters in this edition of the *Handbook* and who, we hope, will gain from the work presented across its four volumes. Many of these colleagues will find their contributions to developmental science represented in the pages of this edition. We thank them for these contributions. As well, we are grateful to them for another reason. Many of these colleagues will also be training the next generation of developmental scientists, young scholars whom we hope will be inspired by this edition of the *Handbook* to undertake scholarship that will make subsequent editions even better and more useful.

We wish these younger scientists well in this intellectual journey. As such, with the hope that their scientific

aspirations will be realized, we dedicate this seventh edition of the *Handbook of Child Psychology and Developmental Science* to them.

Volume 3 Preface

Like all the other volumes of this *Handbook*, Volume 3 was originally planned by two editors. Together, we drew up a list of the topics we wanted covered and sent invitations to the scholars we wanted to recruit. Early in the process, however, my coeditor, Cynthia García Coll, was offered the opportunity to assume editorship of the discipline's best-established journal, *Child Development*, and the burdens associated with that demanding and prestigious task made it impossible for Cynthia to continue with her role as editor of this volume. I certainly missed her advice and insights, and hope she is pleased with the way the volume developed.

In Cynthia's absence, I was even more reliant on the editor-in-chief, Richard Lerner, and his editorial team at

Tufts University. Rich's suggestions about contributors, along with wise counsel and tactful interventions when necessary to focus the attention of tardy contributors, have helped shape this volume in every respect, and the "back-office" team headed by Jarrett Lerner played an invaluable role in turning our aspirations into reality.

Last, but by no means least, I benefited from the goodwill, generosity, and persistence of 22 separate teams of scholars who created the chapters, accommodated multiple requests for revision, and worked with the editors to create the thoughtful, clear-eyed, and forward-looking chapters that make this volume an invaluable resource for the field.

INTRODUCTION

The aim of this volume is to provide a comprehensive assessment of developmental scientific scholarship in relation to social, emotional, and personality development. As with the other volumes in this *Handbook*, contributing authors were selected on the basis of their ability to summarize and synthesize what is known about their designated topics while identifying crucial issues that seem destined to become the focus of important theory-driven research in the years ahead. Whereas contributors to the first edition of this *Handbook* (then, the *Manual of Child Psychology*; Carmichael, 1946) could plausibly claim to have surveyed and cited essentially all scholarly work on their chosen topics, the voluminous literature that has accumulated with increasing pace in the decades since has made that aspiration not only impossible but also undesirable. Readers need informed guidance when either distinguishing between truly important and mundane contributions or discerning those interesting and important lines of inquiry likely to dominate scholarship in the immediate future. Time alone will tell whether our contributors have been prescient, but every reader can recognize the authors' mastery, synthetic ability, and interpretive perspectives.

The 22 chapters that follow provide authoritative and eloquent introductions to topics that lie at the forefront of

contemporary scholarship, and it would be impossible to do justice to their richness, originality, or points of intersection in this brief introduction. Instead, my goal is considerably more modest. In the next section, I draw attention to four overarching themes explored and illustrated in the chapters that follow. Thereafter, I briefly introduce each of the chapters, drawing attention to key themes or insights, especially those that might represent useful points of intersection or cross reference for readers and scholars eager to reassemble the developmental science necessarily disaggregated into the more manageably sized chunks and topically organized chapters of which this volume is comprised.

CROSS-CUTTING CONCEPTUAL ISSUES

The contributors to this volume explore a variety of topics, but their chapters share a number of significant features that are briefly highlighted in this introductory chapter.

Organizational Developmental Contextualism

Like contributors to the other volumes in the seventh edition of the *Handbook of Child Psychology and Developmental Science*, the contributors to this volume have all embraced organizational developmental contextual frameworks to

2 Processes Underlying Social, Emotional, and Personality Development

guide their conceptualization of ontogenetic processes (see Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1, for a discussion of the relational developmental systems paradigm within which these frameworks are conceptually embedded). This nearly universal convergence of theoretical orientation is noteworthy, representing as it does the transformation of a subdiscipline that was once dominated by the proponents and adherents of grand theories. Viewed in retrospect, there is little doubt that the research motivated by the grand theorists and conducted by themselves and their acolytes enormously advanced our understanding of human development, as documented in many of the landmark chapters published in previous editions of the *Handbook/Manual*, all the way back to the first edition in the Wiley series published about 70 years ago. By the same token, the steady accumulation of evidence held the keys to the destruction of these grand theoretical edifices, as it became apparent that their ability to account for significant portions of the variance in developmental outcomes left most of the variance unexplained.

One response to this realization was to incorporate ideas and findings central to competing theoretical frameworks, simultaneously expanding researchers' ability to explain aspects of development while undermining the purity and coherence of specific theoretical approaches. As documented more fully and eloquently in Volume 1, the frameworks that have since evolved reflect awareness that development is multiply determined and that single-minded focus on any one type of influence is almost certainly misleadingly incomplete. Instead, as several contributors show in the chapters that follow, human development is shaped by both those species-specific and individually differentiating biological processes that are the product of evolutionary and intergenerational transmission; that these biogenic propensities are shaped by sociogenic experiences of ancestors and of the individuals themselves from the time of conception; that each individual's phenomenological construction of interactions and relationships from the onset of postnatal life, constrained as they are by cognitive developmental structures, condition the effects of social experience on the developing sense of self and on a range of behavioral propensities; and that the behavior and beliefs of both the socialization agents and developing children are profoundly influenced by dynamically changing aspects of the behavioral and sociocultural context. It remains to be seen whether developmental scientists can create one or more theoretical frameworks that simultaneously represent and recognize the complexity of human developmental processes while generating testable predictions and hypotheses.

Few developmental scientists would contest the evidence regarding the importance of each of the formative factors mentioned above, although researchers (like the contributors to this volume) tend to focus their attention selectively on a subset of the formatively significant factors. This strategy has fueled explosive growth in the number of published papers exploring aspects of social, emotional, and personality development. The absence of strict and definitive theoretical predictions, however, have allowed researchers to focus attention on easily answered questions while sidestepping the more theoretically challenging and (often) more central questions. Whether developmental science continues to advance our understanding of human behavior in the next few decades will depend, in large part, on the success of efforts to address these complex but seldom explored interdisciplinary questions about poorly understood and vaguely described developmental processes. Readers who are so motivated will find the following chapters invaluable, because all of the authors have clearly identified not only what we (as a discipline) currently know and believe, but also what questions need to be framed and addressed if we are to advance our collective understanding.

The Focus on Individual Differences

The ascendance to prominence of the organizational contextual developmental framework was potentiated by a shift in the 1970s from a focus on normative aspects of social, emotional, and personality development to an emphasis on individual differences, a shift that made evident the inability of any of the grand theories to account for the rich diversity of developmental trajectories and outcomes that were readily apparent. This concern with individual differences continues to the present, and dominates each of the chapters in this volume, although the contributing authors painstakingly analyze the factors accounting for individual differences in the context of normative processes, thereby creating more coherent and persuasive portraits of human developmental processes than would otherwise be the case.

Diversity and Internationalism

By the same token, the nearly universal embrace of the developmental organizational contextual approach is responsible for another common feature of these chapters: Recognition that developmental trajectories and contexts are extremely diverse despite the fact that most of our knowledge has been derived from studies of individuals growing up in a small number of quite unrepresentative

socioecological contexts. Although developmental science is an increasingly international field, as the list of contributors makes clear, it has long been dominated by the United States, with disproportionate representation of research participants from relatively advantaged White European American backgrounds. Relative to that template, scholars decades ago began bemoaning the implicit assumption that those whose backgrounds deviated from this norm must be deficient in some ways, although serious focus on representative populations emerged much later, and until two decades ago, children growing up outside the United States were seldom studied except, on rare occasions, when select groups of children from other countries were misleadingly portrayed as representative of comparison cultures.

Meaningful cross-cultural research is increasingly common today, fortunately, supported by a growing number of developmental scientists who grew up outside North America, and the urgent need to recognize and study more diverse groups within and outside the United States is universally recognized. Although concerns with diversity have not animated scholarship on all aspects of developmental science equally, as perusal of the following chapters makes clear, it is widely recognized as a pressing need, and the amount of attention to this topic provides a sharp point of distinction between contributions to this as opposed to earlier editions of this *Handbook*.

Prominent Phases of Development

One final historical change that also deserves mention is the phase of development accorded the greatest attention by researchers and scholars. During the 1960s, students of social, emotional, and personality development focused most attention on children in early to middle childhood. There was relatively little concern with infancy, and when adolescents were studied, they were the university students who could easily be surveyed by instructors doubling as researchers. In the 1970s, however, the focus switched to infancy, driven in part by the publication of Bowlby's (1969) seminal treatise on attachment theory and the resultant spirited debates between attachment and social learning theorists about the ways in which early social relationships shaped development. Over the ensuing decades, the focus on infancy has declined and scholars have increasingly recognized the importance of adolescence, with more recent recognition that the newly designated phase, *early adulthood*, might deserve much more attention than it has been accorded hitherto. Readers of this volume will accordingly observe that the contributing authors

have predominantly focused on childhood and subsequent phases of development rather than on the earliest years of life. There are significant exceptions, however, with many contributors emphasizing the formative importance of infancy for aspects of development more typically associated with (and studied in) later years of life.

OUTLINE OF THE VOLUME

Contrasts between earlier editions and the seventh abound, and the differences are perhaps most dramatic and obvious when examining the methods employed by researchers seeking to explore social, emotional, and personality development. Particularly when seeking to understand the infant's mind, earlier generations relied on parental reports, fanciful speculation, and the occasional observational diary kept by distinguished biographers such as Darwin, Piaget, and Preyer. Only in the 1960s did researchers begin to deploy techniques such as visual preference and habituation paradigms to explore infant abilities and tendencies, especially in the perceptual realm, as evident in Kessen, Haith, and Salapatek's (1970) masterful and encyclopedic contribution to the third edition of the *Handbook/Manual* published the year after Bowlby's (1969) influential book on attachment and before the resultant wave of research on infant social and emotional development crested. Fittingly, the present volume—like the first in the Wiley series in 1946—opens with a broad and engaging introduction to the ingenious ways in which contemporary developmental scientists study social and emotional behavior in their efforts to elucidate developmental processes. In their chapter, Brownell, Lemerise, Pelpfrey, and Roisman (Chapter 2) describe in turn how and why researchers use observational, verbal report, and psychobiological measurement strategies, the strengths and weaknesses associated with each of these, and how researchers can maximize the reliability and validity of the information they obtain. Brownell and her colleagues make clear that the most useful insights have come, and surely will come in the future, from research driven by clear theories and hypotheses and from studies employing multiple complementary methods, rather than any single approach, with its inevitable weaknesses and limitations. Sadly, a scan of most journal tables of contents reveals how frequently contemporary researchers ignore these fundamental admonitions, whereas close readers of later chapters will observe just how frequently the seminal and enduring contributions to the scholarly literature are all marked by careful adherence to Brownell and colleagues' admonitions and guidance. Where Chapter 2 underscores

4 Processes Underlying Social, Emotional, and Personality Development

the role of sound methodology in the generation of knowledge and understanding, Chapter 3 addresses a topic typically dominated by atheoretical and jumbled observation by illustrating the transcendent value of coherent and organizing theoretical frameworks. Specifically, Coall, Callan, Dickins, and Chisholm richly document how the prenatal period of human development has implications for later development by drawing on an evolutionary life history approach. Whereas evolutionary psychologists are often criticized for using a caricature of evolutionary theory to generate post-hoc and untestable explanations of contemporary human behavior, Coall and his colleagues powerfully demonstrate how a thorough understanding of biological processes at both the population and molecular levels (and everywhere in between) allows us to conceptualize the dynamic nature of the relationship between gestating mothers and the organisms (concepti, fetuses) growing within them in a coherent way that explains why, how, and how much experiences during the prenatal period influence later individual development, as well as the development of offspring and subsequent generations of descendants.

In recounting formative prenatal processes (which were, coincidentally, the focus of Carmichael's own contributions to the 1946, 1954, and 1970 editions of the manual that once bore his name), Coall and his colleagues focus attention on the hypothalamic-pituitary-adrenal (HPA) axis that, among other things, modulates and mediates reactions to psychological challenges and stresses. Discussion of the HPA axis is also at the heart of Chapter 4, in which Gunnar, Doorn, and Esposito introduce and explain the conceptualization of the psychoneuroendocrinology of stress. As noted by Brownell and her colleagues in Chapter 2, developmentalists (along with many other psychologists and neuroscientists) have taken advantage of the ease with which cortisol levels can be assessed noninvasively to add measures of cortisol to studies in which stress might be anticipated or feared. Gunnar and her colleagues clearly document how much we have learned about the developing HPA axis and its role in mediating individual reactions to psychological challenges. As we might expect, a burgeoning understanding has brought recognition that single measures of cortisol levels are often uninformative, even misleading, whereas careful and comprehensive assessments in which cortisol levels are viewed in relation to diurnal, individual, and contextual factors can render assessments richly informative about individual status as well as about developmental processes. Furthermore, advances in our understanding of stress reactivity, and

more particularly of the HPA axis's functions, have made necessary widespread recognition of the extent to which the future functioning of the axis can be powerfully, perhaps irrevocably, altered by excessive earlier activation in response to influential experiences, as Gunnar et al. explain, complementing Coall et al.'s discussion of prenatal experiences and their sequelae in Chapter 3. Taken together, the two chapters roundly and conclusively document the untenability of simplistic biogenetic determinism by illustrating the complex and bidirectional links between biology and experience.

This realization evokes memories of the nature–nurture dichotomy that long bedeviled developmental science by promoting a kind of dualism in the analysis of developmental processes. Nowhere was this more evident than in discussions of temperament and personality, the focus of Chapter 5 by Chen and Schmidt. Psychologists have been assessing personality almost as long as they have been assessing intelligence, and the early emerging individual differences in behavioral style known as temperament have fascinated parents, pediatricians, nurses, psychologists, and psychiatrists for more than half a century. Indeed, the classic New York Longitudinal Study was undertaken and reported by child psychiatrists Thomas and Chess (1977) to show that stable individual differences were evident from infancy. Since Thomas and Chess's pioneering work, Chen and Schmidt show, scholars have struggled to determine exactly how many distinct dimensions of temperament there are, how they originate, how they can best be assessed, whether and how they change over time, how they relate to the dimensions of personality that have been studied extensively in adulthood, and how they interact with environmental factors to determine adjustment. These issues and conundrums endure to the present, and growing recognition that temperament is neither immutable nor necessarily innate has been complemented by increasingly sophisticated attempts to understand both the associations between psychophysiological processes and behavioral manifestations and the extent to which these powerful individual differences shape and are shaped by experiences, beginning in utero and continuing across the life span.

The dynamic interactional processes involving young children and the adults charged with their care move to the foreground in Chapter 6, in which Thompson discusses research and theory in relation to early relationships and self-regulation. Building on a theme raised earlier by Gunnar and her colleagues, Thompson draws attention to the dependence of young infants on interventions by adults to regulate their states of arousal before showing

how researchers and scholars have elucidated the gradual transition of responsibility for emotion regulation to young children themselves. Studying these developmental processes, researchers have been particularly impressed by the magnitude of individual differences in the nurturing and regulatory behavior of different adults (especially parents) and the enduring impact of these individual differences on their offspring's development. Attempts to unpack the processes have dominated research on early social relationships for decades, as Thompson (1998, 2006) has documented in earlier editions of this *Handbook*, and we have thus learned a considerable amount about the developmental processes that underlie early social development and the emergence of self-control and regulation in the first few years of life.

The focus shifts in Chapter 7 from the ways in which individual developmental trajectories are shaped by experience to the factors and processes that minimize and mitigate harmful effects of adverse experiences. This topic has gained in prominence over the last several decades as we have simultaneously learned both how many factors, singly or in concert, can affect the course of development among children in risky circumstances and how variable the effects of these factors can be. Resilience in the face of adversity helps explain and reconcile these apparently contradictory bodies of knowledge, argue Luthar, Crossman, and Small in Chapter 7. They further show that, whereas resilience was once viewed as a characteristic of individuals somewhat akin to a dimension of temperament or personality, it is now viewed as a complex concept vested in the individual, his or her social and physical context, social history, and the interaction among these, although considerably more research remains to be completed before the multilevel complexity of resilience, and its implications for developmental science, will be understood. Luthar and her colleagues emphasize that research on resilience is fundamentally applied in nature, that protective factors have difficulty overcoming the pernicious and pervasive risks posed by chronic and severe maltreatment (a point underscored by Cicchetti and Toth in Chapter 13), and that successful interventions for children will require more focus on parental well-being and its correlates.

Chronic illness and disability are intrinsic characteristics that typically distinguish individuals from their relatives, rather than making them similar to one another, as Crnic and Neece show in Chapter 8, and they can have equally extensive and multifaceted effects on development. As noted in multiple chapters throughout this volume, however, these effects are both direct and indirect as well

as bidirectional. Many chronic conditions are associated with enduring differences in physical, cognitive, and emotional function that directly affect attainments and behavior throughout childhood and, indeed, across the life span. Equally, however, these conditions, and their associated effects on the affected individual's behavior, can powerfully affect the well-being, relationships, and behavior of other key people in their lives, most notably their parents and members of their families, and these can in turn affect the ways in which those people interact with the probands, indirectly affecting their experiences and their developmental trajectories. Broad individual differences of diverse origins among probands and family members, and the heterogeneity of the conditions that have been identified and studied, combine to ensure that our understanding of the processes, and especially of powerful variations therein, remains quite superficial, and thus have compromised our ability to develop, implement, and test interventions designed to ameliorate or reverse destructive developmental processes.

Unlike characteristics such as resilience, vulnerability, or chronic illness, race and ethnicity are ascribed characteristics and class is an inextricable aspect of family background. Where Luthar and her colleagues show in Chapter 7 how elements of the social environment can simultaneously produce change and buffer against those effects, the focus shifts even more emphatically to characteristics of the socioeconomic context in Chapter 9, in which Marks, Ejesi, McCullough, and García Coll explore the implications of discrimination for child and adolescent development. In the course of development, children soon become aware of some superordinate and externally evident categories (e.g., gender, race, ethnicity) into which people, including other children, can be sorted. They also learn, all too quickly, that these categories underlie patterns of discriminatory judgment and prejudice on the part of others, including adults, and that these judgments and prejudices often come to account both for the discriminatory treatment they receive from others to whom they are both similar and different, and for them to begin treating others in like fashion (see also Killen & Smetana, Chapter 17). Marks and her colleagues trace the developmental course from perceptual to social discrimination and review evidence of the ways in which prejudice and discrimination diminish and affect, to varying degrees, both those who are prejudiced and those against whom they discriminate. In a world characterized by a rapidly expanding population, increasing levels of migration, and dramatically evident differences in skin color, ethnicity,

6 Processes Underlying Social, Emotional, and Personality Development

religion, gender, and language, the urgency of efforts to understand better the relevant developmental processes could hardly be exaggerated.

The twin processes of discrimination and prejudice are also at the heart of Chapter 10, written by McLoyd, Purtell, and Hardaway, which focuses more narrowly on the implications of race, class, and ethnicity for people making the transition from adolescence to adulthood. McLoyd and colleagues' overarching message is simple but powerful: Discrimination, especially against people of color and those from minority ethnic groups, profoundly limits the opportunities available to many individuals, and these restrictions have enduring—lifelong—implications, foreclosing educational and professional occupations for which they would otherwise be suited and thereby limiting their aspirations, achievements, incomes, and the opportunities that they can open up for their own children. McLoyd and her colleagues elucidate the extent to which constraints on the adult generation limit the social capital, including the social contacts and networks that play a crucial role in opening metaphorical doors for young adults in an increasingly competitive world. These intergenerational processes remain at least partially responsible for the failure of early interventions to have enduring transformational effects on the respondents' lives and for the perseveration, if not intensification, of intranational inequality in a growing proportion of both developed and developing countries around the world.

Discrimination attributable to race, class, and gender have tragically long histories, and have been the focus of both scholarly and impassioned multidisciplinary attention for centuries. By contrast, widespread awareness of discrimination on the basis of sexual orientation is of far more recent origin, even though individuals with non-heterosexual orientations must have existed for millennia, whether or not their freedom to act on their inclinations was severely constrained. Individuals with same-sex orientations have also had children far longer than is generally recognized, often in the context of heterosexual marriages consummated to satisfy individual, familial, or societal expectations. Within the last few decades, however, increasing numbers of gay and lesbian adults have made their orientations public and have sought to raise children, singly or in the context of same-sex relationships, and a substantial literature exploring the implications of their children's development is summarized by Golombok and Tasker in Chapter 11, within the context of a broader consideration of changing family environments. In a comparatively short period of time, Golombok and Tasker

report, developmental psychologists have come to recognize that the majority of children in Western countries grow up in nontraditional family environments, including households that do not involve married mothers and fathers with genetically related children. By examining the research literature on single, cohabiting, step, assisted reproduction, and same-sex parent families, Golombok and Tasker show that initial assumptions that any deviation from traditional family constellations would inevitably have adverse effects on children's development have proven unfounded. Nevertheless, some family structures are associated with enhanced risks of maladjustment on the part of children. The growing body of research helps document that family processes, rather than family structures, better explain developmental trajectories for children in different family contexts.

Almost all children grow up in some kind of family, making that environment of near universal relevance, whereas significantly fewer children have encounters with the legal system. Those children are the focus of Chapter 12, written by Lamb, Malloy, Hershkowitz, and La Rooy. These children are a heterogeneous group, who may enter the system as witnesses, victim witnesses, suspects, or as the focus of public or private law proceedings designed to make decisions about where the children should live. Lamb and his colleagues show in detail how a variety of interacting factors influence children's performance in legal contexts, regardless of the specific roles they are playing, and that the failures of various adult professionals to recognize the specific and unique capacities and limitations of children in legal situations help to stack the deck against them, reducing the chances of fair and equitable treatment and protection. By contrast, supportive practices that recognize developmental differences can dramatically affect children's level of performance. Accordingly, a sizable portion of Lamb et al.'s chapter recounts examples of ways in which important practices and procedures could be altered, informed by our growing understanding of children's developing characteristics.

Apart from the substantial number of children who have some (often tangential) contact with the legal system because their separating parents cannot agree on post-separation living arrangements, most of the children who encounter the legal system are the presumed victims of child maltreatment, and the effects this has on children's development are the focus of Cicchetti and Toth's chapter (Chapter 13). Decades of research, mostly conducted by these scholars, have elucidated in some detail exactly how histories of maltreatment adversely affect and compromise

children's development, and these findings are summarized in this chapter. Readers will be particularly struck by the amount of evidence now available to document the neurophysiological mechanisms whereby maltreatment affects children, and the extent to which studies documenting the adverse effects of maltreatment on children's development has also substantially enriched our understanding of normative developmental processes. Cicchetti and Toth's chapter further complements Gunnar et al.'s (Chapter 4) description of the ways in which neurophysiology can be transformed by repeated stressful experiences, and Luthar et al.'s (Chapter 7) analysis of individual differences in reactions to stressful life experiences, such as maltreatment, and particularly of the factors that promote resilience in such circumstances.

Following this series of chapters concerned with factors that affect children's development and performance, the focus shifts to specific aspects or "products" of development, beginning in Chapter 14 with Hughes and Devine's focus on "theory of mind," the ability to perceive that others do not know the world as we, as individuals, do. Since Wimmer and Perner (1983) first drew attention to an apparently abrupt transition in this regard around 4 years of age, and Frith (Frith & Happé, 1994; Frith, Happé, & Siddons, 1994) observed that this awareness was often lacking or deficient in children and adolescents labeled autistic a decade later, hundreds of studies have explored the emergence of theory-of-mind understanding in typically and atypically developing children, with most research underscoring just how important this aspect of development appears to be. In their chapter, Hughes and Devine show how an understanding of theory of mind grows out of everyday social interactions beginning in early infancy as well as how cultural differences in parental behavior parallel cultural differences in theory-of-mind understanding. Both sets of findings underscore the role of social experiences in fostering development in this domain and recent research examines how theory-of-mind understanding continues to develop from early childhood to adolescence.

As both Hughes and Devine (Chapter 14) and the authors of Chapter 15 agree, theory-of-mind understanding not only emerges from social interaction, but also powerfully affects social interaction. Nowhere is this more evident than with respect to prosocial behavior, which, as Eisenberg, Spinrad, and Knafo-Noam show conclusively in Chapter 15, becomes increasingly sophisticated over time. Extensive research, often drawing on observations of children interacting with peers and parents in experimental,

educational, and home settings, shows that prosocial behavior is evident from early in life, and that its continued development, as well as children's own understanding of what it means, are fostered by the reactions of parents, teachers, and peers who play increasingly important roles in this aspect of socialization. Eisenberg and her colleagues further underscore the extent to which this area of research has been enriched by efforts to understand the biogenetic factors that may underlie prosocial behavior, and in particular its neurophysiological correlates and bases. They rightly caution that both the biogenetic and socialization influences may often be mediated by their effects on individual differences in self-regulation, emotionality, and agreeableness as well as on the nature of their social relationships. In addition, it is clear that an enhanced understanding of prosocial beliefs and tendencies may also advance our understanding both of aggression and bullying as well as of effective forms of intervention, as noted by Eisner and Malti in Chapter 19.

Like prosocial behavior, achievement motivation and school engagement are influenced by agents of socialization both inside and outside the family (Wigfield, Eccles, Fredricks, Simpkins, Roeser, & Schiefele, Chapter 16). Despite continued engagement over time with significant socialization agents (parents, teachers) eager to promote achievement and school engagement, however, Wigfield and his colleagues draw attention to a significant decline over time in the extent to which adolescents around the world appear motivated to achieve. Their efforts to understand this surprising but robust developmental pattern are framed by an expectancy-value model of achievement that seeks to explain the development of motivation by showing how children's expectancies and values are influenced both by their own experiences when undertaking novel challenges as well as by the attitudes and expectations of those around them and how these, in turn, influence children's performance, persistence, and task choice. Furthermore, unlike most developmental models, the model explored by Wigfield and his colleagues includes cultural factors and historical events as intrinsic components.

Is prosocial behavior moral? To the extent that morality is centrally concerned with evaluations of the ways in which people treat others, the question is certainly appropriate. Of course, students of morality within philosophy and psychology have long debated whether morality merely involves behaving prosocially, or whether there are some universal features of morality, such as the principles of justice and equity, and there has been considerable focus over the last few decades on the cultural and subcultural

8 Processes Underlying Social, Emotional, and Personality Development

differences in moral behavior and evaluation that Killen and Smetana explore in Chapter 17. In our increasingly integrated world characterized by ever-increasing international engagement and migration, these issues are particularly pertinent, and they also have major implications for developmental scientists. Killen and Smetana further show how students of morality have successfully identified the complexity of morality in early life, revealing that moral competencies are related to intentionality and emotion understanding, and explore the challenges posed to morality in childhood and adolescence by the stereotyping, interpersonal conflicts, and social inequalities encountered in everyday social life.

If morality defines the ways in which individuals seek to behave toward and to evaluate the behavior of others, then the focus of Chapter 18 on conceptualizations of the self is profoundly different. In the century and a quarter since William James (1890) published his seminal work on this topic, many psychologists have pondered the developmental processes by which individuals come to define the essence of their continuity, aspirations, background, and history, as well as of the ways in which these complex interrelated constructions are altered or elaborated in response to social experiences. In Chapter 18, Spencer, Swanson, and Harpalani address these universal and enduring issues from the perspective of minority youth in the United States, illustrating (as do McLoyd and her colleagues in Chapter 10) how the legacy of discrimination and inequality not only forecloses the concrete opportunities for many non-White youth but limits their self appraisals and aspirations in ways that have lifelong and intergenerational implications. By showing how individual trajectories are shaped by intrinsic as well as contextual factors, Spencer and her colleagues again illustrate the heuristic usefulness of the dynamic developmental contextual approach adopted by most contributors to this volume. Through a focus on minorities in the United States, with an emphasis on race, ethnicity, color, and gender, Spencer et al. draw attention to processes that affect youth regardless of cultural contexts, and highlight the implications of privilege for self-appraisal processes.

Aggressive and violent behavior is the focus of Eisner and Malti's review (Chapter 19). Students of aggressive behavior in childhood and adolescence have often worked alongside and have used the same methods and theoretical approaches as those studying the social-cognitive aspects and socialization of prosocial behavior (Chapter 15), interpersonal relationships (Chapter 22), and gender differences (Chapters 20 and 21), but the field has been

dominated by debates between those who emphasize the evolution and inevitability of aggressive behavior and those who focus on social factors, in the form of parental and peer behavior and social norms, that appear to regulate individual behavior. Proponents of both families of theories about the development of aggressive behavior can point to persuasive evidence of at least some limited significance, but adherents of both approaches have been shaken out of their metaphorical comfort zones by evidence that the levels of serious interpersonal violence have dropped precipitously worldwide, apparently regardless of tangible changes in economic, political, or criminal justice policy. As Eisner and Malti observe, such well-documented trends have revealed how much is still not understood about the determinants and developmental origins of violence and aggressive behavior.

The next two chapters are concerned with gender and sexuality. Specifically, gendered development is Hines's focus in Chapter 20. Gender is one of the so-called ascribed human characteristics, and there has long been controversy about the existence, extent, and provenance of behavioral differences between males and females. Hines shows that many of the gender differences studied by psychologists are quite small, and that mean-level differences between the sexes are often associated with substantial degrees of overlap, such that many females, say, have scores above and below the mean scores for males, and vice versa. For a long time, and in some circles even today, debates have ensued between those who assume that the differences are biologically determined and the others who believe that they are the result of social construction processes, and the vehemence with which these beliefs are held, along with the methodological difficulties associated with conducting definitive research on this complex topic, have inhibited careful research addressing these questions. As Hines shows, however, gendered behavior appears to be a classic example of the ways in which biological and social factors interact and complement one another, with ample evidence that both types of factors play important roles in the emergence and development over time of gender-differentiated behavior of all sorts.

In the succeeding chapter, Diamond, Bonner, and Dickenson (Chapter 21) ask a slightly narrower, though related, question about the development of sexuality, a topic that has attracted researchers' attention much more recently than have questions about gender differences more generally. In large part, scholars' failure to address this question until the 21st century can be attributed to a cultural unwillingness to recognize sexual feelings and

behaviors in children and adolescents, thereby leaving this important facet of development poorly explored and inadequately understood. Somewhat surprisingly, perhaps, progress in this field has also been hindered by basic disagreements among researchers about the operational definitions of various sexual orientations, with the different approaches adopted by different research groups accounting for contradictory answers to some apparently fundamental questions about, for example, the stability of sexual orientation. Diamond and her colleagues also draw attention to poorly recognized gender differences in the stability and meaning of sexual orientation and show how these may have important implications for our understanding of gender socialization more generally.

Sexuality and sexual orientation are enacted socially, in the context of interactions with others, including romantic relationships, but just as developmental researchers long shied away from careful examination of sexuality in childhood and adolescence, so too did they pay scant attention to the development of close friendships and romantic relationships in these phases of life, choosing instead to focus on social interactions with peers more generally. In Chapter 22, Furman and Rose focus on a growing body of research on the characteristics and development of friendships, romantic relationships, and other dyadic peer relationships. The review highlights the extent to which such relationships bring together individuals with unique personalities and histories whose backstories play important roles in shaping the parameters of their relationships as well as their developmental course and outcomes, including longevity. For the same reason, friendships and romantic relationships have much in common, although they have tended to be the focus of different research groups who regrettably overlook potential commonalities and have created bodies of literature that intersect less than would be desirable. One troubling theme, evident particularly in the research on emergent romantic relationships, highlights the surprisingly high levels of interpersonal violence in these relationships.

In Chapter 23, finally, King and Boyatzis discuss the role of spirituality and religion in childhood and adolescence. This topic is relatively new to developmental science, having made its debut in the Sixth Edition with a chapter focused on theoretical issues. As with many other contributors, King and Boyatzis use a developmental contextual framework that focuses on both individual and contextual factors to show that religion is a significant force in the lives of most American children and adolescents, that its salience is attributable to the family and (to a lesser

extent) community factors, and that individual differences in both spirituality and the commitment to religion are associated with individual differences in civic engagement, concern about others, and other indices of psychological adjustment. Interestingly, differences associated with the type of religion (e.g., Catholic, Jewish, Mormon) appear to be much less significant than might be expected, but there is a pressing need for research on the role of religion and spirituality in the understudied parts of the world (especially in Asia and Africa) where religious affiliation is a central component of self-identity and, often, ethnicity and political orientation. Indeed, perhaps because religion is a much more significant social institution in the United States than in other research-intensive countries, King and Boyatzis's chapter is dominated by research on and by Americans.

CONCLUSIONS

It is impossible to do justice to 22 richly insightful and thorough chapters so briefly, and the preceding paragraphs merely telegraph some key features of the contributions while drawing attention to some overarching themes and points of intersection. Each of the chapters will reward readers with an up-to-date knowledge and understanding of the topics covered, but it is perhaps worth ending this introduction with a word of caution. Increasing levels of specialization have led over the last several decades to a situation in which researchers and scholars master vast bodies of knowledge about narrower and narrower topics. To understand development fully, it is necessary to recognize that the processes or functions or behaviors that are the focus of any scholar's research co-occur alongside and inextricably affect the dozens of other processes, functions, or behaviors that are the focus of other researchers' work. As a result, although the salami-sliced child may be easier to study, it is important to acknowledge the inevitable risk of ignoring or overlooking the whole developing child and his or her sociocultural and historical environment.

If this introduction entices readers to reach beyond the chapters focused on their own narrow interests, to recognize some of the ways in which different aspects of development must be viewed in broader context, and to research previously unstudied topics and questions, then this chapter will have succeeded. Developmental science has never had more to offer, but the risk of centrifugal disintegration has never been greater. Along with the entire

10 Processes Underlying Social, Emotional, and Personality Development

editorial team, I earnestly hope that this *Handbook* helps counteract the forces that threaten the field's coherence and integrity.

INTRODUCTION

From its scientific origins in the 19th century, the study of human development has grappled with issues of how to measure behavior, emotion, perception, and cognition in immature, often minimally verbal organisms, and how to do so in ways that capture change while at the same time preserving core constructs over periods of developmental transformation. Measurement must permit the study of

Writing of this chapter was shared equally by all authors. It was supported, in part, by grants from the National Institute of Child Health and Human Development. normative, or interindividual changes in functioning with age, as well as ipsative, or intraindividual differences. This challenge is especially difficult because development occurs at multiple levels of organization, from molecular to group-level processes, all of which affect and are affected by socioemotional behavior and events. And children themselves produce distinct measurement challenges because of their many age-related immaturities, from attentional, cognitive, and linguistic to social, emotional, and self-regulatory, which demand unique, often age-specific assessment strategies.

G. Stanley Hall, one of the field's founding fathers, consigned the study of development to minor status because research with children in the 19th century relied on observational measures rather than reaction time, psychophysiological measures, and introspection, which

then characterized the new science of experimental psychology, a perspective shared by Wundt (Cairns, 1998). However, as detailed by Preyer (1888) in his acclaimed baby biography, *The Mind of the Child*, observational measures were indeed scientific if they adhered to several standards, including direct, unobtrusive data collection by multiple unbiased observers, conducted several times per day, with immediate, detailed recording. Preyer thus presciently foreshadowed many of the measurement standards adopted by developmentalists who have used observational methods over the ensuing century and a half. Hall and his students, meanwhile, put questionnaire methods to work, collecting hundreds of responses from thousands of children of various ages as well as their parents or teachers (e.g., Hall, 1893), thereby establishing another of the field's primary measurement approaches. The third major approach to capturing development, measures rooted in the child's physiological and neural response systems, also has its origins in the field's early history. Boring (1929), the great historian of psychology, traced the roots of experimental psychology to the experimental physiology of the late 18th and early 19th centuries. By the early 20th century, physiological techniques were being used with children. These included cardiac recording and electroencephalography (EEG) in newborns to identify normative response patterns; by mid-century, evoked cardiac and neural responses were used with infants and young children to study developing responsivity to auditory and visual stimuli (Eichorn, 1970; Kessen, Haith, & Salapatek, 1970).

These three measurement approaches characterize the study of most aspects of development, including socioemotional development, and they are used to organize the current chapter. We focus the chapter on these *sources* of measurement because these are the tools of the trade, the fundamental means by which we describe and attempt to understand change and continuity in development. A detailed analysis of the *facets* of measurement (Messick, 1983), such as types of scores, response categories and characteristics, or competence–performance distinctions, is beyond the scope of this chapter, but see Hartmann, Pelzel, and Abbott (2011) for a brief discussion of measurement facets in developmental research. The chapter also does not address design (e.g., longitudinal, quasi-experimental, or microgenetic designs) or analytic methods and issues (e.g., growth modeling, item response theory); for substantive treatments of these topics the reader is referred to Teti (2005) and Laursen, Little, and Card (2012).

BRIEF HISTORY OF MEASUREMENT IN THE STUDY OF SOCIOEMOTIONAL DEVELOPMENT

In the first *Handbook of Child Psychology* (Murchison & Anderson, 1931), John E. Anderson introduced the chapter on methods with this observation:

In the history of any science there can be discerned two trends, one consisting of the main body of fact and generalization... and the other of the methods and techniques by means of which problems are attacked. A problem... does not become a scientific problem until a method of attack can be set up. (p. 1)

Anderson thus recognized that efforts to understand development are only as good as the basic principles and available means of measurement. Measurement in socioemotional development has often meant trying to quantify what *cannot* be seen, including emotions and motivation, temperament and personality, beliefs and norms, and social perception and understanding, in addition to what *can* be seen such as emotion expression, aggression, prosociality, and relationship qualities. The perils of interpreting measures of the unseen, particularly in infants and young children, without benefit of converging language-based techniques, are very real (e.g., Perner, 2010) and have been recognized from the earliest era of developmental science (Koffka, 1924). However, advances in technology have produced new measurement options, especially for the unseen, opening both new opportunities and new challenges. For example, many social and emotional developmental processes can now be linked to genetic, biochemical, and brain activity correlates.

Measurement approaches have reflected the theoretical zeitgeist of the time. Early in the 20th century, during the period sometimes referred to as “dust-bowl empiricism,” observational methods were extensively used to describe children's social behavior and interaction in their everyday environments (Barker & Wright, 1951; Sears, 1975). This approach fell from favor with the rise and dominance of learning theories, including social learning theory, in the 1930s and 1940s, which emphasized laboratory experiments and constrained response options to specific events designed to address questions about social phenomena such as imitation and aggression (Cairns, 1998). In the 1950s, interviews and questionnaires were widely used to study childrearing attitudes and parenting practices (e.g., Whiting & Child, 1953). These mid-century measurement procedures were consistent with the theoretical emphasis on a unidirectional model emphasizing social influences

operating on a passive child. The goal was to identify factors in the social environment that explained social and emotional behavior.

Several theoretical shifts in the 1960s and 1970s changed the measurement landscape. With increasing recognition of Piaget's theoretical work, an emphasis on the active child began to take hold. Bell's (1968) classic paper on bidirectional effects, presaged and in part inspired by Sears's (1951) earlier call for the study of dyadic processes in social behavior, led to a growing focus on interactions, including the child's contributions. Simultaneously, concerns about the ecological validity of small-scale laboratory experiments with constrained response options and artificial stimuli (McCall, 1977) began to send investigators back into children's everyday environments (Bronfenbrenner, 1979), or to simulate those environments in the lab (e.g., Ainsworth & Bell, 1970), employing observational methods once again. This trend was further catalyzed by the rise of theories emphasizing the biological and evolutionary bases of behavior, accompanied by ethological methods that relied on naturalistic observation (e.g., Blurton-Jones, 1972). At the same time, other investigators were enlarging the theoretical space to include multiple levels of social context as determinants of development (Bronfenbrenner, 1979; Lewin, 1954), from family to neighborhood to culture, which also demanded observational procedures for capturing the formative features of settings and contexts. Current research in socioemotional development now uses the full range of measurement approaches that established the science of child development, including observational methodologies, verbal reports from interviews and questionnaires, and structured laboratory tasks.

In the past few decades, new methodologies have arisen, adding to measurement possibilities and ushering in new questions and levels of explanation. Many of these include the very measures whose absence Hall rued in the early days of the science, such as reaction and looking time measures, psychophysiological assessments of heart rate and vagal tone, pupillary dilation, and stress hormones. New measures of neural activity such as functional magnetic resonance imaging (fMRI) and near-infrared spectroscopy (fNIRS) have been added to the armory and, most recently, measures at the level of the genome and epigenome. Grounded in the biological correlates of behavior, these procedures permit us to measure psychological events and processes that are often not open to observation or self-report. The technologies making them available have been motivated in part by developmental questions about

the physiological and neural systems that regulate emotion and social behavior. Although these measurement procedures come with their own challenges, they also permit a truly multilevel approach to the study of socioemotional development, generating explanations that cut across all levels of organization and functioning from gene to brain to behavior. Notably, these approaches also permit us to examine more precisely the role of experience in development and how plasticity itself may develop (e.g., Dennis, Buss, & Hastings, 2012). Thus, developmental science has become progressively more multimethod, multilevel, and transactional in its approaches to measuring children's socioemotional functioning and the processes that produce both age-related change and individual differences.

CROSS-CUTTING THEMES IN DEVELOPMENTAL MEASUREMENT

The three sources of measurement that structure this chapter (observational, verbal report, and psychobiological measures) possess unique strengths and limitations. Developmental researchers must also confront a number of assessment issues that cut across measurement approaches; we review the most important of these below. First, we focus on general measurement concerns; then we consider issues surrounding specific methodological choices. Detailed consideration of each source of measurement and its specific issues then follows.

General Measurement Issues

Measurement quality determines the credibility of scientific inferences, whether the methodology is classic or cutting-edge. We discuss three issues that are central to measurement quality in developmental science: validity and reliability; characterizing individual differences in development as categories or as continua; and assessing stability and change over time.

Validity and Reliability

There is no more fundamental set of concepts in scientific measurement than validity and reliability. Validity refers to how *accurately* a measure of a construct assesses the latent entity of interest. Developmental psychology, like most of psychological science, was strongly influenced by the classic work of Cronbach and Meehl (1955), who outlined a general approach to demonstrating *construct validity*. In the original formulation, a measure acquires

construct validity based on its pattern of causal associations with other variables to the extent that these reproduce the pattern implied by a theory. Importantly, evidence of this sort comes in two distinct forms—*convergent* validity (a measure assesses what it should) and *discriminant* validity (a measure does not assess what it is not intended to; see Campbell & Fiske, 1959).

Reliability, in contrast, reflects *consistency* of measurement. Distinct reliability issues are associated with different types of measurement. The myriad diagnostics available for assessing measurement reliability must therefore be tailored to both the method and the question. For example, test-retest reliability indicates how consistently the same indicator applied to the same sample produces the same measure. In contrast, the key reliability concern for questionnaires is whether items that are combined to operationalize each construct show internal consistency—that is, whether items covary sufficiently to suggest that they are measuring a single latent entity, often determined using Cronbach's alpha. For observational measures, on the other hand, interrater reliability is of paramount concern—that is, the degree to which observers' scores on the behaviors of interest agree, typically assessed using kappa for categorical variables and the mathematically related intra-class correlation for continuously distributed measures. Absent measures with adequate validity and reliability, researchers lack the scientific basis for making inferences about human development: Invalid measures will mislead about how development is structured and what affects it; unreliable measures will produce potentially idiosyncratic, unrepeatable results.

Categories and Continua

Although much of developmental science has been devoted to measuring and explaining normative, age-related change, recent decades have increasingly focused on individual differences in children's functioning. This, in turn, has generated unique measurement challenges. One is the issue of *taxonicity*—that is, whether individual differences are distributed as discrete categories or as continua. Historically, developmental psychologists have tended not to think of this as an empirical question, but rather a matter of convenience, preference, or theoretical orientation. This is unfortunate because understanding whether variation is categorically or continuously distributed can have significant implications for empirical research. For example, it has been well documented that imposing a categorical structure on dimensional data can attenuate predictive validity by impairing statistical power (e.g., Fraley &

Spieker, 2003; MacCallum, Zhang, Preacher, & Rucker, 2002).

Methodological tools developed by Meehl (1995) allow researchers to determine whether individual differences in a latent variable represent naturally occurring categories or continuous variation. It is a positive sign that such tools are increasingly being used by developmental psychologists (e.g., Fraley & Spieker, 2003; Roisman, Fraley, & Belsky, 2007). Wider use of such *structure uncovering* methods is an especially important goal because typological methods, such as cluster and latent class analysis, reveal groupings in developmental data regardless of whether natural groupings actually exist.

Stability and Change

A critical measurement dimension relevant to developmental science is the stability and change in constructs *over time*. Assessments can demonstrate stability/continuity and change/discontinuity over development in several conceptually and empirically distinct ways. There are two especially crucial elements: (1) *rank order* continuity, and (2) *mean-level* stability (Caspi, 1998, provides an excellent taxonomy; for a detailed discussion, see Bates & Novasad, 2005).

Rank order (or differential) continuity refers to whether individuals maintain their order relative to other individuals in a given sample on a given construct over time, typically assessed using a correlation coefficient. The key challenge is that there may be different reasons for low rank order continuity. There may be real changes in the rank ordering among individuals; for example, the aggressive 3-year-old may become a nonaggressive adult. But a second reason is that the construct and its markers may change with age. For example, “bites others” may index aggression among preschoolers but it functions poorly for this purpose among adults. In this case, aggression takes different forms over time and the measurement of aggression must reflect this to be able to identify continuity and discontinuity over development. In short, to characterize what Sroufe (1979) described as the *coherence* of individual development, it is crucial that measurement decisions anticipate such “heterotypic” forms of continuity.

Mean-level stability and change, in contrast, reflect increases, decreases, or stability in the average level of an attribute over time, identified using paired-samples *t*-tests or growth-curve analysis of longitudinal measures. Mean-level change is instructive about the normative course of development, although good inference requires that the units of measurement can be meaningfully compared over

time. This means that the scale points for a given measure are anchored to observable behaviors or other nonarbitrary metrics (Blanton & Jaccard, 2006).

Choosing Measurement Methods: Issues and Considerations

A multitude of considerations enter into the choice of particular methods. We briefly discuss four concerns that cut across particular methods as they apply to developmental science: characteristics of children as participants; the use of multiple informants and levels of analysis to converge on a given developmental phenomenon; measurement equivalence across varying developmental contexts; and ecological validity of measures obtained from or about children.

Participant Characteristics

Children's age, cognitive level, and literacy often dictate measurement choices (Woolley, 2006). Looking-time measures are used with infants but rarely with children and adolescents. Similarly, observational methods are used frequently with infants and young children whereas interview methods are not appropriate, although the latter can be used with slightly older children. Observational measures of children's behavior or of parent-child interaction are often used in conjunction with parent or teacher reports. All are used less frequently with adolescents and adults for whom self-reports are more typical. Once participants are cognitively and linguistically mature enough to follow directions and fill out self-reports, other participant characteristics such as literacy or culture may influence measurement decisions. In many cases, converging methods and multiple informants may be optimal.

Multiple Informants and Multiple Levels of Analysis

Developmental scientists have become increasingly committed to the use of multiple informants and a multiple-levels-of-analysis approach to measurement. The complexity of developmental questions makes such approaches especially valuable. Because development entails adaptation across a wide range of contexts, multiple informants can provide more valid and reliable insight into socioemotional competence than can a single informant or self-report. Further, because developmental scientists are interested in mechanisms underlying the predictive strength of distal resources and experiences in children's lives, multiple methods are needed to capture social, emotional, cognitive, and physiological processes at varying levels of operation.

Multi-informant and multilevel approaches also bring unique challenges. Perhaps the most vexing is the degree to which assessments of a given child diverge across informants, even when measures are parallel and well validated. This has led to interest in the context specificity of behavior (see below) and in potential sources of informant bias. Similarly, although multilevel approaches have proven fruitful in many domains, they can generate almost limitless independent and dependent variables, mediators, moderators, and confounding variables, increasing the likelihood of finding statistically significant associations due to chance alone, particularly when samples and expected effect sizes are small (see Roisman, Booth-LaForce, Belsky, Burt, & Groh, 2013).

Context

Measurement always occurs in a specific context. Strictly speaking, this means that children's responses are unique to a given measurement procedure in a given setting, whether it is the particular relationship measured, the particular informant queried, the measurement type or location, or larger contextual factors such as participants' or experimenters' culture, language community, socio-economic status, school, or neighborhood. Effects may be stronger or weaker when measured in some contexts than others, or they may operate in different directions, or even be caused by different factors. If measures are not equivalent across measurement contexts, our assumptions about the universality of a given behavior, psychological characteristic, mode of functioning, or developmental process may be erroneous as a result (Henrich, Heine, & Norenzayan, 2010; Knight & Zerr, 2010; Norbury & Sparks, 2013).

Concerns about contextual influences on measurement differ from questions about contexts as causal factors in development. The latter focus on issues about how to measure context itself, which is not considered in this chapter (see Bronfenbrenner & Morris, 2006, or Lerner, Dowling, & Chaudhuri, 2005, for a discussion). It is nevertheless worth noting that certain theoretical perspectives have raised novel questions about how to conceptualize the nature of context and thus how it should be measured. For example, dynamic systems theories conceptualize context as an integral component of ongoing interactions rather than as a distal entity acting on individuals from without. From this perspective, context can vary moment-to-moment, as well as over longer time spans in the form of stable behaviors, relationships, and networks (Veenstra & Steglich, 2012).

There is no simple solution to the problem of context effects in measurement. Empirical study of the similarities and differences in the same construct measured in similar ways across populations (notwithstanding concerns about the cultural relevance of some measurement approaches), as well as patterns of similarities and differences within cultures and subcultures, increasingly inform both measurement and theory. Recognizing and understanding contextual factors in measurement must remain a high priority. This will require broadening the populations studied, the questions asked, and the measurement approaches used.

Ecological Validity

Related to questions about context effects in measurement are concerns about the ecological validity of measures. Although ecological validity is often considered in discussions of experimental design, juxtaposed against the need for experimental control, concerns also arise regarding how measures are obtained. For example, playground observations can capture children's natural play behaviors, prosocial behavior, aggressive behavior, and peer associations. Although similar measures can be obtained from structured observations in a standard laboratory setting, laboratory observations cannot duplicate many of the conditions that exist on the playground—such as large numbers of children with the option of choosing interaction partners or large, open play spaces—thereby imposing limits on the ecological validity of laboratory observations. At the same time, a structured laboratory task, such as having friends plan a trip or discuss something they disagree on, can be more ecologically valid than interview or self-report measures of relationship quality or conflict resolution.

Some laboratory measures may be particularly problematic for ecological validity. Psychophysiological and neurophysiological measures require children to provide responses in novel environments and to wear or be attached to unfamiliar equipment. The nature of the equipment may limit children's response options, for example requiring them to sit or lie still to minimize movement artifacts. As developmental psychologists increasingly use such methods, it will be important to consider how highly artificial laboratory environments alter the meaning of children's responses and how interpretation of the findings may be constrained by low ecological validity. Some investigators have begun to confront this issue by making such environments more comfortable and congenial, especially for younger children. For example, in one laboratory an astronaut space game and theme were used to "normalize" psychophysiological recording (Hubbard et al., 2002).

Many of these cross-cutting issues will be revisited in greater depth and further illustrated as we now turn to detailed discussion of each of the three primary sources of measurement: observational methods, verbal reports, and psychobiological approaches.

OBSERVATIONAL METHODS

Observational methods are widely used in studies of socioemotional development because they permit the study of both interactive processes and individual behavior. This is critical given that social interaction is a formative process in development, and socioemotional development is most fully understood within the larger social matrix in which it is embedded. Although human beings tend to observe and interpret one another's behavior continuously, doing so under the rigorous standards of science often proves challenging.

As noted earlier, the study of socioemotional development includes a long history of observing children's behavior and interactions to address both descriptive questions and theoretically derived hypotheses. The revival of observational methods in the 1970s was accompanied by advances in technology, including compact video-recording devices and digital keyboard data-collection devices, along with advances in data-analytic techniques to permit complex sequential and time-series analyses of interactions (Bakeman & Gottman, 1986). In the late 1970s, several influential volumes were published on the use of observational procedures in studies of socioemotional development (Cairns, 1979; Lamb, Suomi, & Stephenson, 1979; Sackett, 1978). Since then, observational methods have figured centrally in the study of most of the major constructs in socioemotional development, as evident in the other chapters of this volume. Sackett (1978) noted five critical criteria for determining the scientific utility of observational research: (1) fit between research questions and observed behaviors; (2) appropriateness of the observational context for addressing the research questions; (3) accuracy and reliability of observers; (4) generality of observations and measures over time and samples; and (5) appropriate statistical treatment of the measures. Here we focus on the first four of these.

Why Observe?

There are many reasons for using observational methods: (a) when participants cannot respond verbally (e.g., infants,

animals); (b) when instrumented or automated measurement techniques are unavailable or inappropriate (e.g., data collection in home or childcare); (c) when verbal report or standardized tests are not appropriate for the research question (e.g., infant-parent attachment) or the behavior is not typically available to conscious self-report (e.g., timing of postural adjustments or facial expressions during interaction); and (d) when the primary questions concern nonverbal behavior (e.g., emotion) or social behavior (e.g., sharing), particularly when these involve interactions unfolding in time together with others' behavior.

Observational methods are used to generate dependent measures within both correlational and experimental designs. They are also used to create independent variables in quasi-experimental designs as, for example, when comparing solitary, reticent, or outgoing preschoolers on aspects of temperament and psychophysiology (Henderson, Marshall, Fox, & Rubin, 2004). Thus, observational procedures assessing social and emotional functioning are used to test hypotheses about the effects of socioemotional processes on development, from behavior at the individual level, to relationships at the dyadic or triadic level, to group dynamics.

Technological advances have expanded the possibilities for what can be observed and how, from head-mounted cameras and eye-tracking technology (Frank, Vul, & Saxe, 2012; Yoshida & Smith, 2008), to synchronized behavioral observations and physiological measures (e.g., Hubbard et al., 2004; Smith, Hubbard, & Laurenceau, 2011), to automated facial recognition and coding (Messinger, Mahoor, Chow, & Cohn, 2009). In the NICHD Study of Early Child Care and Youth Development (NICHD Early Child Care Research Network, 2005), a 10-site intensive longitudinal study of development from birth through 15 years, observations at home, in the lab, and in child care or school constituted the core behavioral assessments at each age beginning at 6 months, attesting to their utility and relevance across childhood and adolescence, both as indicators of social and emotional processes that shape development and as measures of developmental outcome. Indeed, some have argued that direct observation of behavior constitutes the gold standard for psychological measurement (e.g., Kagan, 1998).

What to Observe?

Segmenting the stream of behavior and translating its dynamic qualities into measurable units requires a multitude of decisions. Observational research, like any other measurement approach, is affected by the investigator's

theoretical focus. Unlike instrumented assessments, standardized tests, or verbal report, observational methods rely on human perception, judgment, and evaluation. The apparent face validity of naturally occurring behavior can be misleading, requiring that special care be given to considering one's assumptions and underlying conceptual or theoretical biases when establishing systems to quantify complex behavior. We discuss these issues in greater detail in the "Measurement Quality of Observations" section.

Decisions About What to Record and How

Because behavior is continuous and dynamic, decisions about which aspects of behavior to record, when, and at what level of analysis, as well as how to interpret the recorded behavior, are partly based on the research question and partly on the researcher's particular lens. The pragmatics of the observation setting (e.g., live or in vivo observation versus video recording) might also constrain what is recorded. For example, live, real-time observations severely limit both the number of different events or attributes that can be coded and any sort of time-based or duration information. Issues of reactivity or visual access to events of interest may constrain video recordings of events like playground bullying or sleep-related behaviors, although newer technologies have shown promise (Pepler & Craig, 1995; Tapper & Boulton, 2002). Recording decisions carry important implications for analysis and interpretation (Lakes & Hoyt, 2008).

Observation systems are formal sets of rules for breaking down the stream of behavior into meaningful, quantifiable units of information. This includes selecting and defining the relevant behaviors and establishing the sampling method. Decisions include what will be recorded, how, when, and by whom, as well as the settings or conditions under which observations will occur. The measurement dimension comes from assigning a given code (e.g., attend to parent) to a particular behavior or behavior constellation (e.g., orient head and eyes toward parent's face for a given time). Observation systems are thus the concrete measuring tools or gauges that permit precise quantitative answers to specific empirical questions.

Common metrics include how often a behavioral event occurs (frequency); how long until it first occurs (latency); how long it continues once begun (duration); the time since the last occurrence (lag); the intensity, magnitude, or quality of the behavior, and other accompanying attributes or modifiers of the behavior (e.g., directionality).

Coded events may be mutually exclusive (e.g., attend to parent versus attend to object), or may overlap (e.g., attend to parent and smile), each with different implications for analysis (Bakeman & Gottman, 1986).

Dyadic or group-level events such as mutual gaze between parent and child, rather than the behavior of individuals, can be formally observed. One way to represent dyadic processes is by aggregating behavior coded at the individual level. For example, Kochanska (1997) captured cooperativeness and shared positive affect between parents and their children, which she labeled “mutually responsive orientation,” by compositing conceptually and empirically related behaviors of each individual during social interactions. However, aggregating behavior of individuals may not capture the unique qualities of interactions and relationships that emerge from partners’ dynamic mutual adaptations to one another over time and the fact that each individual’s behavior is incorporated in the other’s responses. An alternative is to observe and measure qualities of the dyadic interaction as a whole, using indices that take the behavior of both partners into account such as “synchrony,” “harmony,” “mutuality,” or “shared affect” (Aksan, Kochanska, & Ortmann, 2006; Fogel, 1993; Harrist & Waugh, 2002).

The measurement implications of these distinct ways to approach dyadic processes are not always obvious. To determine how the two approaches differ empirically, Moore et al. (2012) examined the factor structure of individual and dyadic measures for infants and parents interacting during semistructured face-to-face play. Individual measures included amount and duration of gaze and affect directed to the partner; dyadic measures reflected the degree of mutuality between the partners’ behavior in time, including matched affect, synchrony in affect changes, and flexibility in responding to one another’s affect changes. Dyadic measures largely loaded on different factors than individual measures of infants’ or parents’ behavior, suggesting that each contributed unique information about the interactions. Similarly, Aksan et al. (2006) found that individually coded social bids, response quality, and affect tapped features of parent–infant interaction distinct from dyadically coded measures of cooperation, coordination, and harmony. Nevertheless, some complex or temporally extended behavioral codes may capture enough of the partners’ behavior with each other that aggregating the behavior of individuals can appropriately represent dyadic processes (Patterson, 1982), or even group-level processes such as sex-segregation (e.g., Martin & Ruble, 2010). Thus, the extent to which dyadic characteristics and processes can be adequately portrayed by observing behavior at the

level of the individual depends on how behavior is observed and measured; at the same time, dyad- or relationship-level observations likely provide unique information. It must also be recognized that the behavioral interdependencies between interacting individuals produce statistical nonindependence, posing significant analytic challenges (Kenny, Kashy, & Cook, 2006).

A more substantive issue concerns the degree to which discrete molecular behaviors, whether counted or timed, adequately represent the nature and complexity of the construct being measured. For example, “social competence,” operationalized in terms of molecular behaviors such as frequency or duration of eye contact, smiling, or conversation between peers, has sometimes been difficult to validate. In response, some researchers use more molar measures, including children’s social orientation and behavioral flexibility, organization, and effectiveness under particular conditions (see Bierman & Welsh, 2000, for a review).

Interestingly, behavioral measures from molar observation systems tend to exhibit greater stability over time and to cohere more closely with other measures of children’s functioning than measures from molecular observations (Brown, Odom, & Holcombe, 1996; Cairns & Green, 1979). This is because molar observations are engineered to capture enduring characteristics of the individual as part of the coding, locating the individual within the presumed population distribution of the coded behavior or quality. Molecular coding, in contrast, captures momentary aspects of behavior that may be context- and person-specific.

A concern sometimes voiced about molecular coding is that it is too fine grained to represent actual psychological processes, or that it is the organization or patterning of behavior rather than its elemental components that governs socioemotional responses (Bierman & Welsh, 2000). However, dissecting behavior is often necessary to understand fully its higher-level organization or its temporal structure. Moreover, molecularly coded behavior can be composited across contexts, time, or partners to represent more stable characteristics of individuals and interpersonal or contextual influences on behavior. Most fundamentally, understanding socioemotional processes—what elicits, maintains, and regulates behavior and emotions intrapersonally and interpersonally—requires the use of multiple levels of observation and analysis, from molar to molecular.

Decisions About Sampling the Stream of Behavior

In addition to considering which behaviors and features of behavior to record, decisions must be made about how to sample behavior in time, that is, how often to record events. Under continuous recording, the targeted behaviors

are typically counted or timed as they occur (event sampling) to yield frequencies and rates. When events are not discrete and countable, such as bouts of sustained attention or participation in cooperative play, or when frequency counts are not meaningful representations of the behavior, then time-based records such as latencies or durations of behavior are important. But latencies and durations are less appropriate than event sampling for brief or fleeting behaviors or for high-frequency behaviors.

Sequences of behavior can also be recorded. For example, one might record “infant look away” → “parent talk” → “infant attend” as a sequence that occurs within some predefined period after the onset of the prior behavior (time lag). Sequences can also be defined by the number of behaviors that follows targeted antecedent behavior (event lag). Sequential analysis adds important information about interactive processes, including bidirectionality.

When continuous recording is not possible or would be unduly burdensome or costly, as with a large taxonomy of high-frequency events observed *in situ* such as playground or childcare observations, time or interval sampling may be appropriate. The stream of behavior is sampled in discrete, time-limited intervals, and observers record only whether a given event occurred or not within that interval. Intervals may be successive or discontinuous, as when the observer watches in one interval and records in the next. Sampling intervals can be of any length, from seconds to hours, with interval length scaled to the events being recorded. Long intervals are needed to capture low-frequency or highly variable events (e.g., physical aggression) but would be impractical for high-frequency events (e.g., smiles). However, long intervals will underestimate frequencies of short-duration events; short intervals, in contrast, will overestimate frequencies of long-duration events. Although this method loses the richness of continuous recording, it can still provide a reasonable approximation of event frequency as indexed by the number of recording intervals in which the event(s) of interest occurred.

When observing large groups of children, a technique called focal-child or scan sampling is sometimes used in which the behavior of a given child is recorded exclusively for a fixed period of time, after which the observer shifts focus to another child (usually randomly selected) and records that child’s behavior for the same amount of time until a fixed amount of observation time is accumulated for every child. When these samples are brief they are sometimes referred to as scan samples or momentary time sampling and a fixed number of scan samples is usually obtained. Focal-child sampling can provide substantial child-level information such as how often different

children on the playground are approached by or rebuff peers.

Finally, ratings of observed behavior are used to document qualitative features such as intensity, or aspects of behavior that cannot be identified with clear onsets and offsets, such as fear of novelty or parental sensitivity. Observations are typically conducted for longer intervals, over multiple interactions, sometimes over multiple partners and contexts. Observers then rate the qualities of the behavior on one or more Likert-type scales. Because rating scales are meant to capture more stable attributes or qualities of individuals, rather than moment-to-moment behaviors and interactions, they are often used in studies of individual differences, such as parental style or children’s social competence, whereas frequencies, sequences, or durations are more often used in studies of moment-to-moment processes and developmental change such as the form of parent–child communication. It is important to recognize that by their very nature rating systems are often developmental. This is because the age-appropriateness of the behavior is taken into consideration in defining the rating scale. For example, behaviors indicating parental sensitivity with an infant might be considered intrusive with an older child. Similarly, the same frequency and intensity of physical aggression would be rated as more extreme for an older child than it would be for a toddler. Thus, rating systems often cannot be used to detect normative, age-related change itself, although they can detect individual differences in changes from the norm over time. More molecular observation systems preserve the differences in actual behavior and thus are often more appropriate for the study of developmental change and context-sensitive differences in behavior (see Cairns & Green, 1979, for more detailed discussion of these distinctions).

The larger issue in sampling the stream of behavior is the nature of the correspondence between behavior and time. Behaviors are not uniformly distributed in time, but rather vary depending on the behavior and the context. Some behaviors—such as activity level or sensitive responsiveness—are distributed continuously. Other aspects of behavior, such as turn-taking in mother–infant interaction, are discrete and distributed discontinuously, but are still fairly regular and predictable. Still other behaviors, such as aggression or communicative bids, are distributed quite unevenly in time and some behaviors, such as impulsive responses or temper tantrums, are unpredictable. The complexity of this issue is compounded by the fact that even discrete behaviors occur over time and the same behavior may consume different amounts of

time on different occasions. A brief instance of aggression (quickly grabbing a toy from a peer) might have quite different meaning for both aggressor and victim than a more prolonged instance of aggression (disrupting a peer's play by grabbing or scattering the other child's toys over several minutes). Conversely, some behaviors may be conceptually discrete yet more continuous in actual practice. Peer cooperation, for example, although distinct from other types of behavior such as aggression, typically encompasses a range of behaviors that unfold in time and involve mutual accommodation and coordination of intentions as well as actions; it is only in the aggregate that a bout of cooperation can be identified. Continuous behavior, cyclical behavior, and sporadic behavior each pose unique recording challenges and demand different sampling strategies (see Radke-Yarrow & Zahn-Waxler, 1979, for a fuller discussion).

Who Does the Observing?

In observational research, humans serve as the measuring instruments. As with all measuring instruments, evidence for standard, consistent measurement (i.e., calibration) must be demonstrated. Human observers, though harder to calibrate than mechanical instruments, can provide more sensitive and nuanced measurement. To do so requires well-defined behaviors and coding criteria, thorough training, and regular assessment of reliability. Next we discuss issues related to the choice of observers, contrasting the utility of untrained observers versus trained observers. We also discuss the problem of reactivity in observational research.

In Situ Observers

Generally speaking, the gold standard in observational measurement is the use of trained observers. However, for practical reasons, untrained individuals have sometimes functioned as observers in children's natural settings. For example, mothers have kept records of their children's receptive language (e.g., Fenson et al., 1994) or prosocial behavior (e.g., Zahn-Waxler, Radke-Yarrow, & King, 1979). Teachers or camp counselors have also been employed (e.g., Hinshaw, Simmel, & Heller, 1995). Such in situ observers have greater opportunity to observe the phenomena of interest; it may not be possible or practical for trained observers to be present at key times to record behaviors of interest. In situ observers also have the advantage of being unobtrusive, reducing participant reactivity.

Despite these advantages, in situ observers present several problems. A major concern involves the quality of the data. If in situ observers have little training in the observational system, they may interpret key constructs in unknown ways. Related to this, interrater reliability is more difficult to obtain between in situ observers. In addition, in situ observers' frames of reference may be influenced by different amounts of experience with children, or by gender, race, socioeconomic status, or culture, which may shape judgments about what is normative (Seifer, 2006). Finally, in situ observers may have systematic biases that influence how they record or rate the behaviors of interest. These are especially likely when the observers have relationships with the children being observed. For example, when mothers and trained observers rated children's temperament based on brief video clips (Seifer, Sameroff, Dickstein, Schiller, & Hayden, 2004), trained observers and parents showed good agreement when children were strangers to the parents (average $r = .83$), but very poor agreement when parents' own children were rated (average $r = .11$). Parents rated their own children more positively than did observers; they also rated their own children more positively than the standard children. This systematic bias argues against the use of parent report alone to measure child behavior (Seifer, 2006). Training and supervision can improve observer-parent agreement (e.g., Teti & McGourty, 1996; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992), but the extra effort can be substantial and costly.

Trained Observers

Trained observers offer a number of advantages, including understanding the importance of objectivity and adherence to standard definitions of the phenomena of interest. Cultural, gender, and other biases can be minimized by careful training. Despite these considerable advantages, data collected by trained observers can be costly due to the time needed for training and data collection. However, when the research question concerns children's actual behavior, trained observers are considered optimal (Seifer, 2006; Yoder & Symons, 2010).

Some research suggests that nonexpert raters who capitalize on their intuitive expertise may sometimes be able to deliver valid and reliable data (Baker, Messinger, Ekas, Lindahl, & Brewster, 2010; Waldinger, Schulz, Hauser, Allen, & Crowell, 2004). Note, however, that this depends on which aspects of behavior are being coded and who the participants are. For example, Baker, Messinger, et al. (2010) compared ratings by trained observers with those by untrained undergraduates without research experience

who had been given brief descriptions of each construct. Videotaped parent-child interactions were coded for the amount of family conflict and the degree of maternal sensitivity. For conflict, the concordance between expert and nonexpert raters was quite high ($r = .81$). However, when children with behavior problems or autism were excluded, concordance fell noticeably ($r = .69$). Concordance for maternal sensitivity was lower as well ($r = .65$). Non-experts were especially poor at detecting the “emotional supportiveness” component of maternal sensitivity. Note also that the nonexperts rated only a few global behaviors, unlike trained coders who can code a multitude of both molar and molecular aspects of behavior. This research shows that nonexperts can be good observers for familiar, relatively straightforward, intuitively accessible constructs, particularly when the sample includes extreme instances of the behavior. However, they cannot replace trained, expert observers for capturing multiple, simultaneous, complex, and nuanced features of behavior. Nevertheless, studies examining in greater detail which aspects of behavior nonexperts can (and cannot) reliably code and under what circumstances their observations equal those of expert coders in accuracy and nuance (e.g., with brief training, over different time intervals) would be valuable. Finally, some have argued that using nonexpert raters can not only improve efficiency in collecting observational measures, but may also contribute to our understanding of the face validity of particular constructs (Baker, Haltigan, Brewster, Jaccard, & Messinger, 2010).

Reactivity in Observational Research

The clear advantage of trained observers is the reliability of measurement (see “Measurement Quality of Observations” below). However, in a natural setting, trained observers can be more obtrusive than in situ observers. The presence of unfamiliar people might influence participants to behave in ways they would not normally behave, including refraining from noxious behavior or increasing more socially desirable behavior (Kazdin, 1982). Depending on participant age, awareness of being observed may exacerbate reactivity, even when video or audio equipment is used in place of an observer. Although numerous sources discuss reactivity and countermeasures, the extent to which reactivity is a problem in observational research is an empirical question that has received only limited attention (F. Gardner, 2000; Yoder & Symons, 2010). As a result, relatively little is known about the extent to which reactivity occurs, under what conditions, and whether some participants are more or less prone to reactivity than others due to age, personality,

gender, or cultural factors. Even less is known about the effectiveness of countermeasures to reduce reactivity.

Most studies of reactivity to naturalistic observation have been conducted with audiotaped family interaction at home (F. Gardner, 2000). Reactivity is tested by varying the level of obtrusiveness (e.g., live versus unmanned recording; observer present versus not) and by comparing early and later sessions, or parts of sessions, for habituation effects. Obtrusiveness and habituation have shown few effects on coded behaviors (F. Gardner, 2000; Yoder & Symons, 2010). However, study conditions can maintain participant awareness of being observed, obscuring reactivity effects. For example, Johnson and Bolstad (1975) varied obtrusiveness by having an observer present or absent for alternate sessions and using audio recording to capture family interaction. Analyses showed no obtrusiveness or habituation effects. But given the brevity of the sessions (45 minutes each) and the fact that when the observer was not present the parent had to turn on the recorder, it is reasonable to assume that parents were well aware of being observed. In a study where parents were interviewed post-observation (Russell, Russell, & Midwinter, 1992), fathers reported being more influenced by being observed than did mothers, and reported wishing to enhance their image as parents by inhibiting some behaviors. The lack of evidence for habituation is hard to interpret. It could mean there was no reactivity, but it could also mean that whatever the level of reactivity was, *it did not diminish over time*. Given that parents (more than children) possess the self-regulation abilities to control their behavior, failure to find habituation is perhaps not surprising. Note that in the one study that did find evidence for habituation, participants were preschool-age children with considerably less mature self-regulation (Kier, 1996).

The observation context may exacerbate or mitigate reactivity, but there are few systematic studies comparing reactivity across contexts. As one example, Craig, Pepler, and Atlas (2000) examined bullying in elementary school children when behavior was recorded in the classroom using a manned video camera versus on the playground with a video camera located inside the school using a telephoto lens. Observed bullying was nearly twice as frequent on the playground. Given the contrasting conditions (large versus small space, nonobvious versus obvious camera) and the fact that participants were children (less awareness, poorer behavior regulation than adults), it seems possible that the less obtrusive playground recording minimized reactivity. It should be noted that teachers were equally unlikely to intervene in bullying episodes in both contexts,

so the context difference was not related to differences in teacher reactions. Behavior may also be affected by whether participants are asked to “act naturally” or are given a task. For example, in one of the few studies examining reactivity to in-home videotaping of mother–child interaction, the observation context (dinner time versus a structured task) influenced mothers’ controlling and supportive behaviors, but there were also interactions with time (Session 1 or 2), context (dinner or task), and marital status (married or divorced) on mothers’ supportive behaviors (Pett, Wampold, Vaughn-Cole, & East, 1992). Thus, reactivity might not be present uniformly across participants and contexts. Systematic studies of the effects of participants’ gender, age, personality, or other factors such as context have yet to be done, and there is little clear evidence about the effectiveness of particular countermeasures.

Structured Observations and Laboratory Tasks

Observations of behavior in everyday environments are costly with respect to training and data collection. Further, they may not be useful for addressing behaviors that are infrequent but have high impact in the natural environment; behavior that is difficult to observe because it occurs out of the purview of adults; behavior that changes when observers are present; behavior that can bias observers who cannot be kept blind; or behavior that must be observed under similar conditions across contexts or over time. Observing under more structured conditions or using laboratory-based tasks to assess children’s socioemotional competence can circumvent many of these issues.

Why Structure Observations?

Structured observations and tasks offer more efficient measurement by creating analogs of everyday settings that increase the frequency, intensity, or duration of specific behaviors of interest and permit control over some of the extraneous features of naturalistic settings. For example, to heighten the probability that aggression, negative affect, or their correlates will be observed, settings and stimuli have been structured to intensify children’s self-interest and proneness to conflict by limiting the availability of attractive resources or promoting competition during peer interaction (e.g., Charlesworth & LaFreniere, 1983). The likelihood of parent–child conflict has been increased by creating analogs of particular family interaction contexts such as toy cleanup or prohibitions of children’s behavior (e.g., Laible & Thompson, 2002), or by pairing parents

with difficult children who are not their own (Anderson, Lytton, & Romney, 1986). To assess emotion expression, emotion regulation, or emotion dissemblance, children are led to believe they will receive an attractive prize, but are given something undesirable (e.g., Kieras, Tobin, Graziano, & Rothbart, 2005). Or children may be provoked by a peer confederate who cheats or taunts them during a rigged game to elicit negative affect and corresponding regulatory strategies (e.g., Hessler & Katz, 2007).

Structured observations and tasks can facilitate empirical investigation of age-related social and emotional behavior because children’s behavior is elicited and measured in similar ways over time and contexts (McDermott & Fox, 2007). Unlike in natural settings, every child has the same opportunity to exhibit the target behavior(s). Thus, standardization permits valid within- and between-child comparisons over time. Nevertheless, measures derived from structured situations and tasks are subject to the same validity and reliability considerations as other measurement approaches (Hughes & Haynes, 1978).

From a conceptual standpoint, structured laboratory situations and tasks facilitate hypothesis testing by providing a more telescoped view of specific granular processes that represent the child’s broader socioemotional functioning. Because structured methods are typically used to evoke particular behaviors under standardized conditions, the measures generated can contribute to causal inferences, which demand manipulation and control to rule out alternatives. Indeed, laboratory studies of social processes such as social learning, aggression, and prosocial behavior were dominant in the 1960s and 1970s for these reasons (Grusec & Lytton, 1988). Although unpopular for a period, structured observations and tasks are now part of the regular repertoire of methodologies and measurement approaches used to study socioemotional development from infancy through early adulthood.

What Is Structured?

Structured observations and tasks can vary in the amount of structure and standardization and in the kinds of measures collected, including unobservable responses such as physiological or neural responses. The specific nature of the structured assessment varies depending on the intended target behavior, from adult–child or child–child interaction to children’s individual behavior, social skills, or emotional responses (Haynes & Wilson, 1979). Decisions about what to structure depend on the research question and theoretical framework. Aspects of structured observations that are manipulated or constrained generally include one or more

of the following: the social setting, the partner's behavior, the specific task, or the child's response.

The social setting. Structuring the social setting includes the child's partner(s) or the physical features or stimulus qualities of the situation. Analogs of social contexts such as peer or parent-child interaction permit precise analysis of quantitative and qualitative features of children's social skill and style; their ability to organize effective social and emotional responses under specific conditions; their role in influencing others' behavior; and the quality of their relationships. For example, playing, conversing, or competing with familiar, same-age, or same-gender peers produces different demands than doing so with unfamiliar peers, adults, older or younger peers, and/or with opposite-gender peers (McDermott & Fox, 2007). Similarly, key dimensions of parent-child interaction may differ between mothers and fathers (Cabrera, Linver, & Brooks-Gunn, 2007).

Because social and emotional processes are influenced by features of social context (Dirks, De Los Reyes, Briggs-Gowan, Cella, & Wakschlag, 2012), the social setting should be structured to mirror the complexity of real-life interactive contexts as much as possible. However, children might exhibit different skills in different contexts, and those who are competent in one context may be less so in another. Moreover, developmental changes in socioemotional abilities, and differences in cultural norms for behavioral and emotional expression, can produce different profiles of competence across social interactive contexts. It remains a challenge for the study of socioemotional development to capture the specific aspects of functioning that vary in response to contextual variation (Zeman, Klimes-Dougan, Cassano, & Adrian, 2007).

A review by Bierman and Welsh (2000) of laboratory-based analog social settings from preschool to adolescence illustrates the broader issues. In the "group interaction method," children are observed in small peer groups during cooperative or competitive activity, with partner characteristics or skills, group size, group task, or the amount of adult-imposed structure manipulated. In the "friendship dyad method," children are observed with a known friend, and the interaction task is manipulated, varying from discussing the friendship, to cooperatively planning something pleasant (e.g., birthday party), to negotiating a limited resource or resolving moral dilemmas, to engaging in competitive games. In the "social challenge method," individual children are confronted with a specific social task such as entering an ongoing peer group activity or solving a social or communicative

problem. Across these methods, settings and tasks change with age to remain developmentally appropriate, from predominantly play-oriented in same-gender dyads or groups at the youngest ages to predominantly conversation- and discussion-oriented in mixed-gender dyads or groups at the oldest. Thus, the social setting can be structured in a variety of ways to investigate dynamic social interaction and children's socioemotional competencies and deficits across development.

The partner's behavior. Structuring the partner's behavior permits investigators to isolate experimentally specific aspects of parent or child behavior hypothesized to influence children's social functioning, or to generate selected social or emotional processes thought to function causally. An adult partner is typically provided with specific instructions or asked to engage in particular kinds of behavior with the child. For example, to assess socialization styles or strategies, parents are sometimes asked to try to teach children difficult tasks or to get the children to help the parents with chores or other tasks. To examine the effects of parent anger or marital conflict on children's social behavior, emotions, and regulatory coping, parents or other adults may stage interactions featuring verbal or physical conflict with manipulations of critical factors such as content, intensity, aggressiveness, how affect is expressed, and whether and how conflict is resolved (e.g., Cummings, 1995). In a classic study, Parpal and Maccoby (1985) determined the causal role of parent-child reciprocity in socialization by training mothers to respond positively and contingently to children's social bids during play and then contrasting children's later compliance with trained versus untrained mothers.

Although more challenging procedurally, peer partners' behavior may also be structured and manipulated. For example, in a study of children's responses to peer provocation, children played a video game with an unfamiliar peer (confederate) to win valued prizes (Underwood, Hurley, Johanson, & Mosley, 1999). The game was rigged to the confederate peer's advantage, and confederates were trained to make standard provocative remarks during the game about their own and the other child's prowess or lack thereof while children's emotional responses and coping strategies were assessed. Subsequent studies have added other manipulations of partner or condition, compared children with different risk profiles, and have assessed physiological correlates of behavior during or after the game (e.g., Hessler & Katz, 2007; Hubbard, 2001; Smith et al., 2011), yielding rich, detailed data at multiple levels

of analysis. When children are too young to serve as confederates, one child may be taught something about a task or situation and then grouped with one or more naïve peers to assess communicative skills, peer influence, or other social-exchange processes (e.g., Ashley & Tomasello, 1998; Hanna & Meltzoff, 1993). Thus, structuring the partner's behavior makes it possible to isolate specific, nuanced dimensions of social processes that affect children's socioemotional functioning or that are reflected in it.

The specific task and child's response options. When the individual child's behavior or competence is of interest and the child is studied alone rather than during social engagement, structuring the task and the child's response is typical. Tasks and stimuli are created to elicit social or emotional responses under standard, controlled conditions outside of interactive contexts, but which are meant to provide similar demands. Such measures are sometimes referred to as performance measures (Bierman & Welsh, 2000). Unlike structured observations in which partners and their behavior may be standardized but children's behavior is free to vary, more structured tasks tend to restrict the children's responses. For example, children may be asked to watch social or emotional displays while looking-time to particular display features is recorded (e.g., Serbin, Poulin-Dubois, Colburne, Sen, & Eichstedt, 2001). There are few standard tasks and procedures for measuring social and emotional development (McDermott & Fox, 2007; Morris, Robinson, & Eisenberg, 2006). Instead, such tasks tend to be specific to the particular construct under investigation. As a result, the measurement issues are often unique to those constructs as well (Adrian, Zeman, & Veits, 2011).

Nevertheless, a number of such tasks have become used quite extensively with demonstrated validity, a few of which are noted here for illustrative purposes. During early infancy, the "still-face" procedure, in which an adult briefly stops interacting during face-to-face interaction, has become very widely used to assess infants' social responsiveness, emotion regulation, and communicative skill in both typically and atypically developing populations (Adamson & Frick, 2003). A commonly used measure of emotion understanding in later infancy is the "social referencing" task in which an adult displays positive or negative affect toward an ambiguous object, and the infant's approach or avoidance is measured (e.g., Walden & Baxter, 1989). In toddlers, the "rouge" task (Amsterdam, 1972) is the standard means to assess objective self-awareness, a major milestone in early socioemotional development. A spot of rouge or lipstick is placed surreptitiously on the

infant's face and the infant is shown his or her reflection in a mirror. Self-awareness is indicated when the child touches the spot on his or her own face rather than touching the baby in the mirror. The "delay of gratification" task is frequently used with preschool-age children to index their ability to regulate affect and behavior, a formative individual difference with remarkable predictive ability into adolescence and adulthood (e.g., Casey et al., 2011). It requires the child to wait without touching an attractive toy or food while the experimenter is out of the room; duration of the wait is assessed, with the waiting period adjusted for the child's age. In middle childhood, structured tasks are often used to assess individual differences in achievement motivation (Dweck, 2002). Typically, the child works on a problem-solving task such as a puzzle or arithmetic or memory problems. The task is either especially easy, resulting in a high rate of success, or especially difficult, resulting in a high rate of failure. Children are then given the opportunity to work on the same or another set of tasks, and their persistence and willingness to continue problem-solving is assessed. Before the second set of tasks, children's performance is sometimes explicitly evaluated by an adult (e.g., "you're really good at this"; "you tried really hard at this") to determine the effects of different kinds of praise or feedback on achievement motivation. In adolescence, structured tasks are often used to assess risk-taking, especially emotional risk-taking (e.g., M. Gardner & Steinberg, 2005).

This somewhat arbitrary selection of structured tasks spanning infancy through adolescence makes it clear that there can be as many tasks as there are constructs. Although these particular tasks have become well-established, most such tasks and procedures are designed for a given study and seldom test or report key psychometric data. It is equally clear that each task comes with its own unique measurement issues, including how ecologically valid and representative children's restricted responses are and how best to interpret them.

The advantages of structured observations and tasks include simple, straightforward procedures; substantially reduced coding burden; standardization and control of both task administration and performance assessment, including computerized presentation and response options for some tasks; manipulation of the social and emotional conditions under which children are observed; the availability of more refined, process-specific indices; and the potential for linking task-related behavior and associated socioemotional processes to physiological correlates or neural underpinnings. The primary disadvantages are the

relatively narrow range of functioning typically assessed on a given task, and thus inflexibility in capturing diverse behaviors and processes; situation-specific or task-specific demands that may vary by age or culture, making it difficult to study stability and continuity in the target behaviors or processes; issues surrounding the ecological validity of the laboratory setting, restricted stimuli, and constrained response options; and the noninteractional nature of many such procedures. Furthermore, in situations that expose children to or elicit anger, frustration, or other negative emotions or problematic behaviors, ethical considerations dictate that only brief or low-intensity responses be evoked (Cummings, 1995; Hubbard, 2005), possibly limiting the inferences that can be drawn and the generalizability of the findings.

Measurement Quality of Observations

The reliability, validity, and utility of observational measures are conditioned on the theoretical paradigm, on whose behavior is observed and for what purpose, and on the measurement context. Observational measures feature unique sources of error that can affect validity and reliability. Construction of an observation system must take these into account in determining which behaviors to observe, under what conditions, and in operationally defining the relevant behaviors. Issues of representativeness and generalizability are fundamental to all measurement procedures; observation of children's actual behavior, even under natural conditions, does not solve the problem of external validity, rather it raises unique issues.

Reliability

Interobserver agreement and observer reliability are related, but not identical, standards for determining consistency across observers. As noted earlier, interobserver agreement refers to the agreement between observers about what they have seen and recorded (Bakeman & Gottman, 1986; Yoder & Symons, 2010). It can be examined as point-by-point agreement on the occurrence and nonoccurrence of behaviors, or whether a given behavior occurs within a specified time window. Historically, percent agreement has been used to index interobserver agreement, but this can be inflated by chance agreement, especially when there are few coding categories and when the expected distributions are much higher for one category than for others. When categories are mutually exclusive and exhaustive, correction for chance agreement (e.g., coefficient kappa) is recommended (Bakeman & Gottman, 1986; but see Yoder

& Symons, 2010, for cautions). Interobserver agreement can also be indexed by concordance on rank ordering of behaviors using intraclass correlations (Yoder & Symons, 2010). As opposed to interobserver agreement, observer reliability refers to the accuracy of measurement, typically with respect to agreement with a "gold standard" observer or observers. Using such a benchmark can increase confidence in the accuracy of live coding systems. It can also enhance interobserver agreement across laboratories and is standard practice for published observational coding systems like the Classroom Assessment Scoring System (CLASS; La Paro & Pianta, 2003) or the Strange Situation (Ainsworth, Blehar, Waters, & Wall, 1978).

Because reliability can be adversely affected by small behavior samples (Bakeman & Gottman, 1986; Yoder & Symons, 2010), as a rule of thumb at least 20% of the data are checked for interobserver agreement; the frequency of checks is dictated by the occurrence of the least frequent codes. Additional random, unannounced checks of interobserver agreement are essential to prevent drift and reliability decay. Because reliability estimates are inflated when coders are aware of being checked, coders should be blind to which observations are checked. One disadvantage of live coding is that it is difficult to keep observers blind to reliability checks.

Observer Inference and Bias

It is often assumed that inferring competence from direct observation of behavior requires less inference than from laboratory tasks or standardized tests. However, most observational methods require some degree of inference or interpretation by observers, with more molecular codes generally requiring less than more molar codes. For example, judging which facial muscles are activated during a facial expression as in the molecular facial action coding system (e.g., Cohn, Ambadar, & Ekman, 2007) requires less interpretation than does judging whether a child has exhibited a "sad" or a "fear" face, which are more molar codes; and the latter, in turn, requires less inference than judging whether a child has exhibited "distress" or "avoidance," which are still more molar. Furthermore, observers can be biased by their own idiosyncratic perceptions or by the individuals being observed. When ratings are used, some raters may consistently rate the same behavior or quality higher or lower than others. Observers may also have common biases based on shared norms and attitudes about the observed behavior such as what represents "typical" or "average" behavior and what indicates an extreme (Hoyt, 2000).

These issues are illustrated by studies of bias in observations of aggression. Observers are more likely to attribute aggressive intent and judge behavior as aggressive if it is performed by a boy or if the observer is told the child is a boy (e.g., Pellegrini et al., 2011). This appears to be truer of male than female observers, even when observers are highly trained (Pellegrini, 2011). Presumably, shared norms about gender differences in aggression, combined with observers' own gender schemas, produce such biases. Indeed, when observers were given instructions that activated gender schemas about aggression, they were more gender-biased in their judgments than with gender-neutral instructions (Lyons & Serbin, 1986). Similarly, interactions between observer race and target-child race have been found during observations of children's social behavior (Lethermon, Williamson, Moody, & Wozniak, 1986).

Issues of bias in observational research are especially difficult when observers and observation systems are from a different culture than the child being observed. These extend beyond adequately observing differences in the structure or organization of children's activities and social encounters. Similar practices or experiences may have different meanings in different cultures. Consider, for example, constructs like maternal sensitivity, warmth, and intrusiveness, or child interest, sociability, or hostility. Cultural groups differ in norms, attitudes, and assumptions underlying such constructs, and when they do it can be difficult and even misleading to apply observation systems developed in one culture to another (Knight & Zerr, 2010). Measures so derived include information about the observer or the rating scale in addition to the children or adults being observed. Moreover, socioeconomic, caste, or national origin differences within cultures create intracultural differences in norms and practices. Thus, even within cultures, observations can produce unreliable, invalid, or contaminated measures of children's social experiences or competencies. The importance of minimizing both observation system bias and observer bias is paramount, and can be achieved by acquiring substantial knowledge about the behavioral norms of the observed population; careful, precise behavioral criteria, preferably paired with culture-neutral instructions; multiple, independent raters; and thorough training (see Yoder & Symons, 2010, for a discussion of defining behavior in coding systems and training observers).

Validity

For the legions of papers published with 5, 10, or 15 minutes of observation of children's behavior, there are few

data available to ascertain the psychometric properties of the measures, including construct validity or even ecological validity. Indeed, some evidence suggests only low to moderate correlations across different observations within a single setting like the home (e.g., free play versus toy cleanup; Seifer, Sameroff, Anagnostopolou, & Elias, 1992), and poor correspondence between behavior at home and in the lab on similar tasks (see F. Gardner, 2000, for a review). Leyendecker, Lamb, and Scholmerich (1997) found that brief observations yielded unstable measures of mother–infant interaction quality, but that stability increased with more extended observation periods.

The measurement of temperament illustrates many of the issues. There has been a move to supplement parent-report measures of children's temperament with behavioral observations of children's behavior during standard laboratory tasks (e.g., Gagne, Van Hulle, Aksan, Essex, & Goldsmith, 2011), or at home (see Stifter, Willoughby, Towe-Goodman, & the Family Life Project Key Investigators, 2008) or school (e.g., Bishop, Spence, & McDonald, 2003). However, agreement among these methods can be quite poor. Observers differ from other reporters in their training and frames of reference. Moreover, observers' reports are confined to the period observed, whereas parents' ratings represent the whole of their experiences with the children. However, parents can be biased in their perception or reporting of their own children's behavior whereas observers presumably are less so (Seifer et al., 2004).

Stifter et al. (2008) used structural equation modeling to examine the contributions of method and trait factors to ratings and observations (methods) of temperament (trait). Parents reported on their infants' temperament; observers rated global temperament following extended home observations; and different observers coded videotapes of children's behavior during challenge tasks in the home. A model based on both method and trait factors fit the data best. Parents and observers converged on ratings of positive but not negative aspects of temperament. Home observers and observers coding videotaped challenge tasks converged on both positive and negative aspects of temperament although agreement was modest.

More encouraging results emerged when a single, more circumscribed temperament trait, behavioral inhibition (BI), was examined (Bishop et al., 2003). Observers coded videotapes of children's interactions with an adult stranger at their preschool or kindergarten, and agreement with mother, father, and teacher reports was examined. Correlations between observers' BI ratings and parents'

and teachers' ratings ranged from .25 to .46, with higher agreement when only the children rated high and low in BI were considered (from .35 to .60). Agreement between specific observer-coded behaviors (e.g., gaze, speech) and parents' or teachers' BI ratings varied depending on the behavior and the rater. Such results suggest that there is better correspondence between observations of temperament and parent or teacher report when one aspect of temperament is assessed *and* the observational context is designed to elicit that aspect of temperament.

These studies show that whether observational measures of behavior converge with measures from parents and teachers depends on the nature of the construct in question and the context, with better agreement within than across contexts. More than modest convergence may be difficult to achieve. Longitudinal data provide the opportunity to test the predictive validity of observational measures. For example, in the case of antisocial behavior, observational measures may have greater predictive validity than parent report (e.g., Patterson & Forgatch, 1995).

Although variability in behavior across measurement contexts may be considered problematic for validity, some investigators have argued that theoretical models should be revised to incorporate such variability as a meaningful indicator of functional differences in children's socioemotional behavior and to begin to understand why such variability occurs (Dirks et al., 2012). For example, children's performance on laboratory-based emotion regulation tasks does not always cohere across tasks. Yet this variability can be informative in differentiating among subtypes of regulation such as effortful, voluntary control (shifting attention or activating behavior) versus more reactive, less voluntary control (behavioral inhibition or impulsive approach behavior) (Spinrad, Eisenberg, & Gaertner, 2007). Similarly, the frequency of parents' negative or positive comments during a laboratory-based parent-child discussion of a conflict may not correspond to rates at home. Yet it may still provide valid estimates of functional relations such as emotional tone, mutual responsiveness, acceptance, and joint problem-solving (Haynes & O'Brien, 2000).

External validity. Among the primary dimensions of external validity for observational measures are whether the behavior being observed is the most appropriate for the question, an important component of the larger behavioral repertoire, and relevant to the psychological processes under investigation (Schmuckler, 2001). A central issue is whether the behavior sample is representative of the child's typical behavior in everyday settings. Whether the

behavior sample is both representative and sufficiently captures events of primary interest is especially crucial when the behavior occurs infrequently or variably (Stoolmiller, Eddy, & Reid, 2000; Yoder & Symons, 2010). Low rates of behavior or high day-to-day variability can undermine both the reliability and validity of observational data (Lakes & Hoyt, 2008). Note, however, that the frequency of a behavior does not necessarily correspond to its weight in defining or shaping children's socioemotional functioning. For example, both aggression and prosocial behavior, which occur infrequently in natural contexts (Pellegrini, 2011), are particularly influential in determining children's acceptance or rejection by peers (see Furman & Rose, Chapter 22, this *Handbook*, this volume). Acquiring an adequate sample of such behavior from observations in children's everyday environments requires lengthy sampling periods over multiple sessions. When this is not possible, statistical corrections can be applied to account for differences in rate and/or variability (Stoolmiller et al., 2000). Alternatively, a structured observation or introducing a standard elicitor increases opportunities for participants to display the behavior of interest. Ainsworth's Strange Situation, a structured, lab-based observational procedure for assessing infant-caregiver attachment, was devised to solve the problem of low rates of attachment behaviors in unstructured home observations (Ainsworth et al., 1978). Less than 30 minutes in length, its reliability and validity have been well-established in hundreds of studies, attesting to its representativeness and utility (see Lamb, Thompson, Gardner, Charnov, & Estes, 1984, for further discussion). Notably, children's attachment behavior in the Strange Situation differs from their behavior at home, yet their behavior in the lab predicts many other aspects of socioemotional development, even into adulthood (Sroufe, Egeland, Carlson, & Collins, 2005).

A core assumption of structured observations and tasks is that the child's behavior is representative of, or at least correlates with, the corresponding behavior in natural, unstructured settings. However, concerns arise about how closely the analog situation approximates the everyday world (F. Gardner, 2000; McCall, 1977), how characteristic the families are who agree to come into the laboratory (Bronfenbrenner, 1979; Henrich et al., 2010), and how accurately the measures represent children's social competence and relationships (Bierman & Welsh, 2000). For example, some studies have found that family decision-making interactions are more positive at home than in the lab, but parents are more engaged with their children in the lab and more restrictive and less helpful

at home (Cone, 1999). Still, it should not be assumed that observations of behavior in analog settings are necessarily less representative than observations in the natural environment (Schmuckler, 2001). Indeed, the number of uncontrolled influences on behavior in natural settings far exceeds those in structured contexts, producing greater error and instability in the measures, with accompanying concerns about reliability and validity.

Finally, all settings constrain behavior and the constraints may vary across settings. For example, playground observations of children from different schools may include varying playground physical characteristics, amount of recess time or teacher supervision, or number of children, all of which can influence the behavior(s) of interest. Similar issues arise when comparing across home observations (Leyendecker et al., 1997; Seifer et al., 1992). In structured observations and tasks, instrument effects are a related and important source of influence (Messick, 1983). Instrument effects refer to response variability arising from interactions between child characteristics (e.g., temperament, mood, fatigue) and the format or conditions of measurement, including the structure of the setting (e.g., who participates, for how long, the physical layout) and experimenter behavior. The significance of setting influences has long been recognized (e.g., Barker & Wright, 1954; Bronfenbrenner, 1979; Elder, Modell, & Parke, 1993; Lewin, 1954), but there is no consensus on the criteria for evaluating what is appropriately representative and for whom (see Schmuckler, 2001, for a fuller discussion). Fundamentally, decisions must be based both on the theoretical framework and on judgments about whether critical aspects of the behavior of interest have been captured.

Observational Methods: Summary and Conclusions

Observational methods are the only way to capture real-time behavior, including dyadic and group interactions as well as individual social and emotional behavior. They are especially useful in research with nonverbal children, when behavior is not under conscious control or available to self-reflection and report, and when automated measurement is not feasible. They are thus extensively used to study socioemotional processes throughout the life span.

Many decisions enter into the construction of observation systems and collecting observational data, including what to observe, how, when, where, and who should observe. Behavior can be counted, timed, or rated; behavior

as specific as individual facial muscle movements or as general as dyadic harmony can be coded. Unique issues surround the stability and generalizability of molecular versus molar behavior records and must be considered when designing coding systems. How to sample the temporal dimension of behavior, breaking up the continuous behavioral stream, poses another set of issues. Events or sequences of events, time intervals, or individuals can be sampled, as can qualitative features of behavior such as valence or intensity. Whether behavior is brief or sustained, frequent or infrequent, continuous and predictable, or irregular and unpredictable, affects sampling decisions. Who observes depends in part on decisions about what and how to record, as well as the context in which observations are made. Access to the behaviors of interest and participant reactivity; bias, accuracy, and sensitivity of observers; and costs of training must all be considered as they can affect data quality.

Observations may occur in everyday environments or in structured analogs of natural settings. Features of the setting, the partner(s), or the child's response options may be designed to evoke aspects of behavior that are difficult to observe or occur infrequently. Structured observations and tasks also offer a degree of manipulation and control that is unavailable in unstructured, naturalistic observation, giving every child the same opportunity to exhibit the behaviors of interest, and permitting a sharper, more detailed focus on particular aspects of socioemotional competence. However, structured observations come with their own issues, from setting or task demands to possible ethical issues in attempting to elicit negative emotions or behavior.

Because observational measures depend on human judgment, they are prone to bias and error. Being observed can also produce reactivity in those observed, often altering their behavior in unknown ways. Common reliability procedures and careful training ensure agreement and accuracy across observers, but observers can nevertheless be biased by shared norms and frames of reference such as their own culture or gender. In particular, "best practices" for observations of children from diverse cultures and socioeconomic strata have not been established (Whitcomb & Merrell, 2013), so caution is required when interpreting such data.

Questions of validity are raised by relatively modest agreement between observational measures and parent report measures of the same construct, and between observational measures of the same construct across contexts. However, there may be advantages to modeling such variability more formally to understand why it occurs,

including the possibility that such measurement error actually reflects multiple constructs. Observational measures are also subject to external validity concerns arising from decisions about which aspects of behavior to sample, when, and in what contexts, particularly when the frequency of behavior does not reflect its importance in children's socioemotional functioning.

Observational methods remain among the most routinely and widely used measurement approaches in the study of socioemotional development because of their versatility and their ability to capture complex behavior and interaction in many different settings. For investigators who cannot themselves collect observational measures, or who wish to expand their access to observational data, an important initiative to share video-based observations among developmental scientists has recently been introduced (<http://databrary.org>). This federally funded resource will collect and permanently archive video data from hundreds of researchers while protecting the privacy and confidentiality of the research participants. Readers are encouraged to consult, use, and participate in this scholarly community and its pioneering efforts to advance the understanding of behavior and development via observational methods and measures.

VERBAL REPORT: INTERVIEWS AND QUESTIONNAIRES

Verbal report methods provide a window into mental processes and representations, allowing the measurement of constructs that are difficult or impossible to capture with observations. Researchers can assess children's and adults' knowledge, opinions, and beliefs, as well as judgments about their own and others' current and past behavior. Verbal reports include a range of procedures, from puppet-assisted interviews for preschoolers and young children to web-based questionnaires with young adults. Participants can report on themselves, on others, or on key developmental contexts, such as parents reporting on their children's school or judging influences on academic performance (e.g., Stevenson, Chen, & Shin-Ying, 1993). Participants might report what they or others would do in hypothetical situations or what might happen if they behaved in various hypothetical ways (e.g., social information processing and moral judgment interviews). Verbal reports are especially valuable in measuring unobservable influences on behavior when perceptions, beliefs, or attitudes do not correspond to reality. For example, adolescents' beliefs about the

prevalence of drinking among peers predict their own future alcohol consumption even when their beliefs do not correspond with peers' actual behavior (e.g., "false consensus effect," Neighbors, Dillard, Lewis, Bergstrom, & Neil, 2006).

A number of issues are common to all verbal report methods. Researchers need a well-conceptualized research question with well-defined variables and clear operational definitions. In cross-cultural research, the conceptual and measurement equivalence of the operational definitions must be demonstrated (Church, 2010). Decisions must also be made about the extent to which the instrument will be structured. When all participants receive the same questions (most structured), comparisons among participants are facilitated. However, follow-up questions for some answers (less structured) can provide more detailed information. Item construction and selection are subject to theoretical biases; when new measures are constructed, best practice involves careful psychometric evaluation and publication of the items and other instrument characteristics. The validity of verbal report measures can be affected by social desirability biases and the burden on participants' time or effort. This is especially important for young children whose attention span places limits on interview length, and for teachers who may be asked to complete multiple reports on many students.

Culture or socioeconomic status may be associated with communication differences between researchers and participants, influencing how participants interpret questions or how researchers interpret responses, creating systematic measurement error (Callaghan et al., 2005; Church, 2010). Particularly in face-to-face interviews, such differences may color participants' views of the relative power or status between themselves and the interviewer, affecting responses in various, sometimes unknown, ways. Authority and power differences are also important considerations when adults interview children (D. Eder & Fingerson, 2003). Interviewers need training in building rapport with participants, and for studies with culturally diverse participants, interviewers from similar backgrounds can be helpful.

A key consideration in the construction and use of verbal report instruments is their developmental appropriateness. Language comprehension, literacy, and cognitive and attentional maturity of the participants influence the age-appropriateness of the instrument. Young children often need training and visual aids to use scaled responses (e.g., "like a lot" to "don't like"). Interviews may be preferred with young children or when literacy is in doubt. With retrospective reporting, there are likely to be

developmental differences in memory for past events as well as distortions of memory (e.g., Roisman, Padrón, Sroufe, & Egeland, 2002). Developmental and individual differences in the suggestibility of participants also exist (e.g., Bruck & Melnyk, 2004; Ceci, Papierno, & Kulkofsky, 2007), making interviewer training critical (see below). Finally, as is true of verbal report measures at any age, but perhaps especially so with children, the response format (e.g., positive versus negative responses; forced choice versus scaled responses; number and wording of anchors on a Likert scale) can influence responding as much as the content of the items (e.g., Lamb & Fauchier, 2001). Hence, when participants range widely in age, literacy, or cognitive development, issues of interpretability of measures and response equivalence across participants are crucial considerations.

Verbal Report: Interviews

Because of their flexibility, interviews are used to assess a wide range of constructs from self-concept and self-esteem (e.g., R. A. Eder, 1989; Harter & Pike, 1984), emotion knowledge (Denham & Couchoud, 1990; Morgan, Izard, & King, 2010), and moral cognition (e.g., Turiel, 2006), to parental meta-emotion philosophy (Katz, Maliken, & Stettler, 2012). Interviews are used with parents, teachers, and children. Because they are often used with younger children whose abilities to complete paper-and-pencil or web-based instruments are limited, we focus on this age group. We distinguish between children as informants about themselves and their experiences, knowledge, or beliefs, and their peers as informants about them.

A number of special considerations apply to interviewing children. For preschool age children, whose verbal comprehension lags behind that of older children and adolescents, developmentally appropriate language is needed to permit them to understand the interview questions. Further, because developments in verbal production lag behind comprehension, the extent to which children can verbalize what they know or understand is another concern. Interviews that require free response answers are likely to underestimate younger children's knowledge and understanding. For this reason, researchers have created interview formats permitting children to point to alternatives or to simple visually depicted scales. Although such strategies can circumvent some language production concerns, they do not solve the problem of how to elicit meaningful explanations for forced-choice responses. Young children's verbal limits remain a significant barrier

to interview-based inferences about some aspects of early social understanding and to age-related comparisons in the growth of socioemotional competence.

Other concerns include children's attention span, conceptions of time, memory, and other cognitive demands. With preschool or early elementary school-age children, longer interviews may yield diminishing returns as children become fatigued or bored and their attention wanders. Programmed breaks or multiple short sessions may be necessary. Interview formats that are engaging and child friendly can also help (see "Child Informants" section). Because young children's conceptions of time develop slowly (Friedman & Lyon, 2005), they may be unable to report some kinds of information reliably. For example, research on the use of structured diagnostic interviews has found that children younger than 10 years cannot reliably report the timing and duration of symptoms (Edelbrock & Bohnert, 2002). The cognitive load of the task is also relevant; interview questions that require children to hold information in working memory can underestimate younger children's competence (Case, 1992). Common remedies for interviews that ask questions about story characters in a sequence of events are to accompany the story with illustrations, to retell the story after a series of questions, or to ask the child to retell it.

The interview method has been characterized as time- and cost-effective due to reduced training demands and data collection time relative to other methods (Edelbrock & Bohnert, 2002). However, appropriate training is essential to minimize measurement error. In many laboratories, interviews are conducted by undergraduate and graduate students who must be trained to establish rapport with children (and their parents, teachers, or school officials), be sensitive to the children's perspectives and developmental level, and to understand ethical considerations related to questioning children. The need for standard procedures is also paramount. For example, naïve interviewers sometimes inadvertently point to a particular value on a response scale or hold the response scale with the correct end closer to the child. Given children's suggestibility (e.g., Bruck & Melnyk, 2004), it is crucial that interviewers be trained to avoid such nonverbal slips and to monitor and control other nonverbal behaviors. Below we review common interview formats used with children.

Child Informants

Puppet-assisted interviews. Puppets are often used to make interviews more engaging and to facilitate responding. For example, R. A. Eder (1989) measured young children's

self-concepts with two puppets who presented alternatives based on Harter and Pike's (1984) self-report instrument. Puppet 1 might say, "I keep my room neat and clean" whereas Puppet 2 would counter, "My room is really messy." Children were asked to pick the puppet who was more like them. Eder found that children as young as 3.5 years provided internally consistent responses that exhibited test-retest reliability. The Berkeley Puppet Interview, adapted by Ablow and Measelle (1993) from this technique, has been used to measure domains of self-knowledge, including academic competence, achievement motivation, social competence, peer acceptance, depression/anxiety, and aggression/hostility (Measelle, Ablow, Cowan, & Cowan, 1998), conduct problems (Arseneau, Kim-Cohen, Taylor, Caspi, & Moffitt, 2005), and children's reports of the parenting they experience (Sessa, Avenevoli, Steinberg, & Morris, 2001). Children's reports of their own behavior showed convergent validity with other reporters and their reports of the parenting they received converged with those of observers, but less well with their mothers' reports.

Puppet-based interviews have also been used to measure children's emotion discrimination and emotion situation knowledge (e.g., Denham & Couchoud, 1990). Blank-faced puppets act out emotion-eliciting vignettes, and children select the emotion face that reflects how the puppet is feeling. Children's responses have been shown to relate concurrently and longitudinally to their social and emotional competence (e.g., Denham et al., 2003). In other studies, children have used puppets or dolls to represent themselves and to act out what they would do or say in hypothetical situations (Murphy & Eisenberg, 1997), or in emotion- or attachment-based story endings (MacArthur Story Stem Battery; Bretherton, Ridgeway, & Cassidy, 1990). Because such procedures reduce the demand for verbal responses and create a familiar play-like format, they are especially valuable with preschool and early elementary school-age children.

Hypothetical situation interviews. Because storytelling is natural, engaging, and enjoyable, interviews with young children often involve telling the child a story and then asking questions about the story. Stories involve hypothetical, easily imaginable situations; they may have either hypothetical characters or characters known to the child, including the child him/herself, and can be illustrated with line drawings (e.g., Harper, Lemerise & Caverly, 2010) or presented as video clips (e.g., Lemerise, Fredstrom, Kelley, Bowersox, & Waford, 2006). Questions following the stories include evaluating characters' motives or the

appropriateness of their actions; predicting what characters might do and why; asking children how they feel about the characters' actions or what they themselves would do; what their own goals would be in that situation; or what the consequences might be of various responses to the situation. Responses can be forced choice, choosing a response on a scale, or free response. Because of its flexibility, this general approach is widely used in studies of moral and prosocial reasoning (e.g., Eisenberg, 1986; Killen, Lee-Kim, McGlothlin, & Stangor, 2002; Turiel, 2006), social information processing (see Lemerise & Maulden, 2010, for a review), theory of mind (see Wellman, Cross, & Watson, 2001, for a meta-analysis), and other aspects of social cognition (e.g., conceptions of friendship; Selman, 1980).

Interpretation of children's responses to hypothetical situations rests on the assumption that children's answers reflect their understanding and that their responses are associated with their behavior. However, these assumptions may not always be valid, and the nature and strength of relations between children's interview responses and their knowledge and behavior is an empirical question. The "happy victimizer" phenomenon illustrates the first assumption (e.g., Arsenio & Kramer, 1992). In these studies, children were told stories in which one child victimized another child and then received a material gain or achieved a personal goal. Children were asked to attribute emotions to both the victim and the victimizer. Children had no trouble attributing negative emotions to victims, but children younger than 6 or 7 years attributed positive emotions to victimizers (the "happy victimizer"), whereas older children attributed mixed or negative emotions to victimizers. This finding has been interpreted as reflecting an important milestone in moral development (e.g., Malti & Keller, 2010). However, the developmental difference may lie not in moral reasoning, *per se*, but in children's ability to reason about hypothetical characters. When children were asked to imagine themselves as the victimizer (rather than imagine a hypothetical victimizer), they attributed negative emotions to the self-as-victimizer at earlier ages (Keller, Lourenco, Malti, & Saalbach, 2003), suggesting that reasoning about hypothetical characters may involve greater cognitive load than reasoning about the self (see also Callaghan et al., 2005; DeLoache, 2011). Thus, researchers must be cautious in making inferences about what reasoning about hypothetical characters reveals about young children's social understanding.

Social information processing research, which focuses more on individual differences than developmental change,

also utilizes hypothetical situations accompanied by line drawings or videotaped vignettes. Children are often asked to imagine they are one of the story characters, usually the victim of a provocation or the child who is excluded by a group of other children. The other child (or children) in the stories is/are hypothetical peers, often described as “a kid you know called X.” After telling (or viewing) the story, questions are asked to assess one or more steps of social information processing. A large body of research using this paradigm has demonstrated individual differences in how children perceive and evaluate story characters, with the strongest individual differences demonstrated when the provocateur’s intent is ambiguous (see de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002, for a meta-analysis). These findings are commonly interpreted as reflecting individually stable patterns of reasoning. However, another body of research using stories featuring the child’s own peers calls this interpretation into question (see Lemerise & Maulden, 2010, for a review). These known peers varied in the nature of the affective ties they had with the participants (e.g., good friends, enemies, or neutral peers; or liked/disliked). Results showed that children gave the benefit of the doubt to friends and liked peers as provocateurs, but judged disliked peers and enemies more harshly even when they were portrayed similarly. Thus, children’s responses varied depending on the nature of their relationship with the peer whose actions they were reasoning about. These results, along with those above, demonstrate that the degree to which children’s responses reflect their actual understanding or behavior is an empirical question and should not be assumed.

Peer Informants

Peers are in a unique position to observe and report on the behavior and relationships of children they know. They have access to interactions and events that adults are not likely to witness or that may cease *because* an adult is present. Peers, teachers, and observers exhibit good convergence on a number of aspects of social behavior (Cillessen & Mayeux, 2004). Among the most common peer informant measures are those derived from sociometric methods.

With a long history in psychology (Cillessen, 2009), sociometric methods are widely used to study social and emotional development, especially peer relations. Children are asked to nominate, rate, or rank their classmates or other peers (e.g., at summer camp) according to how much they are liked or disliked; the ensuing scores are then combined to derive measures of social preference

and social impact in the peer group (see Gifford-Smith & Brownell, 2003, for a review). Children can also make behavioral reputation nominations, as in Class Play-type measures where they indicate which children are the most aggressive, prosocial, popular, and so on for roles in a play (Masten, Morison, & Pellegrini, 1985). Researchers then identify specific types of peer relationships such as friendships (defined as mutual like-best or best friend nominations) or enemy relationships (defined as mutual like-least nominations) (Hartup & Abecassis, 2002). Peer likeability, status (popularity, rejection), or behavioral reputation can also be measured (e.g., Asher & Hymel, 1981). Subgroups of children can be compared in studies of social behavior and reasoning. For example, children who are rejected by their peers and receive many nominations for aggressive behavior can be compared to children who have average, rejected, or popular status and are nonaggressive (e.g., Lemerise, Gregory, & Fredstrom, 2005; Lemerise et al., 2006). These subgroups have been shown to differ significantly in social and academic competence (Coie, Dodge, & Kupersmidt, 1990; Lemerise et al., 2005). Peer reports can also be used to study the properties of children’s social networks (e.g., Farmer & Xie, 2013; Neal & Neal, 2013; Rodkin & Hanish, 2007).

When used with older children and adolescents, sociometric measures are usually collected as either paper-and-pencil or computer-assisted questionnaires (see van den Berg & Cillessen, 2013, for a comparison). With preschool and younger elementary school children, interviews are used. In one widely used, reliable, and valid procedure (Asher, Singleton, Tinsley, & Hymel, 1979), children are first trained to use a simple 3-point scale. They are then presented with photographs of their classmates and asked to rate how much they like each one or to nominate the peers they like most and least by pointing to the relevant photos. Note that this procedure is game-like and the child makes active responses. Also, the 5-point scale used with older children is modified to a less cognitively demanding 3 points. This procedure can also be used for younger elementary school children with a few modifications (e.g., Lemerise, 1997).

A number of factors affect the quality of sociometric measures (Bukowski & Hoza, 1989). The timing of data collection matters because children need to get to know their peers well enough to report on them. Reliability is affected by participation rates, with higher participation rates associated with higher reliability (e.g., Marks, Babcock, Cillessen, & Crick, 2012). Behavioral reputation nominations, which are based on observable

behaviors or peer consensus, exhibit better reliability at lower participation rates than do nominations for liking or friendship, which reflect children's individual reactions to peers (Marks et al., 2012). Data collection in middle or high schools where children have classes with a variety of different peers across the school day creates additional challenges (Poulin & Dishion, 2008) because the peer group is much larger and children may not know all of their peers equally well. Unlimited nominations have been suggested to produce more valid data under these circumstances (Marks et al., 2012; Terry, 2000). Moreover, long, alphabetized lists of grade-mates can produce list-position biases in children's nominations, with peers higher on the list nominated more frequently (Poulin & Dishion, 2008). Thus, for middle and high school settings that do not have self-contained classes, shorter, randomly generated lists that sample from the larger peer group are recommended (Bellmore, Juvonen, & Jiang, 2010). These issues notwithstanding, because sociometric methods, unlike parent or teacher reports, combine the judgments of many reporters, the resulting measures, particularly continuous sociometric measures, have been shown to have reasonably high stability and predictive validity (see Jiang & Cillessen, 2005, for a meta-analysis).

Verbal Report: Questionnaires

By late elementary school age, children become able to complete instruments on their own with some guidance, as demonstrated by sociometric methods. By adolescence, interviews begin to be supplanted by questionnaires as the primary form of verbal report. Structured questionnaires have long been the workhorse of individual differences research across the social sciences and many of the strengths and limitations of this method flow from its core characteristics. Specifically, questionnaires require researchers to develop *a priori* conceptualizations of the key axes on which individuals are likely to vary in a given domain, and then to select items (i.e., questions) to capture behavioral, cognitive, or affective indicators of these constructs. Participants then rate each item to characterize aspects of themselves or others (e.g., parents rating their children). Likert-type rating scales are often used to reflect the *degree* (i.e., from "not at all" to "very much") or *frequency* (i.e., how often) of the item. In developing and validating questionnaire measures, data are subjected to exploratory and confirmatory factor analysis to determine whether the putative indicators of the constructs map onto

them as expected, similar to the process for demonstrating convergent and discriminant validity. Once validated, individual items are averaged or summed to provide measures of the constructs of interest (Floyd & Widaman, 1995).

Questionnaires are the most cost-effective and efficient means for collecting large amounts of standardized data and have been used effectively for this purpose since the 19th century. They make it possible to collect parallel information about a construct from a wide range of individuals who may encounter the child in different developmental contexts. For example, to assess children's social competence, a well-validated measure of social skills, such as Gresham and Elliott's (1990) Social Skills Rating System (SSRS), can be administered to mothers and fathers to capture information about the child's social behavior in the home, and also to the child's teachers or childcare providers to assess socially skilled behavior in a peer context. Widely used questionnaires like the SSRS and the Achenbach System of Empirically Based Assessments (ASEBA; e.g., Achenbach, Edelbrock, & Howell, 1987), which primarily assesses psychiatric symptomatology, have been developmentally tailored so that the same measures can be collected from early childhood, as soon as the behaviors of interest emerge, through adulthood, making them especially valuable to studies of developmental continuity and change.

Questionnaires do have notable limitations. First, of necessity they reflect a particular conceptualization of the constructs being measured. The questions are assumed to represent the most appropriate sample from the universe of possible items pertinent to the domain of interest. Thus, there is little opportunity for respondents to inform the researcher's conceptualization of how they may vary in a given domain. Second, even when questionnaires are administered in precisely the same manner to all informants, different groups of individuals may interpret the same questions differently. This issue is one of *measurement equivalence*, necessary for making inferences across groups. Indeed, in addition to careful translation and back-translation of items, establishing measurement invariance (e.g., factorial and intercept) is necessary for valid analyses of cross-cultural and cross-ethnic similarities and differences (e.g., Cheung, Pomerantz, & Dong, 2013; Haltigan et al., 2014). With these considerations in mind, we illustrate some common applications of questionnaires over development to provide a flavor for how they are used in research on children's socioemotional development.

Questionnaires From Infancy to Early Adulthood

Infancy. Questionnaires designed to assess socioemotional functioning in the first 2 to 3 years tend to be administered to primary caregivers, particularly mothers. In addition to probing aspects of parents' own experiences (e.g., parental depression, with the CES-D; Radloff, 1977), parents are frequently asked to report on their children's experiences or characteristics such as temperament. For example, at the 1- and 6-month assessments in the NICHD Study of Early Child Care and Youth Development, mothers completed Carey and McDevitt's (1978) Infant Temperament Questionnaire, rating items on a 6-point scale to assess overall difficulty. This measure was a reliable moderator of the predictive significance of observed sensitive caregiving, with more difficult children either disproportionately negatively affected by low-quality caregiving or differentially susceptible to both lower- and higher-quality caregiving (Roisman, Newman, et al., 2012; see Chen & Schmidt, Chapter 5, this *Handbook*, this volume, for further discussion of temperament measures).

Early childhood. Questionnaire methods become more diversified with older children, increasingly focused on distinct aspects of socioemotional development. Questionnaires such as those contained within the ASEBA, which assesses symptoms of psychopathology, can reliably track both internalizing and externalizing symptomatology as early as 2 or 3 years of age. Similarly, questionnaires such as the SSRS assess multiple aspects of socially skilled behavior from as early as children can sustain interactions with their peers. As children become progressively more engaged with others outside the family in a widening array of contexts, childcare providers and teachers become key informants about the children's behaviors and experiences, using questionnaires that parallel those for parents (e.g., Teacher Report Form, TRF, the teacher-report ASEBA questionnaire).

Middle childhood and adolescence. The reliance on adult informants shifts in middle childhood when self-reports become more routinely used. Versions of the ASEBA, like the Youth Self-Report, and other instruments that require self-reflective reporting, like Kovacs's (1992) Child Depression Inventory (CDI), become age-appropriate as children's ability to reflect objectively on their own physical, psychological, and behavioral qualities becomes more robust and differentiated. As an objective sense of self becomes consolidated, instruments like Harter's Perceived Competence Scales (Harter, 1982) track children's self-concepts in domains such as

academics, peer relationships, and other salient aspects of identity. Similarly, children become able to report on their friendships, including activities and features that index relationship quality; attitudes such as school and achievement attitudes, or gender and race stereotypes; and emotional responses or states such as loneliness or feelings of rejection. They can report on actual behavior like risk-taking, antisocial behavior, or religious and civic engagement. And they can report on others' behavior (peers, friends, or parents).

Although this creates a wealth of possibilities for capturing multiple perspectives from different informants about socioemotional competence in a variety of domains, two limitations must be noted. First, there has been a long discussion in psychological science about the degree to which even adults are able to consciously access the information that questionnaires typically request (Nisbett & Wilson, 1977). Questionnaires often require respondents to summarize information over extended periods of time and to weigh and balance dynamic and variable behaviors, attitudes, or feelings. This is especially demanding for children and poses difficulties for children's self-reports of affective and cognitive experiences which other informants are unlikely to be able to validate. Parents, too, are poor at recalling descriptive information about their own approach to, say, childrearing years earlier (Yarrow, Campbell, & Burton, 1970). Second, the covariation among self-, parent, and other adult (e.g., teacher) reports of the same child's behavior tends to be modest (De Los Reyes, Thomas, Goodman, & Kundey, 2013). Mothers and fathers show more agreement with each other than do parents with teachers, suggesting that context-specific child behaviors may explain part of the difference. However, parents rate their own children more positively than others do (Seifer et al., 2004), also suggesting rater bias or socially desirable responding. Hence, the hopeful view that data from multiple informants might simply be averaged to increase the validity of questionnaire assessments of socioemotional development has proven to be naïve. Although low convergence among measures of the same construct produces significant barriers to interpretation, the fact that it is consistently found and that different informants provide unique predictive information about children's socioemotional functioning (De Los Reyes & Kazdin, 2005), raises the possibility that informant discrepancy can itself be predicted (e.g., as a function of age, child characteristics, or construct) and is worth investigating in its own right (Hourigan, Goodman, & Southam-Gerow, 2011).

Adulthood. A final developmental shift in questionnaire use occurs as adolescents transition to early adulthood (18–25 years). First, teacher and parent reports become less commonly used through the end of high school. Self-reports—and later, romantic partner—reports—fill this gap. Second, the experiences captured by questionnaires also change, with a shift toward romantic and vocational experiences (Roisman, Masten, Coatsworth, & Tellegen, 2004), as well as aspects of antisocial behavior that increase notably across the transition to adulthood (Moffitt, 1993).

Verbal Report: Summary and Conclusions

Flexibility is a clear strength of verbal report methods. Interviews and questionnaires are used to measure a range of constructs, including mental representations and emotional experiences that would not be accessible by other means. Compared to observational methods, verbal report methods are more cost- and time-efficient, with questionnaires more so than interviews. Despite these advantages, there are limitations in the application of verbal report methods. Verbal reports can be constrained by memory distortions and other biases, and some constructs may not be accessible to verbal report, particularly when young children are the respondents. Developmental considerations such as linguistic and cognitive ability and literacy levels restrict the use of both interviews and questionnaires, which makes parents, childcare providers, or teachers necessary informants about very young children.

Interviews begin to be used when children reach preschool age, but the developmental appropriateness of interview demands must be carefully considered to ensure that the procedures are engaging and the results interpretable. Interviewer training ensures standardization and controls for inadvertent nonverbal behavior that might enhance children's suggestibility. Finally, in the absence of converging measures, cautions apply in interpreting interview results as reflecting stable developmental levels or individual characteristics.

As children reach late middle childhood and adolescence, questionnaires largely replace interviews. Children's growing cognitive abilities, vocabularies, reading skills, and capacity to focus attention and follow directions make it possible to capitalize on the more time- and cost-efficient questionnaire method. However, individual differences in the very skills that enable this shift may compromise validity. For these reasons, especially for elementary school children, training children on the response scales

and reading the questions to them can be essential. Given the large numbers of college students who require remedial reading courses (Bettinger & Long, 2009), due diligence seems appropriate beyond elementary school as well. Finally, careful attention to measurement invariance at multiple levels of analysis is required to use questionnaire data validly across culturally diverse groups.

PSYCHOBIOLOGICAL MEASURES: NEUROPHYSIOLOGY, PSYCHOPHYSIOLOGY, AND GENETICS

Extraordinary progress has been made over the past two decades in the development and application of methods to quantify biological correlates of human socio-emotional development. The field can now truly adopt a “molecules-to-mind” approach, studying key phenomena across multiple levels of analysis, from genes, to brain, to behavior, to the broader environmental context (e.g., Somerville, 2013). A driving force has been the development and refinement of neuroimaging methods, especially functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and functional near infrared spectroscopy (fNIRS), to study brain function across the life span (e.g., Nelson & Luciana, 2008). Advances in molecular genetics and the integration of molecular and behavioral genetics have also propelled the field forward, as have advances in epigenetics. Interdisciplinary research teams now combine genetics with neuroimaging and psychophysiological methods to measure constructs across levels of analysis, and, increasingly, across the life span. Each of these measurement approaches is discussed in this section.

As a group, psychobiological methods are powerful, but as with any measurement approach, researchers need a well-conceptualized research question with well-defined constructs and clear operational definitions to maximize the interpretability and validity of inferences. Also like other measurement methods, psychobiological methods require a high level of specific training and expertise to be implemented appropriately. However, unlike the other methods discussed in this chapter, training in psychobiological techniques or the interpretation of measures derived from them is not currently part of routine graduate education in most developmental psychology programs. As such, they are often used in the context of large multidisciplinary research teams, with attendant logistical hurdles.

Psychobiological measures involve several trade-offs. For neuroimaging techniques, there is often a trade-off

between invasiveness and the degree of spatial resolution. Another trade-off exists between temporal and spatial resolution: EEG has excellent temporal but poor spatial resolution whereas fMRI exhibits the opposite qualities. Different psychobiological methods provide complementary but independent measures. It is always best to triangulate on a particular construct utilizing several different methods, each appropriate to the question of interest and the developmental level of the participant.

Psychobiological measures also have notable weaknesses. Threats to data quality are a major issue. Perhaps even more than other techniques, the misapplication of psychobiological measures can generate data that seem informative but are actually misleading. For instance, movement artifacts not only ruin neuroimaging measures, but, when unnoticed, can lead to false, but plausible, conclusions. With these considerations in mind, we review several psychobiological approaches used with children and the measures they generate, their advantages and disadvantages, and the exciting opportunities becoming available.

Neurophysiological Measures

Neurophysiological measurement approaches can significantly enhance the explanatory power of theories of social and emotional perception, regulation, understanding, and reasoning, thereby contributing to our understanding of socioemotional behavior. They can: (a) improve models of social and social-cognitive processes via activation-based *dissociations*, that is, when one brain region or network is activated differently by different tasks, whereas another area shows the opposite pattern of activation; (b) inform understanding of the relative timing or structure of social and cognitive processes; (c) facilitate integration of information from diverse methodologies (e.g., genetics, lesion studies, animal models, and behavioral performance); and (d) help adjudicate between competing psychological theories.

Because a complete account of socioemotional development must include an understanding of brain development, methods for studying *in vivo* brain function have gained positive traction. The brain is highly dynamic and active in its responses to environmental inputs and the activities of the individual, and we are just beginning to acquire the empirical database needed to understand how structural and functional changes in brain size, composition, and organization relate to developments in social and emotional domains. In the sections to follow, we

describe the three functional neuroimaging techniques that are being used most widely to study the development of human social and emotional brain function.

The evaluation of each technique can be informed by two key concepts, *contrast* and *functional resolution* (Huettel, Song, & McCarthy, 2009). Contrast is the intensity difference between quantities being measured by an imaging system, for example oxyhemoglobin levels. Contrast is determined mostly by signal-to-noise ratios, or the magnitude of the intensity difference between quantities divided by the variability in their measurements. Contrast applies to both temporal and spatial properties of neuroimaging methods. Considering the temporal and spatial resolutions of an imaging technique along with the quality of the experimental design and task selection (no technique is useful in the absence of a valid experimental design), the *functional resolution* of a technique can be determined. Functional resolution refers to a measurement technique's ability to identify the relation between underlying neuronal activity and a cognitive or behavioral phenomenon. Functional resolution is limited both by the intrinsic properties of a brain measure and by the researcher's ability to manipulate key features of the experimental design to allow interpretable variation in the phenomenon of interest; this makes the selection of tasks critical, as with any other method in developmental science.

The Social and Emotional Brain

Humans are, at their core, social and affective beings, but these essential characteristics have often been treated as sources of noise to be excluded from controlled experiments. This has changed dramatically in the past 20 years, owing in part to remarkable new discoveries in social and affective neuroscience. Neurophysiological measures not only promise to advance our understanding of basic processes in social and affective development, but they have also opened up an entirely new area of inquiry, brain development itself, including both structural and functional development, particularly as it is shaped by and adapts to experiences, whether biological (e.g., hormonal changes of puberty) or environmental (e.g., social demands and rewards of adolescent peer networks).

Neuroscientists became interested in how the brain processes social information when it was discovered that neurons within the temporal cortices and amygdaloidal complexes of monkeys were sensitive to and selective for social objects (e.g., faces and hands) and complex social stimuli (e.g., actions in a social context; direction of gaze) (e.g., Brothers, Ring, & Kling, 1990;

Desimone, 1991). Brothers et al. (1990) coined the label “social brain” to capture the emerging idea of a network of brain regions dedicated to processing social information. The key assumption is that human beings, in response to the unique computational demands of their highly social environments, have evolved mechanisms and an associated, dedicated neural system supporting abilities such as recognizing other agents and their actions, individuating others, perceiving others’ emotional states, analyzing others’ intentions and dispositions, sharing attention with others, and representing others’ perceptions and beliefs.

A network of neuroanatomical structures and their connections described as the “emotional brain” includes the amygdala as a central component. Emotional experience involves at least three elements: (1) identifying emotionally salient cues, (2) producing affective states and emotional behavior as a response to these cues, and (3) regulating affective states and behavior (Herba & Phillips, 2004). Phillips, Drevets, Rauch, and Lane (2003) proposed two parallel neural systems of emotion processing: (1) a system comprising subcortical and ventral-frontal cortical regions important for identifying emotionally salient cues, and (2) a system comprising dorsal-frontal cortical regions important for regulating subsequent behavior. These brain regions may be activated differentially as a function of the emotion encountered and the process being assessed.

Studies of the social and emotional brain frequently emphasize the unique contributions of specific neuroanatomical structures. This analytic perspective is helpful in providing a framework for organizing emerging understanding of brain development, but it does not fully reflect the complexity of interactions among brain regions. These structures undoubtedly function in parallel and are better understood as components in a network of regions subserving different aspects of social and emotional processing. To date, the functional development of some of the components of this system has been studied, but their developmental integration generally has not. Moreover, the possible role of changes in functional connectivity over development as a process underlying socioemotional development demands more empirical and theoretical attention (e.g., Dosenbach, Petersen, & Schlaggar, 2013). We are now well positioned to remedy this neglect owing to developments in neuroimaging and data analytic techniques.

Functional Magnetic Resonance Imaging (fMRI)

Functional magnetic resonance imaging (fMRI) offers outstanding spatial resolution to visualize networks of

neuroanatomical structures involved in aspects of brain function related to socioemotional processing and development. This technique requires a magnetic resonance imaging (MRI) scanner, a high rate of image acquisition, and specialized pulse sequences to measure localized brain activity. These sequences take advantage of the endogenous blood-oxygen-level-dependent (BOLD) contrast to image brain activity. This technique does not depend on ionizing radiation and does not require invasive procedures, making it suitable for longitudinal investigations of children.

Ogawa, Lee, Kay, and Tank (1990) discovered the BOLD intrinsic contrast mechanism: Because neurons do not store reserves of glucose and oxygen, essential to their proper function, an increase in neuronal activity requires immediate delivery of glucose and oxygen via the bloodstream. Elevated levels of oxyhemoglobin occur in active brain areas, changing the surrounding ratio of oxy- to deoxyhemoglobin, thereby providing a localizable proxy for brain activity detectable by MRI. The change in levels of oxyhemoglobin is typically localized to within 1 or 2 mm of the neural activity. As the neurons in specific brain regions “work harder” to perform a specific task, they require more oxygen. This hemodynamic response peaks around 4–6 seconds following the onset of neuronal activity, setting a limit on the temporal resolution of fMRI. Thus, measures acquired from fMRI are indirect proxies for location, amount, and timing of brain activity in response to specific stimuli or tasks. An accessible exposition of BOLD contrast measurement and outstanding coverage of all aspects of fMRI design, data acquisition, analysis, and interpretation can be found in the first comprehensive textbook of fMRI (Huettel et al., 2009).

Information from fMRI measures about the nature of neural activity is limited in several ways. First, research in rhesus monkeys comparing simultaneous recordings of the BOLD signal via fMRI and local field potentials via electrodes implanted directly into the cortical surface demonstrates that the BOLD contrast reflects mainly the inputs to a neuron and the neuron’s integrative processing within its body, and less the output firing of neurons. It is also important to recognize that the BOLD signal cannot provide information regarding direction of information flow. In particular, because it relies upon a relatively slow vascular response, the overall signal represents the summation of feedback and feed-forward information flow. Similarly, both inhibitory and excitatory inputs to a neuron from other neurons sum and contribute to the BOLD signal such that, within a neuron, the inputs might cancel out, leaving a net zero response; in this case, theoretically important brain

activity is present, but it is not detected by fMRI. An excellent and authoritative discussion of these and many other important issues concerning the BOLD response and its interpretation is provided by Logothetis (2008).

Illustration of fMRI

Theory of mind development in middle childhood. Imaging measures of children's brain activity have revealed heretofore unknown details about the development of some psychological functions such as the ability to think about one's own and others' thoughts, or "theory of mind" (TOM; see Hughes & Devine, Chapter 14, this *Handbook*, this volume; and Carpendale & Lewis, Chapter 10, this *Handbook*, Volume 2). fMRI studies of adult brains have revealed a small and remarkably consistent set of cortical regions associated with thinking about others' thoughts: bilateral temporoparietal junction (TPJ), medial prefrontal cortex (mPFC), and posterior cingulate cortex (PC) (e.g., Ochsner et al., 2005; Saxe & Kanwisher, 2003). In a study by Saxe, Whitfield-Gabrieli, Scholz, and Pelphrey (2009), children's brains also differentiated parts of stories that described the characters' thoughts from parts describing other facts about people and parts describing the physical context. However, in children, unlike in adults, the right TPJ was not significantly more selective than the mPFC for mental-state information relative to other social facts. Indeed, the differential selectivity of the TPJ was positively correlated with age. In contrast to the view that false belief reasoning, one component of TOM, is largely mature before 6 years of age (e.g., Wellman et al., 2001), these findings suggest that the neural organization underlying TOM is still developing as late as Age 9. Although the implications for developmental theory are as yet unclear (Saxe, 2013), one conclusion does seem clear and illustrates the power of imaging measures to contribute to theoretical progress: The existence of late-emerging cortical selectivity undermines the argument that category-selective brain regions in adults constitute evidence for innate and early maturing domain-specific cognitive or perceptual modules, including a domain-specific module for TOM.

The importance of addressing movement artifacts in fMRI. Because of the potential for brain imaging techniques to inform developmental theory, age-specific measurement issues are especially important. Movements of a participant during fMRI lead to blurry images and artifact-ridden measures, a fact that limited the use of this technique to adults for nearly a decade. Historically, the focus on movement artifacts in fMRI has been on large head movements, often defined somewhat arbitrarily as movements greater than

3 mm. fMRI was thought to be relatively impervious to effects generated by smaller movements. More recently, however, it has become evident that even tiny movement artifacts (0.004 mm), though not causing noticeably blurry images, can lead to insidious biases in fMRI analyses, even leading to false conclusions (Power, Barnes, Snyder, Schlaggar, & Petersen, 2012; Van Dijk, Sabuncu, & Buckner, 2012).

The results of a series of papers representing groundbreaking advances illustrate this dilemma. First, via highly innovative, mathematically complex analyses of resting-state functional connectivity data, two papers reported that short-range brain connections start off strong in school-age children and weaken over the course of development into young adulthood, whereas long-range connections begin weak in children and strengthen over time (Dosenbach et al., 2010; Fair et al., 2008). However, two subsequent papers demonstrated that these developmental findings are actually an artifact of uncontrolled age differences in head motion, with younger children moving more than older children, adolescents, and adults (Power et al., 2012; Van Dijk et al., 2012). Notably, these newer results also call into question all previous reports of age-related changes in studies using fMRI. When evaluating developmental changes in fMRI measures, one needs to, at a minimum, determine whether there are also age-related changes in the mean level of movement. Note that in the aforementioned articles, when age-related changes in head movement were controlled, developmental effects generally disappeared, suggesting much more continuity than change in brain function from early childhood to adolescence and early adulthood. Voos and Pelphrey (2013) provide a more extended discussion of these issues and offer suggestions for techniques to eliminate movement artifacts at the source and to correct for observed movement differences.

Electroencephalography/Evoked Response Potentials (EEG/ERP)

In contrast to fMRI, EEG/ERP directly measures the firing of groups of cortical neurons. As one processes information, neuronal activity creates small electrical currents that can be recorded from noninvasive sensors placed on the scalp, providing precise information about the timing of processing and clarifying brain activity at the millisecond pace at which it unfolds. EEG/ERP and fMRI are complementary imaging methods. Both are appropriate for studying brain function and its development from infancy (or, for fMRI, the fetal period; see Thomason et al., 2013) through late adulthood. The high temporal

resolution of ERP complements the high spatial resolution of fMRI, and both have been critical in understanding several aspects of typical and atypical social development. From fMRI measures, we learn what brain regions are involved and whether different regions are activated more or less at different points in development or demonstrate different developmental trajectories. From ERP measures, we learn how specific stages of processing develop insofar as the same brain regions can perform distinct functions at different time points in processing, and we learn about developmental differences in the timing of the stages of social and emotional processing. The classic monograph by Luck (2005) is an outstanding introduction to and tutorial about EEG/ERP.

Illustration of EEG/ERP

Identifying abnormal socioemotional development in infancy. ERP measures have revealed subtle differences in processing of social information at the neural level in children at risk for autism, even in the absence of overt behavioral differences. Autism spectrum disorder (ASD) is an early-onset, neurodevelopmental disorder marked by impairments in reciprocal social interaction and communication and the presence of repetitive or restricted interests and behaviors (American Psychiatric Association, 2000). The lack of reliable indicators of ASD during the first year of life has been a major impediment to diagnosis and treatment: In the absence of a firm diagnosis, treatment is often delayed for 2 or more years until behavioral symptoms emerge. Given its strong social components, Elsabbagh et al. (2012) hypothesized that neural sensitivity to eye gaze in early infancy would predict later development of ASD. Notably, there is little behavioral evidence of disruption in eye-gaze processes in infants later diagnosed with the disorder. The researchers recorded ERP while 6- to 10-month-old high-risk infants (siblings of a child with ASD) viewed faces with dynamic eye gaze directed either toward or away from them. Neural responses to dynamic eye-gaze shifts during the first year predicted clinical outcomes at 36 months, despite similar gaze patterns measured by eye tracking. The authors concluded that neural responses to eye gaze in the first year of life reflect disruptions in basic developmental processes leading to the later emergence of ASD.

This finding illustrates that measures of brain function can index developmental and individual differences in underlying processing mechanisms that are otherwise impervious to study because they do not produce overt behavioral evidence. EEG measures can thus be leveraged

even in very young infants as “neural signatures” of processes that are not available to observation or verbal report. Further, some neural signatures, for example ERP responses indexing face perception, may be remarkably consistent across the life span, allowing researchers to measure certain aspects of socioemotional processing using identical neurophysiological methods even when major developmental changes demand alterations in other measurement strategies (e.g., a shift from behavioral observation to verbal report).

Functional Near-Infrared Spectroscopy (fNIRS)

Because fMRI and EEG/ERP have been used to study the social and emotional brain primarily with 6- to 10-year-olds and adolescents, the organization of these neural systems in the infant and young child remains largely unexamined. In the past two decades, a new neuroimaging technique has emerged that appears to be quite promising for unlocking an understanding of the developing brain in very young humans, as well as in older children and adults (Gervain et al., 2011). The noninvasive, functional near-infrared spectroscopy (fNIRS) uses emitters and detectors attached to the scalp. Because it is less sensitive to motion, fNIRS can be utilized in less-constrained, more ecologically valid social paradigms than fMRI and EEG/ERP.

Like fMRI, fNIRS measures changes in blood oxygenation. However, fNIRS employs light in the near-infrared segment of the spectrum (800–2500 nm) to measure brain activity at and just beneath the cortical surface. Although the scalp and skull are opaque to visible light, they are almost transparent to light in the near-infrared range. Because blood absorbs light photons differently depending upon how much oxygen is present, by shining a near-infrared light into the head and measuring the intensity of the exiting light, fNIRS can reveal the differential absorption of light as a function of blood-oxygenation level. As with fMRI, this provides an indirect measure of brain activity. Furthermore, fNIRS measures both oxygenated and deoxygenated hemoglobin in brain tissue, providing two distinct (but correlated) indicators of neural activity, making fNIRS capable of absolute measures as opposed to only baseline-relative measures, increasing its flexibility (Gervain et al., 2011).

Illustration of fNIRS

Face processing in infants. A number of studies have used fNIRS to examine social and emotional processes in neonates to toddlers. Several have focused on the development of face processing. The ability to localize

neural signatures of face processing in infants who are awake and actively attending to visual displays is unique to fNIRS. Findings show that at 4 months, the temporal cortex of infants activates selectively to faces relative to other objects (Blasi et al., 2007; Csibra et al., 2004). At 6 months, infants exhibit increased activity to upright versus inverted faces in the right temporal cortex (Otsuka et al., 2007). At 8 months, activity in temporal regions is observed independent of viewing angle (Nakato et al., 2009). Researchers investigating responses to dynamic social stimuli such as eye and mouth movements have identified bilateral superior temporal and inferior frontal cortical activations in infants starting as early as 4 months, consistent with activation observed via fMRI in older children, adolescents, and adults in response to the same kinds of stimuli (Grossmann, 2008; Lloyd-Fox, Blasi, & Elwell, 2010). Gervain et al. (2011) provide a comprehensive review of fNIRS studies of infants.

One might wonder why everyone does not use fNIRS all the time given its advantages. From the perspective of head motion, the observation is correct. But there are always critical trade-offs with functional neuroimaging techniques. fNIRS only measures activation at the cortical surface. The light used to image brain function does not return to the optodes from deeper cortical areas and, critically, subcortical areas. Because many of the key social and emotional brain areas are deep within the cortex or are part of the limbic system, they are invisible to fNIRS. Moreover, the more hair on the participant's head, and the thicker the skull, the more difficult it is to use fNIRS, so it works best in infants and young children.

Psychophysiological Measures

Prior to the advent of technologies for directly probing patterns of neural activation, much biologically informed research on socioemotional development focused on indicators of the human stress response, and indeed continues to do so to evaluate how social experiences such as the transition to childcare are reflected in stress-related reactivity as well as children's diurnal cortisol rhythms (Watamura, Donzella, Alwin, & Gunnar, 2003), possibly in lasting ways (Roisman et al., 2009).

The human stress response is subserved by two distinct biological systems. Short-term stress responses are produced via the sympathomedullary pathway (SAM) reflecting the sympathetic branch of the central nervous system, which is opposed by the parasympathetic branch of the autonomic nervous system (ANS). Developmental

studies today use a wide variety of ANS response indicators to assess SAM-mediated activation, including surface measures of electrodermal response as well as assays of enzymes like salivary α -amylase. In contrast to shorter-term SAM-mediated stress responses, longer-term stress responses are regulated by the hypothalamic-pituitary-adrenal (HPA) system, often interrogated using measures of the stress-related hormone cortisol. Below, we discuss in greater detail methods of probing the SAM and the HPA stress systems in the study of socioemotional development.

Sympathomedullary Pathway (SAM)

The ANS is subdivided into two components: the sympathetic nervous system, concerned with mobilizing the body's fight-or-flight response; and the parasympathetic nervous system, involved in freezing and immobilizing behaviors. Activation of the sympathetic nervous system is most often measured via electrodermal response (EDR) or heart rate (HR). EDR measures the electrical conductance of the skin, which varies with its moisture level. The sweat glands of the skin are controlled by the sympathetic nervous system. Thus, increases in moisture, and electrical conductance, indicate arousal in the sympathetic nervous system. Similarly, HR has been used as a measure of sympathetic nervous system reactivity, with HR increases reflecting sympathetic nervous system arousal (although, note that HR is under both sympathetic and parasympathetic regulation).

HR and EDR have been used to examine autonomic nervous system correlates of multiple aspects of social and emotional processes in development. For example, Dozier and Kobak (1992) measured EDR during the Adult Attachment Interview to demonstrate that insecure adults showed evidence of stress-related inhibitory activation while talking about their childhood experiences (see also Roisman, Tsai, & Chiang, 2004). The *Handbook of Psychophysiology* (Cacioppo, Tassinary, & Berntson, 2007) provides a comprehensive treatment of HR and EDR, including recording issues and examples of their use in studying social and emotional development.

Developmental scientists have most often studied the parasympathetic nervous system by measuring HR variability, using electrocardiogram (ECG) data to examine vagal tone (e.g., Porges, 2001). Vagal tone has been used frequently as a physiological correlate of emotion regulation and arousal (e.g., Porges, Doussard-Roosevelt, & Maiti, 1994). It is controlled by the vagus nerve, which is connected to the cranial nerves that help to support and

regulate social behavior via facial expressions. Higher vagal tone is thought to be related to calmer, more regulated, and more positive social behavior (Porges, 2011). Porges (1997) proposed that the mechanism underlying this association is the inhibitory effect of vagal tone on the sympathetic nervous system. The available research paints a mixed picture. Some researchers have reported negative associations between higher vagal tone and measures of sympathy and prosocial behavior (e.g., Zahn-Waxler, Cole, Welsh, & Fox, 1995). Others report positive correlations (e.g., Fabes, Eisenberg, & Eisenbud, 1993). Still others report no correlation (e.g., Eisenberg, Shepard, Fabes, Murphy, & Guthrie, 1998). Sample characteristics must be considered to understand the inconsistency in findings. For instance, the sample in which negative relations were found included children at risk for externalizing problems. Relations between vagal tone and empathy-related responding may also differ by gender (e.g., Eisenberg et al., 1996; Fabes et al., 1993). Despite these caveats, measures of vagal tone have become established as valuable, real-time indices of two key theoretical constructs, emotion arousal and regulation. Notably, these are neither readily observed nor easily accessible to self-report.

Hypothalamic-Pituitary-Adrenal System (HPA)

Functioning of the HPA system in infants and children (see Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume) is most often assayed via measures of cortisol from blood, saliva, or urine. Cortisol, a steroid hormone, is released during periods of increased stress. It is important to differentiate between the cortisol awakening response (CAR) and basal cortisol level. The CAR is part of the diurnal cortisol pattern; it is a reactive measure, peaking upon awakening in the morning. Basal levels of cortisol also follow a diurnal pattern but additionally reflect average levels of cortisol over periods of days or even weeks. These two measures can be used to index different constructs. The CAR is more dynamic and indexes changes in context and transient mood states whereas basal levels index more enduring and trait-like stable constructs (Fries, Dettenborn, & Kirschbaum, 2009). For instance, if parents report that their child was emotionally dysregulated and acting out one day, both they and the child will tend to have a dysregulated CAR the following morning. This is because the stresses of the previous day led to an incomplete unbinding of cortisol receptors over the course of the evening. In contrast, the prior day's stresses would not be reflected in basal cortisol levels because these index more chronic stress levels.

Research using HPA-system measures has tended to focus on infancy through middle childhood. For instance, an extensive body of research has examined the effects of poor early caregiving on the development and regulation/dysregulation of the HPA system and its influence on neural systems supporting social and emotional abilities, especially emotion regulation (e.g., Fisher, Van Ryzin, & Gunnar, 2011). More recent research highlights how the HPA system remains "open" to reorganization during adolescence (e.g., van den Bos, de Rooij, Miers, Bokhorst, & Westenberg, 2013). This new emphasis on the reorganization of the HPA system during adolescence is opening exciting venues for research that transcends previous notions of hardwired critical periods for the development of this system and its correlates.

Genetic Variation

An organizing theme in developmental theory concerns the contributions of genetics and environment to variation in behavior and adaptation. Although the nature–nurture dialectic has long generated valuable theoretical discussion, beginning in the second half of the 20th century emphasis shifted toward environmental explanations of social and emotional development, resulting in several decades of research in which genetic influences were relatively neglected. This environmental bias was enshrined in the paradigmatic design in socialization research—the prospective, longitudinal study involving between-family comparisons in which variability between, but not within, families was examined. However, technological advances in human genetics have made it possible to measure genetic variation directly. This has produced both insights and challenges as well as opportunities for understanding how genes and environments work together to influence development. We anchor the discussion of these measurement approaches in the historical context that provided the impetus for embracing them: quantitative behavior genetics.

Quantitative Behavior Genetics

At the close of the 20th century, critics of socialization research (e.g., Rowe, 1994; Scarr, 1992) cogently argued that the ubiquitous correlations repeatedly documented between parenting behaviors and child outcomes might not be due to parenting, *per se*, but instead to the effects of genes shared within families. This is because the between-family research design confounds genetic and shared-environment sources of variability in children's behavior. For a wide variety of outcomes, identical twins are more similar to

one another than are fraternal twins (Turkheimer, 2000), suggesting that genetic variation plays a role in individual differences. Further, the results of biometric modeling, in which the relative effects of genetic, shared environmental, and nonshared environmental variance are estimated, have suggested that the effects of shared environments are often relatively small (Plomin & Daniels, 1987; but see Roisman & Fraley, 2008), leading some writers to speculate that parental influences are minimal and have no long-term effects on development (Harris, 1995).

One positive outcome of two decades of discussion of these issues has been the increased use of behavior-genetic research designs in the study of social development. To be sure, the limitations of behavior-genetic designs should not be minimized (Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000). Nonetheless, the use of adoption designs (where biological overlap between caregivers and children does not represent an internal validity threat) and comparisons of identical twins (who share 100% of their genetic variation) and fraternal twins (who share 50% on average) provide a means for beginning to unconfound genetic and environmental contributions to socioemotional development.

The most commonly used approach decomposes individual differences on a variable of interest using the ACE model (Neale & Cardon, 1992). According to this model, variation in an outcome arises from three latent sources. The additive genetic component (A) represents the degree to which genetic variability contributes to variation in the outcome of interest; the common environment component (C) represents the degree to which variation shared by siblings in the same family contributes to the outcome; the nonshared environment component (E) represents the degree to which variation not shared by siblings (e.g., due to differential treatment by parents or different experiences in the peer group) contributes to the outcome. The nonshared environment component also reflects random measurement error.

The ACE model can be extended in ways of particular interest for socialization researchers, including to study the etiology of the *associations among variables*, by decomposing correlations between social developmental “inputs” and “outcomes” into A, C, and E. For example, using the twin subsample of the Early Childhood Longitudinal Study-Birth Cohort, Roisman and Fraley (2012) showed that early parental support was associated with later academic skills ($r = .32$), social competence ($r = .15$), and externalizing behavior ($r = .11$) in kindergarten. Crucially, behavior-genetic modeling demonstrated that the shared

environment accounted for virtually all of the correlation between parenting and academic skills, roughly half of the association between parenting and social competence, and approximately one-fourth of the correlation between parenting and externalizing behavior.

Because the ACE model lumps gene \times shared environment interactions into the estimate of A, it can be construed as biased toward genetic explanations. In part to address such concerns, some investigators have examined whether putative assessments of the environment (e.g., socioeconomic status) moderate the magnitude of the estimates of A, C, and E. For example, Turkheimer, Haley, Waldron, D’Onofrio, and Gottesman (2003) reported that the heritability of IQ (i.e., the magnitude of the A component) was notably smaller among children living in poverty than it was for their high-SES counterparts, suggesting environmental modulation of the degree to which genetic variation contributes to general mental ability (i.e., G \times E interactions). Similar arguments may be possible for socioemotional outcomes. This issue also reminds us that estimates of genetic variation in any characteristic depend on the degree of environment variability (relevant to the outcome) across families within the selected sample. Further, it is important to recall that this approach provides an indirect indicator of genetic effects based on genetic relatedness rather than a direct assessment of relevant genetic polymorphisms.

Molecular Genetics

Quantitative behavior genetics has emphasized genetic and environmental influences at the aggregate level, with the sources of variation inferred on the basis of participants’ genetic relatedness. Given that inferences about genetic mechanisms are distal and therefore relatively imprecise, there is increasing interest in the direct measurement of genetic variation. This typically involves genotyping two distinct kinds of genetic variability: variable number tandem repeats (VNTRs) and single nucleotide polymorphisms (SNPs). VNTRs indicate a location in a genome where a short nucleotide sequence is organized as a tandem repeat, with some children carrying shorter and others longer repeats of the genetic sequence of interest. SNPs, in contrast, are a kind of DNA-sequence variation in which a single nucleotide (A, T, C, or G) differs between individuals. In general, individuals inherit both a maternal and paternal variant of a polymorphism (sex-linked polymorphisms like MAOA being a notable exception), meaning that the latent variability can be operationalized in a number of ways.

Researchers often explore a variety of measurement models, including additive genetic models (i.e., number of “risk” alleles of the polymorphism), dominance models (grouping individuals as carriers of the “risk” allele or not), and models that contrast hetero- versus homozygotes on the SNP or VNTR. For example, individuals inherit short (“risk/plasticity”) or long (“non-risk/plasticity”) forms of the serotonin transporter polymorphism (5-HTT). Investigators may choose to measure how many short forms participants carry (0–2), whether they carry the putative risk variant or not (homozygous long versus homozygous or heterozygous short), and so on. Much molecular-genetic research involves the use of simple genetic association designs, where an SNP or a VNTR is correlated with a psychological phenotype of interest. For example, Lakatos et al. (2000) reported that carriers of the 7-repeat variant of the dopamine D4 receptor (DRD4) are at enhanced risk for disorganized attachment (but see Bakermans-Kranenburg & van IJzendoorn, 2004).

One advantage of measures of molecular genetic variation is the possibility of identifying genetic variants that interact with environmental exposures, in addition to genetic “main effects.” For example, Caspi et al. (2002, 2003) captured the field’s imagination with their suggestion that the effects of environmental exposures (e.g., to life stress and maltreatment) might be amplified by directly measured genetic vulnerabilities. Belsky and Pluess (2009), among others, have further suggested that at least some genetic variants may be more plausibly viewed as *plasticity agents*, making some individuals more susceptible to the effects of both negative *and* positive environmental inputs (see Roisman et al., 2012).

An emerging concern in this area is the replicability of findings. Studies may produce null findings or fail to replicate seminal findings for many trivial reasons, including inadequate measurement of key constructs and low statistical power. Undoubtedly, some of the unevenness in the candidate-gene literature is attributable at least partly to these factors. But it is arguably even more problematic that there are millions of possible genetic markers that could be examined in such studies, combined with what has been termed flexible “investigator degrees of freedom” (Simmons, Nelson, & Simonsohn, 2011); this has made it possible for investigators to report statistically significant associations in underpowered studies while failing to report the effects of other genetic polymorphisms that generate null results.

It is too early to know whether the molecular genetics of behavioral development will blossom into a replicable

science, possibly by examining measured genetic variation at a higher level of abstraction or via Genome Wide Associations Studies. Even so, it is important to remember that measurement factors are inexorably tied up with theory and research design in affecting the strength of the inferences that are possible. In this instance, much molecular-genetic research, paradoxically, is open to the very same critique levied against other between-family studies in that the research design cannot rule out genetic contributions to the environmental variables examined in such studies. For example, if exposures to life stressors in part reflect evocative effects of genetic variation that lead some children to experience more negative life events than others, Caspi et al.’s (2003) seminal finding that the predictive significance of life stress is stronger for individuals containing the short “risk” (versus long) form of the serotonin transporter polymorphism (5-HTT) may reflect evidence of epistasis (i.e., a gene \times gene interaction) as much as gene \times environment interaction.

Epigenetics

The frontier in the genetics of development, epigenetics, concerns the effects of the environment on gene expression (Meaney, 2010). The term “epigenetics” was coined by Waddington (1942) in formulating the concept of the epigenetic landscape. He used the term to describe the developmental differentiation, during interaction with the environment, of embryonic cells from an initial pluripotent state, that is, able to develop into any type of cell, to a specific cell phenotype. Cells with identical DNA differentiate into skin, brain, kidney, or muscle cells, and stay that way across the life span. Accordingly, a brain cell’s daughter cell inherits not just a genetic sequence, but also the epigenetic state of being a brain cell.

The concept of epigenetics has expanded as understanding of the molecular mechanisms has flourished and as measurement techniques for detecting and indexing epigenetic processes have been developed. The term epigenetics is now used to refer to heritable, functionally relevant modifications to the genome caused by mechanisms other than changes in the underlying nucleotide sequence of the individual’s DNA—hence the prefix *epi-* (Greek: *επί*, “on top of”) (Riddihough & Pennisi, 2001). Examples of epigenetics include alterations in DNA methylation and histone modification—structural alterations in DNA that occur in response to environmental conditions without altering the DNA sequence itself (Fraga et al., 2005; Kaminsky & Petronis, 2009). Both mechanisms regulate gene expression, via either enhancement or inhibition.

Epigenetic changes can be produced as a consequence of aging as well as environmental influences. As such, the importance of epigenetics in the development of cancer, neuropsychiatric disorders, and other diseases is increasingly evident.

Developmental scientists are keenly interested in epigenetics because these mechanisms might help to explain how early life experiences can alter brain development and thus influence later social and emotional functioning. To illustrate, the type of mothering a rat receives as a pup calibrates how its brain responds to stress throughout its life (Weaver et al., 2004). Rats raised by less-nurturing mothers are more sensitive to stress when they grow up. This lifetime effect is driven by a reduction in glucocorticoid receptors resulting from alterations in DNA methylation: Rats raised by less-nurturing dams tend to have more methyl groups attached to the promoter region, the “on” switch, of the glucocorticoid receptor gene. These methyl groups block access by the transcription factors that turn the gene on. As a result, fewer receptors are produced. There is preliminary evidence for similar functional mechanisms in humans. For example, McGowan et al. (2009) demonstrated that childhood abuse alters HPA stress responses and increases the risk of suicide later in life. More research is necessary to determine definitively whether these results involve the predicted mechanism, but this is clearly an exciting area for future work.

Environmental factors later in life can also induce epigenetic changes. For example, the brain-derived neurotrophic factor (BDNF) gene was downregulated in the hippocampus of adult mice exposed to social stress in the form of chronic bullying by a bigger mouse (Tsankova, Renthal, Kumar, & Nestler, 2007). This reduction in BDNF activity is linked to epigenetic modifications involving histones, tiny protein spools that keep DNA wrapped up. Chronic stress triggered an increase in a type of histone methylation that suppresses gene activity by keeping the DNA containing the BDNF gene tightly wound. This led to increases in behaviors indicating a depressive state.

Despite extraordinary progress, the study of epigenetics and human behavior is very much in its infancy. If the sorts of findings described above can be extended to humans, epigenetics could be key to understanding the interface between environmental and biological processes in shaping developing social behavior. Although enthusiasm is high about the potential for this field, there are some important caveats. First, there is as yet very little evidence in humans that epigenetics connects early-life experience to behavioral outcomes later in life. Moreover,

one major methodological obstacle will make finding proof exceedingly difficult: There is a limited supply of human brain tissue and it is obviously not possible to obtain brain tissue from living children. Yet, there are some viable options. For instance, investigators have recently pioneered the use of blood-cell lines to study gene expression in humans (Luo et al., 2012). Many of the genes expressed in the brain are also expressed in blood. But it is too soon to know whether this approach will pay off. The correlation between gene expression in brain and blood is unclear, and blood and brain cells do not necessarily undergo the same epigenetic changes in response to a given life experience. Finally, training in the methods and measures of molecular genetics is not yet routine in developmental graduate programs, making research on developmental questions the province of multidisciplinary teams.

Psychobiological Measures: Summary and Conclusions

In this section we reviewed the basic principles of the three most widely used neurophysiological methods for the study of social and emotional development: fMRI, EEG, and fNIRS. Neurophysiological measures can reliably document developmental continuity and change while helping to adjudicate among competing theoretical accounts of key socioemotional phenomena. Each method comes with its own profile of strengths and limitations, and no single method is appropriate for every question. Although the development of techniques to image brain structure and function has added substantially to developmental studies across levels of analysis in infants, children, and adolescents, longitudinal data remain scarce. Measurement over time within participants will be critical to our understanding of how changes in brain structure and function connect up with changing behavioral, cognitive, and social-cognitive capacities in development. Thus, the best science will emerge from longitudinal studies of both brain and behavior using converging measurement approaches.

The earliest biological indices employed in developmental research, psychophysiological measures including heart rate and vagal tone, stress-hormone assays, and electrodermal skin response, remain critical tools today. These measures provide fundamental insights into a level of analysis not available to conscious report, such as stress, arousal, reactivity, and regulation. Measures of the SAM and HPA systems allow examination of how stress and emotion regulation influence brain and behavioral development. Measures of each system provide different

theoretical insights; measures of the SAM reflect the effects of shorter-term stress responses, whereas those of the HPA reflect cumulative effects of long-term stressors. Earlier research focused on the role of early experiences on subsequent organization of the HPA, whereas newer work is exploring adolescence as a second “critical period” for the reorganization of this system. As with other measurement techniques, studies using psychophysiological measures have generated mixed results, highlighting the need to consider potential sources of confounding group and individual differences. Yet these potential confounds also present targets of opportunity for scientists interested in individual differences in socioemotional development.

Supported by technical advances in genotyping and an increasing embrace of biologically informed explanations, the study of genetic contributions to socioemotional development has witnessed a sea change over the last several decades. More complex behavior-genetic research designs are being used to improve causal inferences. Research is also emerging that examines the role of specific genetic variants that directly contribute to and moderate the predictive significance of developmental experiences. We have emphasized the multivariate nature of this work, along with the likelihood that specific genetic variants probably have relatively small individual effects on development. Hence, replicability of work focused on specific SNPs and VNTRs will be crucial, as well as for epigenetics studies. This will necessitate large samples as well as more contained expectations about the magnitude of the expected effects.

LOOKING AHEAD: OPPORTUNITIES AND CHALLENGES FOR MEASUREMENT

As illustrated in the preceding section, technical innovations have provided a number of exciting opportunities in the measurement of social and emotional constructs, but also interesting challenges. We focus on three cases that illustrate both the excitement and challenges that lie ahead: (1) human research that cuts across levels of analysis, from genes, to brain, to social behavior; (2) neuroimaging studies of true social interactions between social partners in real time; (3) triangulation of research methods.

Bidirectional Transactions Among Genes, Brain, and Social Behavior

Discoveries in genetics and epigenetics have shed new light on old debates on the relative contributions of nature and nurture. In part because of advances in measurement

technologies, developmental scientists now recognize not only that developmental changes are driven by complex transactions across multiple levels of organization including the environment, behavior, cognition and emotion, brain, and genes (Gottlieb, 1992), but also that they can investigate these transactions. As a result, in human and animal models there is now clear evidence for the full bidirectionality of these transactions. The now-common use of *in vivo* pediatric brain-imaging techniques together with the revolution in modern molecular genetic and epigenetic techniques offers an unprecedented opportunity to implement a truly developmental perspective, integrating multiple levels of analysis across the full life span.

Nowhere is this clearer than in the area of imaging genetics: applying functional neuroimaging techniques to the identification of genetic effects on brain information processing. At its core, this approach is a form of genetic association analysis (Hariri, Drabant, & Weinberger, 2006; Hariri & Weinberger, 2003). Rather than focusing on a behavioral phenotype, imaging genetics targets the physiologic response of discrete brain circuits during specific forms of information processing, including emotional and social information. Ideally, imaging genetics studies are targeted at genes with clearly defined functional polymorphisms. These polymorphisms are then associated with specific physiologic effects, starting at the cellular level and working up to the level of distinct brain circuits that reflect the underlying cellular mechanisms. Studies must also consider variability in imaging task performance in interpreting potential gene effects because typical imaging signals (e.g., the BOLD response in fMRI) are closely linked to task performance. The experimental tasks employed in imaging genetics studies must maximize sensitivity and inferential value, as the interpretation of gene effects depends on the validity of the paradigm. Measurement issues, therefore, although often seemingly mundane, are at the crux of inference quality, whether measurement is as low-tech as naturalistic observation or as high-tech as imaging genetics.

To illustrate, Hariri and Weinberger (2003) have proposed that the response of brain regions subserving emotional processes in humans (e.g., amygdala and prefrontal cortex) may be more objectively measurable than the subjective experience of these processes. They have also demonstrated that functional polymorphisms in serotonin genetic markers weakly related to behaviors are more strongly related to the integrity of these underlying neural systems. Functional neuroimaging, by rapidly acquiring hundreds of repeated measures of brain function within a

single participant, offers a powerful means for investigating genetic influence on the activity of specific brain circuits during processing of discrete stimuli or performance of distinct behaviors. The power afforded by the statistical advantages of signal oversampling and averaging, and the biological advantages of prebehavioral phenotypes, may allow investigators to identify robust gene effects on brain information processing in considerably fewer participants than typical behavioral studies and with much greater sensitivity. Ideally, associations between gene variants and regional patterns of brain information processing will not only elucidate the biological mechanisms underlying previously shown links with behavior, but also direct attention to new behaviors that are mediated by brain systems influenced by gene variants and vice versa.

Despite the promise of these technological advances, the application of imaging genetics to our understanding of social and emotional development is currently limited by at least three major challenges: (1) although more powerful than conventional genetic association studies, the work still involves individual variables with small effects; (2) imaging genetics remains inherently correlational and suffers from an absence of detailed analysis of mechanisms; (3) all imaging genetic studies to date have focused on cross-sectional samples of adolescents and young adults in racially and culturally homogeneous samples. There is a great need (and opportunity) for longitudinal designs to examine the influence of genetics on developmental trajectories of the social brain and social behavior in varying populations. If these challenges can be addressed, imaging genetics research is poised to dramatically increase our understanding of how genetic variation interacts with the environment to shape developing brain and behavior.

Using Neuroimaging to Study Real Social Interactions

Especially relevant to socioemotional development is exciting work applying neuroimaging techniques, particularly fNIRS, to the study of actual face-to-face social interactions. All three of the neurophysiological methods reviewed earlier have been used to study social interactions. In fMRI, this has been called “hyperscanning” (Montague et al., 2002) and involves connecting two fMRI scanners over the Internet to allow dyads to interact with each other while functional MRI is acquired in synchrony with the behavioral interactions. The first hyperscanning studies involved two players engaged in a simple game of deception (Montague et al., 2002). The chief advantage of this approach is that it allows investigation of brain and behavior in dyadic interaction in a controlled social setting. Brain activity that precedes and follows the actions of another

person can thus be scrutinized. It is even possible to study the degree to which two players become synchronized in generating correlated activity so that the brain activity in one player can be predicted from the brain activity of the other player. With fMRI, this might reveal a regional pattern of activity in one brain that is consistently correlated with similar activity in the other brain. The possibility of observing activity in a large number of voxels (spatial units representing 3-D pixels) in both brains while individuals interact opens up truly novel scientific possibilities for discovering underlying neural relationships and spawning new approaches to understanding the neural basis of social exchange.

Despite this promise, hyperscanning presents particular technical hurdles, especially with children. For example, the challenges associated with preventing excessive motion during the fMRI scan are doubled in child dyads. Moreover, the two scanners must be calibrated with each other to reduce between-scanner variability, a potential source of statistical noise. Such noise, combined with interparticipant variability, has to be accounted for in statistical analyses of the linked imaging data sets. These complexities are probably why hyperscanning studies of children have not yet appeared.

With EEG (silent and less invasive than fMRI), one can move a step past hyperscanning to conduct “two-person neuroscience” or “2PN” (Hari & Kujala, 2009; Konvalinka & Roepstorff, 2012). With 2PN, the unit of analysis becomes the dyad, and the members of the dyad, unconstrained by the enclosed MRI system, can interact face-to-face in naturalistic social interactions, opening a new vista of social and affective neuroscience research. This approach has not yet been applied to studies of development, although the possibilities are enticing. One could imagine, for example, face-to-face interactions between an infant and a parent to study the brain dynamics of early social exchanges involving the imitation of mouth movements and facial expressions. ERP/EEG measures are, however, still quite susceptible to small movements, including the eye blinks, facial movements, and hand and arm gesticulations that are part of even the simplest face-to-face interactions. The steady growth in the use of fNIRS, with its greater tolerance for movements including eye blinks and motor actions, is creating perhaps the best opportunity for more realistic, ecologically valid studies of face-to-face social interactions in children and across the life span (e.g., Cui, Bryant, & Reiss, 2012).

Although the 2PN approach can address novel and important questions in socioemotional development, new analysis techniques are needed for quantifying data from

simultaneous recordings to maximize its potential. These include capturing the time-varying, asynchronous properties of dyadic interactions; analyzing properties of the brain network comprising areas from two brains during interaction; and connecting neural measures with behavioral measures.

Triangulation of Research Methods

Psychophysiological, neurophysiological, and genetic measures represent an emerging wave of measurement in developmental psychology, and it is expected that an increasing number of studies will incorporate them. A critical consideration is how they relate to observational and verbal report measures of the same or related constructs. Studies that use these measurement approaches in conjunction with well-understood paradigms and measures are essential to establishing the validity and utility of their empirical findings (e.g., Pfeifer & Peake, 2012).

To illustrate concretely, Hubbard et al. (2002) measured anger in 8-year-old children during a structured laboratory task in which children played a game with a peer confederate who cheated obviously and repeatedly and then won a valuable prize. Measures included autonomic nervous system responses (HR and EDR); observer-coded facial and nonverbal anger expressions from videotapes of the sessions; and children's self-reported level of anger after each turn of the game while watching their videotape after the session was over. The different measures of anger (physiological, observational, self-report) showed distinct associations with one another as well as with teacher reports of children's reactive and proactive aggression. Furthermore, it became evident that each index captured a different aspect of the emotion system and that these operated somewhat independently. Thus, any single measurement approach cannot capture the complexity of children's anger and its associations with other aspects of social functioning that converging measures at multiple levels of analysis can.

In a study of individual differences in attachment-related systems in mothers, Atzil, Hendler, and Feldman (2011) triangulated neural measures (fMRI of social and emotional brain networks in response to vignettes of own and other infants), hormonal measures (plasma oxytocin, a neuropeptide associated with social affiliation), and behavioral measures (gaze, affect, vocalization, and touch during mother–infant interaction). Differences in mothers' behavioral style of interacting with their infants (synchronous versus intrusive) were characterized by different patterns of organization in limbic and social and emotional cortical

systems, and different patterns of association between the neural and hormonal systems. The insights gained point to unique and otherwise undetected differences in the motivational processes underlying healthy versus at-risk parenting styles, with the former more heavily based in the reward system and more organized, and the latter more heavily based in the stress system and more disorganized.

Finally, that opportunities arising from new measurement approaches also create novel challenges is illustrated by the need to develop ecologically valid tasks for indexing adolescent social sensitivity that can be administered in the laboratory in real time while participants undergo fMRI or other neurophysiological techniques. This effort is motivated by the desire to understand major developmental transitions in adolescent social experiences and behavior, such as heightened responsiveness to the peer group (Albert, Chein, & Steinberg, 2013), including emotional reactivity to social evaluation and social standing, often involving real or perceived cues to inclusion and exclusion by peers. Studying developments in the socioaffective neural circuitry underlying responses to social and emotional information can provide important information about the component mechanisms involved (e.g., emotional reactivity, emotion regulation, emotion evaluation, cognitive control) (Somerville, 2013). Several interesting tasks have been designed for this purpose, including a social-feedback task in which adolescents receive positive or negative feedback from several (putative) peers who are evaluating the adolescent's photograph for likeability; a "chat-room" task in which the adolescent is selected or rejected by a (putative) peer to chat online about mutual interests; and a cyberball task in which the adolescent plays a ball-tossing game with two (putative) peers who stop throwing the ball to the participant after they have all been playing together (see Somerville, 2013, for an overview). These have been validated with self-report, behavioral (eye-tracking), and psychophysiological (pupillary response) measures. Moreover, developmentally unique patterns of activation have been discovered when adolescents undergo fMRI while engaging in these tasks. The findings suggest age-specific enhancement of some affective response systems, greater perceptual and cognitive vigilance to positive and negative feedback, and greater emotion regulation effort, little of which is observable behaviorally or accessible to self-report (Albert et al., 2013; Somerville, 2013).

Looking ahead, with rapid progress in the growing understanding of brain development, molecular genetics, and the physiological bases of behavior, developmental scientists are now in a position to study directly, in humans, bidirectional transactions among levels of analysis from

genes, to brain, to behavior and the environmental context. Methodological advances and accompanying measurement techniques are providing insights into long-standing questions about social and emotional development while at the same time opening up a vast array of novel questions. Developmental science now possesses an arsenal of tools that can be deployed synergistically to adopt a true “molecules-to-mind” approach to the study of social and emotional behavior and development.

CLOSING NOTES

With this promise in mind, we conclude by noting several truisms that remain important at all levels of analysis and for all measurement approaches. First, throughout the chapter we have emphasized the need for well-conceptualized constructs and research questions to guide measurement decisions. Poorly conceptualized research questions will not lead to informative results, no matter the quality or sophistication of the methods used. Equally important is the fit between the method and the questions being asked. Good ideas tested with poorly chosen methods also will not yield informative results.

Methods must also fit the developmental characteristics of the participants. Whether children are asked to reason about hypothetical characters, to recall onset of symptoms, or to hold still for EEG/ERP or fMRI measures, if the task demands are not age-appropriate, conclusions about otherwise well-measured constructs may be invalid. Further, because infants and young children may function in qualitatively distinct ways from older children and adults, similar behavior may have different meaning to young children than to older children or adolescents, or may arise from different sources. For example, peer aggression is at its height in toddlerhood and is normative, motivated by instrumental desires or the wish to engage others; it is therefore correlated with sociability and positive social approach. Peer aggression in adolescence, in contrast, has different motivations and functions, is not normative, and is correlated with antisocial behavior. Similarly, the same behavior may have different meanings in different cultures. Converging measurement approaches and careful attention to validity concerns are thus required to be confident that the same construct is being measured across ages, contexts, or cultures.

Additional caution must be exercised when the measures are removed from the constructs of interest, especially when those constructs are theoretically complex

(Baumeister, Vohs, & Funder, 2007). For example, eye movement data or pupillary responses are increasingly used to examine abstract constructs such as morality, false belief, or motivation in preverbal children. Yet these response measures are not in themselves informative about such constructs. This limits the validity of bottom-up inferences and makes interpreting such measures crucially dependent on theory (Aslin, 2007; Oakes, 2012). Similarly, although neuroimaging data are rich and visually compelling, measures of the brain’s behavior are just like other measures of behavior, subject to the same validity constraints, and must be interpreted within a theoretical context.

Finally, as the range and complexity of measures available to developmental scientists grows, vigilance is required to avoid errors of statistical inference that often accompany access to a wide variety of analytic choices and variables. Based in multiple levels of analysis and multi-informant assessments, modern social developmental science is fraught with the peril of producing type I and II errors. For example, the massive amount of data generated in a single neuroimaging session can generate powerful insights, but also presents the real potential to generate type I errors without appropriate controls for multiple comparisons. Indeed, if—as is widely assumed—many effects in social development are modest in magnitude, sample size and power become critical. Investigators must resist the temptation to engage in research practices that can call into question the replicability of findings (Simmons et al., 2011).

INTRODUCTION

Interest in prenatal influences on child development and adult constitution, health, and behavior is ancient, going back at least to Aristotle, and the literature is voluminous; yet before ethological and evolutionary perspectives on

human behavior and development gained prominence, it was a “gray area” of modern science (Stott, 1973, p. 770). As recently as 1982, Chalmers issued the following judgment: “the paucity of theoretical models in this predominantly empirical field is sufficient evidence in itself that the nature of the research is generally uncoordinated and seemingly patternless” (Chalmers, 1982, p. 329).

The situation is now different. In this chapter we examine maternal influences on fetal development, birth outcomes, infant/child health, and behavioral development from the perspective of evolutionary theory. We show how evolutionary theory provides “coordination” and “pattern” to the abundant empirical evidence of prenatal influences. We focus on maternal psychosocial stress and nutrition, environmental toxins, and the crucial role of placental physiology and epigenetic processes in transducing these maternal effects to the fetus, its subsequent postnatal growth, development, and health, and potentially, the well-being of its descendants. Our approach is a multilevel synthesis, utilizing a broad evolutionary perspective to examine how an organism responds to its environment down to specific physiological examples and their epigenetic regulation.

It is beyond the scope of this chapter to examine all of the processes that influence prenatal development. We focus on one process of prenatal development that embodies information about a broad range of maternal environmental factors in the fetus: the hypothalamic-pituitary-adrenal (HPA) axis (see Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume, for a review). The HPA axis is highly conserved across vertebrate species and carefully aligns development with environmental stressors in species as distant from humans as the spadefoot toad (Denver, 1997). Stress hormones influence expression of 10% of the genotype across metabolism, growth, repair, and reproduction (Phillips & Matthews, 2011) and are therefore able to adapt whole life cycles to adversity. During pregnancy, the specific mechanism involved is the enzyme 11beta-hydroxysteroid dehydrogenase type 2 (11 β -HSD-2). 11 β -HSD-2 is involved in limiting the amount of maternal cortisol, a stress hormone that crosses the placenta from the mother to the fetus. Cortisol itself is involved in the epigenetic regulation of 11 β -HSD-2. Moreover, during pregnancy the expression of 11 β -HSD-2 is influenced by maternal stress, nutrition, hypoxia, reproductive hormones, and some toxins and pollutants. This mechanism interprets a range of maternal signals in ways that tend to ensure a more appropriate fit between the fetus and the environment into which it will be born than would otherwise be the case.

Because “nothing in biology [the study of life] makes sense except in the light of evolution” (Dobzhansky, 1973), we show in this chapter how an evolutionary perspective on prenatal influences helps to synthesize diverse disciplines and produce new research avenues. Our review begins, in the section titled “History of Development Within Evolutionary Theory,” by examining the interaction between development and evolution culminating in modern epigenetics. The next section, “Life History Theory: Evolution and Development,” provides an overview of life history theory, the branch of evolutionary theory devoted to the interaction of developmental and evolutionary processes, especially the evolutionary consequences of environmental effects on the timing of development or life history stages. In the next two sections, “Prenatal Stress, Endocrine Responses, and Offspring Development” and “Prenatal Nutrition, Fetal Development, and Offspring Phenotype,” we review the impact of maternal stress and nutrition, respectively, during pregnancy on fetal development. “Prenatal Toxins, Teratogens, and Development” extends this to examine the impact of prenatal exposure to toxins on the growing fetus with focus on pollutants of emerging concern. Finally, in “Future Research and Theoretical Perspectives,” we highlight future empirical and theoretical pathways suggested by this unique synthesis.

HISTORY OF DEVELOPMENT WITHIN EVOLUTIONARY THEORY

In this section, we provide a historically grounded discussion of the role of development within evolutionary theory that brings us to modern developments in epigenetics. This section is designed to develop a particular way of thinking about development, from an evolutionary perspective, that then frames our more contemporary discussions of prenatal development. Crucially, this perspective can be applied rigorously to other phases of the human life cycle. Ultimately, this section builds the logic underlying an evolutionary developmental (“evo-devo”) perspective on prenatal development.

Basic Distinctions

It is quite typical for undergraduate behavioral sciences students to encounter the “nature versus nurture” debate early in their studies. How much of each contributes to the final form of focal traits? One common misinterpretation is to assume that nature or nurture are mutually exclusive

causes of a trait. This can be understood as a category error because nurture is something that happens in nature, where nurture can mean anything from parental investment to learning. Parental investment and learning are naturally occurring activities. More typically, the debate is understood as one of *nativism* versus *empiricism*. Here the argument is about whether a trait is innate and fully formed at birth, or requires a period of learning and development in order to reach capacity.

This debate has long historical roots extending to Pythagoras. The conceptual distinction in his time was between *preformation* and *epigenesis*. Various preformation theories were in place. Preformationism is the idea that all traits are fully formed at conception, when male and female gametes meet. Conversely, Aristotle articulated a form of epigenesis, suggesting that all four of his “causes” were in play during the development of an organism. Both parents contribute *material* causes during coition, upon which *efficient* causes act to bring about the *formal* cause with its *final* purpose. Thus epigenesis is the idea that form gradually emerges over time. In this way, a distinction was made between growth (merely an increase) and development (a change in form and function). Modern thinkers understand epigenesis as morphogenesis and differentiation (Haig, 2004). Haig has noted that causal models of epigenesis include roles for a diverse array of variables including hormones, growth factors, and the mechanical effects of loading and gravity, all of which could be included in Aristotle’s set of efficient causes.

Given the vast empirical evidence of developmental change, it would be philosophically difficult to defend pure preformation in these modern times. The only viable version of preformationism is one that proposes innate plans that unfold along prespecified lines with no significant deviation from those lines. Such plans would be regarded as essential contributions (in Pythagorean terms) that predetermine the final form. With the emergence of the Modern Synthesis in evolutionary biology in the 20th century, this position became possible as genetic inheritance and the guiding role of genes came to dominate scientific discourse.

Evolution

Evolution is not a process, but rather a kind of change. Charles Darwin (1859) detailed this change with much empirical evidence and some abstract description, transforming a basic idea of gradual change over time into something very much more specific. As Godfrey-Smith (2010) has noted, many scholars have tried to continue

the abstraction that Darwin began in the later stages of his book. Here is a now-classic example:

1. Different individuals within a population have different morphologies, physiologies, and behaviors (phenotypic variation).
2. Different phenotypes have different rates of survival and reproduction in different environments (differential fitness).¹
3. There is a correlation between parental fitness and offspring fitness (fitness is heritable).

These three principles embody the principle of evolution by natural selection. While they hold, a population will undergo evolutionary change (Lewontin, 1970). Darwin’s own focus was on evolutionary change within biological systems. His principal effort was to explain the apparent design seen in nature, such that phenotypic traits appeared to fit aspects of their environment in the same way that a carpenter’s tools service specific actions (Dawkins, 1986). The canonical example of specialized beaks in the Galapagos finches demonstrated this alignment between phenotypic traits and the environment. At the time, Darwin did not have a theory of inheritance or of how new variations were introduced. Although originally conducted in Darwin’s time, Mendel’s work on particulate inheritance was rediscovered in the early part of the 20th century and seen as incompatible with Darwinian evolution. Mendel had demonstrated that traits could be passed on as discrete units, which we now know as genes, in contrast to some views of blended inheritance proposed by Darwin himself, among others. Moreover, the kind of trait variation that Mendel demonstrated within populations was at odds with the graded variation claims of Darwinians. It was the emergence of population genetics, resulting from the mathematical work of Fisher, Haldane, and Wright (Gould, 2002; Ruse, 2003) that saw the reconciliation of Mendelian and Darwinian views. Huxley (1942) named this marriage of ideas the Modern Synthesis.

¹From this point, the term *inclusive fitness* rather than *differential fitness* is adopted. Inclusive fitness is the sum of direct fitness, achieved through reproduction, and indirect fitness, achieved through the reproduction of genetic relatives. Modern evolutionary theory adopts this mid-level theoretical concept to capture life-history dynamics for individuals. The assumption is that organisms act to maximize their average lifetime inclusive fitness through a series of trade-off decisions across time. These decisions happen at all levels of biological organization and are captured by formal life history theory, which is discussed in the section titled “Life History Theory: Evolution and Development.”

Bateson had introduced the notion of genes and alleles to the analysis of Mendel. The Modern Synthesis saw genes as the fundamental unit of inheritance, and different alleles as contributing to different phenotypic trait variants. These variants could enter into the abstract Darwinian process of natural selection according to the three principles detailed above. Natural selection would sift variants, retaining some and removing others. Over many generations, new phenotypes would arise through the interactions between different phenotypes and the environment. Moreover, Morgan had discovered that genes could spontaneously mutate, thereby introducing new variants, or alleles, into the population and allowing the emergence of novel traits (Ruse, 2003). These changes need not be dramatic; they could be quite subtle changes expressed as small differences at the phenotypic level. Natural selection was the process that gradually changed gene frequencies within a gene pool over long historical time, operating on small differences between variants. In this way, at the population level, there would be a relatively smooth and normal trait distribution, but, at the level of individual inheritance, trait variants would be passed on in the discrete fashion described by Mendel.

Evolution and Development: During the Modern Synthesis

We have already noted the distinction between growth and development—the difference between increase and change in form and function. Because both evolution and development are changes in form and function extended over time, there is the clear potential for analogy and homology (Gould, 1977). Haeckel firmly linked evolution and development, and understood the pattern of development as mechanically caused by evolution. The pure form of recapitulation he proposed has not stood the test of time, but the idea that developmental processes have been subject to natural selection remains. However, the conceptual relationship between development and evolution has become increasingly complicated since the advent of the Modern Synthesis.

Other theories of evolution and inheritance persisted in the immediate post-Darwinian world. One that is pertinent to our subsequent discussion of epigenetics is Lamarck's proposal that acquired characteristics could be inherited. In its simplest form, Larmackianism suggested that the use of a phenotypic trait induced developmental changes over time, such that the trait was increased or amplified. The disuse of a trait saw its diminution and loss. Use, or disuse, was

guided by behavior and environmental context. The "new" used traits were then supposedly passed on to subsequent generations (Richards, 2006).

As the Modern Synthesis consolidated during the first half of the 20th century, scholars began to abandon any residual allegiance to this Lamarckian idea. Indeed, during this time there was some discussion about what, if anything, could be retained from Lamarck (Waddington, 1942). For advocates of the Modern Synthesis, genetic mutation introduced new variants (alleles) to the phenotype, and natural selection sifted those alleles through the interaction between the phenotype and the environment. With the discovery of DNA in 1953, all was chance (mutation) and necessity (selection) for hardline Modern Synthesis biologists (Monod, 1971).

Waddington introduced the notion of the *epigenotype* and *epigenetics* to distinguish the complex set of processes that allow the formation of a phenotype from a genotype (Waddington, 2012). The term epigenetics is derived from epigenesis and Waddington used it to refer directly to developmental processes, as Pythagoras had before him. Waddington understood these processes as being, to some extent, under genetic control. The amount of regulatory control could be referred to as the degree of buffering of an organism's development relative to the perturbations of genetic and environmental variation. More famously, Waddington referred to developmental trajectories as more or less canalized as a consequence of such regulation. The discussion of development within the context of natural selection made Waddington a pioneer of evolutionary developmental biology, or evo-devo as it is more often termed (Haig, 2004).

Waddington took this explanation a step further and proposed a process of genetic assimilation. Genetic assimilation amounts to the production of a mutation that could preemptively trigger a canalized developmental trajectory (pre-DNA). Waddington's (1942) example was of calluses on the feet and legs of ostriches. Such calluses form in response to pressure induced by walking and crouching. Yet, these calluses are seen in ostrich embryos. The evolutionary story, accordingly, is that calluses were a developmental response to environmental stimuli with selection producing skin that formed calluses. This was highly canalized. The "genes for" callus formation would rely upon a specific threshold and duration of exposure to pressure in order to produce the phenotype. However, a mutation that changed the values for this—effectively setting the pressure threshold and duration close to zero—emerged and was selected for. The natural movements in

an egg were sufficient for calluses to emerge in the embryo, and the newly hatched ostrich was prepared for contact with the ground immediately.

Evidence of genetic assimilation under artificial selection also came from Belyaev's remarkable "farm fox experiment" (Belyaev, Plyusnina, & Trut, 1985; Kukekova et al., 2011; Lindberg et al., 2005; Trut, Oskina, & Kharlamova, 2009). With the goal of understanding the role of genetics in the domestication of dogs from wolves, Belyaev began in 1959 a carefully controlled regime of artificial selection for "tameness" (reduced fear and aggression) in the previously undomesticated silver fox, a close relative of the wolf. Three lines of selection were established: tame, aggressive, and unselected. The first sign of tameness, tail-wagging, appeared after just four generations. A few generations later, kits selected for tameness began to demonstrate positive, affiliative behavior (approach, sniff, lick) to humans. By the 15th generation, 18% of the tame fox line received this highest tameness score; by the 20th generation, 35% received this score; and after 35 generations, 75% received it. Since 1959, well over 45,000 foxes have gone through the experiment.

Having selected for tameness and achieved it, the most obvious interpretation would be that the farm fox experimenters had artificially selected the "gene for" tameness. In fact, they appear to have selected for regulatory genes that made a difference in development. As in all birds and mammals, positive, affiliative, or hedonic behavior develops in foxes before negative, fearful, or agonistic behavior (for example, in humans, social smiling appears at about 6–8 weeks and fear of strangers at about 8 months). Kits of the unselected line first showed fearful behavior at about 6 weeks whereas kits of the tame line did not show fear until 9 weeks or later. In other words, selection for nonaggressiveness worked by slowing the rate or prolonging the period of the development of fear/aggression—that is, by delaying the trigger or raising the threshold for activation of the neuroendocrine mechanisms that mediate agonistic behavior. By the 40th generation, tame foxes differed from aggressive foxes in adrenocortical, serotonergic, and limbic functions related to downregulation of the HPA axis. The overall effect of selection for tameness was heterochrony—specifically neoteny, a form of pedomorphism ("child shape") brought about by slowed or prolonged development—such that adult tame foxes look and act more like their ancestral juvenile wild foxes than their ancestral adult wild foxes. The ostrich and fox examples show how genetic assimilation permits the inheritance of acquired characteristics.

Haeckel saw evolution as driving development, with development involving the unfolding of the latest design. Waddington saw selection as controlling development, but also saw development as a process of buffering the organism against the vicissitudes of life. His focus on canalization and genetic assimilation portrayed development as a form of calibration to the life circumstances of an organism. Canalized processes dealt with the day-to-day variations encountered, and genetic assimilation provided a hypothesis about how selection could tailor development over time. This view has been firmly entrenched in the Modern Synthesis and developmental processes are now seen as adaptations for reproduction, moving an organism from a single-celled zygote, which cannot reproduce, to a mature adult capable of reproducing (Bonner, 1993).

The information represented in a zygote's DNA is derived from or is about the environments of its *ancestors*, not its current environment. Because environmental change is more or less constant, this "old" information is not necessarily a good predictor of the zygote's future environment. As Waddington put it, "The main issue in evolution is how populations deal with unknown futures" (Waddington, 1969, p. 122). Development buffers the organism against unknown futures, the vicissitudes of changing environments, by enabling the developing phenotype to be affected by or to embody "new" information about the environment in which it develops. Because selection operates only on phenotypes, not genotypes, environmental effects on phenotypes can create novel phenotypes as targets of selection. Through canalization, genetic assimilation, epigenetic inheritance, and the many kinds of learning, novel phenotypes can become heritable. Indeed, developmental plasticity, the capacity of the phenotype to be affected by the environment in potentially adaptive ways, is an important driver of evolution (West-Eberhard, 2003).

Modern Epigenetics

In the first decade of the 21st century evolutionary developmental biology has reestablished itself within biology and more specifically within behavioral biology (Bateson & Gluckman, 2011; Jablonka & Lamb, 2005; Weber & Depew, 2003; West-Eberhard, 2003). However, over the past 15 years the use of the term epigenetics has markedly increased in the relevant literature (Haig, 2012). This marks a resurgence of an interest in epigenesis, as understood since Pythagoras.

For contemporary scholars, epigenesis is morphogenesis and differentiation; it is development. The epigenetics

of Waddington referred precisely to this, and claimed a conceptual space between the genotype and phenotype in which epigenesis happened as a consequence of epigenetic processes. Epigenesis was under genetic control and epistatic interactions stabilized development in the face of genetic and environmental variation or noise. These factors operated above the gene level, which is captured by the etymology, *epi-* (above). Within Waddington's pre-DNA formulation is the idea that genes require regulation, if only to allow tissue differentiation, and this is also central to modern genetics.

The particulate view of inheritance contributed by Mendel launched genetic thinking, and population genetics produced the Modern Synthesis. However, since the discovery of DNA, genes are no longer regarded as particulate (Keller, 2000). Genes are understood as functionally described portions of DNA, the function of which is to code for particular amino acid sequences or to control the expression of another segment of DNA. Those amino acids sequences, or polypeptide chains, are then folded into proteins.

The structure of DNA, or deoxyribonucleic acid, consists of two strands of sugar and phosphoric acid in a double helix, joined by pairs of four bases: adenine (A), thymine (T), guanine (G), and cytosine (C). The sequence of bases along a single strand of DNA encodes amino acid sequences and is decoded in two steps: (1) *transcription* and (2) *translation*. First, the sequence of base pairs from a single strand of the double helix is copied to a single stranded messenger ribonucleic acid (mRNA) molecule. The formation of mRNA is similar to DNA replication but in this case the base uracil (U) substitutes for thymine and pairs with adenine (A). Thus the code from the DNA strand is *transcribed* (in its complementary form) to a strand of mRNA. Once formed, mRNA exits the cell nucleus, and joins with ribosomes in the cytoplasm of the cell. Ribosomes can be regarded as reading devices that move along the length of the mRNA, exposing triplets of bases, or codons. Transfer RNA (tRNA) molecules deliver specific amino acids to the ribosomes during this reading process. Each tRNA molecule has a codon. As the ribosomes read the mRNA, three bases at a time, tRNA molecules are attracted to their complementary codon and attach to the mRNA, bringing their amino acid with them. These amino acids join to form a polypeptide chain, which is later folded into a specific protein. It is in this way that the complementary form is *translated* to its original sequence, and this sequence codes for a specific amino acid chain and a specific protein.

Transcription is not a free-for-all but is highly regulated by transcription factors, which are proteins that effectively act to repress or activate gene transcription. Transcription factors operate by binding with regulatory portions of the genes themselves (see Pabo & Sauer, 1992, for a useful overview) and are influenced by environmental factors. Modern epigenetics focuses on this regulation.

For transcription factors to operate, they must be able to access DNA. This physical demand is not always met. DNA is organized into clumps that consist of a small number of base pairs. At the center of these clumps are histone proteins to which the DNA is bonded. The DNA and histone complex is termed chromatin. The manner in which chromatin is organized is referred to as the nucleosome. Nucleosomes are generally tightly organized structures and this reduces the opportunity for transcription factor binding. A solution to this is the chemical alteration of the histone proteins through acetylation, phosphorylation, and methylation, in order to change the nature of their bond to the DNA. Histone modification can also decrease the opportunity for transcription factor action.

Histone modification is one mechanism that allows transcription regulation. The direct addition of a methyl group to cytosine on the DNA is another—and this is most closely associated with the modern concept of epigenetics. Methylation of cytosine can prevent the binding of transcription factor and suppress transcription. Ultimately, methylation acts to silence gene expression.

There is increasing evidence of perinatal methylation and a role for this form of regulation in parenting effects and environmental modification of behavioral phenotypes in animal models (Champagne, 2013; Youngson & Whitelaw, 2008). In this way, a form of quasi-Lamarckianism has emerged in which characteristics can be acquired or developmentally induced, and their effects transmitted to the next generation. These effects are the result of proximate epigenetic mechanisms acting to modify gene expression. As they have no impact on DNA code, they do not violate the central dogma of molecular biology. In many ways these mechanisms appear to be adaptations designed to calibrate organisms to their environment (Dickins & Rahman, 2012). Next we present two examples of epigenetic mediated calibration of an organism to its environment.

Epigenetic Effects of Parenting Behavior

Weaver and colleagues (2004) provide a good example of epigenetically mediated parenting effects in rats.

Maternal behavior directed toward pups during lactation can be grouped into distinct behavioral syndromes. These syndromes consist of licking and grooming behavior (henceforth, licking) and arched-back nursing (henceforth, nursing). Individual mothers can exhibit licking and nursing at high or low frequencies and the particular pattern of their maternal behavior influences the adult end-state of their pups. For example, a pup exposed to a high-licking and nursing mother will develop into an adult with relatively lowered fear response and cortisol reactivity compared with the pup of a low-licking and nursing mother. Cross-fostering paradigms have demonstrated that this effect is not genetically mediated (see also Champagne, 2008). The amount of licking and nursing performed by a mother is a consequence of her own stress response and environment such that highly stressed mothers exhibit the low-licking and nursing behavioral pattern.

Weaver and colleagues (2004) presented correlational data suggesting differential methylation of glucocorticoid receptor promoter gene sites among adults raised by different maternal types. This gene directly affects the inhibitory feedback of the HPA, which is the neuroendocrine mechanism responsible for the passive stress response. The less sensitive the HPA axis is to inhibition, the more chronic is the stress response. Using a cross-fostering paradigm, Weaver et al. were able to support the hypothesis that maternal behavior affects methylation on this gene. This methylation occurs during oocyte and spermatocyte maturation, which occurs postpartum, and is transmitted through the germ line. The methylation itself is a consequence of increased serotonin activity and its secondary messengers, which are known to be involved in the regulation of gene expression. The serotonin response is another endocrine activation caused by maternal care. The full details of this methylation process are as yet unknown but it is clear from Weaver et al.'s results that methylation is involved.

It is noteworthy that these methylation effects are reversible (Weaver et al., 2004). One hypothesis is that exposure to stress leads rat mothers to lick and nurse at a lower rate, thereby calibrating their offspring's stress response to a more sensitive mode and one which will more readily produce the behaviors most appropriate in the stressful environment into which they were born. This can last across generations but extinguish if stressful conditions are removed. This clearly has adaptive value and could act to maximize inclusive fitness across a number of generations. As Dickins and Rahman (2012)

note, one would expect such mechanisms to be present in organisms that exist in stochastic ecologies or that adopt generalist strategies.

Epigenetic Effects of Maternal Nutrition

Kuzawa (2005) introduced the concept of "intergenerational phenotypic inertia." On the basis of extensive evidence that a mother's birth weight is among the strongest predictors of her offspring's birth weight (even more so after controlling for mothers' gestational age at birth), Kuzawa revisited the 35-year-old hypothesis that the nutritional experiences of a mother when she was a fetus can affect the intrauterine nutritional environment that she provides her own offspring, especially her daughters (e.g., Ounsted, Scott, & Ounsted, 1986; Wells, Sharp, Steer, & Leon, 2013).

Kuzawa noted that, among survivors of the Dutch Hunger Winter of 1944–1945 (A. D. Stein & Lumey, 2000), daughters who were exposed to their mother's undernutrition were significantly lighter at birth than Dutch girls born between 1944 and 1946 whose mothers were not exposed to the Hunger Winter. Furthermore, individuals who were prenatally exposed to the famine showed—six decades later—less DNA methylation of a gene that regulates growth (IGF2) than their unexposed, same-sex siblings (Heijmans et al., 2008). Kuzawa's intergenerational phenotypic inertia model provided an adaptationist rationale for expecting the effects of prenatal malnutrition or stress to last more than one generation: When environments are stochastic over time scales greater than a generation, 9 months of gestation cannot provide the fetus with enough information upon which to "predict" its own, within-generation optimal growth and development (Nettle, Frankenhuys, & Rickard, 2013). This is referred to as the "predictive adaptive response" (PAR) model, which we discuss separately in "Future Research and Theoretical Perspectives" at the end of this chapter. Therefore, Kuzawa argues, intergenerational phenotypic inertia provides the fetus with information, not only about the environment into which it will be born, but the environment into which its mother was born, and perhaps even its mother's mother, and so on, back an unknown number of generations. Intergenerational phenotypic inertia "has the effect of limiting changes in growth rate in response to short-term ecologic fluctuations, and thus may allow the fetus to cut through the ecologic 'noise' of seasonal or other stochastic influences to read the 'signal' of any longer term nutritional trends in the local ecology" (Kuzawa, 2005, p. 17).

Conclusion

Waddington's view of epigenetics has found new ground in modern epigenetics. Histone modification and methylation allow a complex and varied array of alterations to gene expression, which in turn affect the phenotype. As the maternal behavior example demonstrated, methylation can occur in response to external inputs (in this case the maternal environment), not only affecting the current organism but also future generations. Moreover, the reversible nature of parental effects make them candidates for facultative (e.g., developmental) adaptations. In the following section, we present life history theory and facultative reproductive strategies as developmental trajectories that may help scientists to organize understanding of factors that influence prenatal development.

LIFE HISTORY THEORY: EVOLUTION AND DEVELOPMENT

Evolution and development are intertwined for two reasons. First, selection operates only on phenotypes (the material organism) not genotypes (information represented in the organism's DNA), but phenotypes must develop (from DNA) before they are exposed to selection. Second, the life cycles of all sexually reproducing organisms begin with a single-celled zygote, but zygotes must develop into adults before they can reproduce. Development is thus an adaptation for reproduction (Bonner, 1965, 1993; West-Eberhard, 2003). Life itself is development; phenotypes are life cycles in progress. Life history theory is the branch of evolutionary theory devoted to the study of life cycles. It views life cycles as reproductive strategies—that is, naturally selected patterns of growth and development for maximizing reproductive success under particular ecological conditions. It focuses on the evolution and interaction of life history traits (e.g., number and size of offspring, interbirth interval, length of lactation, age and size at maturity, postreproductive life span, total life span; see Table 3.1).

Fitness

Reproductive success is fitness (direct and/or indirect—i.e., inclusive). By definition, fitness is *measured* in terms of relative reproductive success (selection leads to individuals who bequeath *more* copies of their genes to succeeding generations than others in their breeding population). But it *consists* of work—the work required by the three

TABLE 3.1 The Minimax and Maximin Reproductive Strategies

Reproductive strategy	Minimax: Maximize current reproduction (r-strategy)	Maximin: Maximize future reproduction (K-strategy)
Ecology	More variable and/or unpredictable	More constant and/or predictable
Mortality rates	Often catastrophic, nondirected, density independent	More constant, directed, density dependent
Survivorship	Low in early life	High in early life
Population size	More variable, nonequilibrium	More constant, equilibrium
Intra- and interspecific competition	More variable, lax	More constant, intense
Traits favored by selection	Rapid development Early reproduction High reproductive rate Low parental investment Small body size Semelparity (large litters) Short life span	Slow development Delayed reproduction Low reproductive rate High parental investment Large body size Iteroparity (small litters) Long life span

Source: Adapted from "On r- and K-Selection," by E. R. Pianka, 1970, *American Naturalist*, 104, pp. 592–597, and "r- and K-Selection Revisited: The Role of Population Regulation in Life-History Evolution," by D. Reznick, M. J. Bryant, and F. Bashey, 2002, *Ecology*, 83(6), pp. 1509–1520.

main components of fitness: (1) survival, (2) growth and development, and (3) reproduction (reproductive effort), which includes finding a mate (mating effort) and producing and rearing offspring (parenting effort or parental investment [discussed shortly]). Work requires resources that are sooner or later always limited. These include the raw materials of life, matter (nutrients) and energy, but also nonmaterial time, safety or security, and information. Time is a resource because doing work takes time, and because organisms have finite life spans, time devoted to one kind of work takes away from the time available to do another kind (opportunity costs). Security is a resource because no environment is without some degree of risk or uncertainty in the flow of resources.² Information is a resource because the better an organism knows its environment, the more efficiently it can acquire other resources. Because selection inexorably favors individuals with greater fitness—but greater fitness requires more work and hence more resources—something has to give. Therefore, evolutionary biology's assumption of optimality (Parker & Maynard Smith, 1990) holds that natural selec-

²Risk refers to environmental threats to survival and reproduction. Uncertainty refers to the probability of such threats.

tion favors organisms' capacity to allocate their resources preferentially to their most pressing adaptive problem. This entails trade-offs. Resources allocated to survival, for example, cannot be allocated to growth and development,³ and resources allocated to producing children (increasing their quantity) cannot be allocated to their growth and development (increasing their reproductive value or quality).

The Current–Future Trade-Off

Of all the trade-offs identified (at least 45 among 10 major life history traits [Stearns, 1992]) the most important or all-encompassing is that between current and future reproduction (Charnov, 1993; Stearns, 1992). This trade-off may be intraindividual (within a life cycle) or intergenerational (influencing descendants). At issue in the intraindividual current–future trade-off is whether it would be better for the organism's lifetime reproductive success to reproduce now, in the current breeding season (or as soon as possible), or wait for another opportunity in the more distant future. For example, consider a nursing mother: Would it be better for her lifetime reproductive success to continue nursing her current child or cease nursing and have another (future) child? Continuing to nurse not only consumes maternal resources but has diminishing benefits for the child's fitness as he or she grows. Therefore, at some point the lifetime fitness benefits accruing to the mother from allocating her resources to the current child will be less than those she would receive if she ceased investment in her current child and allocated them instead to a future child.

At issue in the intergenerational current–future trade-off is whether it would be better for the organism's genetic representation in arbitrarily distant future generations to have more offspring in the current generation (i.e., to maximize its own lifetime reproductive success). This trade-off arises from the fact that, just as fitness is inherently a relative measure (never high or low, only higher or lower), so too is the time at which it is measured relative or arbitrary. What counts in evolution is not only lifetime reproductive success but lineage continuation—that is, staying in the “evolutionary game” (Gillespie, 1977; Slobodkin & Rapoport, 1974). The evolutionary success of a reproductive strategy depends not only on the number of children, but also on the number of grandchildren,

³This trade-off may underlie nonorganic failure to thrive: Highly stressed infants may reallocate metabolic resources from growth and development to maximize their chance of sheer survival.

great-grandchildren, great-great-grandchildren, and so on. All organisms that ever lived did so because none of their direct ancestors failed to reproduce. That is, none of them failed to adapt their reproductive strategy to the prevailing environment.

The major determinants of both the optimal intraindividual and intergenerational trade-offs are environmental risk and uncertainty in (a) local age-specific extrinsic mortality rates⁴ and (b) the availability and flow of energy and nutrients. The former determines the probability of death at a given age and the latter determines the capacity of parents to invest in offspring. Theory and observation show that, when environmental conditions are risky or uncertain, with high or unpredictable extrinsic mortality rates and few or uncertain resources, organisms in general, including humans, tend to reproduce early and often (Chisholm, 1999b; Hill & Kaplan, 1999; Promislow & Harvey, 1990, 1991; Schaffer, 1983; Stearns, 1992). Maximizing the number of offspring reduces the chance of lineage extinction because it maximizes the chance that at least one will survive and reproduce, while increasing the number of offspring reduces the resources parents can invest in each, which only further reduces offspring quality. When conditions have been severe enough, long enough, parents have few resources to invest anyway, so downside risk protection against lineage extinction is still the optimal (most efficient) evolutionary strategy. It can be evolutionarily rational to pay the cost of having many low-quality offspring because minimizing investment in offspring quality maximizes the chance of staying in the evolutionary game. This minimax strategy maximizes reproductive output in the short term, within a life span, so is often called the “current” reproductive strategy—as opposed to the “future,” or maximin strategy.⁵

The maximin strategy is to maximize the chance of obtaining the minimum necessary or possible fitness benefit for continuing the lineage. Whereas the minimax strategy is for downside risk protection against lineage extinction, the maximin strategy is for setting the stage

⁴Extrinsic mortality is the risk of death beyond the control of an individual organism. It is the age-specific probability of death imposed by the environment on all members of a population (Stearns, 1992).

⁵The minimax and maximin strategies are idealized end-points of a continuum. Chisholm and Coall (2008) used these terms because they have more intuitive meaning than their technical predecessors, the *r*- and *K*-strategies (Pianka, 1970; Reznick, Bryant, & Bashey, 2002).

for the future, conserving resources to invest in future reproduction. Theory and empirical evidence show that when environmental conditions are relatively secure, with predictably low mortality rates and adequate resources, organisms in general, including humans, tend to reproduce later and less often (Chisholm, 1999b; Hill & Kaplan, 1999; Low, Hazel, Parker, & Welch, 2008; Placek & Quinlan, 2012; Promislow & Harvey, 1990, 1991; Schaffer, 1983; Stearns, 1992). While minimizing offspring number can be evolutionarily risky in high-mortality environments, in relatively secure environments this is not such a problem. And by having fewer offspring, parents can invest more in each, thereby increasing their quality (growth, education, health, job prospects ...) and setting the stage for the production and nurturing of grandchildren, great-grandchildren, and so on, in the future (see Table 3.1).

In sum, there is no a priori “best” reproductive strategy; the optimal, evolutionarily rational strategy in one environment is not likely to be optimal in another. Humans have a long evolutionary history of selection for the capacity to develop the maximin strategy (investing heavily in fewer children). But because of our long history of selection for developmental plasticity, it is painfully obvious that we also have the capacity to develop the minimax strategy (investing fewer resources in more children) in risky and uncertain environments. One question addressed in this chapter is: What does this mean for mothers and the development and health of their unborn children?

Parent–Offspring Conflict in Utero

The most pressing adaptive problem for the unborn child is surviving long enough to grow and develop well enough to reach term. Because the conceptus, embryo, and fetus are so utterly dependent on resources provided by the mother, the uterus is surely the riskiest, most uncertain environment they will ever inhabit, if indeed they survive it. Empirical evidence shows this and parent–offspring conflict theory helps to explain why.

Recent reviews suggest that, among Western women known to be pregnant, 11%–22% miscarry in the first 5–20 weeks of pregnancy (Ammon Avalos, Galindo, & Li, 2012; Katz, 2012), with the incidence increasing dramatically with maternal age (up to 84% in 48-year-old women; A.-M. N. Andersen, Wohlfahrt, Christens, Olsen, & Melbye, 2000). Howell (1979) noted that, among the !Kung, a modern hunter-gatherer society, the incidence of known miscarriage was 9%. French and Bierman (1962) reported a similar incidence of 9.9% on the Hawaiian

island of Kauai, but L. Henry (1976) reanalyzed their data and argued that the actual incidence was much higher, at 23.7%. Wasser and Barash (1983) suggested that as many as 50% of all conceptions do not result in live births; Roberts and Lowe (1975) put the figure higher still, at 78%. The point is that, even today, gestation constitutes a universal selection funnel, a period of intense natural selection on every conceptus, embryo, and fetus to adapt to its ecological niche—the uterus—to maintain or increase the flow of maternal resources across the placenta (Stearns, 2005).

Humans, like all anthropoid primates, have a hemochorial placenta (Mossman, 1987), in which maternal and fetal blood are in especially close contact (Rutherford, 2013). Luckett (1974) even argued that the trophoblast layer of the human placenta is more invasive than the uterine walls of any other primates (see also Power & Schulkin, 2012). Even if the rates of conception loss, fetal wastage, and miscarriage were no higher in our evolutionary past than today, modern rates, multiplied by thousands of generations, would have provided selection ample time to favor fetal adaptations for eliciting parental (maternal) investment throughout pregnancy. At the same time, however, selection would also favor maternal adaptations for investing wisely, in an evolutionarily rational way. The crucial point here is that what is evolutionarily rational for the fetus is not necessarily evolutionarily rational for the mother. In other words, parent–offspring conflict is inevitable; there is an inherent conflict between the fitness interests of mother and fetus.

Because both the trade-off between current and future reproduction and parent–offspring conflict theory focus on the allocation of limited resources among competing interests, the two can be synthesized logically (Coall & Chisholm, 2003). Under safe and predictable conditions, with low and predictable mortality rates and adequate and predictable resources, mother and fetus can resolve this conflict through “cooperation”; each can afford to give a little. This increases the resources available to the fetus and may improve fetal growth and health. But under conditions of risk and uncertainty, where the availability of resources or their allocation is restricted, this conflict can be fatal for mother and/or fetus. If the fetus survives, the reduced investment may be the source of future ill-health.

Parent–offspring conflict (Trivers, 1974) follows from the logic of parental investment theory (Trivers, 1972). Rephrasing Trivers’s definition, parental (maternal) investment is “any investment by the *mother* in an individual *fetus* that increases the *fetus’s* chance of surviving (and hence reproductive success) at the cost of the *mother’s*

ability to invest in other offspring" (Trivers, 1972, p. 139). These "other offspring" may be existing, current children or potential, future fetuses. The conflict is between: (a) what is evolutionarily rational for the fetus: increased maternal investment will increase its chances of survival (its reproductive value or quality or health); and (b) what is evolutionarily rational for the mother: decreased investment in the current fetus allows her to reallocate resources to existing offspring or future fetuses, thereby increasing her reproductive success (future quantity of offspring). Trivers argued that, because mother and fetus are not genetically identical, they do not have the same inclusive fitness interests (Hamilton, 1964) and are therefore expected to "disagree" about the optimal trade-off between offspring quantity and quality. In sum, the issue is that while the mother has a 50% fitness interest in each of her offspring, each offspring has 100% fitness interest in itself, in the sense that it carries copies of its father's genes as well as its mother's.

Haig (1993, 1996, 1999) developed a sophisticated application of parent–offspring conflict theory for modeling maternal–fetal interaction (see Figure 3.1). When maternal resources are limited (e.g., in risky and uncertain environments), any maternal investment in the fetus entails a trade-off; that is, for every benefit (B in Figure 3.1) a fetus gains from maternal resources, there will be a correlated cost (C in Figure 3.1) to its existing or future siblings. Because the mother is equally related to all her offspring, current and future, it is evolutionarily rational for her to invest equally in each according to their capacity to benefit from the resources invested. Therefore, the mother is expected to seek the best possible balance between the benefit to the existing fetus and the cost to its existing or future siblings. In other words, after a point (x_1 in Figure 3.1), the increased benefit to the current fetus of her continuing the same high rate of investment will be outweighed

by detracting from the resources she could invest in existing or future offspring. At that point, therefore, the mother is expected to begin diverting resources from the current fetus to other existing or future children. To reiterate, parent–offspring conflict and the trade-off between offspring quantity and quality mean that developmental adaptations to stressful (risky/uncertain) fetal environments can have *evolutionarily* adaptive consequences for the mother (to reduce investment) that are nonetheless *developmentally* disadvantageous for the fetus's future health affecting their physical and social-emotional development.

PRENATAL STRESS, ENDOCRINE RESPONSES, AND OFFSPRING DEVELOPMENT

The prenatal period is a time of rapid cell multiplication and cell differentiation (i.e., development). As with other periods of rapid growth, environmental insults can disrupt development. The protected uterine environment of mammalian pregnancy is designed to support fetal growth and buffer the fetus against many challenges that affect the mother. In this section, we use the perspective of human evolutionary ecology to examine the impact of a range of stressors on development, including stressors in the maternal psychosocial environment, nutritional stressors, disease pressures, and exposure to toxicants in the local environment. These stressors are generally examined within a biomedical or pathology model of human health. As described above, we focus on these changes as potentially adaptive responses to environmental change or developmental plasticity that in some cases produce the extremes of normal variation in a trait and pathology.

Developmental Plasticity

Plants and animals that develop in heterogeneous environments typically have the ability to alter their phenotypes in response to those environments (Bateson, Chapter 6, this *Handbook*, Volume 1; Via & Lande, 1985). The response of an individual's phenotype to this environmental variability is referred to as phenotypic plasticity (Piersma & Drent, 2003; Stearns, 1982; West-Eberhard, 1989, 2003). Development can be broadly defined as "all of the phenotypic change during the lifetime of an individual" (West-Eberhard, 2003, p. 32). Therefore, developmental plasticity refers to changes in an individual's phenotype in response to environmental change throughout his or her life span. There is a tendency in this literature to refer to phenotypic changes (e.g., physiology, growth,

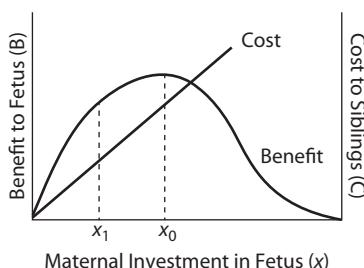

Figure 3.1 Representation of the trade-off between maternal investment in current fetus versus existing or future siblings.

Source: Adapted from "Genetic Conflicts in Human Pregnancy," by D. Haig, 1993, *Quarterly Review of Biology*, 68(4), pp. 495–532.

mental health) induced by the environment as being *programmed* (Whimbey & Denenberg, 1967). We will use such terminology, but it is crucial to remember that these changes are latent potentials, part of the individual's norm of reaction, and are elicited by the environment, not created by it (Bateson, 2007).

The prolonged development of humans provides the opportunity for humans to perceive and evaluate (not necessarily consciously) their environments and respond in ways that maximize their fitness. In the human life cycle, the environment can initiate developmental trajectories that result from the allocation of resources via reproductive strategies and have important consequences for the adult phenotype. The plasticity that is such a striking feature of human development provides the opportunity to make assays of both the biological (Ellison, 1990, 1996) and social (Chisholm, 1999b; Draper & Harpending, 1982) developmental environments. If these assays accurately predict the adult environment, they are likely to provide a fitness advantage (Bateson et al., 2004; Hill & Kaplan, 1999). The range of possible phenotypes that can be expressed is referred to as a reaction norm (Stearns & Koella, 1986) and is limited by phylogenetic constraints (Worthman, 1999). It is this developmental plasticity that enables the individual to respond to the environment and is genetically encoded (Bateson, 1982; Oyama, 1985; Surbey, 1998). Indeed, phenotypic plasticity is one of the most important human evolutionary adaptations (Hrdy, 2000; Stearns, 1982).

Across multicellular species, an organism's developmental environment has consequences not only for its own growth, development, and reproduction, but also for its descendants (Bateson et al., 2004; Coall & Chisholm, 2010; Kuzawa, 2005; Mousseau & Fox, 1998; West-Eberhard, 2003). The influence of early postnatal environments on growth, development, behavior, and health are well established (Bateson & Martin, 1999; Chisholm, 1999b; C. J. K. Henry & Ulijaszek, 1996; Kuh & Ben-Shlomo, 1997). Recently, evolutionists have focused on the intrauterine environment, the broad range of challenges that influence the uterine environment, and their consequences for fetal development and subsequent health.

Reduced fetal growth is associated with higher rates of perinatal morbidity and mortality (Kramer, 1987) and an increased risk of developing coronary heart disease, hypertension, and diabetes in adult life (D. J. P. Barker, 1994, 2004). Experimentally inducing fetal growth restriction in animal models (via the administration of synthetic glucocorticoids, inducing maternal stress, controlling the

maternal diet, or reducing placental function) results in cardiovascular, metabolic, and endocrine changes throughout childhood and even into adulthood (McMillen & Robinson, 2005). Moreover, these same factors are central to fetal programming (Fowden, Giussani, & Forhead, 2006), placental adaptation (Tegethoff, Greene, Olsen, Meyer, & Meinlschmidt, 2010), and epigenetic changes in early development (Vaiserman, 2012). This burgeoning focus on the intrauterine environment has culminated in a new paradigm initially referred to as the Barker Hypothesis, fetal programming, or fetal origins of adult disease (FOAD), and now the developmental origins of health and disease (DOHaD). Within the DOHaD paradigm there has been a particular focus on birth weight, placental weight, and placental weight to fetal weight ratio (hereafter placental ratio) as indicators of the quality of the uterine environment. We examine these further on.

Fetal Growth

It is well known that reduced fetal growth predicts subsequent morbidity and mortality. In a review of the epidemiological literature, Kramer (1987) identified a number of maternal factors associated with intrauterine growth restriction (IUGR), including demographic and psychosocial elements of the mother's environment, obstetric factors, nutritional status, morbidity during pregnancy, toxic exposures, and prenatal care. Placental efficiency plays an integral role in two of the three main causes of reduced fetal growth, which are: (a) abnormal placental structure and/or function; (b) inadequate maternal supply of oxygen and/or nutrients due to either maternal factors or placental factors; and (c) decreased ability of the fetus to use the available supply (Brodsky & Christou, 2004).

Increasingly, the role of maternal constraints on fetal growth—and even that of future generations—are receiving attention (Gluckman & Hanson, 2008; Kuzawa, 2005; Kuzawa & Quinn, 2009; Lewis, Cleal, & Hanson, 2012; Ounsted et al., 1986; Wells, 2003). For example, in a study of 513 low-risk pregnancies, Coall, Charles, and Salafia (2009) found that maternal birth weight was the only factor that consistently predicted children's fetal and placental growth, affecting outcomes including birth weight, placental weight, placental ratio, placental surface area, and placental thickness.

Birth weight is a crude proxy for determining the adequacy or inadequacy of the intrauterine environment (Salafia et al., 2008; Wilcox, 2001). Less commonly used measures of fetal growth that have advantages for research

take into account what the fetus's optimal growth "should" or "could" have been. Constructing fetal growth standards that include only the nonpathological variables is the best way to accurately represent optimal birth weight (Gardosi, 2004). Among other measures, the percentage of optimal birth weight (POBW) was developed from a study of the nonpathological influences on birth weight in Western Australia (Blair, Liu, de Klerk, & Lawrence, 2005). This continuous measure of the appropriateness of fetal growth utilized the whole birth weight range by comparing each individual's birth weight to the birth weight for individuals of same gender, gestational age, and maternal height, age, and parity.

From the perspective of life history theory, fetal growth is a measure of resource flow to the fetus (parental investment). A more direct measure of the resource flow is provided by proportionate birth weight. Proportionate birth weight is the neonate's birth weight as a proportion of the mother's weight and represents the amount of parental investment made during gestation (May & Rubenstein, 1985). This characteristic remains remarkably constant at 5% across all eutherian (placental) mammal species (Land, 1985). Recently, proportionate birth weight has been used as a more direct measure of resource flow to the fetus and, therefore, of parental investment throughout gestation (Coall & Chisholm, 2010). A range of insults have a measurable impact on the uterine environment and health in the next generation. It is important to recognize, however, that insults not producing visible effects on birth weight can still have consequences for fetal programming and adult health (Gluckman & Hanson, 2010). Much of this buffering of the fetus against the maternal environment is achieved by placental adaptation.

Placental Weight and Placental Ratio

Placental growth and development are strongly correlated with the growth trajectory of the fetus and have a major influence on birth weight (Salafia et al., 2005, 2008). The placenta has evolved to provide a protected environment to support fetal growth, buffering the developing organism from environmental insults (Lewis et al., 2012; Wooding & Burton, 2008) and preparing it for the postnatal environment it is likely to inhabit (Gluckman, Hanson, & Spencer, 2005). (Again, we discuss the "predictive adaptive response" [PAR] model separately in "Future Research and Theoretical Perspectives.") The placenta is crucial for regulating the physiological functions that determine fetal growth. The functional efficiency of the placenta may be

challenged by disturbances in the maternal environment, such as poor nutrition, illness, medications, and maternal stress (Tegethoff et al., 2010). The effect of such disturbances may create adverse intrauterine conditions resulting in adaptations (which are often under endocrine control) by the placenta (Coan et al., 2010; Myatt, 2006), and when the placenta is not able to adapt, adverse outcomes for the fetus (Sandman & Davis, 2010).

In epidemiological studies, the role of the placenta is often extrapolated from placental weight. Placental weight is generally associated with placental function (Bell, Wilkening, & Meschia, 1987; Robinson, Owens, de Barro, Lok, & Chidzanga, 1994). Like birth weight (Godfrey, Breier, & Cooper, 1999; Harding, 2001; Wilcox, 2001), placental weight is the end product of a chain of events that include the growth and development of the placenta throughout gestation (D. J. P. Barker & Thornburg, 2013; Coall et al., 2009; Salafia et al., 2005).

As with other aspects of biology, early beneficial adaptations that improve survival can have later costs in morbidity and shortened lives (Kirkwood & Austad, 2000). Research in the field of DOHaD has shown that a high placental ratio is associated with higher blood pressure throughout childhood (V. M. Moore et al., 1996) and into adulthood (V. M. Moore, Cockington, Ryan, & Robinson, 1999) and may predispose individuals to adult illnesses such as hypertension, glucose intolerance, blood coagulation disorders, and coronary heart disease (D. J. P. Barker, 1997; D. J. P. Barker, Bull, Osmond, & Simmonds, 1990; Forsén, Eriksson, Tuomilehto, Osmond, & Barker, 1999; Forsén et al., 1997; Law, Barker, Bull, & Osmond, 1991; Phipps et al., 1993). Some researchers, however, have found a U-shaped association between placental ratio and coronary heart disease in men (Martyn, Barker, & Osmond, 1996). Others have found an association between placental weight, but not placental ratio, and subsequent blood pressure (e.g. Blake et al., 2001; Whincup, Cook, Papacosta, & Walker, 1995; Williams, St George, & Silva, 1992), some have found sex differences (S. J. Taylor, Whincup, Cook, Papacosta, & Walker, 1997), and others have found no effects of gender (Burke et al., 2004; Leon et al., 1996; Martyn et al., 1995; Matthews, Lewis, & Bethel, 1994). It may be that a relatively large placenta does not directly cause adult disease but signals the fetal supply line throughout gestation (Robinson et al., 1995). However, animal and human studies have both shown that placental size and placental ratio play important roles in fetal adaptation to the maternal environment (Faichney & White, 1987; Godfrey, 2002; Kingdom, 1998; Robinson et al., 2001; Steyn et al., 2001).

In remarkable accord with the theoretical predictions from Haig's (1993) application of parent–offspring conflict theory to the uterine environment, the DOHaD perspective proposed that increased placental ratio was an adaptive placental response to intrauterine growth restriction (D. J. P. Barker et al., 1990). Initial studies involving sheep showed that moderate dietary restrictions at various times during pregnancy were associated with increased placental weight (Faichney & White, 1987). This was interpreted as "an attempt by the fetus to compensate for the reduced supply of nutrients in the maternal blood" (Faichney & White, 1987, p. 373). This compensatory placental growth maintained fetal growth in the ewes that had their diets restricted late in pregnancy, and may actually have increased the resource flow to the fetus when the dietary restriction was removed. It must be recognized, however, that although similar responses have been documented in humans, this may be an oversimplified picture. Note that the timing of dietary restriction and the previous nutritional state of the ewes are known to influence placental responses (D. J. P. Barker et al., 1993; Robinson et al., 2001). In a natural experiment, Lumey (1998) reported that women conceiving or in the first trimester of pregnancy during the Dutch Hunger Winter of 1944–1945 had relatively heavy placentae, while birth weights remained static. Lumey interpreted this as compensatory placental growth in response to reduced maternal nutrition. Both animal (Robinson et al., 1994) and human models (Wheeler et al., 1994) supported this interpretation.

Environmentally Appropriate Adaptation, Not Pathology

This application of evolutionary theory challenges the common perception that increased placental weight is pathological (Lao & Wong, 1999, 2001; Naeye, 1987). For example, infants born at high altitudes have reduced birth weights (Mayhew, Jackson, & Haas, 1990), higher placental weights (Kruger & Arias-Stella, 1970), and show structural changes that improve the efficiency of oxygen transfer between mothers and fetuses (Mayhew et al., 1990; see review by Zamudio, 2003). This placental adaptation can improve fetal growth (Mayhew, Jackson, & Boyd, 1993). Moreover, there is evidence that increased placental size can improve fetal survival. In appropriate-for-gestational-age infants of insulin-dependent diabetic mothers, a higher placental ratio was

associated with an increased likelihood of offspring survival (Evers, Nikkels, Sikkema, & Visser, 2003). Increased placental size in insulin-dependent diabetic pregnancies are likely to reflect the larger placenta necessary to maintain a fetus when the placenta is less efficient (Lao & Ho, 2002). More generally, placental adaptation to the uterine environment, which maintains fetal growth, is a normal process of pregnancy (Pardi, Marconi, & Cetin, 2002). Therefore, pregnancies in which the placentae show evidence of compensatory growth resulting in increased placental ratios may actually represent appropriate responses to suboptimal uterine environments of diverse origin in the short term, rather than pathology itself (Adair & Thelander, 1925; Fox, 2000; C. G. Kaplan, 2008).

DOHaD, as the name suggests, is interested in this developmental plasticity because of its impact on health. Here we move away from the biomedical-pathology models and explore these phenotypic changes from an evolutionary perspective (i.e., viewing them as the normal, adaptive responses to challenging maternal environments). The placenta evolved because the closer link between the mother and fetus buffers the developing organism from environmental insults, thereby increasing survival and ultimate reproduction (Wooding & Burton, 2008). Reproductive success is what drives evolution and placental function is crucial for successful reproduction (Lewis et al., 2012). Postnatal pathology arises when the trade-offs with other components of fitness entrain developmental trajectories that increase short-term survival at the cost of ill health and premature mortality in the future. These costs include low birth weight, preterm birth, altered stress reactivity, rapid childhood growth, early reproductive development, and short life spans. If these costs minimize the chance of lineage extinction—that is, if they increase the chance of reproducing at all in the harsh or unpredictable environments that cause them—they may also be evolutionarily rational (Borgerhoff Mulder, 1992; Chisholm, 1999b; Harpending, Draper, & Pennington, 1990; Stearns, 1992). Pathologies may also result when the postnatal environments for which the maternal challenges have prepared the fetus change, creating a mismatch between postnatal physiology and environment (Gluckman & Hanson, 2008, 2010). In sum, life history theory views many of these changes as adaptations to environmental challenges that maximize survival and, ultimately, reproduction.

Consistent with this view, we next examine the impact, first, of maternal stress on early development, second,

the role of maternal nutrition, and last, the increasingly apparent role of toxicants in the environment. We begin by discussing the meaning of *stress*.

Stress, Stressors, and Adaptive and Maladaptive Coping

Environmental stress not only affects development but does so in potentially adaptive ways by entraining alternative reproductive strategies (Belsky, Steinberg, & Draper, 1991; Chisholm, 1993; Worthman, 1999). *Stress* has long been a slippery concept, with considerable disagreement about its meaning (Cohen, Kessler, & Gordon, 1995; McEwen, 1995). We view stress in a general way, as a broad range of environmental stressors or challenges, including social-emotional or psychosocial stress, inadequate nutrition, and toxicants. We focus first on the psychosocial stress entrained by the perception of negative life events, a fairly objective measure of environmental risk and uncertainty (Cohen et al., 1995). We refer to the other stressors as biological stressors. These are factors such as malnutrition, disease, toxicants, and material poverty and include the physiological and energetic stressors associated with them (Ellis, 2004; Ellison, 1990; Thayer & Kuzawa, 2011). Therefore, biological stress represents situations of reduced biological resource availability. It must be stressed that, while we treat psychosocial and biological stressors as independent factors, they should not be seen as mutually exclusive because there is considerable interplay between them and they are often inseparable (Chisholm, 1999b; Coall & Chisholm, 2010). The survival, growth and development, and reproduction of all organisms always depend on biological resources (e.g., nutrition, disease), but because of our species' reliance on cooperation, social exchange, and sharing to gain access to these resources, our life history, as with most other primates, depends on the availability of psychosocial resources.

Any analysis of psychosocial stress must consider individual differences in the ability to cope with or adapt to stressors (e.g., Ellis, 2004). Paramount for our intensely social species is the social-emotional support that can dramatically enhance individual coping styles, life satisfaction, and sense of control (Compas, Slavin, Wagner, & Vannatta, 1986; A. Steptoe & Marmot, 2003; Suldo & Huebner, 2004; Thoits, 1982). These psychosocial resources serve as buffers against the cumulative cost of constantly adapting to environmental challenge (allostatic load; McEwen, 1995) and are known to reduce

the impact of stressful life events on adult health (Compas et al., 1986; Greenberg, Seltzer, Krauss, Chou, & Hong, 2004; B. H. Kaplan, Cassel, & Gore, 1977; Patterson & McCubbin, 1984). Stress has a direct effect on adult outcomes such as mental health and an indirect influence via the impact it has on relationships that constitute these psychosocial resources (McEwen, 2000; Thoits, 1982). Everything else being equal, an increase in the level of psychosocial stress results in a reduced availability of psychosocial resources (Ellis, 2004; S. E. Taylor & Seeman, 1999). Therefore, psychosocial stress not only puts wear and tear on an individual's physiology but also consumes valuable psychosocial resources. From an evolutionary perspective, coping with psychosocial stress is work, and like any other work, it requires resources, in this case, social-emotional resources.

In adulthood, the social support provided by family and friends is important for adjustment to life events (Runtz & Schallow, 1997). Across cultures, social support and social networks are associated with less depressive symptomatology during pregnancy and after childbirth (Byrd-Craven & Massey, 2013; O'Hara, 1986; Surkan, Peterson, Hughes, & Gottlieb, 2006). Furthermore, even for women in low-stress environments, intimate social support during pregnancy is commonly associated with improved birth outcomes (Hoffman & Hatch, 1996; Wakeel, Wisk, Gee, Chao, & Witt, 2013). While the evidence is not conclusive (Bryce & Stanley, 1991), several studies have shown that social support interventions during pregnancy can reduce the rate of low-birth-weight births (Norbeck, DeJoseph, & Smith, 1996). The association between social support and birth weight appears to operate through improved fetal growth rather than longer gestation (Feldman, Dunkel-Schetter, Sandman, & Wadhwa, 2000; Rothberg & Lits, 1991). In a study of 3,073 low-income women receiving general psychosocial services during pregnancy, social support was associated with a reduced risk of delivering low-birth-weight babies (Zimmer-Gembeck & Helfand, 1996). It is clear that people employ both adaptive (e.g., social support) and maladaptive (e.g., alcohol and nicotine) coping mechanisms. The interacting influence of prenatal stress and social support on fetal growth and development is mediated by poor maternal coping mechanisms that include risky health behaviors (Orr et al., 1996; Zuckerman, Amaro, Bauchner, & Cabral, 1989). Evidence suggests that social support and stress are important determinants of smoking (McCormick et al., 1990; Rodriguez, Bohlin, & Lindmark, 2000) and prenatal

weight gain (Hickey, 2000). It is the maladaptive coping strategies that elevate stress hormones, influence nutrition and exposure to toxins during pregnancy, and lead to poor fetal development (Sandman & Davis, 2010).

Maternal Stress During Pregnancy and Early Development

Before Barker advanced the fetal origins of adult disease (FOAD) paradigm in 1986, the question was *whether* stress during pregnancy could affect fetal or child development (Bryce & Stanley, 1991). However, because of his pioneering work and rapid progress in FOAD's successor, DOHaD, the questions now are: *How* does maternal stress affect the developing fetus or child, *what are the processes* whereby these early effects might predispose poor adult health, and *to what extent* do these adult effects constitute evolutionarily adaptive “programming” of the fetus's or child's developing physiology and organ systems by the intrauterine environment (Sandman, Davis, Buss, & Glynn, 2012)?

There is now abundant evidence that maternal psychosocial stress during pregnancy is a risk factor for abnormal pregnancy/delivery, fetal abnormalities, and poor adult health. The effects of stress on the mother include the premature rupture of membranes, preeclampsia, excessive weight gain, and preterm labor and birth (Dole et al., 2003; Newton, Webster, Binus, Maskrey, & Phillips, 1979); those on the fetus include reduced fetal growth and low birth weight (Newton & Hunt, 1984; Wadhwa, Sandman, Porto, Dunkel-Schetter, & Garite, 1993), which in turn are associated with increased infant and child morbidity and mortality, impaired psychological development, and increased morbidity in adulthood (Istvan, 1986; Tegethoff et al., 2010).

Virtually all research into the effects of maternal stress during pregnancy has used either subjective self-ratings of anxiety/depression or more objective measures of stressful life events. Intriguingly, however, because the two measures do not predict the same outcomes, different pathophysiology pathways seem to be involved (Pacak & Palkovits, 2001; Richardson, Zorrilla, Mandyam, & Rivier, 2006; Tegethoff et al., 2010). For this reason alone, research on prenatal influences must be multivariate, incorporating (a) objective indices of stressful life events, (b) individuals' subjective impressions of their stressors and their meaning, (c) their own and others' responses to these stressors, and (d) the biochemical, physiological, neuroendocrine, and immunological processes involved.

Biological Mechanisms of Maternal Stress

The steroid hormone cortisol is a key component of the HPA axis, the “fight-or-flight” response of all vertebrates. It has two evolutionary functions, one short-term, the other long-term. Its short-term function is to maximize the probability of survival in the face of some immediate threat. For example, negative life events typically (but not always, as is commonly thought) activate the HPA axis that stimulates the adrenal cortex to release glucocorticoids (cortisol). This response is adaptive in the short term in that it helps to maintain homeostasis in the face of environmental (including social-emotional) challenges (Cohen et al., 1995; McEwen, 1995; Repetti, Taylor, & Seeman, 2002; Selye, 1957; Tsigos & Chrousos, 2002; Wingfield & Sapolsky, 2003). Its long-term function is developmental: Cortisol is essential for immune function, glucose metabolism, and fetal (e.g., brain) development and the maturation of fetal organs (e.g., lungs; Lupien, McEwen, Gunnar, & Heim, 2009; Reynolds, 2013). Growing up in a chronically risky or uncertain environment entails chronic threats, chronic psychosocial stress, and chronic HPA activation. As we saw above (in “Life History Theory: Evolution and Development”), in chronically risky and uncertain environments the optimal reproductive strategy is the minimax strategy of maximizing current reproduction through accelerated development and early childbearing. Chronic psychosocial stress and high levels of cortisol “predict” risky or uncertain environments and may help to entrain evolutionarily adaptive developmental responses (Finch & Rose, 1995; Worthman, 1999; Worthman & Kuzara, 2005).

The stress response begins with the hypothalamus, which integrates the nervous and endocrine systems. Stress, defined as any challenge to the body's homeostasis (McEwen, 1995; Selye, 1957), activates the HPA axis. In response to a stressor, the hypothalamus releases corticotrophin-releasing hormone (CRH), a peptide hormone that travels through local blood vessels and binds to receptors on the plasma membranes of cells in the anterior pituitary gland. This stimulates the production of adrenocorticotropic hormone (ACTH), which enters the blood and travels around the body, having its primary influence on the cells of the adrenal gland. ACTH acts on the cortex of the adrenal gland to stimulate production of glucocorticoids (GCs), steroid hormones that include cortisol and corticosterone (Nakamura, Sheps, & Arck, 2008; Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume).

The hypothalamus also directly influences the adrenal gland medulla via the sympathetic nervous system. Neurons of the sympathetic nervous system from the hypothalamus synapse in the adrenal medulla and release the hormones epinephrine and norepinephrine. These hormones stimulate rapid, organism-wide responses to a stressor in the form of an elevation in heart rate, respiratory rate, and release of energy reserves in preparation for quick responses to environmental threats (Sapolsky, 1994).

Because steroid hormones can cross the plasma membranes of cells, the effects of glucocorticoids are mediated by glucocorticoid receptors (GRs), which have been identified in the cells of almost all tissues within the body. GCs regulate a variety of important functions and are essential for life in adult mammals. Excessive levels of GCs, however, potentially affect many internal systems by dysregulating biological homeostasis (Nakamura et al., 2008).

Fetal exposure to GCs and CRH are essential for fetal growth and development, but excess levels can be detrimental. During pregnancy, due to the elevation of maternal CRH levels, maternal GC production and secretion are increased. High levels of GC hormones are necessary due to their potent and long-term effects on cellular function in almost all organ systems, particularly in regard to cellular differentiation and homeostasis (Burton & Waddell, 1999). Later in pregnancy, exposure to GCs is essential for the maturation of fetal organs and systems (Ellman, Dunkel Schetter, Hobel, Glynn, & Sandman, 2008). Throughout pregnancy, while fetal and maternal neuroendocrine functions are largely independent, because of placental barriers to most maternal hormones, they still interact (Lester, Marsit, Conradt, Bromer, & Padbury, 2012). Approximately 10%–20% of maternal GCs cross the placenta to the fetus (Seckl & Meaney, 2006).

Gitau, Cameron, Fisk, and Glover (1998), examining the relationship between maternal and fetal cortisol levels, showed that, although fetal levels are lower than maternal levels (indicating the metabolism of 80%–90% of maternal cortisol by the placenta), they are correlated, but not with gestational age. Even so, a 10%–20% contribution of maternal cortisol to the fetus could still double fetal concentrations. This study also measured the amount of unmetabolized cortisol crossing the placenta at 15%. Although most cortisol is metabolized by the placenta, high maternal concentrations can affect fetal concentrations because 40%–50% of fetal cortisol is derived from the mother (Gitau et al., 1998). Cortisol also plays a central role in fetal programming of adult

disease (Harris & Seckl, 2011; Reynolds, 2013; Seckl & Holmes, 2007).

Circulating glucocorticoids (GCs) that potentially influence the tissues of the body are regulated by the 11 β -HSD enzymes: 11 β -HSD-2 inactivates cortisol, converting it to the inactive cortisone; conversely, 11 β -HSD-1 activates cortisone back into cortisol, increasing local GC levels in tissues. In the placenta, circulating maternal GCs, including cortisol, are metabolized by 11 β -HSD-2 into the inactive form, cortisone (Benediktsson, Calder, Edwards, & Seckl, 1997; R. W. Brown et al., 1996). These placental enzymes catalyze and modulate ligand access to the glucocorticoid receptor (GR). Therefore, the 11 β -HSD enzymes are referred to as the feto-placental barrier to maternal GCs. Because GCs are potent and have long-lasting effects, changes in the maternal environment that increase GC exposure may persist long after the original insult, thus acting on tissue accretion, differentiation, and programming of the fetal HPA axis (Fowden, Giussani, & Forhead, 2005), changing baseline levels for physiology, metabolism, and behavior (Lester et al., 2012; Seckl & Meaney, 2006).

Twenty years ago, Edwards, Benediktsson, Lindsay, and Seckl (1993) proposed that low levels of 11 β -HSD-2, and concomitant overexposure to maternal cortisol, reduced fetal growth and programmed adult disease risk. Since then, it has been shown that overexposure of GCs to the fetus reduces fetal growth, increases the risk of developing hypertension and metabolic disorders, and inhibits fetal HPA-axis development (Burton & Waddell, 1999; Seckl, 1997). Moreover, Stewart, Rogerson, and Mason (1995) showed a positive association between placental 11 β -HSD-2 activity and birth weight. In humans, 11 β -HSD-2 activity is inhibited by medical disorders involving increased fetal exposure to cortisol such as preeclampsia, maternal asthma, and intrauterine growth restriction (O'Donnell, O'Connor, & Glover, 2009). Moreover, a deficiency in 11 β -HSD-2 is associated with fetal growth restriction and increased risk of hypertension in adulthood (White, 2001). Maternal stress downregulates 11 β -HSD-2 in both animal and human studies (Glover, Bergman, Sarkar, & O'Connor, 2009; Mairesse et al., 2007). Thus, elevated levels of maternal stress can downregulate 11 β -HSD-2 activity, allowing more maternal cortisol to cross the placenta and reduce fetal growth.

Maternal environments that activate the HPA axis, thereby raising cortisol levels, can also affect CRH levels and lead to preterm birth. Questionnaire studies linking measures of perceived stress, stressful life events, racism, and domestic violence with preterm birth suggest that

maternal stress shortens gestation (Hoffman & Hatch, 1996; Istvan, 1986). Increased levels of stress hormones have also been associated with preterm birth (e.g., Wadhwa et al., 1993). Rather than suppressing CRH, as in the hypothalamus of nonpregnant individuals, the relation between GCs and CRH during pregnancy is stimulatory, with levels of both rising throughout gestation leading to parturition (Ellman et al., 2008; Reynolds, 2013; Sandman & Davis, 2010). In response to maternal cortisol, the feto-placental unit activates the placental CRH gene, increasing placental CRH synthesis and secretion to the fetus. This stimulates the maternal pituitary to release ACTH, and thus cortisol from the maternal adrenals. Maternal cortisol again stimulates CRH, creating a positive feedback loop and potentially high fetal exposure to GCs. By the end of pregnancy, cortisol levels are up to 3 times higher than nonpregnant levels.

High levels of CRH are also involved in the cascade of events resulting in myometrial activation and parturition, and thus preterm birth when this cascade is activated earlier in pregnancy. Preterm birth is directly correlated with low birth weight and suboptimal development of the brain and other tissues and organs. Resulting adverse outcomes include structural changes in the brain, negative temperament, impaired cognition, and the developmental programming of adult pathophysiologies such as metabolic and cardiovascular diseases (Mairesse et al., 2007; Reynolds, 2013; Sandman & Davis, 2010).

From an evolutionary perspective, however, maternal stress–induced preterm birth, low birth weight, and their resulting pathophysiologies may not—strictly speaking—represent pathology so much as the normal, evolutionarily adaptive response by mother and fetus to their respective risky or uncertain environments (Ellman et al., 2008). This may be so for three reasons: First, elevated maternal stress hormones, whether due to psychosocial stress, malnutrition, or exposure to environmental toxins (e.g., cadmium), may accelerate maturation of fetal organs and systems in preparation for a “predicted” shorter gestation. Second, in high-risk environments, where the probability of survival for the mother and fetus is reduced, maternal–fetal competition for resources increases and maternal stress hormones may allocate resources away from the fetus to the mother, resulting in fetal growth restriction but increasing the mother’s chance for “predicted” future reproduction (Haig, 1993; Stearns, 2005). A more moderate view of such maternal–fetal competition suggests that mother and fetus can “co-adapt” to each other as a unit, compromising on the allocation of maternal

resources (Kölliker, Royle, & Smiseth, 2012) so that nutrient flow to the fetus simply reflects maternal condition and access to resources (Coall & Chisholm, 2003; Jansson & Powell, 2007). Third, in all of the above, apparently detrimental maternal stress effects on the fetus might, at least sometimes, represent adaptive fetal programming for survival and growth and development (and thus, ultimately, reproduction) in the risky and uncertain environment that caused their mother’s stress in the first place and therefore “predicts” that such risk and uncertainty will continue in the future (Gluckman, Hanson, Spencer, & Bateson, 2005).

Stress During Pregnancy and Developmental Outcomes

The evolved human capacity for developmental plasticity means that maternal prenatal stress can have either, or both, deleterious effects on fetal development and future health as well as evolutionarily adaptive programming effects. The nature and duration of the maternal stress, together with the timing of impact during gestation, determines the severity of fetal developmental outcomes, depending on the stages of development and the number of organs and systems affected (Fowden et al., 2005). We review, below, a number of factors associated with stress during pregnancy to illustrate the diverse impacts prenatal stress can have.

Fetal brain development commences during the third week postconception with structural development of the central nervous system (CNS) extending to Week 20 of pregnancy, providing ample opportunity to incur insults that may result in impaired development (Kurjak, Medic, & Salihagic-Kadic, 2004; K. L. Moore, 1989). There is strong evidence that stress has an impact on fetal development of the brain and CNS, including effects on brain morphology, receptor density and sensitivity, CNS function, and the activity of the autonomic and neuroendocrine systems (Stanton, Lobel, Sears, & DeLuca, 2002). GCs play an important role in the survival and maturation of CNS neurons as different regions of the brain express GRs at different stages of development. This allows for selective effects of stress throughout gestation (Lupien et al., 2009; Nyirenda, 2006; Seckl & Meaney, 2006).

The fetal brain also appears to silence 11β -HSD-2 expression and activity during gestational Weeks 19 to 26, indicating the role of GCs in aspects of brain development (Nyirenda, 2006). Animal studies, including those involving primates, show that excessive GC exposure in utero influences hippocampal and related complex functions,

including cognition, behavior, memory, coordination of autonomic activity, and importantly, the regulation of the endocrine systems (Seckl & Meaney, 2006).

These programming effects on the hippocampus include fetal HPA-axis deregulation. Several studies have demonstrated that the HPA axis is sensitive to excessive GC exposure in utero, with repeated animal studies showing that excessive GC exposure during development permanently alters HPA-axis function, accounting for exaggerated HPA-axis reactivity in adulthood (Nyirenda, 2006). The hippocampus expresses both types of corticosteroid receptors (GRs). There is also evidence that increased levels of GCs are associated with decreased receptor expression in the hippocampus, resulting in hypersensitivity and increased reactivity of the HPA axis (Nyirenda, 2006; Seckl & Meaney, 2006). We turn now to the evidence that the impact of GCs on the CNS and HPA-axis reactivity translates into changes in postnatal behavior, cognition, and mental health.

Behavior, Cognition, and Mental Health

Mounting evidence shows that overexposure to GCs in utero leads to modifications in adult behavior in a number of species (Seckl & Meaney, 2006). In humans, prenatal exposure to elevated maternal stress hormones is associated with behavioral and emotional disturbances during both infancy and childhood (Sandman & Davis, 2010). In one of the first studies of the impact of prenatal stress on the subsequent behavioral adjustment of children, O'Connor, Heron, Golding, Beveridge, and Glover (2002) found, in a longitudinal sample of 7,448 pregnancies, that women who were in the highest 15% of the sample for anxiety at 18 or 32 weeks of pregnancy had children who were 2 to 3 times more likely to be 2 standard deviations above the sample mean for total behavioral and emotional problems at 4 years of age. The association between prenatal maternal anxiety and filial behavioral problems remained after controls for birth weight, potential maternal confounders (age, socioeconomic status), pregnancy-related anxiety, behavioral mediators (smoking and alcohol use), and postnatal (8 weeks) depression and anxiety. Barring the potential influence of maternal weight and postnatal parenting practices, this suggests that the influence of prenatal anxiety was direct (i.e., not through fetal growth, maternal behavioral modifications, or postnatal anxiety and depression). Significantly, prenatal anxiety and postnatal depression both independently predicted childhood behavioral and emotional adjustment problems, and this effect persisted to

7 years of age (O'Connor et al., 2002; O'Connor, Heron, Golding, & Glover, 2003). Unfortunately, the authors did not control for birth length, which has since been shown, in the same sample, to be negatively associated with total behavior difficulties, hyperactivity, and conduct problems at 7 years of age (Wiles et al., 2006). Subsequent to these studies, a veritable feast of investigations have examined these associations in detail and analyzed the physiological processes involved. A likely process is reprogramming of the fetal HPA axis in response to maternal stress.

Maternal prenatal stress and cortisol may reprogram the postnatal HPA axis, influencing adult phenotypes. Maternal cortisol levels, and by association maternal stress and nutrition levels, increase the activation of the HPA axis postnatally. In a sample of 116 mother–term infant dyads, Davis, Glynn, Waffarn, and Sandman (2011) found an increased cortisol reaction to the newborn heel prick test (blood draw) in the neonates of women who had higher cortisol levels during the second half of pregnancy. This association remained evident after adjustment for maternal medical history, socioeconomic status, ethnicity, and sex of the child. Similarly, in 29 mother–child dyads, maternal cortisol and prenatal anxiety levels mid-pregnancy were associated with elevated cortisol levels in response to the first day of a new school year (Gutteling, de Weerth, & Buitelaar, 2005). Such resetting of the HPA axis has consequences for postnatal health and we next examine a specific example: attention-deficit/hyperactivity disorder (ADHD).

A multitude of prenatal and postnatal risk factors, including low birth weight, smoking, alcohol use, stress during pregnancy, and insensitive or abusive parenting increase the risk of ADHD and disruptive behavior disorders (DBDs; Latimer et al., 2012). Some studies have managed to examine the independent impact of maternal stress on ADHD. One of the most striking examples involves a twofold increase in ADHD symptoms in children whose mothers were pregnant during, but not exposed to, the Chernobyl disaster in 1986 (Huizink et al., 2007). Similarly, in the Avon Longitudinal Study of Parents and Children (ALSPAC), prenatal anxiety at 32 weeks gestation was associated with an increased risk of inattention/hyperactivity at 4 years of age (O'Connor et al., 2002). And in a more recent prospective study of 1,247 Finnish children, maternal depression at 10 and 28 weeks of gestation were associated with externalizing problems on the Child Behavior Check List, while maternal postnatal factors (illness, tiredness, and anxiety) were associated with internalizing problems at 12 years of age (Pihlakoski et al.,

2013). As with several other programming effects, there is intriguing evidence of sexual dimorphism in the impact of the maternal environment. For example, Rodriguez and Bohlin (2005) found that maternal stress at 10 weeks of gestation was associated with ADHD symptoms at 7 years, but only in boys. Likewise, examination of a Finnish birth cohort revealed that several measures of placental size were associated with ADHD symptoms in boys, but not girls, at 8 and 16 years (Khalife et al., 2012). These sex differences are intriguing and are consistent with animal and human models and may be underpinned by epigenetic processes.

A consistent finding in the DOHaD literature is that boys are more susceptible to environmental insults during pregnancy than girls (D. Barker, 2003). Male biased effects of prenatal exposures have been found for schizophrenia, autism spectrum disorders, and anxiety (see Bale, 2011). Perhaps, as the faster-growing sex, males are more vulnerable. A possible mechanism underlying the differing impact of maternal stress on the male and female postnatal phenotype is altered sensitivity to GCs. Across several species, females appear to be more resistant and males appear to be more sensitive to GC exposure (Phillips & Matthews, 2011; Seckl & Holmes, 2007). Evidence of differential activation of the HPA axis has been found in animal studies (Liu, Li, & Matthews, 2001). Detailed analyses in mice show that the male vulnerability to prenatal stress, resulting in increased emotionality postnatally, may be attributable to increased placental responsivity with an upregulation of placental gene expression found in the placentae of male but not female mice (Mueller & Bale, 2008). Moreover, the prenatal stress influenced placental epigenetic processes resulting in increased expression of DNA methyl transferases and methyl-binding proteins in the male but not female placentae. Thus, the sex-specific effects of maternal stress on postnatal phenotypes may be transduced via epigenetic processes in the placenta.

What, if anything, do evolutionary models say regarding sex-specific effects? An evolutionary model, sex allocation theory (Charnov, 1982), proposed that, when maternal condition is poor, investment of resources should be allocated to the offspring sex that requires the least investment. As sons grow faster and require more resources to produce, under conditions of prenatal stress the maternal physiology may preferentially allocate resources away from male fetuses and thus increase their sensitivity to environmental insults. Crucially, for this argument, stress hormones appear to provide the link between the maternal condition and the allocation of resources. In a study of European starlings,

Love, Chin, Wynne-Edwards, and Williams (2005) found that elevated maternal corticosterone levels were associated with biasing allocation of resources toward females, with males experiencing higher mortality and being lighter at hatching. This suggests that maternal condition during pregnancy may have sex-specific effects on the postnatal phenotype, including mental and physical health.

PRENATAL NUTRITION, FETAL DEVELOPMENT, AND OFFSPRING PHENOTYPE

No discussion of prenatal development is complete without examining the impact of maternal nutrition on the fetus and its postnatal phenotype. For the vast majority of human history, the primary concern has been malnutrition. Now, with the emergence of the obesity epidemic, overnutrition is of increasing concern (Wells, 2012). Unfortunately for the developing fetus, both maternal under- and overnutrition provide suboptimal environments that can affect early development and lifelong health (Ojha, Robinson, Symonds, & Budge, 2013). Even in well-nourished populations, an imbalanced diet can affect fetal development, and, if not in the form of reduced growth during pregnancy, it can still influence postnatal health (D. Barker, 2003; Kind, Moore, & Davies, 2006). Below, we briefly examine iron, folate, and calcium, important components of the maternal diet, before looking at the consequences of maternal nutrition for postnatal phenotypes.

Iron

Iron deficiency is the most common nutrient deficiency among pregnant women (Guilbert, 2003). The prevalence of anemia among pregnant women worldwide is estimated to be 41.8%, with iron deficiency the leading cause (McLean, Cogswell, Egli, Wojdyla, & Benoit, 2009). Iron demands during pregnancy increase rapidly, especially late in gestation. Peak gastrointestinal iron absorption in pregnant women occurs in the third trimester (Barrett, Whittaker, Williams, & Lind, 1994), concurrent with the increased iron transfer to the fetus. In the absence of adequate maternal iron status, the placenta increases the number of transferrin receptors in order to enhance placental iron absorption in an attempt to maintain adequate iron transfer to the fetus (Cetin, Berti, Mandò, & Parisi, 2011).

Maternal iron deficiency early in pregnancy is associated with an increased risk of low birth weight and preterm delivery (Chang, O'Brien, Nathanson, Mancini, &

Witter, 2003; Scanlon, Yip, Schieve, & Cogswell, 2000). The relationship, however, appears to be U-shaped, with high maternal hemoglobin concentrations in early to midgestation also associated with increased risk of adverse birth outcomes, including preterm birth and low birth weight (Chang et al., 2003; Scanlon et al., 2000).

Iron is required for a number of physiological processes crucial to development, including oxygen transport, energy production, and notably, brain development. Dietary iron deficiency during prenatal development in animal models leads to an alteration in the composition and quantity of neuronal myelin sheaths (Ortiz et al., 2004). Similarly, iron is required for the synthesis of the neurotransmitters serotonin (Martinez, Knappskog, & Haavik, 2001) and dopamine and norepinephrine (Nagatsu, 1995).

Iron deficiency during infancy is associated with long-lasting effects on neurocognitive outcomes, including decreased executive function at the ages of 5, 10, and 19 (Lozoff et al., 2006). While there is a paucity of data regarding the effects of maternal iron deficiency on cognitive function in their offspring, impaired myelination is a potential cause. One study in a rural area of Nepal with a high prevalence of anemia observed improved general intellectual functioning, executive function, and motor skills in 7- to 9-year-old children following maternal supplementation with iron and folic acid compared with a control group (Christian et al., 2010). These findings point to a role for maternal iron deficiency in pre- and postnatal development.

Folate

Folate (folic acid) is an important factor in fetal development because it is involved in a number of biological processes, including acting as a cofactor for many essential cellular reactions, such as amino acid metabolism, DNA synthesis, DNA methylation, and red blood cell production. Fetal development is a time of rapid and sustained cell division and thus the demand for folate increases during this period (McPartlin, Halligan, Scott, Darling, & Weir, 1993). In the absence of adequate dietary folate intake and/or folic acid supplementation, maternal serum and erythrocyte folate concentrations decrease from midpregnancy onward and continue to decline postpartum (Qvist, Abdulla, Jägerstad, & Svensson, 1986).

The implications of maternal folate nutrition on fetal growth have been investigated in a number of studies worldwide which have, however, differed with respect to the baseline levels of maternal folate intake and the inclusion

of supplementation, in the timing of the intervention and dosage used (Baumslag, Edelstein, & Metz, 1970; Blot, Papiernik, Kaltwasser, Werner, & Tchernia, 1981; Czeizel, Dudas, & Metneki, 1994; Fleming, Martin, Hahnel, & Westlake, 1974; Giles, Harcourt, & Whiteside, 1971; Iyengar & Rajalakshmi, 1975; Rolschau et al., 1999). Nonetheless, taken together, these studies support the view that adequate folate intake promotes fetal growth. The clearest finding regarding folate nutrition in pregnancy is that peri-conceptual folic acid supplement use reduces the risk of neural tube defects (e.g., spina bifida) by almost three-quarters (Lumley, Watson, Watson, & Bower, 2001).

Calcium

Maternal calcium intake during pregnancy is inversely associated with the development of hypertension during pregnancy (Ortega, Martinez, Lopez-Sobalar, Andres, & Quintas, 1999; Villar, Belizan, & Fischer, 1983). The benefits of calcium supplementation during pregnancy for hypertensive conditions has been demonstrated in a number of studies, with decreases in the incidence of preeclampsia and hypertension calculated in meta-analyses to be 52%–55% and 25%–35%, respectively (Hofmeyr, Lawrie, Atallah, & Duley, 2010; Imdad & Bhutta, 2012). Maternal calcium supplementation during pregnancy has also been associated with increased birth weight in populations with a low calcium intake, a finding consistent with the reduction in gestational hypertensive disorders (Imdad & Bhutta, 2012). In both of these cases, however, studies conducted in populations with adequate baseline calcium intake (Australia and United States) demonstrated no effect on fetal growth (Crowther et al., 1999; Levine et al., 1997). Furthermore, a decreased incidence of preterm birth has been associated with calcium supplementation and, unlike other birth outcomes, this association was seen in populations with both low and adequate baseline calcium intake (Imdad & Bhutta, 2012).

Nutrition and Fetal Programming

Nutrition is a key determinant of fetal growth and size at term. The initial findings by D. J. P. Barker (1994), linking small size at birth and chronic adult diseases such as hypertension, diabetes, and cardiovascular disease, were thought to result from an imbalance between the maternal supply and fetal demand for nutrients during pregnancy (Phillips, 2004). This hypothesis is now supported by evidence from animal studies (Eriksson, Forsen,

Tuomilehto, Osmond, & Barker, 2003) and longitudinal epidemiological investigations of diet during pregnancy in humans (Ojha et al., 2013; Phillips, 2004).

Prenatal brain development is dependent on adequate nutrition (C. D. Walker, 2005). It is now apparent that the impact of maternal nutrition also extends to mental health outcomes. Prenatal exposure to the Dutch Hunger Winter (1944–1945) in the second or third trimester was associated with an increased risk of affective disorders in both males and females (A. S. Brown, van Os, Driessens, Hoek, & Susser, 2000). In a study of 23,020 Norwegian women, Jacka et al. (2013) found that higher intake of unhealthy foods during pregnancy was associated with increased levels of externalizing problems at 1.5, 3, and 5 years of age. This relation held after adjustment for a range of confounds, including socioeconomic status, depression during pregnancy, and children's postnatal diet. Similarly, in a nonhuman primate model, maternal nutrient restriction during pregnancy was associated with juvenile attentional and behavioral problems (Keenan et al., 2013). Together, these studies highlight a potential role of nutrition during pregnancy for mental health disorders.

The evidence that small size at birth is associated with poorer adult mental and physical health outcomes is substantial. The proximate processes by which these effects could be transmitted throughout a life span, however, are not completely understood. A likely candidate is that maternal undernutrition, like maternal prenatal stress, reprograms the HPA axis and has consequences for postnatal health (Phillips & Matthews, 2011). This makes sense because glucocorticoids are involved in both the stress response and the liberation of glucose for the cells of the body. In a meta-analysis of 11 studies ($N = 2,311$), lower birth weight was associated with higher levels of cortisol during childhood (van Montfoort, Finken, le Cessie, Dekker, & Wit, 2005). Increased stress reactivity to the Stroop Test has also been detected in a study of 721 people who were exposed to the Dutch Hunger Winter prenatally (Painter et al., 2006). In animal models, maternal undernutrition during pregnancy has been associated with the increased expression of glucocorticoid receptor 11β -HSD-1 and the decreased expression of 11β -HSD-2 suggesting programming of gene expression related to the HPA axis (Whorwood, Firth, Budge, & Symonds, 2001). Other areas of interest involve pathways such as the immune process and inflammation during pregnancy, which are also crucial to reproduction, interact with the HPA axis, and contribute to human life history trade-offs (Clancy, 2013; Entringer et al., 2012; McDade, 2005).

Researchers rarely consider that stress hormones may also have a behavioral effect on maternal nutrition. While there is ample evidence in humans that stressful events or administration of CRH increase the eating of comfort food, there has been no study examining the impact of maternal stress on nutritional intake during pregnancy and child outcomes (Entringer et al., 2012). Thus, evidence supports the hypothesis that maternal nutrition influences childhood mental and physical health by reprogramming the HPA axis.

Epigenetics as a Potential Organizing Mechanism

Epidemiological data and evolutionary theory suggest that insults during one generation can have consequences for the growth and development of second- and third-generation descendants (e.g., Bateson et al., 2004; Coall & Chisholm, 2003; Kuzawa, 2005; Ounsted et al., 1986). During development in mammals, there is extensive DNA methylation. Evidence suggests that the majority of methylation occurs during the development of the germ cells (future sperm and ovum) and in the early embryonic cells forming the blastocyst (Reik, Dean, & Walter, 2001; Schaefer, Ooi, Bestor, & Bourc'his, 2007). This methylation follows periods of demethylation in which the epigenetic markers are thought to be "wiped clean" and reset.

The processes responsible for fetal growth and intrauterine programming are regulated by placental nutrient transport. Placental inefficiency is also associated with epigenetic modifications. Jansson and Powell (2007) reported that restriction of protein in the maternal diet of rats induced epigenetic changes in specific genes, the glucocorticoid receptors in the liver of the offspring. Furthermore, genes expressed in the placenta may undergo epigenetic modification in response to disturbances in the maternal compartment due to direct exposure to maternal blood. The methylation of certain genes, such as the trophoblast genes, also results in altered placental structure and function. The effects of methylation due to maternal stressors have direct effects on placental morphology and fetal programming. Nyirenda (2006) suggested that the expression of 11β -HSD-2 is regulated by epigenetic mechanisms (DNA methylation).

PRENATAL TOXINS, TERATOGENS, AND DEVELOPMENT

Research on prenatal development in human evolutionary ecology, life-course epidemiology, and the DoHAD

paradigm predominately focus on maternal stress and nutrition. A stressor often ignored in these analyses, possibly because of the disruptive rather than adaptive nature of exposure, are toxins and pollutants. Just as lower socioeconomic groups are more likely to experience higher levels of prenatal stress and poor nutrition during pregnancy, they are also more likely to be exposed to environmental pollutants (e.g., smoking, workplace, diet). Epigenetic analyses have examined all three of these environmental exposures in relation to health inequalities (Thayer & Kuzawa, 2011). A number of potentially toxic substances are present in the environment as a result of agricultural and industrial practices. Many of these substances persist in the environment and accumulate over time. Human exposure arises through multiple pathways including direct contact with soils, inhalation of particulate matter and household dust, dermal contact, and the consumption of contaminated food or drinking water. In this section we highlight some pollutants and their influence on prenatal development.

Pollutants of Emerging Concern

Unlike many environmental toxicants, metals are naturally occurring, but their concentrations increase as a result of anthropogenic activities. A number of metals have been identified as detrimental to fetal development, if exposure occurs at sufficiently elevated levels. The heavy metals, lead and mercury, have been most widely studied with the adverse effects of these neurotoxicants on developing nervous systems now well established (e.g., Grandjean et al., 1997; Lanphear et al., 2005). However, prenatal exposure to several other metals has also been associated with health effects and, in the case of metals such as cadmium, the effects of low-level exposure are only now being elucidated (e.g., Ciesielski et al., 2012). In addition, there are a number of emerging chemicals of concern, including polybrominated flame retardants, bisphenol A, phthalates, and perfluorinated compounds. These chemicals linger in the human body less than many of the metals, but exposure is widespread, which makes any health effects arising from exposure a significant health concern at the population level. We discuss these pollutants next.

Cadmium

Exposure to cadmium is widespread, with diet and tobacco smoke the major sources. Studies in Japan and China have provided evidence of an inverse relationship between maternal environmental cadmium exposure and fetal

growth (Nishijo et al., 2004; Shirai, Suzuki, Yoshinaga, & Mizumoto, 2010; Zhang et al., 2004). To date, the largest study of the effects of prenatal cadmium exposure on birth outcomes recruited 1,616 mother-infant pairs in rural Bangladesh. Maternal urinary cadmium concentrations, a marker of long-term exposure, were negatively associated with birth weight and head circumference (Kippler et al., 2012). However, stratified analyses revealed that these relationships were exclusively observed with female infants (Kippler et al., 2012). One potential mechanism for this negative effect of cadmium on fetal growth could be that cadmium reduces the expression of 11 β -HSD-2 in human placental trophoblast cells (Yang, Julian, Rubio, Sharma, & Guan, 2006). As detailed above, this placental enzyme protects the fetus from circulating maternal glucocorticoids by converting them to inactive metabolites, and reduced activity of 11 β -HSD-2 has been implicated in intrauterine growth restriction (Shams et al., 1998). Sex-specific effects of 11 β -HSD-2 reduction and impaired fetal growth have been seen following maternal glucocorticoid treatment (Murphy et al., 2003), lending further credence to this possibility.

In terms of neuro-behavioral effects, cord blood cadmium concentrations were negatively associated with both full and performance IQ scores in a study of Chinese children aged 4.5 years (Tian et al., 2009). Furthermore, childhood urinary cadmium concentrations have been associated with the learning disabilities or placement in special education programs in a large representative U.S. cohort of children aged 6–15 years (Ciesielski et al., 2012). However, given the long-term exposure represented by measures of urinary cadmium (biological half-life of 30 years) and the cross-sectional nature of the study, it is unclear whether or not prenatal exposure contributed to this effect.

Tobacco Smoke

Maternal smoking during gestation is known to result in reduced fetal growth, with a decrease of approximately 200 g in infants born to smoking mothers relative to those born to nonsmokers (Rogers, 2009). Tobacco smoke contains more than 4,000 chemicals, one of which is cadmium and hence cadmium may, as discussed previously, play a role in this reduction in birth weight.

Prenatal tobacco exposure was significantly associated with ADHD in a study of 4,704 U.S. children (Braun, Kahn, Froehlich, Auinger, & Lanphear, 2006). Analysis of a nationally representative sample of 8- to 15-year-olds revealed a greater than eightfold increased risk of ADHD

for children who had both prenatal environmental tobacco smoke exposure and postnatal lead exposure (Froehlich et al., 2009), demonstrating the importance of environmental exposures for this prevalent health condition.

A meta-analysis of 14 studies conducted worldwide with a total of over 84,000 children aged 2 years and above revealed that maternal smoking during pregnancy was associated with an elevated risk of the offspring being overweight at the ages of 3–33 years (Oken, Levitan, & Gillman, 2008). Notably, the odd ratios were almost unchanged when adjusted for a range of factors, including parental socio-demographic factors, signifying that social and behavior differences between smokers and nonsmokers were unlikely to account for the increased risk (Oken et al., 2008). Maternal smoking during pregnancy has also been associated with an increased risk of early onset of type 2 diabetes in young adults (Montgomery & Ekbom, 2002) and early onset of puberty in males (Fried, James, & Watkinson, 2001).

Although discussions of prenatal exposures tend to focus on maternal exposures, onset of paternal smoking prior to puberty has been associated with an increase in body mass index (BMI) in male offspring at the age of 9 years, with the effect most pronounced if fathers started smoking when they were aged 10 years or under (Pembrey et al., 2006). This provides compelling evidence of a male-line transgenerational effect.

Polybrominated Diphenyl Ethers

Polybrominated diphenyl ethers (PBDEs) are used as flame retardants in a variety of consumer products including electrical products, computers, upholstery, soft furnishings, polyurethane foams, and children's clothing. There are many PBDE congeners and, due to the differing structures, they are likely to differ in their potential to cause adverse health effects following exposure.

Due to the persistent lipophilic nature of PBDEs, breast milk reflects the body burden of the mother and can therefore be considered an indicator of prenatal exposure. Associations have been observed between PBDE concentrations in breast milk and adverse birth outcomes, with increased PBDE concentrations (BDE-47, -99, -100, and -209) associated with decreased birth weight, birth length, and chest circumference in infants (Chao, Wang, Lee, Wang, & Papke, 2007). Umbilical cord blood PBDE concentrations of BDE-28, -47, -99, -153, -183, and Σ PBDE levels were higher in Chinese infants with adverse birth outcomes (including premature delivery, low birth weight, and stillbirth) than in normal births (Wu et al.,

2010). In addition, higher concentrations of BDE-47, -99, and -100 in maternal serum collected in the second trimester were found to be associated with decreased birth weight in a cohort of low-income Mexican families residing in California (CHAMACOS cohort); with each tenfold increase in maternal concentration of the congeners associated with decreases in birth weight of 115, 114, or 121 grams, respectively (Harley et al., 2011).

A Danish-Finnish study investigated breast milk and placenta PBDE concentrations as two indicators of prenatal exposure, and congenital cryptorchidism in male infants at the age of 3 months (Main et al., 2007). The sum of seven PBDE congeners in breast milk was found to be significantly higher in cryptorchid boys than controls, although this association was not evident in placental PBDE concentrations. In this study, a positive correlation between the sum of PBDE congeners and serum luteinizing hormone in infants was also observed, suggesting a potential ability for prenatal exposure to PBDEs to interact with sex hormones during fetal development.

The ability for prenatal exposure to PBDEs to influence neurodevelopment has been examined. Significant negative associations were observed between higher cord blood PBDEs and neurodevelopmental outcomes in younger children in a New York cohort, with decreases observed in Psychomotor Development Index scores at 12 months (BDE-47), Mental Development Index scores at 24 months (BDE-47, -99, and -100), 48-month Full IQ scores (BDE-47, -100, and -153), Verbal IQ scores (BDE-47 and -100) and Performance IQ scores (BDE-100 and -153). Adverse neurodevelopmental effects associated with increased cord-blood PBDE concentrations were also detected in older children, with decreased Full and Performance IQ scores at 72 months (Herbstman et al., 2010). Furthermore, prenatal exposure to Σ PBDEs was associated with poorer attention and fine motor coordination and decrements in Verbal and Full-Scale IQ in 7-year-olds in the Center for the Health Assessment of Mothers and Children of Salinas (CHAMACOS) cohort in California (Eskenazi et al., 2013). Environmental exposure to PBDEs in the United States, particularly in California, is considerably higher than in Europe, Asia, or Australia, but similar results were observed in a Dutch cohort with a negative association observed between prenatal PBDE exposure (BDE-47, -99, and -100) and attention in children at the age of 5–6 years (Roze et al., 2009). Differences in coordination, visual perception, and behavior were also reported to be associated with in utero PBDE exposure in this cohort (Roze et al., 2009). Concentrations of BDE-209 in breast

milk have been associated with cognitive impairment in infants in cohorts in Spain (Gascon et al., 2012) and Taiwan (Chao, Tsou, Huang, & Chang-Chien, 2011).

PBDE exposure is associated with thyroid hormone concentrations, with increased serum concentrations of congeners BDE-28, -47, -99, -100, and -153 and Σ PBDEs in pregnant women associated with decreased levels of thyroid-stimulating hormone (TSH) (Chevrier et al., 2010). The odds of subclinical hyperthyroidism were also increased by exposure to BDE-100, BDE-153, and Σ PBDEs, although these relationships were not statistically significant (Chevrier et al., 2010). The effects of maternal subclinical hyperthyroidism on fetal development remain to be shown, although an increased odds ratio of infant hearing dysplasia was reported in a Chinese study (Su et al., 2011).

Bisphenol A

Bisphenol A (BPA) is a ubiquitous chemical used in the manufacture of polycarbonate plastics and epoxy resins. It is found in a number of types of food packaging, including in the lining of tins. Biomonitoring in developed countries has revealed that BPA is present at detectable concentrations in the majority (usually $> 85\%$) of urine samples tested, indicating that exposure is now widespread. BPA has been shown to transfer across the human placenta, mainly in the active unconjugated form (Balakrishnan, Henare, Thorstensen, Ponnampalam, & Mitchell, 2010; Morck et al., 2010). BPA is known to have detrimental effects on placental cells, with low, environmentally relevant, doses of the chemical inducing apoptosis in placental trophoblasts via increased expression of tumor-necrosis factor α (TNF- α) (Benachour & Aris, 2009) as well as altering the microRNA expression in cells derived from the first trimester placenta, with suggestions that this may alter the DNA repair capabilities of these cells (Avissar-Whiting et al., 2010).

Consistent with the effects of BPA on placental cells, prenatal BPA exposure has been associated with adverse birth outcomes. The studies to date, however, have been limited, their results are inconsistent, and differing methodologies preclude direct comparisons. Concentrations of BPA in maternal urine during pregnancy were negatively associated with fetal head circumference and fetal weight in a Dutch study (Snijder et al., 2013). This is in contrast to an earlier French study that identified a positive association between maternal urinary BPA collected between weeks 24 and 30 of gestation and the head circumference of

infants at birth (Philippat et al., 2012). Furthermore, a third study, in which maternal urinary BPA concentrations were sampled in the third trimester, demonstrated no significant associations with birth weight or head circumference in the offspring (Wolff et al., 2008).

Because BPA concentrations in maternal urine are known to vary during pregnancy (Braun, Kalkbrenner, Calafat, Bernert, et al., 2011), exposure misclassification is possible when samples are collected at a single time point. Equally, the specific window of vulnerability to BPA exposure in terms of fetal growth outcomes is unknown. It is important to note that the negative associations between maternal urinary BPA concentrations and fetal weight and head circumference in the Dutch cohort were based on urine samples collected at multiple time points during pregnancy, with restriction of analysis to those participants with three urine samples collected across their pregnancy, increasing the probable reliability of the associations identified (Snijder et al., 2013).

Using blood BPA as a measure of exposure, a birth cohort study in Taiwan identified that higher maternal blood BPA concentrations at delivery were associated with an increased risk of low birth weight ($< 2,500$ g) or small for gestational age (birth weight less than 10th percentile compared with national data matched for gestational age and gender of infant). This relationship was significant for male infants only, and remained so after the odds ratios were adjusted for maternal age, BMI, smoking, socioeconomic status, and the maternal lipid blood profile (Chou et al., 2011).

Although BPA has been shown to exert both estrogenic and antiandrogenic effects in animal models, with morphological changes in the male reproductive organs reported, there is a paucity of data demonstrating endocrine disrupting effects of BPA in humans. Maternal occupational exposure to BPA during pregnancy was associated with a shortened anogenital distance in male offspring in a Chinese study of epoxy resin manufacturers (Miao et al., 2011). Similarly, in Chinese men (with and without occupational exposure) urinary BPA concentrations have been associated with declining male sexual function (Li et al., 2010), decreased semen quality with reduced sperm concentration, sperm vitality and motility, and total sperm count (Li et al., 2011), and alterations in sex hormone concentrations (Zhou et al., 2013). Although these cross-sectional studies measured adult exposure, the observed outcomes suggest that further research into the potential effects of prenatal BPA exposure on male sexual development is warranted.

The first birth cohort study to investigate prenatal BPA exposure and neurodevelopmental effects in humans demonstrated an association between maternal urinary BPA concentrations, collected early in the second trimester of pregnancy (Week 16) and externalizing behavior in girls at 2 years of age (Braun et al., 2009). This cohort from Ohio was followed until the age of 3 years, at which point behavioral and emotional regulation were associated with prenatal BPA exposure, with maternal urinary BPA concentrations associated with anxiety, depression, and hyperactivity, with the effects again restricted to girls (Braun, Kalkbrenner, Calafat, Yolton, et al., 2011). However, a second cohort of African American and Dominican mothers residing in New York City (Columbia Center for Children's Environmental Health, CCCEH cohort) found that prenatal BPA exposure, assessed by maternal urinary concentrations at around Week 34 of gestation, was positively associated with emotionally reactive and aggressive behavior in boys at the ages of 3–5 years (Perera et al., 2012). Among girls in this cohort, high BPA exposure was associated with lower scores for anxious/depressed and aggressive behavior, indicating fewer problems in these areas in girls with higher BPA exposure (Perera et al., 2012). The reasons for the disparities between the two cohorts are unclear, although the timing of exposure assessment and the tools utilized in the assessment of child behavior differed between the two cohorts.

In terms of other health outcomes, early second-trimester maternal urinary BPA concentrations have also been associated with parental reports of childhood wheezing early in life, with the effects seen in children between 6 months and 3 years of age (Spanier et al., 2012). In vitro experiments have revealed the ability of BPA to inhibit adiponectin release from human adipose tissue (Hugo et al., 2008). Consistent with this, urinary BPA concentrations have been associated with risk of overweight and obesity in children in both U.S. and Chinese studies, although the effect has not been consistently found in both males and females (Bhandari, Xiao, & Shankar, 2013; Li et al., 2013). However, the potential for prenatal BPA exposure to promote obesity in humans has not been explored.

Phthalates

Phthalates are used in a wide range of consumer products. For example the high molecular weight di(2-ethylhexyl) phthalate (DEHP) is used as a plasticizer in the manufacture of polyvinyl chloride, whereas low molecular weight phthalates such as diethyl phthalate (DEP) and dibutyl

phthalate (DBP) are used in cosmetics and other personal care products. Animal models have demonstrated that prenatal exposure to DEHP, DBP, or benzyl butyl phthalate (BzBP) has a marked effect on fetal Leydig cells, reducing the production of fetal testosterone and insulin-like growth factor 3 (Insl-3) (Foster, 2006). These effects are responsible for a syndrome of male reproductive abnormalities, including shortened anogenital distance, hypospadias, cryptorchidism, and malformations of the epididymis, vas deferens, seminal vesicles, and prostate (Foster, 2006). In rats, the programming window in which androgen action is required for the normal development and masculinization of the reproductive tract has been identified, and this window is believed to correspond to 8–14 weeks gestation in humans (Welsh et al., 2008), although exposure studies have yet to confirm this.

There is currently limited human data regarding the potential for in utero antiandrogenic activities of phthalates on male reproductive tract development. A multicenter U.S. study found that the concentrations of five urinary phthalate metabolites (MEP, a metabolite of DEP, MBP, a metabolite of DBP, and three metabolites of DEHP, the monoester MEHP and the oxidative metabolites MEOHP and MEHHP) assessed in maternal urine collected during gestation (mean week 28.6) were inversely related to anogenital distance in male offspring (mean age at assessment 12.8 months) (Swan, 2008). DEHP metabolite concentrations in maternal urine were also associated with decreased penile width and impaired testicular descent (Swan, 2008). A study in Taiwan of 65 mother–infant pairs measured phthalate monoesters in amniotic fluid collected during routine amniocentesis and categorized infants as high- or low-phthalate exposure based on the median concentrations of individual phthalate monoesters. This study reported significantly shorter anogenital distances in newborn female infants with high as opposed to low monobutyl phthalate (MBP) exposure (Huang, Kuo, Chou, Lin, & Lee, 2009). The relation remained significant after adjustment of the anogenital distance for birth weight and birth length. In contrast to the work of Swan, no relationship between MBP or MEHP in amniotic fluid and anogenital distance was observed in male newborn infants in the Taiwanese study (Huang et al., 2009), although the biological matrix assessed and the timing of both exposure and outcome assessments differed in these two studies. Anogenital distance has been identified as a strong predictor of multiple semen parameters in adult men, which suggests that this measure is a good indicator of male reproductive function (Mendiola, Stahlhut, Jorgensen, Liu, & Swan, 2011).

This demonstrates the possible effects of prenatal phthalate exposure on male reproductive development at the population level; however, there is little information available regarding influences on female reproductive development.

Studies investigating the potential effects of phthalates on the length of gestation and fetal growth have also obtained mixed results. Cord-blood DEHP/MEHP concentrations were associated with decreased duration of pregnancy in an Italian study of 84 newborns, with no effect of phthalate exposure on birth weight detected in this study population (Latini et al., 2003). Similarly, a case-control study of Mexican women and their infants identified higher concentrations of phthalate metabolites in maternal third-trimester urine samples in those who delivered preterm (<37 weeks), with preterm birth cases having elevated odds for having phthalate metabolite concentrations above the median for each of the metabolites analyzed (Meeker et al., 2009). Although correction of urinary phthalate metabolites for specific gravity or creatinine attenuated the odds ratios somewhat, they did remain elevated for certain metabolites, most notably MBP and the sum of DEHP metabolites (MEHP, MEOHP, MEHHP, and MECPP) (Meeker et al., 2009). Furthermore, an inverse association between third-trimester urinary MEHP concentrations and length of gestation was also identified in a study of 311 African American and Dominican women from the CCCEH cohort, with a ~1-day decrease in the length of gestation with each 1 logarithmic unit increase in MEHP (Whyatt et al., 2009). The results for other DEHP metabolites (MEHHP, MEOHP, and MECPP) and the sum of all DEHP metabolites were similar in this study. Conversely, a multicenter U.S. study of 283 pregnant women found that gestation was increased by ~1 day with each logarithmic unit increase in urinary concentrations of the DEHP metabolites MEHP and MEOHP (Adibi et al., 2009). The authors reported that increased concentrations of these metabolites were also associated with increased odds of delivering at 41 weeks or later and of undergoing caesarean section and reduced odds of preterm delivery (<37 weeks) (Adibi et al., 2009). The reasons for the discrepancy between these studies remain unclear.

While the effect sizes were small, a U.S. study reported a positive association between prenatal exposure to low molecular weight phthalates and increased duration of pregnancy and infant head circumference (Wolff et al., 2008). Similarly, concentrations of MBP in amniotic fluid above the median (85 ng/ml) were associated with higher birth weight and birth length in a Taiwanese study (Huang et al., 2009).

Equally, some studies have reported null findings, with no associations observed between maternal urinary phthalate metabolite concentrations and birth outcomes in a study of 149 Japanese women and their infants (Suzuki et al., 2010). However, the timing of maternal spot urine sample collection was not consistent in this study (ranging between 9th and 40th weeks gestation). A French study also found no evidence of a monotonic association between phthalate metabolites and birth outcomes (Philippat et al., 2012).

Conversely, a Chinese study reported a significant increase in the risk of low birth weight (<2,500 g) with higher DBP in cord-blood samples and higher MBP or MEHP in meconium (Zhang et al., 2009). This study also detected an inverse relation between DEHP/MEHP in cord blood or meconium and infant birth length. Maternal occupational exposure to phthalates (estimated by questionnaire only) was associated with decreased placental weight and also decreased fetal growth in a Dutch cohort (Snijder et al., 2012). Consistent with this indication of impaired placental development, maternal urinary phthalate concentrations were associated with placental gene expression in trophoblast differentiation and steroidogenesis pathways (Adibi et al., 2010). Increased maternal phthalate exposure in the early third trimester was correlated with decreased placental gene expression, with results more pronounced for genes of the trophoblast differentiation pathway (Adibi et al., 2010).

The ability of prenatal exposure to antiandrogenic phthalates to influence sexual differentiation of the brain is also being explored. Concentrations of two metabolites of DBP and two metabolites of DEHP in maternal urine (mean 28.6 weeks gestation) were associated with reduced masculine play in boys aged 3–6 years (Swan et al., 2010). Prenatal phthalate exposure also has other influences on neurobehavior in infants and young children. Exposure to low-molecular-weight phthalates during pregnancy was associated with increased motor performance in male infants assessed at 5 days of age in a multiethnic U.S. cohort of 295 mother-infant pairs (Engel et al., 2009). A contrasting effect was seen in female infants in this study, with exposure to high molecular weight phthalates resulting in lower scores for orientation and quality of alertness (Engel et al., 2009). Assessment of 350 infants at 5 weeks of age revealed that exposure to DEHP and DBP at around week 26 of gestation was associated with several neurobehavioral outcomes, with both favorable and detrimental effects noted (Yolton et al., 2011). Higher urinary concentrations of DBP metabolites were associated with improved behavioral organization in infants, with lower

scores for infant arousal, improved movement quality, less infant handling required during testing, and increased self-regulation. Increased urinary concentrations of DEHP metabolites were associated with increased nonoptimal reflexes in male infants only in this study. A Korean study of 460 mother–infant pairs detected inverse associations between third-trimester maternal urinary phthalate concentrations and infant development at 6 months as assessed by the Korean Bayley Scales of Infant Development (BSID-II) (Kim et al., 2011). Mental Development Index scores were inversely associated with natural log concentrations of the DEHP metabolites MEHHP and MEOHP and Psychomotor Development Index scores were inversely associated negatively with natural log concentrations of MEHHP. When the analysis was stratified by gender, stronger inverse associations were observed between all measured phthalate metabolites (MEHHP, MEOHP, and MBP) and both developmental indices in male infants, with no significant associations detected for female infants (Kim et al., 2011).

In older children, third-trimester maternal MBP and monoisobutyl phthalate (MiBP) metabolite concentrations were associated with decreases in psychomotor development at 3 years of age in the CCCHEH cohort, with increased odds of motor delay per logarithmic unit increase of these metabolites in maternal urine (Whyatt et al., 2012). Prenatal MBP exposure was also associated with decreased mental development at the age of 3 in this study, but this effect was only observed in girls (Whyatt et al., 2012). The odds ratios for clinically withdrawn and internalizing behaviors also increased in these children, with logarithmic increases in urinary MBP, MiBP, and monobenzyl phthalate (MBzP). Furthermore, evidence of low-molecular-weight phthalates in maternal urine have been associated with poorer parent-rated behavior and executive functioning in children aged 4–9 years in a multiethnic urban U.S. cohort, with poorer scores for aggression, attention, conduct, depression, and externalizing behavior reported in children with higher prenatal exposure (Engel et al., 2010). An association between increased maternal urinary low-molecular-weight phthalate concentrations in the third trimester and social impairment was also identified in this cohort when children were assessed at the age of 7–9 years (Miodovnik et al., 2011), which suggested persistent effects of prenatal phthalate exposure.

Perfluorinated Compounds

Perfluorinated compounds (PFCs) are used in an extensive range of commercial and industrial applications.

Perfluorooctanesulfonate (PFOS) and perfluorooctanoate (PFOA) are PFCs that are produced either directly or from the metabolism of other PFCs, with half-lives estimated to be around 5 years and 4 years, respectively (Olsen et al., 2007). These chemicals are used as industrial surfactants and may be present in a number of consumer products including nonstick pans, soft furnishings, clothes, and food packaging. PFCs have been extensively used for several decades and persist for long periods in the environment, but human exposure has only been assessed relatively recently, in part due to our previous inability to detect these chemicals with sufficient sensitivity in biological media. Although the use of PFCs was phased out in most countries in 2000, human exposure to perfluorinated compounds remains widespread. Both PFOS and PFOA are known to cross the placental barrier and are prevalent in cord-blood samples, but few studies have investigated the potential health effects arising from prenatal exposure to PFCs.

The evidence to date regarding prenatal PFC exposure and fetal growth is largely consistent, with decreased fetal growth associated with PFOS, PFOA, or both identified in most studies. A study of 293 pregnant women delivering in Baltimore in the United States, and their infants, observed negative associations between PFOS and PFOA concentrations in cord blood and birth weight, ponderal index, and infant head circumference (Apelberg et al., 2007). However, there were no associations between PFCs in cord blood and birth length or length of gestation (Apelberg et al., 2007). The Danish National Birth Cohort was the first large-scale study to investigate the relationship between exposure to PFCs and birth outcomes, with a random subset of 1,400 participants from the larger national study selected. Maternal plasma PFOA concentrations assessed in samples collected early in pregnancy (week 4–14) were inversely associated with birth weight (Fei, McLaughlin, Tarone, & Olsen, 2007). Despite the higher concentrations of PFCs detected in the plasma of overweight or obese women, the relationship between PFOA and birth weight was only significant for mothers with a normal BMI (18.5–24.9) (Fei et al., 2007). PFOS was not significantly associated with birth weight in this study and neither chemical was associated with the length of gestation. A Japanese study of 428 mother–infant pairs observed a negative association between maternal serum PFOS concentrations collected after the second trimester and birth weight (Washino et al., 2009). In contrast to previous studies, no significant associations between PFOA concentrations and fetal growth were detected in this study.

A Canadian study of 252 mother–infant pairs also concluded that maternal PFC exposure had no significant effect on fetal growth and length of gestation (Hamm, Cherry, Chan, Martin, & Burstyn, 2010). An investigation of prenatal exposure to PFCs was undertaken as part of the ALSPAC in Great Britain using stored maternal serum samples (from 1991–1992) collected during pregnancy (median 15 weeks gestation) (Maisonet et al., 2012). In adjusted models, maternal serum PFOS and PFOA concentrations in the upper tertile were associated with an average birth weight in girls that was 140 grams and 133 grams less, respectively, than those of girls with mothers with PFCs concentrations in the lowest tertile (Maisonet et al., 2012). Similarly, maternal PFOS concentrations in the highest tertile were associated with a small decrease in infant birth length. There were no associations between PFOS and length of gestation or ponderal index, nor between PFOA and birth length. The Norwegian Mother and Child Cohort study (MoBa) included 901 mother–infant pairs and compared maternal plasma samples collected at around week 17 in gestation with infant birth weight (Whitworth et al., 2012). The adjusted birth weight z-scores were lower among infants born to women in the highest quartile of PFOS and PFOA, compared with those in the lowest quartile, but this relation was not statistically significant (Whitworth et al., 2012). Finally, the Taiwan Birth Panel Study investigated the potential adverse effects of PFCs on birth outcomes in 429 mother–infant pairs (Chen et al., 2012). Cord-blood PFOS concentrations were found to be inversely associated with a number of birth outcomes including length of gestation, birth weight, and head circumference, but not significantly associated with ponderal index or birth length. In addition, increased PFOS exposure increased the odds ratio of preterm birth, low birth weight (<2,500 g), and small for gestational age. No adverse effects on birth outcomes were observed with exposure to other PFCs, including PFOA. On balance, the evidence shows a reasonably consistent negative association between exposure to PFOS and PFOA prenatally and in measures of reduced fetal growth.

In addition to noting the decreased fetal growth associated with prenatal PFC exposure, the Danish National Birth Cohort followed 1,010 children and found that prenatal PFOS and PFOA concentrations were inversely related to children's weight in the first year, with more pronounced inverse associations between prenatal PFOS and body weight and BMI observed in boys at 5 and 12 months of age (C. S. Andersen et al., 2010). No clear associations were seen between prenatal PFC exposure and child length, and

when stratified by gender, no significant associations were detected between PFC exposure and body weight for girls.

In contrast, in British girls from the ALSPAC study, weight at 20 months increased with increased prenatal exposure to PFOS, with those in the highest tertile for PFOS on average 580 g heavier than those with prenatal exposure in the lowest tertile (Maisonet et al., 2012). Because most studies find that decreased birth weight is associated with prenatal PFOS exposure, this suggests a rapid early growth catch-up that may have implications for long-term child health. Furthermore, there is evidence that the effects of prenatal PFC exposure on anthropometry persist into adulthood, with positive associations between prenatal exposure to PFOA and the prevalence of overweight and high waist circumference (>88 cm) in females, but not males, at 20 years of age in a Danish cohort (Halldorsson et al., 2012). Maternal PFOA concentrations in the third trimester were also associated with biomarkers of adiposity in female adult offspring, with positive associations with insulin, leptin, and leptin-adiponectin ratio, and negative associations with adiponectin (Halldorsson et al., 2012).

The potential influence of prenatal exposure to PFCs on childhood development was assessed in the Danish National Birth Cohort. There was little evidence of a relation between maternal plasma PFOA and PFOS concentrations early in pregnancy and maternally reported motor or mental developmental milestones in infants at 6 or 18 months of age (Fei, McLaughlin, Lipworth, & Olsen, 2008), but PFOS concentrations were weakly associated with a delayed ability to sit unsupported (Fei et al., 2008). Further follow-up of these Danish children at the age of 7, with screening for hyperactivity and attention problems and developmental coordination disorders using parent-completed questionnaires, revealed that prenatal PFC exposures were not related to behavioral problems or motor coordination problems (Fei & Olsen, 2011). However, both the Danish follow-up studies used rather insensitive milestones, with only parent-reported outcomes; studies using more sensitive indicators of neurobehavioral development may yield differing results. However, neuropsychological tests were conducted on children from the Mid–Ohio Valley community exposed to high PFOA concentrations through contaminated drinking water, and no adverse associations between estimated in utero PFOA exposure and performance on these tests at the ages of 6–12 years were observed (C. R. Stein, Savitz, & Bellinger, 2013), although prenatal exposure was not directly measured.

Only one study to date has considered the potential associations between prenatal PFC exposure and the male human reproductive system. In this Danish study, increased maternal PFOA serum concentrations at week 30 in gestation were associated with lower sperm concentration and reduced total sperm count in male offspring at 19–21 years of age, with higher concentrations of luteinizing hormone and follicle-stimulating hormone detected in the blood samples of those with higher in utero PFOA exposure (Vested et al., 2013). No associations were observed between prenatal PFOS exposure and the outcomes measured. Given the widespread nature of exposure to PFOA, these reported decreases in semen quality in adult men following prenatal exposure could pose a significant population health issue and warrant further investigation. Of equal concern is the suggestion that prenatal exposure to PFOS is associated with reduced humoral responses to childhood immunizations at the age of 5 years and increased odds of diphtheria antibody concentrations below the protective level (Grandjean et al., 2012).

Conclusion and Perspectives for Future Studies

Investigations into the potential health effects of prenatal exposures to environmental toxicants are essential and information is mounting. The main challenge in this field is to deal with a number of methodological issues to improve the accuracy of conclusions that can be made. Below we detail some issues that need to be addressed in future research to move the field forward. Epidemiological, *in vivo*, and *in vitro* studies frequently examine the effects of exposure to a single toxicant while environmental exposure involves chronic simultaneous low-level exposure to multiple toxins, which may act through similar or overlapping mechanisms. A number of factors influence fetal growth, including maternal height and ethnicity, parity, gender, and gestational age, but these variables are not always assessed when measuring fetal growth perturbations arising from prenatal environmental toxin exposure. It would be beneficial to take into account the optimal fetal growth for a given infant by considering these factors, thereby allowing the POBW and birth length to be calculated (Blair et al., 2005). This would provide a more meaningful assessment of how exposure affects fetal growth. Longitudinal birth cohort studies are expensive and need to follow up participants for many years in order to accurately ascertain the health effects of prenatal exposure, some of which may not be manifest until the offspring reach adulthood. Epidemiological studies have varied in the

timing and frequency of collection of samples for prenatal exposure assessment and also in the matrix used to assess prenatal exposure (e.g., maternal urine, blood, or hair, or umbilical-cord blood); these differences preclude direct comparisons between studies and may account for some of the reported discrepancies. More inclusive measures will also aid in comparisons across studies and outcomes. For example, cognitive impairment is frequently assessed using executive function or psychometric intelligence, but children with ADHD, for example, are likely to exhibit cognitive impairment only in assessments of executive function and are unlikely to have low IQs (Schuck & Crinella, 2005). Subtle behavioral outcomes may thus be missed.

FUTURE RESEARCH AND THEORETICAL PERSPECTIVES

In examining prenatal influences on development, this chapter has synthesized theory and evidence from a range of disciplines within a multilevel evolutionary framework. The interdisciplinary nature of this perspective provides a fruitful platform for exploring new and existing issues in development. Issues and challenges crucial to future research and theoretical perspectives on prenatal development are highlighted next.

Resource Flow to the Fetus—Not Maternal Nutrition

Our evolutionary approach to reduced fetal growth suggests that the current emphasis of the DOHaD model on maternal under- or malnutrition as the main cause of reduced fetal growth and subsequent increased risk of adult disease may be misplaced. Adverse prenatal environments definitely contribute to reduced placental function and restricted fetal growth, but the impact of maternal nutrition on fetal and placental growth is clearly complicated (Robinson et al., 1994, 2001). The influence of maternal dietary supplementation on birth weight is small (Harding, 2001) and the outcomes depend heavily on the existing nutritional state of the population (Kind et al., 2006). Investigations of maternal nutrient intake and subsequent fetal and placental weights at birth have yielded mixed results (Godfrey, Robinson, Barker, Osmond, & Cox, 1996; Kuzawa, 2005; Mathews, Yudkin, & Neil, 1999; V. M. Moore, Davies, Willson, Woesley, & Robinson, 2004). The model presented in this chapter suggests that the effect of maternal nutrition on placental ratio is a consequence not only of

maternal nutrient intake, but also that the flow of resources from the uterus to the fetus is “negotiated” by the mother and fetus. This model suggests that it is the long and vulnerable fetal supply line, not measureable maternal nutrition *per se*, that determines the ultimate flow of resources to the fetus (Godfrey et al., 1999; Harding, 2001).

As resources from the maternal diet travel along the fetal supply line, what ultimately becomes fetal nutrition is mediated by the mother’s metabolism and endocrinology, uterine blood flow, placental transport and metabolism, umbilical blood flow, and the fetus’s metabolism and endocrinology (Harding, 2001). Therefore, the allocation of resources between competing demands during pregnancy mean that maternal nutrition and fetal nutrition are not the same thing (Gillman, 2002; Harding, 2001). This may also partly explain the finding that maternal insults that do not necessarily affect fetal growth can still have consequences for subsequent postnatal development and health. Our evolutionary synthesis highlights an interaction between the maternal reproductive strategy and diet as a possible explanation for some of the inconsistencies in the studies of maternal nutrient supplementation and fetal growth and the fetal antecedents of adult disease (Coall & Chisholm, 2010; Kramer, 2000; Kramer & Joseph, 1996).

Assisted Reproductive Technologies

Thus far we have considered maternal adaptations to relatively familiar environmental challenges and their health consequences. Assisted reproductive technologies (ART), however, constitute a novel but increasingly common environmental challenge. Since the first IVF baby, Louise Brown, was born in 1978 (P. C. Steptoe & Edwards, 1978), an estimated 5 million children have been born worldwide through ART (Hansen, Kurinczuk, Milne, de Klerk, & Bower, 2013), some 3% of the world’s population (Joy, Gannon, McClure, & Cooke, 2012). The most common ART treatment involves in vitro fertilization (IVF). In industrialized societies, people who plan to have children often delay reproduction in order to accumulate savings (Hammarberg & Clarke, 2005). Unfortunately, delayed reproduction is associated with decreased fertility, leading to greater demand for ART (Oakley, Doyle, & Maconochie, 2008), to a level that most industrialized countries cannot meet (Hoorens, Gallo, Cave, & Grant, 2007).

While the benefits of ART treatments to couples who are unable to conceive are patent, there are also increased risks of poorer outcomes for children conceived via ART (Fisher, Hammarberg, & Baker, 2005; Kalra & Molinaro, 2008).

The higher rate of multiple births in ART pregnancies was thought to account for these differences, but studies examining singleton births confirm that babies conceived by ART are more likely to be born preterm or have low birth weight than children from unassisted conceptions (Squires & Kaplan, 2007). Placentae from ART pregnancies have not been studied extensively (Joy et al., 2012), but, perhaps in response to reduced fetal growth, placentae from ART pregnancies are heavier and have higher placental ratios (Daniel et al., 1999; Haavaldsen, Tanbo, & Eskild, 2012). Other placental pathologies, including low-lying placenta, placenta previa, placental abruption, and poor implantation, are more common in ART pregnancies (Jauniaux, Englert, Vanesse, Hiden, & Wilkin, 1990). Confirming these concerns, the British Scientific Advisory Committee of the Royal College of Obstetricians and Gynaecologists (2012) stated that the babies who emerge from IVF pregnancies are at an increased risk of adverse outcomes such as low birth weight, small for gestational age, and premature birth. Multiple studies have also confirmed increases in the incidence of major and multiple birth defects among babies conceived by ART, with a twofold increase in major birth defects (Bower & Hansen, 2005; Hansen, Kurinczuk, Bower, & Webb, 2002).

Maternal prenatal stress is another factor that may be associated with poorer pregnancy outcomes in ART. During successful IVF pregnancies, couples report higher levels of stress than in successful nonassisted pregnancies (Eugster & Vingerhoets, 1999). Moreover, this is likely to be an underestimation as there is some, albeit mixed, evidence that preexisting stress is associated with the increased risk of unsuccessful IVF pregnancies (Matthiesen, Frederiksen, Ingerslev, & Zachariae, 2011; Sanders & Bruce, 1999). In a study of 837 Danish women, higher levels of negative life events in the preceding 12 months were associated with a reduced chance of becoming pregnant in the first IVF cycle, independent of current perceived stress and depressive symptoms (Ebbesen et al., 2009).

The associations between ART and fetal and placental growth suggest the possibility of fetal programming in these pregnancies. However, the range of factors influencing babies conceived via ART are extensive (inheritance of infertility, ART procedures, stress during pregnancy, nutrition, multiple births, preterm birth, fetal growth restriction) and must be carefully considered before the consequences of ART for child and adult health become clear (Hediger Bell, Druschel, & Louis, 2013). There is increasing evidence that programming effects, associated particularly with adult cardiac and metabolic health, occur in children

born from ART pregnancies (see reviews by Rinaudo & Wang, 2012; Yeung & Druschel, 2013). Importantly, possibly because of the positive parenting practices found in ART families, there is no evidence that children born with ART have poorer cognitive or socioemotional development (see Golombok & Tasker, Chapter 11, this *Handbook*, this volume, for review). Here, postnatal attachment relationships may moderate the impact of prenatal cortisol exposure on postnatal cognitive development (Bergman, Sarkar, Glover, & O'Connor, 2010).

Evidence is mounting that ART procedures produce epigenetic changes in the offspring. Mammals are diploid organisms having two copies of each gene, one from father and one from mother. Generally, the two genes are expressed together. In approximately 40 genes in humans, however, one of these genes is silenced by DNA methylation. Which gene is silenced is determined by whether the gene was from the mother or father. This silencing is referred to as genomic imprinting. Methylation peaks during the development of the germ cells and early embryogenesis (Scott & Moore, 2012), when ART processes are used to manipulate reproduction. Indeed, global gene expression is altered in ART placentae across a range of genes that influence cell differentiation, transmembrane transport, metabolism, and oxidative stress, among other functions (Zhang et al., 2010). These processes (ovarian stimulation, oocyte retrieval, maturation of oocytes, use of immature sperm, injection of single sperm into the cytoplasm [intracytoplasmic sperm injection; ICSI], washing, cryopreservation, and in vitro culture of embryos) could influence genomic imprinting (Manipalviratn, DeCherney, & Segars, 2009), as they do in animal models (Butler, 2009). Although imprinting disorders are rare, epidemiological studies in humans show that an imprinting disorder, Beckwith-Wiedemann Syndrome (BWS), is associated with ART. In a review of ART studies in Europe, the United States, and Australia, involving children who developed BWS, Manipalviratn et al. (2009) reported that approximately 90% of ART-born children showed imprinting defects compared with less than 50% of BWS children born from nonassisted pregnancies. Research in this area is only beginning to explore these associations in humans and (possibly because of the large sample sizes necessary to examine rare disorders) has so far produced mixed results (Vaiserman, 2012).

It is clear that a full understanding of the developmental effects of ARTs cannot be assessed until ART children become parents and grandparents themselves. Perhaps the most important consideration will be the research

designs developed to examine these associations. As for all pregnancies, prenatal maternal stress and nutrition must be considered, but many factors unique to ART pregnancies must be considered as well: the underlying cause of infertility itself, the ART procedures themselves (including delayed fertilization and freezing and thawing of embryos), the medications used to induce ovulation or maintain pregnancy (Hansen, Bower, Milne, de Klerk, & Kurinczuk, 2005), and the couple's emotional reactions to these procedures. In addition, factors known to influence ART outcomes, including the culture media used to store, grow, and protect the eggs and sperm used in some treatments, must all be taken into account (Barnes & Sato, 1980; Trounson & Gardner, 2000). As the number of babies conceived through ART continues to grow, the answers to these questions become increasingly crucial.

Perceived Stress, Objective Stress, and the Biology of Stress

There has been substantial debate about how subjective stress during pregnancy affects maternal physiology such that fetal growth is impaired. The problem is that, although there are many reliable and valid instruments for measuring subjective psychosocial stress, their results do not correlate very well with biological measures of stress during pregnancy (e.g., free cortisol in saliva; Voegtline et al., 2013). In fact, the literature suggests that both pathways—perceived stress and maternal glucocorticoids during pregnancy—can influence maternal physiology and pregnancy outcomes. This review has shown that experiences during pregnancy as diverse as pregnancy-specific anxiety, perceived stress, nutrient restriction, and cadmium exposure can affect maternal and placental stress hormone levels. Because both the mother and fetus are influenced by psychosocial and physiological stressors, the correlation between perceived stress and stress hormones is often low (Sandman et al., 2012). Similarly, the commonly found association between perceived stress and preterm birth is not always reflected in hormonal measures. For example, Kramer and colleagues (2013) found that, while maternal ACTH was associated with cortisol, which in turn enhanced placental CRH, neither maternal cortisol nor CRH were associated with perceived stress, maternal distress, or preterm birth. Research is beginning to establish the independent effects of perceived stress, objective stress, and the biology of stress, suggesting that several at least partially independent pathways might have been operating.

Adaptive Maternal and Fetal Programming

The evidence that prenatal adversity programs fetal physiology and affects subsequent infant, child, and adult phenotypes is well-established. The focus throughout this literature is strongly on the fetus: What impact does adversity in utero have on the fetus and how does this prepare it for a harsher postnatal environment (D. J. P. Barker, 1994)? A new area of research suggests that these events also program *maternal* physiology, potentially creating co-adaptation between maternal and offspring physiology. Another review by Sandman and colleagues (2012) highlighted animal and human evidence that the structure and function of the maternal brain is also programmed in response to stress during pregnancy and that these changes persist over time. They propose that changes in maternal stress reactivity, cognitive function, and the risk of psychopathology in response to endocrine changes throughout pregnancy prepare the mother for pregnancy, childbirth, and postnatal life.

In the general population, CRH levels have been associated with mental health disorders, particularly depression and anxiety (Risbrough & Stein, 2006). Extending this, Yim et al. (2010) examined the relation between placental CRH (pCRH) and postnatal depressive symptoms, finding that women with elevated pCRH levels at 25 weeks of pregnancy were more likely to develop depressive symptoms postnatally. This may be why problems during pregnancy, perceived lack of social support, anxiety, depression, stressful life events, and low levels of social support during pregnancy are closely associated with postnatal depression (Beck, 2001; O'Hara & Swain, 1996; Robertson, Grace, Wallington, & Stewart, 2004). Moreover, mothers suffering from postnatal depression reduce their investment in their new baby (for a review of the evidence, see Hagen, 1999). Thus, maternal stress during pregnancy may signal a risky or uncertain environment to which both the mother's and fetus's physiology respond (Sandman et al., 2012). This dual programming ultimately improves the fit between mother, infant, and environment. Since postnatal depression affects 10%–15% of new mothers (Hagen, 1999), this adaptive interpretation of maternal stress may have clinical significance.

In postnatal development, there is a remarkable synchrony between maternal behavior and neonatal sensory perception (e.g., Brazelton, Koslowski, & Main, 1974; Trevarthen, 2012; Tronick, 2007). During the long period of slow development that is human childhood, this ensures a coordinated mother–infant relationship and transduction

of social environmental cues via attachment relationships, among other systems (Chisholm, 1999a). Ultimately, these “synchronized capabilities” translate to the improved probability of survival and fitness benefits for the mother and infant (Simpson & Belsky, 2008). Therefore, it makes sense that the mother's, not only the fetus's, behavior and physiology are adapted to the environment they share. Future research must examine the interaction between cues in different life stages, as well as transgenerationally, as it is likely the best fit between an organism and its ecology is affected by many environmental cues across different time frames (Nettle et al., 2013).

Childhood Psychosocial Stress: A New Predictor of Maternal Environment

The critical influence of childhood experience on subsequent growth, development, and adult health and behavior is central to many disciplines, including evolutionary ecology (C. J. K. Henry & Ulijaszek, 1996), evolutionary psychology (Belsky et al., 1991), ethology (Bateson & Martin, 1999, 2013), developmental health (Keating & Hertzman, 1999), developmental psychology (Repetti et al., 2002), and epidemiology (Kuh & Ben-Shlomo, 1997). In humans, as with other species (Meaney & Szyf, 2005), the parental environment and parenting behavior have a particularly strong influence on both physical and mental development.

Life history theory predicts that the flow of resources to the fetus (parental investment) during pregnancy will vary according to the mother's developmental environment, her reproductive strategy, her currently available material and social-emotional resources, and those likely to be available in the future (Chisholm, 1993, 1999b; Chisholm & Coall, 2008; Coall & Chisholm, 2003; Ellison, 2005; Gluckman, Hanson, & Beedle, 2007; Jones, 2005; Kuzawa, 2007; R. S. Walker et al., 2006; Wells, 2003; Worthman, 1999; Worthman & Kuzara, 2005). Evidence is beginning to emerge, however, that the developmental trajectories entrained by early stress may reduce the maternal allocation of resources to the fetus during pregnancy, thus limiting fetal development and increasing the risk of poor health outcomes (Coall & Chisholm, 2003, 2010).

Research with the Adverse Childhood Experiences (ACE) Study demonstrates that early stress is associated with higher adult disease and mortality rates (Anda et al., 1999; Felitti et al., 1998). After adjustment for age, race, gender, and education, adverse childhood experiences

(e.g., sexual abuse, domestic violence, imprisonment of a family member) are risk factors for adult diseases such as severe obesity, smoking, physical inactivity, and poor self-rated health. Compared to those with none, individuals who experienced four or more adverse experiences are significantly more likely to develop diseases such as ischemic heart disease, stroke, diabetes, cancer, and chronic bronchitis (Felitti et al., 1998). Moreover, these results have been replicated in four birth cohorts from 1900 to 1978 (Dube, Anda, Felitti, Edwards, & Williamson, 2002) with the risk increasing in a dose-dependent manner in association with the number of childhood stressors experienced (Felitti et al., 1998).

But although there is convincing (albeit retrospective) evidence that the number of adverse childhood experiences predicts increased adult mortality rates, some early stressors seem to matter more than others. This is probably because they reflect or are symptomatic of a child's generally risky or uncertain family environment. In particular, childhood sexual, emotional, or physical abuse and witnessing physical violence between parents tend to be associated with other adverse experiences during childhood (Dube et al., 2002; Gladstone, Parker, Wilhelm, Mitchell, & Austen, 1999). For example, although witnessing parental violence is associated with higher levels of psychological distress and lower levels of social adjustment in adulthood, this association is mediated by the amount of parental care and warmth experienced (Henning, Leitenberg, Coffey, Bennett, & Jankowski, 1997; Henning, Leitenberg, Coffey, Turner, & Bennett, 1996). Moreover, individuals who experience adverse childhood events appear to have more negative life events and experience more anxiety and depression during pregnancy (Benedict, Paine, Paine, Brandt, & Stallings, 1999; Grimstad & Schei, 1999). Efforts to explore the association between early stress, stress during pregnancy, and pregnancy outcomes might thus benefit from better measures of the overall tone or quality of the family environment.

The early psychosocial environment may also affect fetal development via maternal body composition. Psychosocial stressors such as neglect, abuse, and unsupportive home environments have been associated with childhood obesity (Strauss, 1999) and rapid weight gain during childhood. In a study of 5,399 Swedish schoolchildren (2,661 girls), girls with the most rapid weight gain between 7 and 10 years of age also had the highest prevalence of social, behavioral, and learning problems (Mellbin & Vuille, 1989). In a study of 756 Danish school

children, those who were perceived by their teachers to receive little parental support had higher rates of obesity and were 7 times more likely to be obese at 20 years of age (Lissau & Sorensen, 1994). Thus, early stress may ultimately influence fetal growth through its impact on childhood weight gain and subsequently, maternal body composition during pregnancy.

Whether the process is via chronic stress or increased weight gain, it is likely that these childhood experiences are embodied (Chisholm, Burbank, Coall, & Gemmatti, 2005; Hertzman, 1999; Hertzman, Power, Matthews, & Manor, 2001; Krieger, 2001) in the form of altered stress reactivity (Bremner et al., 2003). Consistent with this evolutionary synthesis, increased stress reactivity is associated with lower birth weight (Clark et al., 1996; Ward et al., 2004), lower parental responsiveness (Haley & Stansbury, 2003; Repetti et al., 2002), earlier menarche (Boyce & Ellis, 2005; Ellis, 2004), and earlier first sexual intercourse (Brody, 2002). The resultant increased levels of glucocorticoids can reduce insulin sensitivity and increase fat deposition (Brindley & Rolland, 1989; Tsigos & Chrousos, 2002). Furthermore, studies have identified psychosocial stress as a risk factor for developing the metabolic syndrome in childhood, adolescence, and adulthood (Eisenmann, 2003; Hjemsdal, 2002; Rosmond, 2005). Therefore, via the actions of stress hormones, childhood psychosocial stress may be associated with weight gain throughout the life span and an increased risk of adult diseases, which in turn are associated with reduced fetal growth in the next generation (Lawlor, Smith, & Ebrahim, 2003).

Predictive Adaptive Responses

Above, we referred only in passing to the concept of predictive adaptive responses (PARs) because it deserves its own special discussion. The concept needs clarification and analysis because it has different names in different fields, its meaning is not always made clear, and there are different ways of interpreting the concept. These are significant issues because PARs could have critical implications for understanding and reducing the prenatal origins of health and disease. As commonly understood, a PAR (in the context of this chapter) is a developmental response by the fetus to a uterine environmental cue such that—if it uses this cue to correctly anticipate or “predict” the future environment—the developmental response will

be evolutionarily adaptive in its postnatal environment. Otherwise, if the fetal response does not correctly predict the postnatal environment, whether because the signal was not reliable or the environment changed, there will be a maladaptive mismatch between the developmental calibration and postnatal environment (Gluckman, Hanson, & Spencer, 2005; Godfrey, Lillycrop, Burdge, Gluckman, & Hanson, 2007).

PARs have stimulated extensive discussion and analysis about what information from its prenatal environment the fetus extracts and responds to. This discussion has provided great stimulus to the field, but is currently unresolved. As we have emphasized throughout this chapter, the fetal environment does not purely comprise information from the current environment but from the mother's current and developmental environments, her mother's and her grandmothers' developmental environments, and so on. Therefore, the question arises: How well can we expect 9 months of pregnancy to predict the child and adult environments of the future (e.g., Jones, 2005; Kuzawa, 2005; Worthman & Kuzara, 2005)?

Alternative (although not mutually exclusive) models of how adverse prenatal environments affect development and postnatal health have emerged. In their original form, PARs supposedly prepare organisms for future environments and provide "weather forecasts" via "fetal programming." However, as was discussed in the context of life history theory above, under harsh environments the first priority is to survive. In light of this, various models portray physiological changes during pregnancy as "making the best of a bad start" (e.g., Jones, 2005). This is a form of downside risk protection. An individual born into an adverse environment must change his or her physiology to ensure survival and avoid lineage extinction rather than to "predict" a future environment that may never exist (Chisholm & Coall, 2008). Still other models see early adversity as a detrimental disruption no matter what its environment is like. These models are often referred to as "silver spoon" (the converse as "leaden/wooden spoon") models (Grafen, 1988) and suggest that there is a lifelong fitness advantage or disadvantage associated with the early environments that individuals embody. Throughout this chapter, these different PAR models have been discussed in specific examples. At present, attempts to test the different predictions are underway, with some support for the silver versus leaden spoon model reported (Hayward & Lummaa, 2013). It is important to recognize that these models currently ignore the competing demands of the

mother and fetus. Thus the application of parent–offspring conflict theory to understanding the adaptive functions of prenatal environment may also be a fruitful area of research (Del Giudice, 2012; Gangestad, Caldwell Hooper, & Eaton, 2012).

Attempts to rationalize the PAR models into manageable categories are underway (Monaghan, 2008; Nettle et al., 2013; Wells, 2012) but consensus is some way off. Some useful results have come from comparing the "weather forecasting" and "leaden spoon" PAR models. Nettle et al. (2013) concluded that their model predicted that (a) developmental plasticity would evolve to receive information from the maximum number of environmental cues available (especially if the cues were not highly reliable) and (b) the reliability of cues from year to year would need to be exceptionally reliable to have adaptive value across an individual's reproductive life span or even shorter durations. More empirical and theoretical work is needed to turn the promising field of PARs into strategies for interventions to reduce the prenatal origins of health and disease. We are currently at the threshold of an exciting area of research.

CONCLUSION

In this chapter, we have tried to make two overarching points: (1) The study of prenatal influences is no longer a "gray area" of modern science because (2) evolutionary theory—our only scientific theory of life (and development)—provides the "bio-logical" basis for coordinating the multidisciplinary evidence for prenatal influences and making sense of the patterns that emerge. We have endeavored to present a truly interdisciplinary perspective within an evolutionary, life history theory framework. Maternal stress, nutrition, and exposure to toxins all provide crucial information to the fetus regarding characteristics of the maternal environment about the harshness of their environment, the abundance of resources, contamination of the environment, and the disease load. This provides the developing organism with a guide to the behavioral and physiological strategy it must pursue to increase its chances of survival and reproduction in the new postnatal environment. When this adjustment is made during sensitive periods of development, such as prenatally, the short-term benefit of changes that ensure continued survival may be traded-off against the longer-term costs of lifelong and intergenerational health.

CHAPTER OVERVIEW

Developmental psychology is rapidly becoming a neuropsychobiological field. No longer are we satisfied with documenting developmental trajectories of cognitions,

emotions, and social behaviors, nor are we satisfied with describing and theorizing about how children's transactions in the world influence development. To all of these still critical foci of developmental science, we have added goals of understanding how the genes we are born with, the experiences we have that overlay those genes with chemical marks that control their expression (epigenome), and the physiological responses in our brains and bodies all come together to write the story of our lives. Nowhere is the importance of a multilevel, multidisciplinary, genes-to-society perspective more apparent than in the study of stress and its role in development.

To be fair, the study of stress has always been a psychobiological field from the time Selye first used the term to refer to the body's response to threats to its viability (Selye, 1946). While Selye was focused on physical threats, it quickly became apparent that psychological threats were as potent and often more potent than physical damage to the body in activating stress responses (e.g., Dickerson & Kemeny, 2004). Nonetheless, in developmental psychology the study of the effects of stressful life conditions on children continued for many years as a purely psychological endeavor. An interest in biology and neurobiology entered this part of our field first from biological psychiatry and then in the then-emerging field of developmental psychopathology (see review, Gunnar & Vazquez, 2006). Temperament researchers also brought an interest in stress biology into the field somewhat indirectly through their interest in how mildly threatening events sorted children along a dimension of fearfulness or behavioral inhibition that was reflected in their autonomic and neuroendocrine reactions (e.g. Kagan, Reznick, & Snidman, 1987). However, it was the advent of noninvasive salivary assays for the key stress hormone cortisol that broadly opened the field to questions about the development and regulation of stress biology and how the biology of stress interacts with the child's genetic makeup and experiences to affect the development of our physical and psychological well-being (see review, Gunnar & Vazquez, 2006).

This chapter is about the state of the art in our understanding of the multilevel processes that are involved in how we deal with stressors, how these processes change with development, and how the activity of stress-mediating systems during childhood and adolescence affects our health and functioning. As discussed herein, there are multiple systems that mediate the impact of stress on development; however, the key system from a developmental perspective is the hypothalamic-pituitary-adrenocortical (HPA) system. The sympathetic-adrenomedullary (SAM)

system undergirds the fight-or-flight response to threats, but its catecholamine products, epinephrine and norepinephrine (NE) do not cross the blood brain barrier. In contrast, cortisol, the HPA's product, is a steroid hormone that acts in all parts of the body, with the brain being a primary target for its actions. Cortisol is a gene transcription factor, meaning that it changes the expression of numerous genes. It plays a major role in early development, and the genes it regulates are critical to neural plasticity. Thus, this neuroendocrine system is a developmentalist's dream: not so much a window on what a person is thinking and feeling but a door through which experiences get under the skin and affect development. It is for this reason that, although we discuss both the sympathetic and parasympathetic nervous systems, this chapter is focused on the HPA system. Sadly, readers will find that although it is a developmentalist's dream, it is also a researcher's nightmare because like any neuroendocrine system, the system rapidly adjusts to conditions that provoke its activation. Therefore, as is explained herein, stress is associated with both high and low levels of cortisol production.

In addition, although stress is often construed as something bad, stress is a ubiquitous part of life. Thankfully, not all children experience unpredictable, uncontrollable, chronic stress, which can be toxic to development, but many do and we need to understand individual differences in the impact of this type of stress in order to promote greater resilience and recovery for its victims. All children, however, experience stress as part of their everyday existence. From the impact of infections or cuts and abrasions, which trigger immune reactions that activate the HPA axis, to the threat of social exclusion, failing a test, or flubbing one's lines in a play, there are numerous opportunities in every child's life for stressors to affect development and the effects are often positive. Learning to cope with mild threats to our physical and social selves is an aspect of development that is critical for resilient functioning. As we have known for a long time, it is not so much the actual event as an individual's construal of the event that determines how stressors affect that individual (Lazarus & Folkman, 1984). As we learn to cope with mild to moderate threats, both our bodies and our psyches perceive threats as more manageable and thus we become more resilient to life's hassles and roadblocks. What the field is beginning to show is that multiple neurobiological systems interact with the stress system at different points to mediate the effect of stressors on stress vulnerability and resilience. Understanding how these systems interact is critical to appreciating the role of stress in human development.

The complexity of the neurobiology and psychobiology of stress dictated the choice of topics and construction of this chapter. Nearly 20% of the chapter is devoted to anatomy and physiology, including genetics. Although much of the description is not developmental, our emphasis reflects the critical importance of understanding the physiology of stress in order to use its study to decipher the effects of stress on development. After this we take up a very brief discussion of normative development. Understanding normative processes as they are revealed in relatively low-stress developmental contexts is critical to interpretation of effects of stress in high-stress developmental contexts. We then turn to a discussion of theory. Until recently, there has been no theory devoted to a developmental analysis of stress, although nondevelopmental theories have been applied to children and adolescents. We consider what is currently available and argue that what we have is not yet adequate. The bulk of the chapter is devoted to a key issue in the study of stress and human development. Specifically, what evidence do we have that adversity during children's development affects the neurobiology of stress and stress-induced mental and physical health outcomes through stress-mediating systems? As our discussion of temperament reveals, an equally important question is whether individual differences in temperament are critical moderators of the effects of stress on developmental trajectories. The discussions of both adversity and individual differences lead to the final section on whether vulnerability to mental disorders is reflected in and/or created by aberrant activity in stress-mediating systems.

Throughout this review we were challenged by the fact that the field of stress and development has burgeoned in the past decade. Furthermore, our review crosses multiple fields: genetics, neurobiology, developmental psychology, biological psychiatry, and developmental psychopathology. Given limited room for references, we were forced to only provide examples of relevant research, relying on reviews whenever we could. We have tried, whenever possible, to acknowledge at least one paper from each of the active laboratories in hopes that readers can then track down other important work from these laboratories. It is a sign of the robustness of this research area, however, that in the past decade publications on stress biology and development have moved from specialty journals into journals that rarely used to publish papers with biological measures other than perhaps heart rate. As more readers encounter work on the biology of stress, it is essential that they have a reasonably sophisticated understanding of that

biology. Thus, it is to the anatomy and physiology of stress that we now turn.

HYPOTHALAMIC-PITUITARY-ADRENAL ANATOMY AND PHYSIOLOGY

There are a number of reviews of HPA anatomy and physiology (e.g., Gunnar & Vazquez, 2006; Joëls & Baram, 2009; Levy & Tasker, 2012). Here, we briefly summarize.

The Hypothalamic-Pituitary-Adrenal Axis

Cortisol (CORT), a glucocorticoid hormone, is produced by the adrenal cortex following a signaling cascade initiated in the paraventricular nucleus (PVN) of the hypothalamus (see Figure 4.1). These cells release the neuropeptides corticotropin-releasing hormone (CRH) and arginine vasopressin. These releasing hormones travel to the anterior pituitary where they bind to corticotropin cells signaling the cleavage of a large pro-hormone into adrenocorticotrophic hormone (ACTH) and several endorphins and melanin-stimulating hormones. ACTH is then released into circulation and binds to receptors in the cortex of the adrenal gland, stimulating CORT production. Finally, CORT is secreted into the circulation, acting on its receptors throughout the body. The mature adrenal cortex consists of three regions: one producing aldosterone, a salt-water regulating hormone, one producing dehydroepiandrosterone (DHEA), an androgen with anabolic effects that increases in advance of puberty and also responds to ACTH, and the zone that produces CORT.

Mineralocorticoid Receptor and Glucocorticoid Receptor

Two receptor types, mineralo- and glucocorticoid receptors (MRs and GRs), bind CORT. CORT will bind first to MRs, unless, as is the case outside the brain, the MRs are protected from CORT by an enzyme barrier (11 β -HSD2) that converts CORT into an inert substance (Wyrwoll, Homes, & Seckl, 2011). GRs are occupied as MRs become less available or where they are not present to compete with GR. Throughout the brain, GRs become involved at the peak of the circadian cycle or during stress responses. GRs mediate the genomic stress actions of CORT, while MRs in the brain mediate basal genomic actions (see for review, Gunnar & Vazquez, 2006).

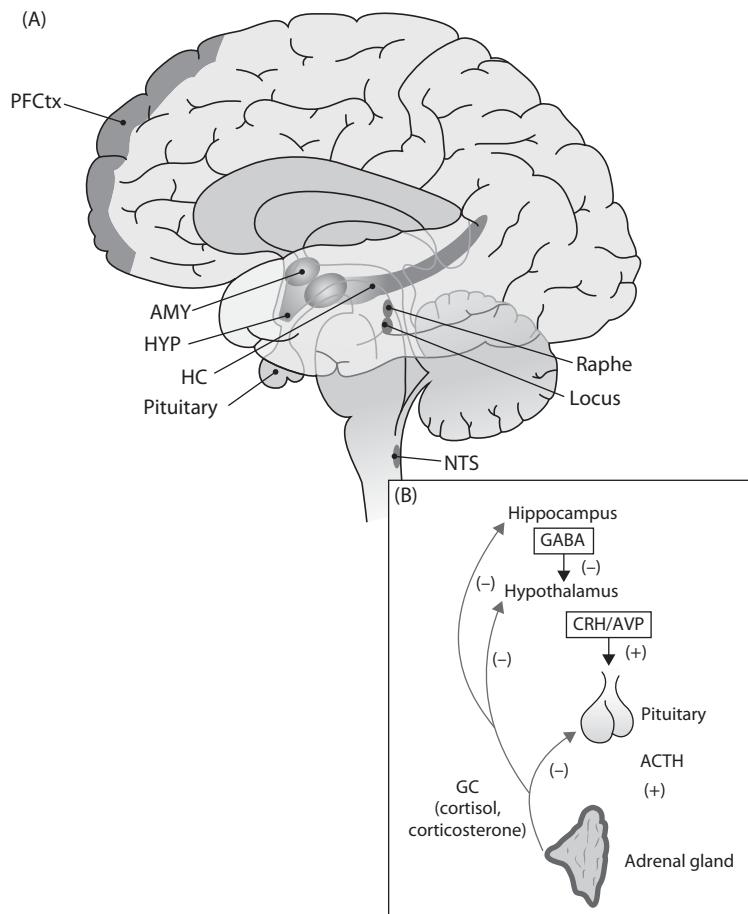

Figure 4.1 The HPA System. Panel A depicts the anatomy of the HPA system and structures important in its regulation. Panel B depicts the activation (+) and negative feedback inhibition (−) pathways of the HPA system.

Panel A: PFCtx = prefrontal cortex, AMY = amygdala, HYP = hypothalamus, HC = hippocampus, NTS = nucleus of the tractus solitarius.

Panel B: GCs = glucocorticoids (cortisol and corticosterone), GABA = gamma aminobutyric acid, CRH = corticotropin-releasing hormone, AVP = arginine vasopressin, ACTH = adrenocorticotrophic hormone.

Source: From “Stress Neurobiology and Developmental Psychopathology,” by M. R. Gunnar and D. M. Vazquez, 2006, in D. Cicchetti and D. J. Cohen (Eds.), *Developmental Psychopathology: Developmental Neuroscience* (2nd ed., pp. 533–577), Hoboken, NJ: Wiley. Reprinted with permission.

Once released into circulation 80%–90% of CORT becomes bound to cortisol-binding globulin, which prevents it from interacting with its receptors. The unbound CORT, being lipid soluble, enters freely into all cells of the body. In the cell’s cytoplasm, CORT binds to its receptors. Receptor binding is mediated by chaperones. Heat shock protein 90 (Hsp₉₀) facilitates CORT binding to its receptors, while a co-chaperone, FK506 binding protein 5 (FKBP5), decreases this affinity (Heim & Binder, 2012). As will be discussed, FKBP5 plays an important role in stress vulnerability and resilience. Once the hormone-receptor complex has been formed, it translocates to the nucleus where it interacts with glucocorticoid responsive elements to regulate gene transcription and protein synthesis.

The time from PVN-CRH stimulation to peak CORT levels in plasma is about 20–25 minutes and about 2 minutes longer for the transition to saliva. Genomic effects take minutes to hours and may last days. Thus, these genomic actions cannot be part of the fight-or-flight response. Indeed, a stress response of the HPA axis is generally considered to be essential to the later phases of coping with stress, rather than fight-or-flight, because it helps to increase energy for the long haul, reverse the effects of other stress mediators, and, through effects on neural systems, alter the organism’s responses to similar threats when they are next encountered (Sapolsky, Romero, & Munck, 2000).

The idea that CORT is not a part of fight-or-flight is now being qualified. It appears that CORT can produce

effects through rapid, nongenomic processes that take about 7 minutes to operate (Tasker & Herman, 2011). Nongenomic effects involve CORT receptors that with stress relocate to the cell membrane. These nongenomic mechanisms help explain fast negative feedback, which we have known for a while occurs before gene-mediated CORT effects could take effect. Nongenomic effects have so far have been noted in the PVN, pituitary, hippocampus, and amygdala. Several nongenomic mechanisms have been identified. One GR-mediated mechanism acts via the endocannabinoid system, and there is increasing evidence that this system plays a role in PVN-located negative feedback. In the amygdala, rapid CORT action operating through this system may contribute to the dampening of responses to repeated stressors (Hill & McEwen, 2010). It appears that many of CORT's nongenomic actions are permissive. That is, operating through these mechanisms, CORT supports and enhances the metabolic, cognitive, and/or emotional processes being used to manage threat.

Corticotropin-Releasing Hormone

CRH is not produced only in the PVN, but also in other brain regions, most prominently the central nucleus of the amygdala (Kovács, 2013). CRH operates by binding to two G-protein coupled receptors (CRHR1 and CHRR2) that are located in different brain regions and have opposing functions. CRHR1 mediates many of the behavioral, hormonal, and autonomic effects of stress. Outside the HPA axis, receptors for CRH (e.g., CRHR1) are located in the basolateral and medial nuclei of the amygdala, prefrontal cortex, hippocampus, cerebellum, and in the reticular formation. CRHR1 antagonists markedly reduce fear and thus are targets for drug treatment. Critically, while CORT acting in the PVN downregulates CRH, in the amygdala chronic elevations in CORT upregulates CRH, increasing fear behavior.

Diurnal Rhythm

CORT is released once per hour in pulses throughout the day. In diurnal animals, the largest pulses are in the early morning hours and smallest at the onset of nighttime sleep. Thus, CORT is high at awakening and near zero 30 minutes after nighttime sleep onset. Imposed on this rhythm is a surge in CORT 30–40 minutes after awakening, the CORT awakening response (CAR) (Fries, Dettenborn, & Kirschbaum, 2009). A robust rhythm of the HPA axis requires near zero levels of CORT around the nadir of

the rhythm. Thus, a common stress signature is slightly elevated late afternoon and evening CORT levels with suppressed early morning levels. The normal CORT diurnal rhythm is regulated by the circadian CLOCK system, (e.g., Kino & Chrousos, 2011), while circadian CORT variation also serves as a peripheral clock that synchronizes other systems including the hepatic, circulatory, and respiratory systems. Consequently, a dysregulated CORT rhythm impairs the functioning of other critical systems.

Stress Response

In the face of threat we mount stress responses to cope and survive. Stress responses are stressor specific (Joëls & Baram, 2009); however, stressors can be grouped into two broad classes. Systemic stressors (e.g., blood volume loss, infection, heat and cold stress) can activate the HPA axis even in a comatose organism. Psychogenic stressors require forebrain processing and elaboration. Activation to psychogenic stressors involves the central nucleus of the amygdala. From the central nucleus of the amygdala, the pathway to HPA activation crosses several synapses and involves the bed nucleus of the stria terminalis. Signals then converge on the PVN to release CRH (Ulrich-Lai & Herman, 2009). Fear of bodily harm and death are highly potent triggers of the HPA response; however, in humans, threats to the social self, particularly if combined with lack of predictability and control, are also powerful activators of the HPA axis and other stress-mediating systems (Dickerson & Kemeny, 2004). The field's most reliable laboratory stressor task is the Trier Social Stress Test (TSST), which threatens the social self through combining public speaking and mental arithmetic while being filmed and judged by a panel (Kirschbaum, Pirke, & Hellhammer, 1993). There is a version for children and now several versions that do not require the large cast of experimenters (e.g., Yim, Quas, Cahill, & Hayakawa, 2010). The TSST can be used with children as young as 7, but becomes more reliable as children get older. Stressor tasks for younger children are more challenging to find and are affected by the child's relationship with the parent who accompanies them to the laboratory (Gunnar, Talge, & Herrera, 2009).

Feedback Mechanisms

CORT controls its own levels through negative feedback via GRs in the pituitary, hypothalamus, hippocampus, and medial PFC (mPFC) (Tasker & Herman, 2011). Mediated by GABA_A receptors, GABA-producing cells surround the

PVN and provide tonic inhibition of the HPA axis. Chronic stress leads to significant downregulation of GABA-ergic synaptic input to the PVN, thus reducing the tonic brake on the system. Regulation of CORT by its own production (i.e., negative feedback) operates on several time scales (Joëls & Baram, 2009). Fast negative feedback occurs within minutes, and in the PVN involves the endocannabinoid system. In the CA1 region of the hippocampus, negative feedback involves cell-membrane MR. Negative feedback that involves genomic mechanisms is slower but critical to HPA regulation. This type of negative feedback involves the hippocampus and mPFC and is mediated by GR. Negative feedback is itself subject to regulation. In response to chronic stress, GR expression is reduced in the hippocampus and mPFC, which reduces negative feedback regulation, but also prevents GR-mediated effects on these brain regions, which can be damaging if prolonged.

Current Methods and Methodological Issues

In this section we focus on the two methods that are the most relevant for research on children and adolescents: salivary and hair cortisol. There are a number of recommended methodological reviews for salivary cortisol (Granger et al., 2007; Gunnar & Talge, 2007; Kudielka, Gierens, Hellhammer, Wüst, & Schlotz, 2012). Numerous substances need to be controlled or avoided in assessing the HPA axis, some general to any mode of sampling, others specific to saliva. Milk in the mouth is a problem somewhat particular to child studies. Milk contains cortisol so samples contaminated by milk tend to have elevated scores (Gunnar & Talge, 2007). Avoiding dairy products within 30 minutes of sampling, rinsing the mouth, and waiting 5 minutes is advised. Medication use is another problem for researchers, especially those studying children at risk for psychopathology. If possible, drug washout periods are advised, but this is not always possible or even advisable for children with serious emotional and behavioral problems. There are various pathways through which drugs affect the HPA system and at least one paper describes a template for using this information and statistical controls to minimize impact on the data (Granger, Hibel, Fortunato, & Kapelewski, 2009). There are challenges with the collection matrix, with passive drool being preferred but not always possible with infants and young children. When swabs are used, those made of synthetic substances are preferred. These have recently become available and are marketed for use in collection. For children, motivating them to mouth these swabs can be challenging.

Several laboratories have found that using small amounts of sweetened drink mix crystals with the swab to get the sweet taste works well. However, depending on what is in the crystals this can lower the pH of the saliva and affect assay dynamics. The solution is to use only a few grains, which have no measurable effects (Gunnar & Talge, 2007).

While cortisol is a stable molecule, it does break down over months and years even in very cold storage and does so more in some samples than others (Kudielka et al., 2012). In a longitudinal study, one would want to avoid shifting levels as assays shift antibody lots, but it is best to assay about every 6 to 12 months.

Timing is critical to any study of the HPA axis. Laboratory tests should take place at the same time for all participants. While late afternoon and evening times are preferred because the axis is more quiescent and elevations are easier to detect, this is unrealistic in studies of infants and young children. Testing all at the same time of day or in time blocks that can be used in the analysis is essential, however. Making sure that time since napping and/or morning awakening is entered into the analysis protocol is also important. A different problem, compliance to protocol, arises when parents take samples at home. Significant numbers of parents misreport when they sample, a problem that is worse for early morning sampling relative to when children are awake (V. C. Smith & Dougherty, 2014). Errors in timing in the early morning result in reports of absent or blunted CARs, which are inaccurate. Use of objective “track cap” monitoring where sampling materials are stored in a device that tracks the time the cap is opened is strongly advised. Recently, despite numerous studies showing that infants and young children lack a CAR, we now know from a study using actigraphy and track caps that the CAR is robust from as early as 2 weeks postnatal (Stalder et al., 2013).

Many times we are less interested in the momentary activity and regulation of the axis than in an overall cortisol production. In these instances, what is needed is a reliable integrated measure of cortisol production. Sometimes what we need is information on cortisol production prior to the onset of our study. We may need a measure of how the axis responded to an unpredictable stressful event that was the reason for the study, but happened before any data were collected. In the last decade, researchers have begun to examine cortisol levels in hair to obtain this type of integrated measure that can serve as a calendar of cortisol production over the past months and is free from problems of protocol adherence (Stalder & Kirschbaum, 2012).

While it is still not clear how cortisol gets into hair, hair serves as a reservoir of cortisol and other chemicals and

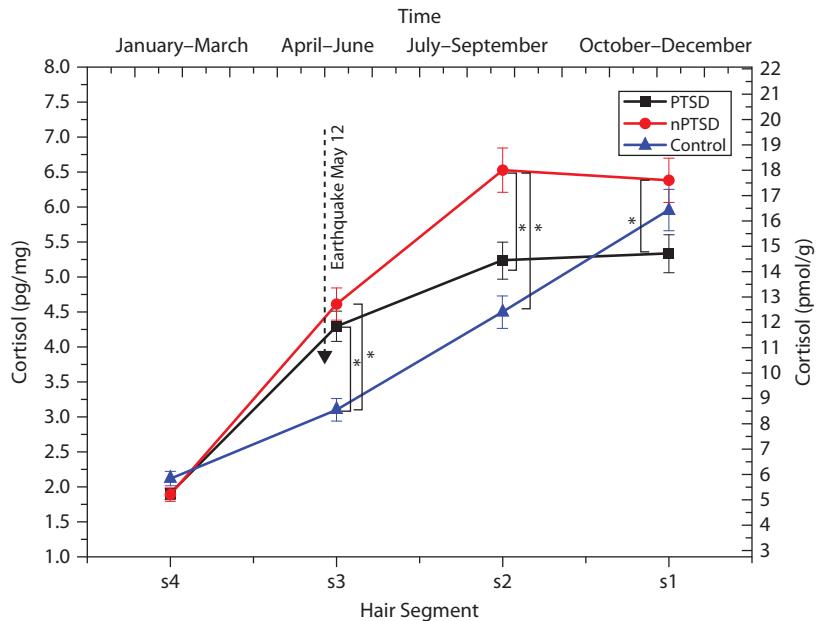

Figure 4.2 Hair cortisol levels in 64 adolescent girls following the Wenchuan earthquake on May 12, 2008.

Cortisol levels in 3-cm hair segments reflect time after and before the earthquake: S1 = 5 to 7 months, S2 = 2 to 4 months, S3 = 2 months before to 1 month after, and S4 = 3 months before the earthquake. The girls were divided into those who developed PTSD ($n = 32$), those who did not (nPTSD, $n = 320$), and nontraumatized controls ($n = 20$). These data show the utility of hair cortisol as a calendar for analyzing the effects of a traumatic event as well as the “washout” effect.

Source: From “Hair Cortisol Level as a Biomarker for Altered Hypothalamic-Pituitary-Adrenal Activity in Female Adolescents With Posttraumatic Stress Disorder After the 2008 Wenchuan Earthquake,” by H. Luo et al., 2012, *Biological Psychiatry*, 72, pp. 65–69.

hormones. Hair grows at roughly 1 cm/month, although there may be age and race differences in rates of hair growth. Counting back 1 cm from the scalp, hair provides a calendar. There are challenges to hair sampling, especially washout, or the decrease in cortisol from scalp to ends of the hair, which is possibly due to hair near the tips being washed more times than hair near the scalp. Both washout and the utility of hair sampling can be seen in Figure 4.2, which shows levels of hair cortisol in female adolescents from two towns who experienced the Wenchuan earthquake in 2008 (Luo et al., 2012). The far right side represents cortisol levels in the past month while the far left side represents levels 1 year before.

Examining cortisol levels in the controls, a washout effect is apparent. However, even with the washout, a strong effect of the earthquake is apparent as is the blunting of cortisol production among girls who developed PTSD. There is evidence that the washout effect may be avoided by changing the way the hair sample is processed (i.e., avoiding isopropanol) as washout may not be due to hair washing as much as to more damaged, older hair being open to the cortisol-leeching effects of isopropanol (Stalder & Kirschbaum, 2012). However, control groups are advised.

NEURO-SYMPHONY OF STRESS— HYPOTHALAMIC-PITUITARY-ADRENAL INTERACTIONS WITH OTHER STRESS MEDIATORS

CORT and CRH do not act alone. There are a number of stress mediators. These mediators all interact in what has been appropriately described as a “neuro-symphony of stress” (Joëls & Baram, 2009). Their interactions vary as a function of the type, duration, and characteristics of the stressor, the developmental stage of the organism, and characteristics unique to the individual, such as genetic background. These stress mediators execute essential functions in their own spatial and temporal niches. Overlap in these niches allows for interactions between them and studies describe direct interactions among individual mediators. We consider some of these other stress mediators next.

Sympathetic-Adrenomedullary and Parasympathetic Nervous System

The sympathetic adrenomedullary (SAM) system is the peripheral effector of the fight-or-flight response and is

critical to our ability to cope with threat. Milliseconds after the perception of threat, preganglionic sympathetic nerves in the spinal cord leading to end-organs are activated; the most important of these for the fight-or-flight response is the adrenal medulla with its production of epinephrine (Ulrich-Lai & Herman, 2009). Epinephrine (E) from the adrenal medulla travels throughout the body to have widespread effects on cardiovascular activity, blood pressure, and energy metabolism. These effects are enhanced by norepinephrine (NE) released from nerve terminals. E and NE effects are fast and short-lived. The half-life of E is 2 minutes. E and NE produced in the periphery do not enter the brain, but NE is produced in the central nervous system, often in coordination with increases in the periphery.

The SAM system is the hormonal component of the sympathetic nervous system (SNS), which, in turn, is one arm of the autonomic nervous system that serves many functions beyond fight-or-flight (ANS; McCorry, 2007). It supports arousal and attention in the central nervous system; thus we see increases in activity mediated by the ANS (i.e., heart rate, blood pressure) on effortful tasks, even if they do not threaten our social or physical selves. For example, effortful tasks like the Stroop or Mirror Drawing increase ANS activity but typically do not increase activity of the HPA axis, nor do they usually increase the production of E from the adrenal medulla. Rather they increase arousal through the release of NE from sympathetic nerve terminals and the production of NE in the brain from the locus coeruleus. These and other effortful cognitive tasks are *not* good tasks if the goal is to produce a fight-or-flight response of the SAM system and activation of the HPA axis.

There are numerous ways to measure activity in the SAM system. Galvanic skin response assesses peripheral NE activity. Salivary alpha amylase measures an enzyme regulated by NE and parasympathetic regulation of saliva flow. Finally, pre-ejection period (PEP), measured by impedance cardiography, is a relatively pure index of E produced from the adrenal gland.

The parasympathetic nervous system (PNS) plays a critical role in stress by helping to restore the conditions under which the body can rest and repair (Porges, 2009). The SAM system is organized for mass action, while the PNS is more targeted. The existence of both afferent and efferent projections from the brain also means that the PNS provides important information about the state of the body. Information travels to the brain along the nucleus tractus solitarius (NTS), which has inputs into the amygdala and

neural systems involved in threat perception and response. Much of the focus on PNS innervation in relation to stress and emotion has focused on the activity of the 10th cranial, or vagus, nerve. The myelinated vagus provides tonic inhibitory input to the heart over the sinoatrial node (the heart's main pacemaker). Decreases in vagal input increase heart rate by *lifting the vagal brake*. Vagal tone is measured as respiratory sinus arrhythmia (RSA) or the variation in heart rate surrounding respiration. Changes in heart rate in response to negative emotional tasks in children are primarily due to changes in vagal tone rather than changes in sympathetic activity.

Central Norepinephrine

Because the enzyme that converts NE to E is present primarily in the adrenal medulla, there is little E in the brain. E and NE produced by the periphery do not enter the brain, although they affect the brain via the NTS (Porges, 2009). Instead, NE in the brain is produced principally by the locus coeruleus (LC) in the brainstem (Benarroch, 2009). Like the peripheral SAM system, the central NE system has many functions in arousal, attention, learning, and emotions. Like CRH, NE also mediates fear behaviors. Another critical role of the central NE system during stress is the formation of emotional memories that can alter future behavior (Roozendaal & McGaugh, 2011). NE acting in the basolateral amygdala (BLA) is essential for the consolidation of emotional memories, and these NE effects require the presence of CORT. Increasing CORT in the BLA during stress through both rapid nongenomic and slower genomic mechanisms enhances the effects of NE. In addition, CORT acting via GR located in the NTS increases NTS NE signals to the BLA, further enhancing the consolidation of emotional memories. These effects have been shown in children, adolescents, and adults where individuals who showed both a large CORT and PEP (adrenal E) response to the TSST had better free-recall of the experience during a pop quiz 2 weeks later than did those who showed less of a CORT response and/or no PEP response (Quas, Yim, Rush, & Sumaroka, 2012). It should be noted that, in contrast to memory consolidation, elevated CORT impairs memory retrieval.

Dopamine

Dopamine (DA) is a major catecholamine neurotransmitter produced in several brain regions, including the ventral tegmental area, which projects to the nucleus accumbens

and PFC. Increases in CORT stimulate production of dopamine through GR receptors. During stress, activation of the ventral tegmental area by CORT results in excessive DA release into the PFC, leading to overstimulation of D1 receptors and impairments in working memory and other executive functions (Shansky & Lipps, 2013). Via GR in the PFC, CORT blocks catecholamine transporters located on glia, impairing their maintenance of DA and NE needed to support PFC-mediated learning, reasoning, and working memory. Via GRs in the PFC, CORT also alters DA cell firing rates. These mechanisms help explain the effect that stress has on self-regulation.

In addition, via interactions with DA, CORT affects activity of the nucleus accumbens allowing stress to modulate the circuits involved in reward (Mora, Segovia, Del Arco, de Blas, & Garrido, 2012). Through GR-mediated genomic mechanisms and membrane nongenomic pathways, rising levels of CORT during the initial phases of the stress response enhance dopamine activity in the accumbens. The behavioral effects of these increasing DA levels are dependent on interaction of the nucleus accumbens with the PFC. There is also evidence that the strengthening of glutamate synapses within the ventral tegmental area is dependent on CORT acting through GRs (Mora et al., 2012). Finally, chronic stress remodels and can impair the reward system, increasing susceptibility to addiction, and these changes involve CORT actions operating through GR.

Serotonin

Serotonin, a biogenic monoamine, plays a critical role in HPA activity. Serotonin is produced in the midbrain raphe nucleus, and one site for its terminals is the PVN, where it induces CRH expression (Chen & Miller, 2012). During development, serotonin is part of the biological pathway that decreases methylation of the GR gene in the hippocampus (Zhang, Labonté, Wen, Turecki, & Meaney, 2013). In turn, during stress, CRH and CORT modulate the synthesis and turnover of serotonin in the raphe (Chen & Miller, 2012).

Oxytocin

Oxytocin (OT) has been identified as a potential mediator of the ability of social support to buffer HPA reactivity. During stress, OT is released from cells in the PVN and from the central nucleus of the amygdala (A. S. Smith & Wang, 2012). Animal studies involving intraventric-

ular administration of OT or human studies involving intranasal administration show reduced anxiety and HPA responses, as well as decreased heart rate and blood pressure responses to stressors. In children, having direct or even phone contact with mothers after the TSST elevated OT and lowered CORT (Seltzer, Ziegler, & Pollak, 2010). Early deprivation of parental care in monkeys impairs the development of the OT system and may reduce the animals' ability to use social support to regulate stress (Winslow, 2005).

Brain-Derived Neurotrophic Factor

Stress remodels the brain and one way this happens is the complex cross-talk between CORT and brain-derived neurotrophic factor (BDNF; Gray, Milner, & McEwen, 2013). BDNF is a neurotrophin that helps regulate nerve cell proliferation, differentiation, survival, and synaptic plasticity. Basal levels of CORT have neurotrophic/neuroprotective effects, enhancing BDNF activity through increasing levels of its receptor, TrkB. During stress, the relation between CORT and BDNF is dependent on timing, levels, and duration of CORT elevations and differs by brain region. In the hippocampus, there is some suggestion that increasing levels of CORT may facilitate BDNF expression until, at some point, excessive levels or levels that are elevated for too long suppress BDNF. Importantly, in the hippocampus, chronic stress produces hippocampal atrophy (which is reversible). Effects of stress in the basolateral amygdala are the opposite of those in the hippocampus and do not appear to reverse during recovery. In the basolateral amygdala, CORT induces increases in BDNF that, in turn, increase dendritic branching and spine density. Some of these effects on amygdalar BDNF are mediated by rapid, nongenomic mechanisms.

Immune System

There is a growing literature on the interaction between the HPA axis and the immune system, particularly with regard to explanations of early life stress and later life health (G. E. Miller, Chen, & Parker, 2011). These interactions are multiple and change across time following an acute stressor. Inflammatory immune cytokines activate the HPA axis, induce fever, and act in the brain to induce withdrawal and depression-like symptoms (e.g., sickness behavior). Elevated CORT and E/NE increase cytokines that have anti-inflammatory effects. Indeed, anti-inflammatory actions are a critical function of CORT.

However, both hyperactivity and hypoactivity of the HPA axis, through different mechanisms, are associated with chronic increases in inflammation and impairments in wound healing. Chronic elevations in CORT may down-regulate GR and produce glucocorticoid resistance, while chronic suppression of CORT levels may fail to restrain inflammatory responses. Stress effects on inflammatory cytokines are believed to be one pathway through which adversity increases the risk of affective disorders.

HERITABILITY AND GENETICS

There are marked individual differences in reactions to stressors. This has led to an interest in heritability of stress reactivity and a search for the polymorphisms that, in interaction with experience, contribute to individual differences in stress reactivity and regulation.

Heritability

Although early heritability studies of the HPA axis were marked by considerable methodological limitations (Barthels, van den Berg, Sluyter, Boomsma, & de Geus, 2003), studies with appropriate sample sizes have begun to reveal the genetic underpinnings of both basal and stress regulation of the HPA axis. In adults, CORT levels shortly after waking show heritability estimates ranging from .34 to .69, whereas later in the day heritability estimates are lower to negligible. One interpretation of these findings is that reactions to experiences during each day mask the trait component of CORT production. This is consistent with evidence that heritability appears high in adults at all points in the cycle when CORT is assessed under laboratory conditions, but are much lower when samples are collected at home (Franz et al., 2010). Using statistical techniques that allow isolation of the trait component should reveal heritability as was shown in a large twin study of children (Van Hulle, Shirtcliff, Lemery-Chalfant, & Goldsmith, 2012). However, even using these techniques, the highest heritability estimates were found for samples taken 30 minutes after waking, and the diurnal rhythm itself showed heritability. For practical purposes, these findings suggest that the CAR may be a particularly useful tool for researchers interested in probing the HPA axis with candidate gene studies.

All studies mentioned above used individuals from low-risk backgrounds. Recently, researchers have examined the effects of adversity on heritability. For example,

among 19-month-old twins, the heritability of HPA reactivity to novel stressors was lower among children reared under high-risk conditions for whom shared environment accounted for considerable variance, while heritability was relatively high among children reared under low-risk conditions (Ouellet-Morin et al., 2008). The utility of heritability studies is limited by their treatment of genetic and environmental factors as independent forces. In order to explore actions of particular genes or sets of genes within an environmental context, molecular genetics studies are necessary.

Molecular Genetics

Multiple genes regulate the HPA axis and its effects. Information about polymorphisms in these genes not only allows for examination of their effect on the axis, but also provides information about behavioral and health characteristics that are mediated by activity of CORT and CRH. Following is a discussion of some genes that appear promising. In some instances, researchers have focused on associations or interactions with individual single nucleotide polymorphisms (SNPs), but other research is considering the influence of haplotypes, or several variants in linkage disequilibrium that are inherited simultaneously.

Corticotropin-Releasing Hormone Receptor 1 (CRHR1)

There are a number of SNPs in the CRHR1 gene. Male carriers of GG genotype of rs110402 and rs242924 SNPs with a history of moderate to severe maltreatment demonstrated significantly higher plasma CORT in response to a DEX/CRH test while A-allele carrier females were the ones to produce larger CORT responses (Heim et al., 2009). (Note that the DEX/CRH test is considered a more sensitive and reliable pharmacological measure of the reactivity of the HPA axis than is obtained by simply administering CRH.) Sex differences in the type of abuse experienced make it difficult to interpret these findings. Measured during childhood, maltreated children homozygous for the TAT haplotype demonstrated significant flattening of the diurnal slope (which appeared to be driven by lower morning CORT levels) compared with children carrying at least one other allele (Cicchetti, Rogosch, & Oshri, 2011). Finally, several CRHR1 haplotypes were found to moderate CORT reactivity in preschoolers and more critically, these haplotypes interacted with other genes in the CRH system, highlighting the complex polygenic underpinnings of HPA reactivity (Sheikh, Kryski, Smith, Hayden, & Singh, 2013).

Given CRHR1 moderation of maltreatment effects on the HPA axis, researchers have also examined whether similar moderation is observed for depression. Particularly pertinent to this review, the CRHR1 TAT haplotype, consisting of SNPs rs7209436, rs110402, and rs242924, has been shown to significantly moderate the effect of childhood maltreatment on the development of depression in adulthood. Findings with the TAT haplotype, maltreatment, and depression, however, have been variable (e.g., Ressler et al., 2010).

Glucocorticoid Receptor (NR3C1)

Multiple polymorphisms in the GR gene have been investigated; only two are discussed here (for review, see Spijker & van Rossum, 2009). The ER22/23EK variant refers to G to A nucleotide changes in two SNPs (rs6189 and rs6190) in codons 22 and 23. This allele is associated with glucocorticoid resistance in response to dexamethasone, a synthetic CORT, but it has not been consistently demonstrated that this allele affects CORT secretion in response to a psychosocial stressor. The minor allele of the BclI variant (rs41423247) represents a C to G transformation that is associated with increased sensitivity to CORT (Spijker & van Rossum, 2009). Minor allele carriers show increased suppression of plasma CORT following administration of DEX and males show decreased HPA-axis responsivity following the TSST. The minor BclI allele may also increase children's susceptibility to maternal psychopathology as assessed using prenatal measures of psychopathology and child behavior at 14 and 36 months of age (Velders et al., 2012). The relatively high frequency of the minor allele (roughly 30%) makes this polymorphism of particular interest.

FKBP5

As noted, as part of the chaperone complex, FKBP5 acts to reduce the affinity of CORT for GR. Increases in CORT stimulate increases in FKBP5, which then decrease the ease with which CORT binds to GR, allowing a short-loop negative feedback mechanism. SNPs in this gene appear to confer differences in induction of FKBP5 in response to elevated CORT and GR activation, and subsequent GR resistance or sensitivity (as reviewed in Heim & Binder, 2012). In healthy adults, individuals homozygous for the T allele of rs1360780 exhibit significantly lower peripheral FKBP5 expression, and several SNPs (rs3800373, rs1360780, and rs4713916) have yielded evidence of exaggerated CORT response even in infants for individuals with at least one copy of the minor allele (Heim & Binder, 2012).

Associated Neurotransmitter Polymorphisms

As described above, the DA, central NE, and serotonin systems all interact bidirectionally with the HPA axis and CRH; thus, not surprisingly, genetic polymorphisms in genes that regulate these systems interact with the axis and CRH as well. For example, a meta-analysis reveals that homozygosity for the gene variant that produces the short version of the serotonin transporter gene (5-HTTLPR) reduces transcriptional efficiency of that gene and increases the CORT response to psychosocial stress (R. Miller, Wankerl, Stalder, Kirschbaum, & Alexander, 2012). Functional variants of the monoamine oxidase (MAOA) and catechol-o-methyltransferase (COMT) genes also affect CORT reactivity via their effects on NE and dopamine. The low-activity alleles of the MAOA gene, a 30-bp VNTR, and COMT gene (val1158met SNP rs4680; met/met), in combination with each other, are associated with increased plasma ACTH and salivary CORT following a psychosocial stressor (e.g., Bouma, Riese, Doornbos, Ormel, & Oldehinkel, 2012). Variation in these systems, as well as others, may affect the HPA axis drive, produce elevated CRH and CORT effects on neural functioning, and influence the efficiency of social support as a stress buffer.

Epigenetics

The structural genome is overlaid by chemical marks, or epigenome, that regulate how the genetic material in each cell interacts with its transcription factors (Szyf, 2012). Epigenetic marks are passed on when the cell divides and, in some instances, from one generation to the next. The epigenome is tissue- and cell-specific, which allows for the tremendous variation in cell types throughout the body. Although much of the epigenome is determined before birth during morphogenesis, postnatal experiences driven by hormones, social experiences, nutrition, toxins, and stress continue to alter the epigenome throughout life.

Methylation is a principal, but not sole, mechanism of epigenesis. DNA methylation refers to the addition of a methyl group to the DNA, which then affects its interaction with transcription factors. DNA methylation occurs in regions where a cytosine is directly followed by a guanine (CpG, cytosine-phosphate-guanine sites or "islands"). Methylation is a bidirectional process, and genes can exist in a range of degrees of openness to transcriptional activity. This range reflects both methylation and histone acetylation and deacetylation (which relaxes or condenses chromatin). Epigenetics provides a powerful means whereby experience can alter developmental trajectories. Although the

epigenome does not alter the structural genome, relations between them are expected. That is, some gene by experience interactions may reflect mechanisms through which the structural genome influences experiential shaping of the epigenome.

As discussed in the section on childhood adversity, during sensitive periods of development, parental care programs the ease with which the GR gene in the hippocampus is transcribed (Szyf, 2012). In rodents, this period is during the first postnatal week when regulatory regions of the GR gene containing the NGF1-A binding, which are completely methylated after birth, are then demethylated as a function of maternal licking and grooming of the pups. Rodents who receive higher levels of maternal care exhibit less methylation at this site and are better able to regulate the HPA axis. It is unknown if there is an equivalent period in humans, but there is evidence that adversity in childhood is associated with differential methylation (see Childhood Adversity section).

There is a growing body of work examining the association between early life adversity and whole genome methylation patterns using either cheek cells or white blood cells, (e.g., Essex et al., 2013). Patterns on these cells will not necessarily correspond to methylation patterns in the brain, and methylation in one type of cell in one region of the brain will not necessarily reflect methylation in other types of cells in other brain regions. It is important to find evidence, using animal models, that stress affects methylation of genes regulating processes important in stress vulnerability and resilience. It appears to do so. For example, in addition to the GR gene, it is clear that early adverse care causes increased methylation of the BDNF gene in the PFC, reducing BDNF expression and contributing to stress-induced impairments in PFC functioning (Roth & Sweatt, 2011). Furthermore, during fetal development elevated CORT programs neural stem cells, upregulating cell cycle-related genes in a GR-dependent manner, and making resulting nerve cells more susceptible to oxidative stress and aging (Bose et al., 2010).

Summary and Future Directions

Several promising research trajectories should guide the study of HPA physiology and human development in the coming years. First, although much has been discovered about PFC regulation of HPA activity, further research is needed to address the development of this top-down regulation together with other stress-mediating systems, interacting in the “neuro-symphony of stress” (Joëls & Baram,

2009). Second, understanding monoamine, neuropeptide, and steroid hormone receptor systems will be vital to interpreting individual differences in responses to stressors. Physiological regulation is strongly influenced by the location, concentration, sensitivity, and function of receptors across tissues and organ systems. Research into how receptor systems develop and their subsequent effects on homeostatic regulation will be essential to understanding stress physiology, neural activity, and behavior. Finally, true developmental research must measure psychological and biological processes at multiple time points to understand the mechanisms involved at each stage of development and the factors contributing to maintenance or change in stress and emotion systems.

NORMATIVE DEVELOPMENT OF THE HPA SYSTEM

Using the HPA system to understand the effects of stress on development requires understanding normative changes in the system’s activation and regulation. These have been described extensively (e.g., Hostinar & Gunnar, 2012) and are summarized here.

Prenatal Period

The HPA axis becomes stress-responsive by the 20th week of gestation. This is the case even though the fetal adrenal gland contains a large fetal zone that helps produce estrogens and involutes over the first 6 postnatal months. Not only does the fetus produce CORT, but maternal CORT can reach the fetus. This raises the question of whether and how CORT influences fetal development. CORT plays critical roles in advancing tissue development, which likely explains why CORT levels in mother and fetus rise toward the end of gestation. However, as in later development, CORT needs to be tightly regulated. Because the fetal liver is immature, its production of binding globulins is low; therefore, even small increases in CORT produce large increases unbound, biologically active CORT. Both MR and GR are present from early in gestation; thus, CORT likely has effects across much of fetal development.

There are numerous checks and balances, however. The enzyme 11 β -HSD2, which converts CORT to an inert substance, is present at the blood-brain barrier, in the placenta, and in fetal tissues. It is highly expressed in the fetal brain between prenatal Weeks 19 through 26, when it is often seen colocalized with GR. As term approaches,

levels decrease. Thus, 11 β -HSD2 likely serves the function of temporarily protecting rapidly developing brain regions from overexposure to CORT (Wyrwoll et al., 2011).

Infancy

Full-term healthy newborns elevate CORT to a variety of even mild stressors. This degree of reactivity remains during the first months of life, but by 3 to 4 months, the axis has become less responsive, perhaps reflecting the development of fast feedback mechanisms.

Events that provoke distress typically also activate the HPA axis; nevertheless, behavioral distress and HPA systems are differentially regulated. Thus, soothing techniques that reduce crying might have no effect on CORT levels, and CORT reactivity may be uncorrelated or only very slightly correlated with crying in many instances (Gunnar & Donzella, 1999).

Three months is an important turning point in development when the infant becomes better regulated and is able to socially engage for longer periods. The diurnal CORT rhythm becomes more stable around this time, although it is only the morning peak and evening nadir that are readily observable. Not until the child gives up the afternoon nap in the preschool years (approximately 3 to 5 years of age) are midafternoon levels predictably lower than mid-morning levels.

In the neonatal period, a variety of stimuli embedded in the caregiver–infant relationship begin to regulate the infant’s HPA system. As reviewed in Hostinar and Gunnar (2012), there is some evidence that the more time the parent and infant spend in physical contact the shorter the bouts of crying and the smaller the CORT elevations to everyday stressors, like being removed from the bath. During these first months when the HPA axis is still highly reactive to stimulation, there is evidence that sensitive responses to infant distress regulate the axis, returning CORT levels more promptly to baseline (Albers, Riksen-Walraven, Sweep, & de Weerth, 2008). The regulatory roles of caregiving activities allow the caregiver to serve as a powerful stress buffer.

However, during these early months, different components of caregiving likely regulate different stress-mediating systems. Thus, facets of caregiving that reduce crying (e.g., feeding, nonnutritive sucking) are less capable of buffering heart-rate responses to painful stimulation, and have no apparent effects on CORT responses to stress (Hostinar & Gunnar, 2012).

The emergence of social relationships as powerful stress buffers is one of the most remarkable phenomena during the

first year of life (Hostinar, Sullivan, & Gunnar, 2014). This appears to occur around the onset of independent locomotion, which corresponds roughly to when the child begins to actively organize security-seeking behavior around attachment figures. At this point it is not just what the attachment figure does but who the person is and his or her relationship with the child that is important. We can see this clearly in studies that have used childhood inoculations as the stressors. Children show marked increases in CORT despite the parent’s presence at 2, 4, and 6 months. Then from as early as 12 to at least as late as 18 months, these elevations are no longer seen and CORT responses remain low in the parent’s presence.

The attachment figure needs to be present to provide buffering during infancy and early childhood. This has been demonstrated in studies of children in childcare. When the parent is present, securely attached children do not show elevations in CORT whereas insecurely attached children do; but in the first days when the parent leaves the child, CORT levels are equally elevated for securely and insecurely attached children. For children who have adapted to their daycares, a secure relationship with their parent may make the HPA axis more sensitive to variations in childcare quality. Thus, securely attached children both produce the largest increases in CORT in poorer quality daycares and the smallest elevations in higher quality ones (Badanes, Dmitrieva, & Watamura, 2012).

We still do not know how the attachment figure’s presence works to provide such a potent stress buffer, although oxytocin and other antistress hormones that are fostered by his or her presence may play a role (Hostinar, Sullivan, et al., 2014). In addition, the presence of the attachment figure may activate brain regions associated with safety signals, thus reducing fear and anxiety even to noxious stimuli. This has been demonstrated in adults for whom viewing an image of the romantic partner while experiencing a pain stimulus activated a safety signal–related neural region in the ventromedial PFC (vmPFC) and reduced the experience of pain (Eisenberger et al., 2011). We do not know how long in development the parent is able to play this stress-buffering role. It may be that parental stress-buffering potency declines in adolescence.

Preschool and Middle Childhood

According to current knowledge, the HPA axis is quite mature by the preschool period. Two psychosocial changes, however, begin to affect its activation and regulation during this period and become increasingly important during

middle childhood: the development of emotion regulatory competencies and the increasing focus on peers and peer relationships.

There are marked increases in the child's ability to regulate behavior and emotions during early childhood. Neurodevelopment of regions in the prefrontal cortex involved in the effortful regulation of behavior (dIPFC) and emotions (vmPFC) may play a role (Belsky & de Haan, 2011). The development of self-regulatory competence should allow the child to modulate activity of the HPA axis more independently. However, there is a complex relation between stress and the PFC and the relations between measures of effortful control and activity of the HPA axis are positive under some circumstances and negative under others (Shansky & Lipps, 2013). CORT is necessary for PFC functions because it supports the central production of DA and NE (Mizoguchi, Ishige, Takeda, Aburada, & Tabira, 2004). Thus higher levels of CORT within basal ranges might support functioning on effortful control tasks if the higher levels occur in anticipation of the task and prepare the child for task demands. This has been demonstrated in several studies. Stress levels of CORT, however, impair prefrontal functioning, in part through the overenhancement of DA production (Shansky & Lipps, 2013). Thus among children experiencing high lifetime stress, the opposite pattern of associations may be found, as was noted among preschoolers in a homeless shelter (Cutuli, Wiik, Herbers, Gunnar, & Masten, 2010). If we measure effortful control in relation to basal or ambulatory CORT levels, negative associations would be expected because children with better self-regulatory abilities should be better able to regulate their emotions and avoid stressful conflicts with others. This has generally been found (Turner-Cobb, Rixon, & Jessop, 2008).

Effortful control also mediates relations between children's emotional dispositions and the quality of their relations with peers. Children who tend to be easily angered when frustrated and those who are exceedingly exuberant have problems with aggression unless they also have good self-regulatory competencies. Although simply inhibiting expressions of anger when provoked might increase adrenocortical and sympathetic activity (Spinrad et al., 2009), because unregulated anger and aggression increase the risk of rejection and ostracism, children with better self-regulatory abilities should, overall, experience fewer stressful social interactions, (e.g., Gunnar, Sebanc, Tout, Donzella, & van Dulmen, 2003).

As noted, threats to the social self are powerful stressors. Rejection and ostracism are powerful social threats that

activate neural pain circuits (Cacioppo & Cacioppo, 2012). Social isolation increases attention to threatening aspects of the environment and in animal studies activates the HPA axis. Peer-rejected preschoolers and older children exhibit elevated CORT at school, although having even one friend reduces this effect (e.g., Peters, Riksen-Walraven, Cillessen, & de Weerth, 2011). It may not so much be peer rejection but loneliness that is stressful for children and youth, particularly if loneliness is chronic (Doane & Adam, 2010).

While some rejected children are simply ignored, others are targets of bullying. Bullying can be highly stressful for children and is associated with significant psychopathology. Only a few studies have examined the relation between peer victimization and CORT and the results have been mixed. There are two reasons for this. First, some victims are also bullies. Bully-victims may be comorbid for conduct disorder and have low CORT levels (van Goozen, Fairchild, Snoek, & Harold, 2007). Second, the duration and intensity of victimization may be critical. When victimizing begins or if it is only occasional it should increase CORT, but after a long period of intense bullying the HPA axis is likely to downregulate (G. E. Miller, Chen, & Zhou, 2007). Intermittent victimization has been associated with elevated CORT, while chronic victimization has been correlated with low CORT in boys (Vaillancourt et al., 2008). Likewise, children experiencing more cumulative stress may exhibit blunted CORT in response to peer victimization (Ouellet-Morin et al., 2011). As children move into preschool and middle childhood, peer relations become increasingly important and problems in relations with peers are important stressors affecting activity of the HPA axis.

Puberty and Adolescence

Adolescence, a period of rapid development and marked changes in social relationships, is also a period when emotion systems and their neural substrates mature and become more sexually differentiated (Dahl, 2004). Sex steroids have regulatory effects on the amygdala and mPFC in adults and although less studied, there is evidence that puberty and increasing levels of gonadal steroids affect the developing brain in a sexually dimorphic fashion (Neufang et al., 2009). Consistent with these findings, activity of the HPA axis becomes sexually differentiated with advancing sexual maturity. For example, in a large sample of youth aged 16 years, CORT levels were higher and ACTH levels were lower in fasting morning plasma samples for girls

than boys (Reynolds et al., 2013). Sex differences in response to social stressor tasks are observed among adults with men responding more strongly than women (Kudielka & Kirschbaum, 2005). Sex differences in responses are not reliably seen in childhood, but emerge around the pubertal transition and are clearly present by mid-adolescence (Gunnar, Wewerka, Fenn, Long, & Griggs, 2009). CORT levels also increase with puberty. The increase is clearly seen in basal levels; whether it is present for reactivity is less clear. CORT reactivity has been reported to increase with pubertal stage/age in some studies (e.g., Gunnar, Wewerka, et al., 2009).

It has been argued that the pubertal increase in HPA activity, along with the increased sexual dimorphism, contributes to girls' vulnerability to depression and to increases in psychopathology for both sexes during adolescence (Dahl & Gunnar, 2009). In animal studies there is evidence that the peripubertal period is a second sensitive period of vulnerability for the HPA system (Eiland & Romeo, 2012). However, at least one study indicates greater invulnerability during this period; specifically, the researchers found that chronic unpredictable stress in the adolescent period in the rat enhanced avoidance learning, whereas it impaired it among adults (Ricon, Toth, Leshem, Braun, & Richter-Levin, 2012). However, as noted by Eiland and Romeo (2012), when similar studies are conducted with adolescent female rats, impairments are noted. Thus sex may influence whether stress increases vulnerability or resilience during puberty.

If stress vulnerability increases during adolescence, it could partly be due to a decrease in the power of parental buffering of the stress system. Just prior to puberty, even being able to phone the mother blocked increases in CORT and increased oxytocin (Seltzer et al., 2010). In children of roughly the same age, allowing the mother to be present and supportive during the speech preparation period of the TSST also blocked elevations in CORT, while providing the child with a supportive but unfamiliar adult did not (Hostinar, Johnson, & Gunnar, 2014). In the same study, parental presence among 15-year-olds had no buffering effect on CORT. Whether this developmental shift is mediated by puberty or psychological changes in the parent-child relationship remains to be determined. In addition, it seems likely that when parent-as-buffer decreases in potency, other social relationships may take over the stress-buffering role. The role of friends and romantic partners as stress buffers in adolescence remains to be explored. Finally, it seems unlikely that parents completely lose their stress-buffering potency for adolescents.

It might depend on the type of stressor facing the youth. This too remains to be examined.

Summary and Future Directions

As the HPA axis develops, both reactivity and regulation shift from infancy to adolescence. From the emergence of attachment figures as stress buffers in infancy to the potential role of romantic partners as regulatory forces in adulthood, social relationships play a crucial role in stress regulation across the life span. Further, as peer structures become more complex during middle childhood and adolescence, social standing may play a critical role in HPA functioning. As research accumulates on the development of self-regulatory skills that emerge in early childhood, care should be taken to examine its relation to stress reactivity and regulation in the context of both children's lifetime stress as well as task demands. At the pubertal transition, future research is needed to understand the potentially differential effects of sex hormones on vulnerability to stress during adolescence. Exploring shifts in stress-buffering social systems during this period is a promising avenue for better understanding these processes.

THEORETICAL PERSPECTIVES

Child development research on the psychobiology of stress has largely been conducted from a developmental systems perspective. Adult work on the psychology of coping has been guided by Lazarus and Folkman's (1984) transactional model, emphasizing individual differences in appraisal and response to events. Both of these perspectives have influenced current thinking. Evolutionary perspectives have also challenged our dominant models.

Allostasis and Allostatic Load

The allostatic load model (ALM) is the most influential psychobiological stress theory (McEwen & Wingfield, 2010). In developing ALM, the starting point was the concept of allostasis, which describes the body's ability to up- and downregulate vital functions to achieve new steady states in reaction to challenge. As a shorthand, allostasis is often defined as "achieving stability through change." There are a number of allostasis-mediating systems; however, CRH and the HPA system, the immune system, and the central and peripheral catecholamine systems have received the greatest attention.

As Selye noted decades ago, activation of these allostasis- or stress-mediating systems allows us to cope (Selye, 1946). In the face of chronic adversity, the mobilization of these systems can allow us to look like we are coping exceptionally well for prolonged periods, and then somehow, we are overcome by disease. Selye thought the disease states were due to exhaustion of these systems. He was wrong. In place of exhaustion, ALM inserts allostatic load (McEwen & Wingfield, 2010). Allostatic adjustments, if frequent or chronic, can take a toll on the body. Allostatic load or overload refers to the wear and tear produced by either too much stress or from inefficient regulation of stress mediators. Inefficient regulation can mean a failure to turn off or return to baseline once the threat has passed and/or a failure to appropriately activate the response. Both under- and overactivation of allostasis-mediating systems can develop through prolonged overuse. The cumulative wear and tear of allostasis and/or dysregulation of allostasis-mediating systems defines allostatic load, which leads to many diseases of aging as well as undergirds cognitive deficits and stress-related mental disorders in some individuals.

Allostasis-mediating systems influence one another, but their relations are expected to be nonlinear and stressor specific (Joëls & Baram, 2009). Different patterns of responses are provoked by different classes of stressors (e.g., infectious agents, social threat) and the time courses differ across systems in their activation and the time it takes for them to affect function. Catecholamines produce their effects quickly and dissipate rapidly, which is why epinephrine and norepinephrine undergird the fight-or-flight system whereas CORT takes 25 minutes to reach peak reactions and its gene-mediated effects can play out over hours and days.

Hypothalamic-Pituitary-Adrenal and Autonomic Nervous System Asymmetry

No one attempts to measure all stress-mediating systems; however, there are increased calls to measure more than one system at a time, especially combining HPA and SAM measurement (Bauer, Quas, & Boyce, 2002). Bauer and colleagues argue that the HPA and SAM systems evolved to work together and moderate levels of co-activation should be related to healthier functioning, while SAM and HPA asymmetries may reflect allostatic load. Because chronic stress tends to downregulate the production of CORT (G. E. Miller et al., 2007) and increase catecholamine production, high sympathetic and low HPA activity may be the product of chronic stress. Some studies (Gordis, Granger,

Susman, & Trickett, 2006) have supported this argument, whereas others have found the opposite results (El-Sheikh, Erath, Buckhalt, Granger, & Mize, 2008).

One challenge in testing the asymmetry hypothesis is that the HPA system habituates to repetition of the same stressor after as little as one trial, whereas the type of chronic stress that downregulates the axis requires presentations of changing and unpredictable stressors. The HPA axis often habituates whereas the sympathetic system keeps responding, particularly if the stressor demands an effortful response (Ursin, Baade, & Levine, 1978). Thus, it is unlikely that symmetry or asymmetry between the HPA and SAM systems will consistently be associated with health or disorder. Rather, the meaning of these patterns will be context and stressor specific, reflecting situational demands, stressor appraisal, and prior experience.

Allostatic Load Model Indices in Children and Adolescents

Allostatic load is measured through systems affected by chronic activation of allostasis-mediating systems. Its indices include high systolic and diastolic blood pressure; high waist-hip ratio; elevated cholesterol (HDL and total); high glycosylated hemoglobin; and high overnight urinary CORT, norepinephrine, and epinephrine. Typically one counts up the number of these indicators. These measures of allostatic load were developed for work with adults and it is an open question whether they are predictive in children whose systems are still developing. Other indices may be sensitive in childhood. We have proposed that a slowing of linear growth may be an index of allostatic load in children (A. E. Johnson, Bruce, Tarullo, & Gunnar, 2011). Evidence is accumulating that the standard allostatic load indicators are useful by later childhood or early adolescence (Evans & Kim, 2012). There is also evidence that individuals who are highly resilient psychologically and behaviorally may exhibit higher indices of allostatic load by late adolescence (Brody et al., 2013). Although this might seem surprising, resilience in the face of heavy odds should require frequent activation of allostasis-mediating systems, producing an accumulating allostatic load.

Although ALM may help explain the development of children exposed to harsh conditions, it is not a developmental model. Because there is increasing evidence that there are sensitive periods in the organization of stress reactivity and regulation, a developmental framework is needed. Similarly, although ALM acknowledges individual differences related to temperament and sex/gender, it does not provide an explanation for these differences or

build predictions based on them. We now turn to a model that does.

Adaptive Calibration Model

The adaptive calibration model (ACM; Del Giudice, Ellis, & Shirtcliff, 2011) is an evolutionary-developmental model based in life-history theory (Coall, Callan, Dickins, & Chisholm, Chapter 3, this *Handbook*, this volume). Its proponents argue that it is an extension of ALM, specifically addressing what they see as its shortcomings. According to ACM, both positive and threatening environments have been part of our evolutionary heritage, and we have evolved to maintain reproductive fitness across a range of environmental harshness. What might be thought of as dysfunction, if reliably produced by harsh experiences, should better be thought of as choice of a different life-history strategy. For example, when early harsh conditions result in earlier-onset puberty, earlier and more frequent reproduction, and greater risk taking, this is viewed as a fast life-history strategy (Belsky, Steinberg, Houts, & Halpern-Felsher, 2010). ACM argues that the stress response system, in interaction with brain neurochemistry, acts as a filter and amplifier of life-history relevant experiences to mediate their effects on life-history traits: growth/learning, maturation/fertility, competition/risk-taking, and pair-bonding/caregiving. Beginning before birth, experiences are sampled by the stress response system, which leads to the selection of different life-history strategies that get modified during each developmental period. In some instances, response patterns may adversely affect the health and happiness of the individual and those around him or her, but they have been selected because they increase reproductive fitness, or did so in the environment in which we evolved.

Perhaps because this model was developed precisely to apply to human development, when measures of the stress response system are discussed, they only include those that can be noninvasively measured in children (i.e., CORT, ANS measures, and perhaps immune). The many other systems discussed in ALM are not a focus, though presumably are not excluded.

There are two aspects of ACM that are of particular note with regards to developmental stress research. First, the model has incorporated the biological sensitivity to context hypothesis (Boyce & Ellis, 2005; see also differential susceptibility hypothesis, Pluess & Belsky, 2010). Accordingly, some individuals are shaped more by their developmental history than are others and, consistent with adaptive calibration, it is reactivity of the stress systems

that determines sensitivity to context. Individuals with relatively nonreactive stress systems tend to have similar life-history strategies across a wide range of life-history relevant environmental inputs. In contrast, those with more responsive stress systems will be more sensitive to context. These individuals will exhibit the socially positive characteristics of a slow life-history strategy (low aggression, high agreeableness, focus on long-term goals, low reproductive rate, high investment in each offspring) if reared in supportive environments, but the socially negative characteristics of the fast strategy (high aggression, early puberty, risky behavior, early pregnancy, low rate of investment in individual offspring) if reared in harsh environments.

On a behavioral level, there is clear evidence that some phenotypes are more sensitive to context, perhaps based on their genetic endowment. What is unclear is whether stress reactivity determines this sensitivity, and whether the relationship is stressor specific or general. As noted by Obradović (2012), reactivity of the PNS has been shown to increase sensitivity to context, but in studies of marital conflict and domestic violence, PNS reactivity reduces sensitivity to context (i.e., tends to buffer children). Thus, simple models that are not context, stressor, and system specific may fail to capture the complexity of the stress-development landscape.

As another outgrowth of the biological sensitivity to context theory, ACM also argues that the stress response system is toned or tuned by the harshness or supportiveness of the early environment. From an evolutionary perspective, this is a form of conditional or predictive adaptation that has evolved to help preadapt the child. ACM argues for a U-shaped function between early care conditions and stress reactivity. Specifically, both highly supportive and very harsh conditions will produce a highly responsive stress response system, which supports sensitivity to the environment, better learning, and good outcomes in supportive contexts, but high vigilance and anxiety in harsh contexts. Moderately supportive, slightly harsh developmental contexts result in a buffered stress response system. ACM also describes a fourth grouping that results in traumatic rearing contexts that is differentiated by sex, with girls remaining vigilant and highly stress reactive and boys becoming unemotional with blunted stress reactivity. These four patterns are expected to be accompanied by differential activity of the ANS and HPA systems as follows: (1) Sensitive (high PNS basal and response activity; high to moderate SNS reactivity and moderate basal SNS activity; high HPA reactivity and moderate basal HPA levels), (2) Buffered (moderate PNS and HPA basal and response

activity, low to moderate SNS basal and response activity), (3) Vigilant (low to moderate PNS reactivity, low basal PNS activity; high SNS basal and response activity, high HPA reactivity, and high to moderate basal HPA levels), and (4) Unemotional (low basal and response activity of PNS, SNS, and HPA systems).

This is a complex theory with many moving parts. Currently, there are only a few studies testing parts of the theory. Critical to the theory is the existence of the four phenotypes and their correspondence to the patterns of stress responding. There is some support for these four groupings. Using finite mixed modeling, these theorists have recovered four patterns that roughly fit the predicted ones, although they only used measures of PNS and SNS activity (Del Giudice, Hinnant, Ellis, & El-Sheikh, 2012). Examination of the results showed that the four groups differed most in baseline skin conductance (a measure of SNS activity), with the Buffered being low and the Vigilant high as predicted; but the Unemotional were moderate rather than low in skin conductance baseline. Counter to expectations, males were not overrepresented in the Unemotional Group, but girls were overrepresented, as predicted, in the Vigilant group.

It is critical in the model that the relation between childhood adversity and the stress response system is *not* linear. There is more evidence of nonlinearity, but not always in the predicted direction. For example, in a study of kindergarteners (4–6 years old), measures of socioeconomic class and measures of adverse family events bore different relations with CORT when assessed at two different times of the school year. In the fall, the expected U-shaped function was found; while in the spring, the relationship was an inverted-U. Measures of adversity were linearly, not curvilinearly related to CORT and many of the associations were moderated by race (Bush, Obradović, Adler, & Boyce, 2011). In a study of 9–16-year-olds, another inverted-U rather than U-shaped function was found, with moderate levels of recent adversity associated with the highest CAR, whereas both the lowest and highest levels of accumulated adversity were associated with smaller CARs (Gustafsson, Anckarsäter, Lichtenstein, Nelson, & Gustafsson, 2010). As in HPA and SNS asymmetry, relations between experience and physiology seem to be contextualized and nuanced, challenging attempts to contain them in simple phenotypes.

The four patterns (Sensitive, Buffered, Vigilant, and Unemotional) are conditional or predictive adaptations, which presumably increase reproductive fitness. This is a difficult concept to prove in human research, but also not a concept peculiar to ACM. A number of researchers

have discussed the possibility that early programming of the HPA axis is a form of predictive adaptation. Predictive adaptation provides a framework in which to understand the “developmental origin of adult health and disease” model (DOAHaD; Gluckman, Hanson, & Beedle, 2007). The idea is that harsh fetal or early postnatal conditions shape an organism with a thrifty phenotype (i.e., a smaller body, lower metabolic rate, reduced behavioral activity, avoidance of novelty and exploration), which reduces the need for food and promotes survival under harsh conditions. If conditions continue to be harsh, a thrifty phenotype fosters longevity and reproductive fitness. However, if there is a mismatch in conditions, poor health ensues. This idea can readily be combined with the ALM to produce predictions of heightened reactivity of allostasis-mediating systems as a function of early adversity leading to obesity and even more rapid acceleration of allostatic load in an overly rich environment (McEwen & Wingfield, 2010).

The ACM, however, does not require a mismatch between programming cues and the encountered environment to result in behavioral and health disorders. In this regard, it should also be noted that Pluess and Belsky (2011) suggested that the heightened stress reactivity and timidity that is reported among offspring of stressed pregnancies (see “Prenatal Stress”) are a different form of programming—specifically, prenatal programming of postnatal plasticity or sensitivity to context.

Finally, predictive adaptation models, although assuming an increase in reproductive fitness, do allow for trade-offs, particularly with regard to longevity. In one example, the type of maternal separation in rats shown to increase reactivity of the HPA axis has also been shown to enhance hippocampal-dependent learning in the juvenile and young adult period followed by rapid cognitive decline in aging rats (Suri et al., 2013). In long-lived animals, such as humans, there may be life-history stages when the stress system is reprogrammed. The ACM describes multiple recalibrating periods from infancy to adulthood. Other models describe fewer. Among these periods, in addition to the fetal/early postnatal period, puberty stands out as potentially important for recalibration prior to the onset of reproductive maturity (Romeo, 2010).

OTHER THEORETICAL PERSPECTIVES OF POTENTIAL RELEVANCE TO DEVELOPMENTAL RESEARCH

While the ALM and ACM are the two most prominent theories guiding studies of stress and development in children,

there are several theories applied only to adults and/or in animal studies that may be useful to include in our developmental models.

Tend and Befriend

As we will note later, there is little evidence of sex differences in HPA-axis activity until puberty. However, that does not mean that boys and girls perceive the world similarly with regards to threats to their physical and/or social selves or that the sexes have evolved and/or have been socialized to cope in the same way. The ACM begins to address this problem, but a much more elaborate theory was proposed for adults. Over a decade ago, Taylor and colleagues (2000) proposed that there are marked sex differences in the organization of stress responses and in the consequences of exposure to stressors. Because the roles of males and females differ with regards to the bearing and rearing of the young, especially in species like ours where males have not been the primary caregivers until recently, the female stress system evolved to manage protection of both the female and her offspring. Thus, unlike males who “fight or flee” under threat, threat activates “tend and befriend” tendencies in women that foster seeking and banding together with others in the protection of the young. With regard to the neurobiology of these stress responses, they argue that the attachment system, supported by oxytocin and endogenous opioid peptide mechanisms, works to keep HPA and sympathetic responses in check during periods of stress. To be effective, nurturing relationships need to be present. Lack of nurturing relationships should be a particularly acute source of stress for women. Female reproductive hormones should play a role in modifying patterns of stress responding or producing patterns that differ from men, and these tendencies should increase with puberty, pregnancy, and childbirth.

There are clear differences in the types of stressors that activate the HPA axis in adulthood, with men being more responsive to stressors involving threats to how others perceive their intelligence and performance and women to situations involving threats of social rejection and exclusion (e.g., Stroud, Salovey, & Epel, 2002). However, some studies show that both men and women increase the type of prosocial behavior that supports social networks in reaction to stress (von Dawans, Fischbacher, Kirschbaum, Fehr, & Heinrichs, 2012). In addition, women do not differ from men in HPA responses to performance stressors at certain points in their menstrual cycle (Kudielka & Kirschbaum, 2005). Thus, as is typical of sex differences, there are more

overlaps in behavior than prototype models would suggest. In addition, as discussed in “Normative Development of the HPA System,” it is not clear when these differences develop; however, this could be an important avenue for developmental research.

Hawks and Doves

As discussed in the section called “Temperament and Stress Vulnerability and Resilience,” shy/inhibited children appear to be particularly sensitive to social stress, yet we do not have stress theories that really address temperamental differences. The one that comes closest is the Hawk and Dove theory (Korte, Koolhaas, WingWeld, & McEwen, 2005). This is an evolutionary theory based on the expectation that populations should include individuals who vary in their typical responses to threats and challenges. The theory describes two phenotypes: Hawks and Doves. Those with Hawk phenotypes are aggressive and bold. They fight or flee when threat is encountered. They are proactive rather than reactive, and take risks. They are at a fitness advantage when energy resources are high but at a disadvantage when energy resources are low because their phenotype requires a good deal of energy to sustain. They are also at an advantage when population density is high because their aggressiveness allows them to compete successfully. Doves, in contrast, prefer to freeze or blend into the background when conditions become threatening. They are risk averse, inhibited, and cautious. They are at a survival advantage when energy resources are low because their strategies tend to conserve energy. They do better when population density is low because they are poorer competitors. These phenotypes are theorized to differ in their underlying stress physiology. Hawks are expected to have low-responsive HPA systems and low basal HPA tone, whereas Doves are predicted to have highly reactive HPA systems and higher basal HPA tone. Hawks are supposed to be more SNS reactive than Doves, whereas Doves are supposed to be more PNS reactive than Hawks. Theoretically, the effects of chronic stress differ for these phenotypes, being associated with problems of impulse control, violence, hypertension, and autoimmune disorders for Hawks and metabolic syndrome, internalizing disorders, and infections for Doves. There has only been one child study to apply the Hawk/Dove model explicitly. In this study, researchers used the Hawk and Dove prototypes to effectively identify factors moderating the effects of harsh parental discipline (Sturge-Apple, Davies, Martin, Cicchetti, & Hentges, 2012). Among the Hawks, harsh

discipline did not affect levels of basal cortisol or vagal tone, but did increase sympathetic tone over time, and this mediated a rise in externalizing problems. Among the Doves, harsh discipline increased vagal tone and basal cortisol levels, while lowering sympathetic tone, and this mediated a rise in internalizing problems. Although it is unclear whether the Hawk/Dove prototypes are the best to use in developmental research, these results suggest that temperamental differences among children will be important to incorporate into our theories.

Summary and Future Directions

None of our models of stress and development are completely satisfactory. The ALM is biologically based and consistent with the complexity of the systems involved in stress responding, but it was never intended to be a developmental theory. The ACM is explicitly developmental, which is a benefit for developmental researchers. However, it elaborates ultimate arguments and does not adequately deal with proximal processes. The patterns it proposes are likely elusive as they suppose much less stressor and context specificity than has been richly demonstrated in the literature. While neither theory is completely adequate, both theories have, in the case of ALM and likely will in the case of ACM, stimulated research. Furthermore, the many concepts derived from or that have been absorbed into these theories and brought into the human developmental literature (e.g., sensitivity to context, differential susceptibility, predictive adaptation) are enriching the study of stress and development. Finally, neither of the main theoretical models deals adequately with sex/gender differences or temperamental differences; thus we might be wise to consider “tend and befriend” and “hawk/dove” models or other similar theoretical arguments as we enrich our models of stress and human development.

CHILDHOOD ADVERSITY: STRESS AND BIOLOGICAL EMBEDDING

Increasingly, we are called to attend to early adversity in order to improve lifelong health. Several research areas converge to fuel this focus. First, there is evidence that the socioeconomic gradient in health may have its roots in childhood social class (Ziol-Guest, Duncan, Kalil, & Boyce, 2012). Second, the evidence that birth weight, as a reflection of prenatal adversity, predicts cardiovascular disease in adulthood established a field termed the fetal

origins of adult disease (Gluckman et al., 2007). Finally, over a half century of research on early adversity in animals provides invaluable insights into the processes through which adversity gets under the skin to affect health and disease (Zhang et al., 2013). Less than a decade prior to the time of this writing, the concept of biological embedding was introduced to provide an umbrella term for a variety of processes through which experience becomes part of our biological makeup during development. The concept of biological embedding has since entered the mainstream of scientific discourse (Shonkoff, Boyce, & McEwen, 2009). Because animal models have been critical to providing hypotheses about biologically plausible pathways through which embedding can occur, key points from this work are highlighted before reviewing the human literature.

Animal Models and Early Life Stress

Nearly all early adversity paradigms manipulate the mother–offspring relationship in some way, either through deprivation, separations, or other manipulations that disturb maternal behavior. Those that do not manipulate the mother–offspring relationship use naturally occurring variations in maternal care to index early adversity (Schmidt, Wang, & Meijer, 2011). Thus, one of the earliest and most productive hypotheses about how adversity gets transmitted is that it alters maternal behavior, which in turn affects the offspring (Smotherman & Bell, 1980). Animal studies, however, have shown that although many early adversity effects are transmitted through maternal care, some are not (Tang, Akers, Reeb, Romeo, & McEwen, 2006). The question of which effects do and do not depend on caregiving has not been addressed in human studies.

The HPA axis has been a prime focus of rodent early experience research. The axis is immature in the rat pup at birth and matures during the first two weeks postnatal when early experiences program GR via regulating methylation of the GR gene (Zhang et al., 2013).

However, it is now apparent that the programming effects of early maternal care extend far beyond epigenetic modification of the GR gene to include (a) the estrogen receptor alpha gene, which influences maternal behavior into the next generation (Champagne, 2012), (b) neurotrophic genes (e.g., BDNF; Roth & Sweatt, 2011), and (c) genes involved in inflammation (G. E. Miller et al., 2011). Studies are now documenting similar programming effects in other species, as well as our own (reviewed in Champagne, 2012, and G. E. Miller et al., 2011).

What is often missed when this literature is translated to the human case is that there is little evidence that these effects in the rodent depend on elevated CORT. Rather, with regard to the GR gene, its epigenetic modification involves stimulation of thyroid hormone, increases in serotonin turnover and greater expression of nerve-growth factor-inducible factor-A transcription factor in the hippocampus (Zhang et al., 2013). Many of the destructive effects on the hippocampus in the rodent are due to CRH, not CORT (Faturi et al., 2010). Thus, we need to be aware that there may be pathways from early adversity to later effects on the HPA system and other stress-mediating systems that are not produced by activity of the axis during the period of early adversity. Because the HPA axis is more mature in humans than in rodents at birth, early adversity effects in humans may involve CORT even when this is not the case in some rodent models.

Finally, the animal literature makes it clear that exposure to stressors early in life is not always associated with poor outcomes. First, the changes produced by early life adversity may actually support survival in harsh and unpredictable environments. Second, in some instances it is the animals that were exposed to stressors who score higher on tests of cognitive performance, exhibit more robust neurodevelopment, and produce lower levels of stress hormone in response to provocation in adulthood (Lyons & Parker, 2007). In these latter instances, it appears that early life stress has served a stress-inoculation function. We are far from understanding what makes some experiences *stress inoculations* whereas others increase the risk of disease and disorder. The possibility that inoculation effects were obtained because the stressor was *challenging but not overwhelming* has been suggested (Lyons & Parker, 2007). However, so far, this is a post hoc explanation. Nonetheless, if we understood what differentiates stressors that inoculate versus those that increase vulnerability, we would have a much better understanding of resilience.

Other Pathways to Early Adversity Effects

In this chapter we focus on the role of early experiences in programming the neurobiology of stress with an emphasis on the HPA axis and the genes regulating it. However, there are other pathways to early adversity effects that should be acknowledged and that may overlap with those examined here. First, early adversity may affect the development of neural circuits through experience-expectant and experience-dependent processes that influence cell death and synapse pruning (Fox, Levitt, & Nelson, 2010).

When these experiences affect the development of neural systems that process threat and orchestrate coping, they may contribute to individual differences in allostatic load across development. Indeed, there is increasing evidence that the amygdala is particularly sensitive to early adversity (Pechtel & Pizzagalli, 2011). There is also increasing evidence that oxidative stress in response to extreme stressors results in damage to DNA, RNA, and lipids (Schiavone, Jaquet, Trabace, & Krause, 2013).

CORT bears a complex, U-shaped relationship with oxidative stress. At low to moderate levels, CORT helps reverse oxidative stress and thus is neuroprotective, whereas at high levels CORT decreases mitochondrial functioning and increases cell death (Aschbacher et al., 2013). These processes may explain why children exposed to longer periods of early deprivation in Romanian orphanages have greater evidence of cellular aging (i.e., shorter telomeres) by middle childhood (Drury et al., 2012). Indeed, in typically developing kindergarten children it has been shown that those who show larger CORT and sympathetic reactions to a stressor protocol have shorter telomere lengths in buccal cells by the end of kindergarten (Kroenke et al., 2011).

Finally, there is increasing evidence that the immune system is programmed by early adversity (G. E. Miller et al., 2011). Early adversity is believed to program heightened reactivity in inflammatory pathways and down-regulate the GR gene that mediates anti-inflammatory effects of CORT. Programmed thus, the immune system interacts with ongoing life stress and the hormonal signals generated by reaction to these stressors in ways that contribute to the onset of cardiovascular disease, tumors, and bone and muscle loss leading to frailty. The programming mechanisms may involve CORT and CRH.

With this as background, we now turn to a review of the major types of early adversity studied in humans: poverty, parental loss, prenatal stress, risky families, and maltreatment. The categories overlap, but each literature has its unique aspects, justifying their separate treatment.

Childhood Poverty and Lower Socioeconomic Position

Socioeconomic position is a contextual factor associated with a host of adverse early conditions. There is increasing evidence that socioeconomic position during childhood predicts health outcomes in childhood and later in life (Shonkoff et al., 2009). A number of studies have found that a lower economic position in childhood is associated with higher CORT levels. Some of these studies have used

income-to-needs ratios in generally low income samples (Blair, Raver, Granger, Mills-Koonce, & Hibel, 2011), others have used parental reports of financial strain (Essex, Klein, Cho, & Kalin, 2002), and still others have used cumulative risk indices composed of adversities common in low income families (Evans & Kim, 2012). Basal CORT has typically been the focus, either as measured in saliva, overnight urine, or in hair (Vaghri et al., 2013). The ages studied have ranged from infancy to adolescence. Not all studies, however, have found evidence of higher CORT with low socioeconomic position. Some have found the opposite (Badanes, Watamura, & Hankin, 2011). It has been argued that one reason sometimes high and sometimes low CORT is found is that the relationship is actually U-shaped (Boyce & Ellis, 2005; Bush et al., 2011; Marsmana et al., 2012). This might be an attractive solution, except that both U-shaped and inverted U-shaped functions have been found, sometimes in the same study at different time points, (e.g., Bush et al., 2011).

Whereas the above studies are all correlational, one study has manipulated family economic circumstances and then assessed the HPA axis (Fernald & Gunnar, 2009). This study used a quasi-randomized design to examine the effects of a conditional cash transfer program on children living in extremely poor communities in rural Mexico. The children were 2 to 6 years old when assessed after the family had been in the intervention for at least 3 years. The sample was large (over 500 intervention and 700 comparison children). The intervention lowered CORT levels but not reactivity and the effect was larger for children of depressed mothers. Low income and financial strain increases maternal depression. Later we will cover the role of maternal depression in the development of stress reactivity and regulation, but here we note that consistent with the Fernald and Gunnar (2009) study, maternal depression appears to mediate the effect of financial strain on children's HPA axis functioning (Hostinar & Gunnar, 2012).

None of the studies cited above provide evidence that early socioeconomic position programs the HPA axis. Evidence of programming has been examined in adult studies that have contrasted current with childhood socioeconomic status. There are very few studies of this sort and the results are mixed. Using a subsample of the 1958 British Birth Cohort, home basal CORT levels assessed at middle age were found to be associated with lifetime socioeconomic position. Low childhood economic position added to the effect but was not sufficient to program a higher basal set point in the HPA axis in adults who improved in socioeconomic status after childhood (Li, Chiou, & Shen, 2007).

On the other hand, using a sample of adults in their 30s who were specifically selected to represent low or high socioeconomic status prior to the age of 5, higher CORT levels were found across the day as evidence that the immune system had been programmed for larger inflammatory responses and poorer containment by CORT (G. E. Miller et al., 2009). These findings were not dependent on current income or position. Of course, even if childhood economic and social circumstances predict adult CORT levels, this would not prove that early socioeconomic adversity programmed the HPA axis. Childhood socioeconomic position may have affected other aspects of the individual's functioning that helped carry its effects forward. This appears to be the case in a study of middle-aged adults for whom childhood disadvantage predicted higher diurnal CORT at middle age (Franz et al., 2013). This effect was mediated by intellectual functioning in early adulthood, which in turn influenced adult socioeconomic position, which then predicted adult CORT. Such findings strongly argue for the need to develop and test cascade models to understand how early adversity ultimately affects stress reactivity and regulation in adulthood. Also, given the variability in results, it is likely that it is not poverty but factors associated with poverty, such as maternal depression leading to lower quality care, that affect the development of stress reactivity and regulation.

Parental Separation and Loss

Loss of a parent in childhood is a risk factor for poorer mental and physical health throughout development (Wilcox et al., 2010). A number of studies have examined CORT in adults who lost or were separated from their parents during childhood. The strongest evidence that such experiences produce long-term effects on the HPA axis comes from studies conducted on adults who were children during World War II and who, for their protection, were sent away from their families. Studying the responses of elderly men and women, one research group (Pesonen et al., 2010) found larger CORT responses to the TSST for those who were separated from their mothers or both parents, but not for those separated only from their fathers.

Interestingly, adults who were separated as preschoolers differed more from the control group than those separated as infants or school-aged children. There are more studies examining adults with childhood bereavement or separation, but none of them differentiated early from later loss. One study of middle-aged men found higher early morning and late afternoon but not bedtime home CORT (Nicolson,

2004). Another study of young adults probed the HPA axis using the DEX/CRH test and found that adults who had experienced loss of a parent or close friend prior to age 19 exhibited larger CORT responses. The largest responses were from those who reported a warmer and more supportive relationship with the parent prior to the parent's death (Tyrka et al., 2008). In sum, studies examining CORT years after childhood bereavement find HPA hyperactivity.

At least two studies have examined HPA-axis activity closer in time to bereavement. For example, children 7 to 13 years old were studied every 6 months for 2 years beginning an average of 19 months after losing a parent in the terrorist attacks on the United States on September 11, 2001. A number developed anxiety, depression, and attention-deficit/hyperactivity disorder (ADHD). Compared with children from the same communities who did not have family members who were killed that day, the bereaved children had higher diurnal CORT levels early in the morning and at 4 p.m. but not at bedtime and they also showed less suppression of CORT to dexamethasone (Pfeffer, Altemus, Heo, & Jiang, 2007).

In sum, there appears to be growing evidence that losing a parent during childhood is associated with anxiety, depression, and a more hyperactive HPA axis. Increased activity of the axis appears to emerge with bereavement and to remain for years, well into adult life. As is discussed in the sections that follow, this contrasts with the effects of maltreatment and trauma, which appear to shift from a hyper- to a hypoactive pattern with time, unless the person develops depressive illness. Parental loss increases the risk of depression, but depression was not necessary to observe increases in HPA-axis set points in the above studies. Clearly the HPA axis can be reset to a higher baseline and response level and stay there for years without becoming downregulated. There must, then, be something different about the neurobiological response to separation and bereavement from the response to other kinds of chronic threats and stressors. Understanding this difference would seem critical in understanding the sequelae of early adversity. One possibility that has not been explored is that the emotions accompanying the initial elevations in CORT (i.e., sorrow versus fear) may set different neuroendocrine and epigenetic processes into motion.

Although studies of childhood loss and bereavement are taken as evidence that early experiences may program the HPA axis, caution is warranted. First, the wide ages over which long-term effects take place raise questions about whether a programming or sensitive period interpretation really is appropriate. If it is a sensitive period effect, it

would appear that the HPA axis is sensitive to programming by loss of an attachment figure from birth until at least Age 19, the oldest age used in these studies. Second, no adult comparison group is included. It is not known whether loss of an attachment figure as a child has a greater long-term effects on the HPA axis than loss that produces grief at any other point. Third, while many of these studies also measured psychopathology, none examined whether the HPA axis mediated associations between bereavement and symptoms of emotional problems. Future studies must address these questions.

Prenatal Stress

Some of the strongest evidence that stress has developmental programming effects comes from research on the prenatal period. We have reviewed the work on prenatal stress and rely heavily on that review here (Gunnar & Davis, 2013). The concept of fetal programming arose with evidence that birth weight and/or preterm delivery predicts adult disorders, including heart disease, diabetes, and obesity. Two major hypotheses have been proposed to explain the processes of fetal programming: malnutrition and chronic exposure to CORT. These may be two related hypotheses because the effect of maternal malnutrition on the fetus has been shown in animal studies to depend on elevated CORT (Monk, Georgieff, & Osterholm, 2013).

Although poor maternal nutrition, exposure to toxins, and infections are all stressors reflecting a harsh environment, researchers have focused more narrowly on the role of maternal psychosocial stress. There is evidence that above nutrition and other risk factors, the mother's mental and emotional state has effects on her fetus. Minority status and discrimination may also conspire to produce prenatal stress and poor birth outcomes. Among immigrants, acculturation, rather than reducing poor pregnancy outcomes, increases low birth weight and premature birth (Callister & Birkhead, 2002). Greater acculturation among immigrant Hispanic women has been associated with a flatter diurnal CORT rhythm during pregnancy, which mediated the association between acculturation and birth weight (D'Anna-Hernandez et al., 2012). In another study of Hispanic women, acculturation predicted higher maternal stress, higher plasma CRH levels at 22 to 25 weeks gestation, and earlier delivery (Ruiz, Dolbier, & Fleschler, 2006).

Individual differences in maternal anxiety and perceived stress predict birth outcomes and child psychological functioning, even after controlling for other confounding factors. These studies, however, could simply mean that

women who are anxious and who report high perceived stress transmit these proclivities to their offspring genetically. This cannot be the case for babies conceived through in vitro fertilizations (IVF) in which the birth mother is not genetically related to the fetus. Studying a large number of twins representing both IVF pregnancies of related and unrelated mothers and fetuses, birth weight, duration of gestation, and conduct problems were all shown to be associated with the birthing mother's stress during pregnancy, regardless of genetic relatedness (Rice et al., 2010). Although more studies of this sort are needed, when combined with the animal studies and the work on natural disasters, it seems that there is clearly a phenomenon to understand. The following questions are relevant to this chapter: (a) are the HPA axis or its hormones and peptides involved in mediating these effects, and (b) do programming effects of prenatal stress include programming of the HPA axis? The answers to these questions are still uncertain, but considerable progress has been made since 2005.

Before discussing these issues, it is necessary to describe the physiology of stress during fetal development more completely (Gunnar & Davis, 2013; Sandman & Davis, 2012). During pregnancy there is an integration of the maternal HPA axis, the placenta, and the fetus's HPA axis (see Figure 4.3). During pregnancy, elevations in maternal

CORT stimulate increases in CRH gene activity in the placenta, resulting in increases in CRH and ACTH. CRH produced by the placenta stimulates increases in both fetal and maternal CORT production.

As the total production of CORT by the mother increases across her pregnancy, so do her levels of binding globulin. Therefore, for part of pregnancy, levels of unbound CORT are within or close to the levels of nonpregnant women. Also, during this time 11β -HSD2 in the placenta increases and serves the function of converting CORT to an inert substance, thus reducing and regulating the ability of maternal CORT to affect the fetus. All of these effects change as the baby approaches term. In the last trimester, levels of unbound, biologically active CORT in the mother increase precipitously as her cortisol binding globulin levels drop. Further opening the fetus to maternal CORT efflux, levels of 11β -HSD2 in the placenta decrease and there is a marked reduction in the fetus of co-localized 11β -HSD2 in GR-expressing cells. Thus under low-stress conditions, the fetus is protected from normal pregnancy levels of maternal CORT during roughly the first two-thirds of gestation, and then open to maternal CORT levels after that. Why? It seems likely that this reflects the dual roles of CORT during gestation; specifically, as a stress hormone and as a maturational hormone. During the last trimester

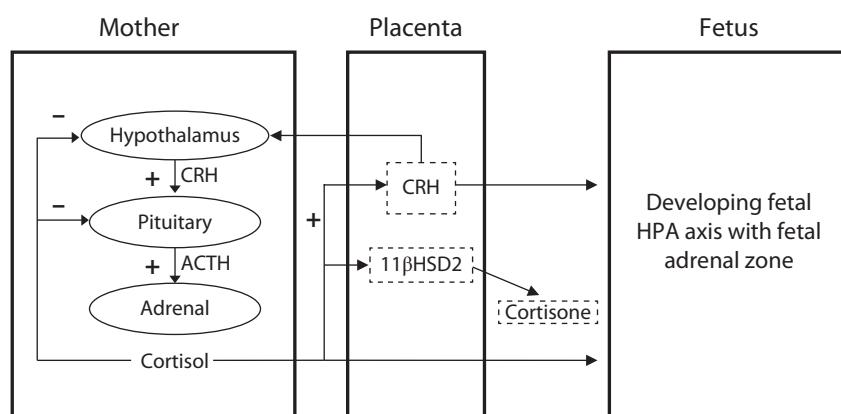

Figure 4.3 Schematic of the maternal, placental, and fetal HPA axis during gestation. During pregnancy, CRH is released from the placenta into both the maternal and fetal compartments. Cortisol *increases* the production of CRH from the placenta. Placental CRH (pCRH) concentrations rise exponentially over the course of gestation; however, the effects of maternal cortisol on the fetus are modulated by the presence of a placental enzyme, 11β -HSD2, which oxidizes cortisol into an inactive form, cortisone. Activity of this enzyme increases as pregnancy advances and then drops precipitously near term, allowing cortisol to promote maturation of the fetal lungs, central nervous system, as well as other organ systems. The fetal HPA axis begins its development early in gestation and becomes increasingly functional with the progression toward term. See text for description.

Source: From "The Effects of Stress on Early Brain and Behavioral Development," by M. R. Gunnar and E. P. Davis, 2013, in J. Rubenstein and P. Rakic (Eds.), *Neural Circuit Development and Function in the Brain* (pp. 447–465), New York, NY: Elsevier. Reprinted with permission.

of pregnancy, CORT serves to mature the infant, preparing it for delivery. For example, CORT stimulates the lungs to produce surfactant, which is necessary to allow the baby to breathe air.

Because the baby needs to experience elevated CORT levels for its tissues to mature, it would seem reasonable to assume that nature has equipped the fetus with the ability to cope with higher CORT levels during the last trimester, although not perhaps the supraphysiologic levels used therapeutically to rapidly mature the infant's lungs when there is the risk of premature labor. In contrast, given the multiple mechanisms present during early pregnancy to protect the fetus from maternal CORT, we might expect that elevated levels in the mother that are high enough to overwhelm these mechanisms will have significant long-term effects. Indeed, when the mother is chronically stressed and producing elevated CORT levels, this serves to downregulate 11 β -HSD2. This has been observed as a function of maternal anxiety and depression during pregnancy (Gunnar & Davis, 2013).

In animal studies, there is strong evidence that the effects of maternal stress on the fetus are mediated by the mother's production of CORT (Meaney, Szyf, & Seckl, 2007). What evidence exists of HPA-axis mediation of prenatal stress effects in humans? The answer to this question is a bit complex. Although there is evidence that maternal CORT affects fetal CORT (as measured in amniotic fluid), associations between maternal reports of stress, anxiety, and/or depressive symptoms do not always correspond to either maternal or fetal CORT levels (Baibazarova et al., 2013). Furthermore, maternal psychological state in pregnancy and maternal CORT levels independently predict child outcomes (Sandman & Davis, 2012). Thus, it is not clear that the HPA axis is the primary pathway through which maternal emotions produce effects on the fetus. What does seem fairly clear, however, is that activity of the mother's HPA axis affects fetal development. Furthermore, there is evidence that the timing of elevated maternal CORT levels matter in determining the nature of the effects.

Given the changes in mother–infant HPA physiology over the course of pregnancy, it has been argued that elevated CORT earlier in pregnancy, before the third trimester, will have more negative effects on fetal development than elevated CORT later in pregnancy (Sandman & Davis, 2012). A number of the results point in this direction. For example, placental CRH (pCRH) levels at 25 weeks gestation predicted increased risk of preterm delivery and increased fearfulness at 2 months postnatal, while

pCRH levels at 31 weeks did not. Likewise, high levels of maternal CORT in the second trimester predicted lower mental development scores at one year, whereas higher levels of maternal CORT in the third trimester predicted the opposite (for review, see Sandman & Davis, 2012). Finally, higher maternal CORT earlier but not later in gestation has also been associated with larger amygdala volume and more emotional problems in 7-year-olds, mediated in part by amygdala size (C. Buss et al., 2012).

In a few of the above studies, effects were observed only in girls (Gunnar & Davis, 2013). There is also evidence in animal studies that prenatal stress differentially affects male and female fetuses with more emotional effects seen in girls and more learning problems observed in boys (Sandman & Davis, 2012). The question of sex differences in the effects of prenatal stress in humans has not been sufficiently examined to allow for conclusions at this point.

There are an increasing number of studies examining whether prenatal stress has programming effects on the HPA axis, although the issue is far from settled. Thus, both pregnancy-specific anxiety and maternal CORT levels during the first trimester have been shown to independently predict higher CORT levels in the child at 4 years during an inoculation stressor and at 5 years in response to starting school (Sandman & Davis, 2012). High levels of CORT in amniotic fluid at 17 weeks gestation, but notably not in maternal saliva, predicted atypical patterns of CORT response to the Strange Situation, compared with moderate to low amniotic fluid levels (O'Connor, Bergman, Sarkar, & Glover, 2013). Controlling for prenatal and postnatal factors, maternal but not paternal prenatal anxiety predicted a blunted CAR and flatter diurnal rhythm in 14-year-old boys and girls (O'Donnell et al., 2013). Finally, in a study of women and their fetuses exposed to anxiety about radiation from Chernobyl, higher CORT levels at 14 years of age were noted for both boys and girls relative to levels for adolescents close in age who were not in utero during this anxious period (Huizink et al., 2008).

The strongest evidence that CORT affects fetal development comes from studies in which the fetus has been exposed to high levels of CORT for therapeutic reasons (Reynolds, 2013). In women at risk for preterm labor, CORT in some form (e.g., betamethasone) is administered. If preterm delivery does not follow, children carried to term provide a model of prenatal CORT effects. The results show reduced birth length, weight, and head circumference, and increases in CORT responses in the neonatal period. Effects are larger when CORT is administered earlier in gestation (i.e., closer to 24 weeks than to 34 weeks, the age range

when the drug is given). Finally, CORT exposure is associated with bilateral cortical thinning, most clearly in the rostral anterior cingulate cortex (Sandman & Davis, 2012).

There is growing evidence that even if prenatal stress affects fetal development, many outcomes are moderated by the care the infant receives after delivery. In the study of prenatal stress, similar findings have been reported for emotional and cognitive outcomes (Bergman, Sarkar, Glover, & O'Connor, 2010). However, there have been few studies examining whether prenatal stress interacts with postnatal caregiving to predict activity of the HPA axis. In one of the few studies available, prenatal maternal anxiety and postnatal caregiving had independent effects on infant CORT responses to the still-face procedure (Grant et al., 2009); however, in another study, postnatal CORT levels were moderated by maternal sensitivity, but only for infants whose mothers had a mental health diagnosis (Kaplan, Evans, & Monk, 2008). Studies are needed to determine whether prenatal stress effects can be eliminated by postnatal caregiving.

To summarize, there is a growing body of evidence indicating that prenatal stress has long-term or programming effects on the fetus, that CORT is involved in at least some of the effects, and that the programming effects may include the HPA axis, increasing basal levels and stress reactivity. There are arguments, however, over how to interpret these effects. Are they impairments or shifts in developmental strategies? There are also arguments over whether the effects are comparable across all levels of prenatal stress or at all points in development. Taking the second issue first, some have argued that the effects of prenatal stress are overstated and that in some populations they enhance development (Dipietro, 2012) or that if mild, they may have positive effects (Sandman & Davis, 2012). The question of whether the effects of prenatal stress should be viewed as impairments or as a reflection of adaptive developmental plasticity are more complex. The programming argument typically has been framed from an evolutionary perspective; specifically, the effects of stress prenatally serve to increase survival of the fetus and the reproductive success of the genes the mother and fetus share. However, the models differ in the importance of the match between pre- and postnatal environment in predicting whether healthy or unhealthy outcomes are predicted. Typically health is predicted in these models when there is a mismatch between the harshness of pre- and postnatal environments (Gluckman et al., 2007). Pluess and Belsky (2011), in contrast, argue that prenatal stress increases fear and stress reactivity but that the effect is to make the

child more sensitive to context; thus the prenatally stressed offspring will do poorly in harsh contexts (environments that match prenatal conditions) but extremely well in supportive ones (environments that mismatch prenatal conditions). There is support for both types of predictions. For example, in a study of maternal depressive symptoms, infants did better in terms of health and IQ in their first year of life if the mother's symptoms were stable from the pre- to the postnatal period and worse if she either developed symptoms postnatally that were not there earlier or the reverse (Sandman & Davis, 2012). In contrast, postnatal experiences may moderate associations between prenatal CORT levels and postnatal outcomes, with some evidence that more reactive infants were more sensitive to postnatal experiences (Bergman et al., 2010). Thus far, there are too few studies that have examined, rather than statistically controlled for, postnatal experiences to differentiate between these perspectives.

Parenting and Risky Family Environments

Repetti, Taylor, and Seeman (2002) coined the term *risky families* to refer to family environments that were chronically stressful and/or deficient in warmth and support. While such families can be found at all income levels, they tend to concentrate more among those lower in income, and thus may mediate some of the effects of socioeconomic position on the HPA axis and lifelong health (Repetti et al., 2002). As already described "Normative Development of the HPA System," the presence and availability of a supportive adult with whom the child has a secure attachment relationship provides a powerful buffer that reduces activation of the HPA axis to a range of potentially threatening events. In the following section we examine evidence that variations in care shape children's stress responses and their ability to regulate those responses. We examine this question first in relation to parental warmth and support and then with regard to harsh discipline and interparental conflict and violence. Finally, we examine the few parenting intervention studies that have examined effects on the HPA axis.

Regarding warmth and support, or rather the lack thereof, despite the ranges of ages studied and the different types of measures used, most studies provide evidence that less supportive care is associated with higher CORT levels and greater CORT reactivity. The largest study was conducted in the Netherlands (Marsman et al., 2012) and included over 1,500 11-year-olds. Children who described less parental support and more parental rejection had

higher basal levels of CORT and higher CARs. Results were obtained controlling for family income. In another large sample of younger children, direct observations of mother–infant interaction at 7 months showed that lower maternal support was associated with less CORT responsiveness at 7 months but overall higher CORT levels by the time the babies were toddlers (Blair et al., 2008). The 7-month measures were obtained in response to a combination of one fear and two frustration tasks. Distress responses to frustration are greater for infants with higher expectations of agency, which might explain the direction of effects at their 7-month age point (Lewis, Hitchcock, & Sullivan, 2004). In another study of 7-month-olds (Grant et al., 2009), using the still-face paradigm that mimics maternal withdrawal of affection, lower maternal sensitivity predicted larger CORT responses. More negative interaction with fathers has also been related to CORT activity in infants at 7 months and in a longitudinal study with toddlers at 24 months (Mills-Koonce et al., 2011). In several studies, mothers who were more withdrawn had children who either showed larger CORT responses to the Strange Situation or exhibited initially elevated and then declining levels of CORT in response to this task (Sturge-Apple et al., 2012).

Nonetheless, higher CORT activity has not always been associated with lower warmth and support. In one of several examples, preschoolers whose mothers were more negative and lower in warmth exhibited a flatter diurnal slope in CORT (Zalewski, Lengua, Kiff, & Fisher, 2012). In this study maternal negativity and low warmth mediated the relations between family income and children's CORT. Notably, in this and another study that also found lower cortisol with lower maternal warmth, the children were drawn from populations for whom low warmth was compounded by poverty and, thus, other adversities. Thus, cumulative stress may have resulted in a downregulation of the HPA axis in these studies.

Hostile, threatening forms of discipline such as yelling and spanking can be frightening to children. While there tends to be a negative association between discipline and parental warmth and support, these dimensions can be disentangled. A small study revealed that mothers who used physical punishment had infants who showed larger CORT responses to maternal separation and interaction with a stranger at 12 months (Bugental, Martorell, & Barraza, 2003).

In a larger study, children on a Caribbean island were sampled for CORT in the morning and evening daily for months. Using each participant as his or her own

control, CORT levels were significantly elevated following bouts of harsh discipline and these elevations were larger than responses to other common stressors (Flinn & England, 1995). Finally, combining three samples of 2- to 6-year-olds that used similar methods, mothers who reported using more shouting with their children had children who exhibited higher CORT levels 20 and 65 minutes after strangers arrived at the homes to assess both mothers and children (Hastings et al., 2011). Other studies have also found positive associations between CORT and harsh discipline, but for only some of their participants. Thus, for example, this association was found among children whose mothers were high on depressive symptoms, but not for the other children who experienced harsh discipline (Essex et al., 2011).

Finally, there is at least one publication reporting an association between blunted CORT and greater conflict. This was a study of preschoolers in which the child wore a voice-activated recorder for one weekend day and CORT was assessed across the day on both weekend days (Slatcher & Robles, 2012). Children who were involved in more conflicts had a lower CORT at wakeup and a flatter diurnal slope. It is unclear whether the conflicts were with parents and there was no measure of parental harsh discipline. These findings might reflect associations with conduct problems rather than with parenting (see “Developmental Psychopathology” later in this chapter).

Poor marital quality and aggressive conflict tactics among parents are important contributors to risky family environments (Repetti et al., 2002). Violent arguments between parents should be a significant stressor for children, but not all children show adverse effects. Indeed, there is evidence that emotional insecurity in response to parental fighting determines long-term effects (Davies, Sturge-Apple, & Cicchetti, 2011). Few studies have examined whether CORT responses in children reflect their insecurity in response to parental conflict. In one that did (Koss et al., 2013), children who were more distressed, more dysregulated, and more involved in parental fights were more likely to show a rising pattern of CORT in response to a simulated parental argument. The other studies by this research group all showed that greater exposure to parental fighting was associated with a smaller CORT response to the simulated fight paradigm (Sturge-Apple et al., 2012). This might be because children accustomed to their parents fighting judged the simulated fight to be of low intensity relative to fights they experienced at home. Indeed, overall, CORT levels decreased from pre- to post-testing in this paradigm. In contrast to children's

responses to a simulated fight, infants exposed to more violence in the home showed larger CORT responses to fear- and frustration-eliciting tasks (Towe-Goodman, Stifter, Mills-Koonce, & Granger, 2012). Likewise, in both kindergarteners (5–7 years) and adolescents, poor marital quality has been associated with higher morning and evening CORT levels (Pendry & Adam, 2007). Although more studies are needed to clarify the effects of marital conflict on children's stress responding, it seems likely that the effects may be twofold: increasing HPA reactivity among children who become emotionally insecure as a result of exposure, and habituating the system to mild examples of parental conflict.

Interventions provide the best proof that parenting affects children's CORT activity. To date, there have been seven randomized clinical trials of parenting interventions in which basal and/or diurnal CORT has been measured. All of these studies have been with infants or preschoolers (e.g., Bakermans-Kranenburg, Van IJzendoorn, Mesman, Alink, & Juffer, 2008; Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; Fisher, Stoolmiller, Gunnar, & Burraston, 2007). This work has shown that interventions that improve parenting lower CORT or, in studies of maltreated children, bring patterns of CORT production in line with those of children in the nonmaltreated comparison group. In one study, the intervention effects were observed only for the children with the 7-repeat DRD4 polymorphism; however, they were the ones expected to be in greater need of the intervention (Bakermans-Kranenburg et al., 2008).

Finally, so far we know of only one study that has examined the effect of a parenting intervention on CORT reactivity. This study was done with the preschool siblings of adjudicated youth who were themselves at high risk of developing conduct problems and antisocial behavior. As discussed earlier, low arousal and the failure to mount physiological reactions to interpersonal threats is believed to play a role in antisocial behavior problems (van Goozen et al., 2007). Thus this intervention was designed to improve parenting, children's social competence, and to *increase* CORT levels in anticipation of entering a new peer group (O'Neal et al., 2010). The results revealed that, over time, the preschoolers in the intervention group showed increasing levels of CORT just prior to entering new peer groups and the increase in CORT predicted reductions in aggressive behavior during peer entry. There was evidence that this anticipatory CORT was correlated with improvements in parenting, but a mediational analysis was not reported. It would be useful to have more studies examining CORT reactivity.

Overall, studies of the relations between parenting and activity of the HPA system provide good support for the hypothesis that the parent–child relationship is important in regulating activity of the system. Furthermore, intervention studies clearly show that parenting plays a causal and not just correlative role in stress hormone activity during childhood. Most studies indicate that adverse parenting is associated with greater activity of the HPA axis. What is unclear in these studies is whether set points have been programmed. The fact that interventions can alter HPA-axis activity in children suggests that results do not reflect stable epigenetic changes in the axis. More long-term studies that include interventions at different ages are needed to determine whether there are sensitive periods for parenting effects on the axis.

Of course, even if the axis is not programmed by normative variations in parental care, brain systems that are developing during periods of poorer parental regulation of the axis might be affected. Thus the importance of parenting effects on the HPA activity does not solely lie in whether long-term effects on CORT are observed. Studies are needed to analyze whether parenting effects on other outcomes, including brain structure and function, are mediated in part through effects on activity of the HPA axis. In addition, there is the possibility that individual differences among children may influence the openness of the axis to programming by parent–child relationship. Finally, it also may be that when poor parenting becomes abusive and traumatic there will be longer-term effects on the HPA axis and on other neurobiological systems involved in defensive responding. We now turn to that area of research.

Maltreatment

Neglect and abuse are potentially traumatic experiences that threaten a child's viability. Experiences of physical and sexual abuse can co-occur with adequate or even good parenting, while neglect is typically more chronic and may even threaten healthy development more severely (De Bellis, 2005). Maltreated children typically experience multiple forms of maltreatment along with other types of adversity during childhood (see also Cicchetti & Toth, Chapter 13, this *Handbook*, this volume). These experiences increase the risk of a range of pathological conditions, although many and perhaps even most maltreated children display remarkable resilience (Cicchetti & Rogosch, 2007).

Much of the neurobiological work in this area has been guided either by adult research on posttraumatic stress disorder (PTSD) or by work on depression. In adults,

these disorders display markedly different neuroendocrine signatures. PTSD is associated with upregulation of the sympathetic nervous systems in conjunction with a downregulation of the HPA axis and increased negative feedback regulation (Yehuda, 2009), while depression is associated with hyperactivity of the axis and reduced negative feedback regulation (Heim, Newport, Mletzko, Miller, & Nemeroff, 2008). One of the major challenges is determining how different signatures could emerge and what effect childhood maltreatment has for those who are resilient and do not develop disorders. We cover issues of depression, maltreatment, and the HPA axis later in the section called “Developmental Psychopathology.” In this section we first focus on adult survivors of childhood maltreatment with and without PTSD. After dealing with the adult literature, we examine the effects of childhood maltreatment on the HPA axis in childhood.

Studies of adult maltreatment survivors provide a fairly consistent picture of the long-term consequences of childhood maltreatment. Across abuse subtypes, adults who were maltreated as children exhibit lower basal levels of CORT later in the day and stronger suppression to dexamethasone (Morris, Compas, & Garber, 2012), as well as blunted responses to psychosocial challenges such as the TSST (Heim & Binder, 2012). Notably, meta-analyses have shown that suppressed afternoon and evening basal levels and enhanced response to DEX do not differ for adult survivors of maltreatment as a function of whether they have developed PTSD or not (Morris, Compas, et al., 2012). In addition, trauma in childhood appears to reduce methylation of the FKBP5 gene in regions of the gene that are responsive to CORT (Klengel et al., 2013). Recall that FKBP5 is the co-chaperone that reduces the ability of CORT to bind to GR. CORT regulates this gene, with increases in CORT increasing gene transcription as one mechanism that protects the organism from being overly affected by stress-stimulated increases in CORT. Thus, demethylation of the FKBP5 gene amplifies the protective mechanism, but protection from some insults can increase risk of others. There is evidence that in conjunction with childhood trauma, individuals who already carry the version of the FKBP5 gene that is hyperresponsive are at risk for developing PTSD, perhaps because stimulation by elevated CORT post-trauma is actually important for normal processing of the traumatic event (Heim & Binder, 2012). Another factor that might increase the risk of PTSD given childhood maltreatment is upregulation of the sympathetic system. Hyperresponsiveness of the sympathoadrenal system is noted among adults with PTSD and adolescents

who will show increasing emotional problems following trauma, but not among trauma-exposed but psychiatrically healthy adults (Lovallo, Farag, Sorocco, Cohoon, & Vincent, 2012).

One reason that the adult work is informative is that pharmacological probes can be used to determine whether changes in CORT production are due to physical changes in the axis as opposed to changes in psychological processing of negative events in higher brain regions. Here the evidence strongly suggests that epigenetic changes within the axis are responsible for the blunting of the CORT response. Indeed, in addition to evidence of upregulation of the GR gene as suggested by enhanced suppression to DEX, blunted ACTH and CORT responses to stimulation by the DEX/CRH test have also been observed in psychiatrically normal adult survivors (Klaassens et al., 2009).

Thus, setting aside adult depression, exposure to maltreatment in childhood appears to downregulate the HPA axis. The processes are complex and interactive, with evidence of upregulated GR but also upregulation of mechanisms that prevent CORT from binding to GR. The complexity within the HPA system should alert us to the general systems nature of adaptation to maltreatment. There are likely many adaptive systems that show this type of reaction and counterregulatory responses. The complexity is nearly overwhelming, so it should not be surprising to find that when the dynamics of development are added, the picture will be unclear, at least until much more is understood about these neurobiological processes.

Indeed, studying children exposed to abuse and neglect has yielded elevated, suppressed, and nonaltered patterns of CORT activity, and there have been a number of good reviews (e.g., Carrion & Wong, 2012; De Bellis, 2005). There are likely a number of reasons for this inconsistency, but the most salient is that this is not only a developing system, but one that may be changing over time in relation to time-since-trauma. This is notable in studies of children with PTSD. Unlike adults with PTSD, children with PTSD tend to exhibit higher than normal levels of CORT (Morris, Compas, et al., 2012). One of the major questions has been whether there is a shift from elevated to suppressed activity as these children mature and, if so, is this shift a function of age or time since the trauma?

At this point the answer is still unclear. Adolescents who were in a relocation camp 2 months after Hurricane Katrina exhibited lower basal CORT levels but not salivary alpha-amylase levels than did age, sex, race, and economically matched comparison teens (Vigil, Geary, Granger, & Flinn, 2010). Thus CORT appeared to already

be downregulated 2 months after a trauma in these youth. In another sample of adolescents, exposure to violence over the previous year was associated with blunted CORT responses to the TSST (Peckins, Dockray, Eckenrode, Heaton, & Susman, 2012). In contrast, in children, those experiencing more traumatic events in the previous year were found to have higher diurnal CORT (Bevans, Cernone, & Overstreet, 2008). In none of these studies were children with PTSD examined separately from other children and many of the children did not carry any psychiatric diagnosis. When children with varying degrees of PTSD were followed from childhood through adolescence and into early adulthood, a shift in basal CORT levels from elevated to blunted occurred approximately 6–8 years posttrauma (Trickett, Noll, Susman, Shenk, & Putnam, 2010). Trickett and colleagues (2010) reported that this shift was more closely associated with time since identification of the trauma than child age; however, this was only one study and the information it contains pertained only to girls who were sexually abused. Notably, however, a similar conclusion was obtained in the meta-analysis described earlier that included adult-onset trauma exposure as well (Morris, Compas, et al., 2012). More longitudinal studies are needed examining different types of trauma exposure for children at different ages to distinguish between time-related and development-related effects.

A second very critical issue is whether the child is experiencing ongoing adversity. Even if the child is no longer being maltreated, his or her ongoing family situation may be difficult and parenting might still be poor. Often, ongoing family stress is not reported or examined. However, as demonstrated by Kaufman and colleagues (1997), maltreated and depressed children show larger responses to a CRH challenge test, but only if they are experiencing ongoing adversity at home. Likewise, for children in foster care, morning CORT concentrations become more dysregulated with each major care transition (Fisher, Van Ryzin, & Gunnar, 2011). Thus current stressors and protective processes may introduce tremendous heterogeneity making it difficult to discern how maltreatment has affected children's stress reactivity and regulation. Another potential problem in the child literature is that there are very few studies of stress responses to challenging tasks. Nearly all of the data pertain to ambulatory levels. This adds additional complications when researchers have taken samples at different times of the day and in different contexts (i.e., coming to the laboratory, in the home, at a summer camp).

Because of the heterogeneity of findings, much of the attention in the child literature has been focused on trying

to understand how individual differences in children might help to explicate inconsistent findings. Thus, Cicchetti, Rogosch, Gunnar, and Toth (2010) examined whether internalizing problems in maltreated school-age children moderated effects on CORT levels assessed during a summer camp. Only children with high internalizing symptoms exhibited altered CORT levels and then only if they had been abused (not just neglected) before Age 5. In a subset of this sample, the same effect was noted for children with the TAT haplotype of the CRHR2 gene, but for this subset it did not matter whether abuse began before or after Age 5 (Cicchetti, Rogosch, & Oshri, 2011). Finally, children with PTSD exhibit higher CORT levels over the day; elevated late afternoon and evening levels in these children predicted decreasing volume of the hippocampus and left ventral PFC (Carrion & Wong, 2012).

We and others have examined children adopted from conditions of deprivation and institutional neglect as a way of examining neglect relatively independently from abuse in children who are not suffering ongoing maltreatment. The results of these studies have also been mixed (Hostinar & Gunnar, 2012). One factor that appears to be significant is whether the child suffered a pattern of growth delay consistent with psychosocially induced short stature (D. E. Johnson & Gunnar, 2011). Children who are stunted at adoption but then exhibit catch-up growth and are no longer stunted at assessment tend to display a flatter pattern of CORT production over the day due to slightly lower morning and higher evening levels (A. E. Johnson et al., 2011).

Importantly, among postinstitutionalized children, late afternoon and evening levels correlate positively with the frequency and severity of the types of problems, specifically indiscriminate friendliness, attention problems, and emotion regulatory problems, that characterize these children (A. E. Johnson et al., 2011; Kroupina et al., 2012).

In all of this work on maltreated children, it is not clear whether the lowered morning levels are characteristic of the children or responses to events on the previous day and evening. There is evidence in animal models that it is critical to bring CORT levels down to near zero in order to reset the diurnal cycle (Akana et al., 1992). In foster care children, CORT levels are suppressed at wake-up on days after the foster parents reported that they were stressed by the child's problem behavior, but not if the foster parents reported child behavior problems that did not create much parenting stress (Fisher & Stoolmiller, 2008). Because, in this intervention study, the intervention lowered parent reports of stress in response to child problem behaviors, one interpretation of the CORT findings is

that stressed parents communicate their irritation with the children, which produces elevated child CORT into the evening hours, which in turn suppresses morning levels. The possibility that morning levels are being driven down by higher levels into the evening is consistent with data on overnight urinary CORT collected from preschoolers adopted from Russian and Eastern European orphanages who were at least 3 years postadoption (Wismer Fries, Shirtcliff, & Pollak, 2008). Although these children's first void CORT concentrations did not differ from those of comparison children, concentrations were higher for those who had suffered severe neglect. Because urinary concentrations reflect activity of the axis many hours earlier, these data suggest increased activity in the late evening and early period after sleep onset. Similar studies combined with salivary measures over the day would be helpful. CORT and sleep are intimately related and thus including sleep measures would be informative (Tininenko, Fisher, Bruce, & Pears, 2010).

Finally, as noted above, there are very few studies examining CORT reactivity among maltreated children, even though most theories involve effects on reactivity rather than basal levels. Here again the results are mixed. Studying 12-year-olds who had been abused by parents, peers, or both, one study reported blunted responses to the TSST with lower CORT responses being associated with more behavioral and emotional problems for the abused children (Ouellet-Morin et al., 2011). Studying postinstitutionalized children of about the same age, we found no difference in response as a function of early institutional care (Gunnar, Frenn, Wewerka, & Van Ryzin, 2009). We did find, however, that the postinstitutionalized children exhibited higher sympathetic tone (Gunnar, Frenn, et al., 2009). Both types of social engagement raised CORT levels in postinstitutionalized preschoolers interacting with strangers (rather than mothers), whereas among children in the nonadopted comparison group, interacting with mothers lowered CORT (Wismer Fries et al., 2008). Despite the ethical challenge of conducting stress tests on emotionally vulnerable children, a much better understanding of how neglect and abuse affect stress reactivity is still needed.

In summary, there is increasing evidence that childhood maltreatment affects the developing HPA axis. The evidence is clearest in studies of adults where there has been enough work to determine that trauma exposure alone is sufficient over time to result in a downregulated HPA system. It is unclear whether age at exposure matters; although, the passage of time does appear to be relevant. Numerous factors moderate these findings, the most

critical of which appears to be the development of affective pathology. PTSD is associated with asymmetrical effects on the HPA (blunted) and autonomic (heightened) systems, whereas depression produces the signature of heightened adrenal production of CORT and often a reduced capacity for negative feedback (e.g., Heim et al., 2008). Longitudinal studies are needed to focus on understanding the relations among maltreatment, stress biology (both HPA and autonomic), and the development of neural systems involved in stress and emotion regulation. These studies, however, will have to examine ongoing as well as prior adversity along with the quality of children's relationships and their ability to use relationships to regulate stress.

General Summary of Research on Early Adversity

As this section has shown, studies of early adversity have burgeoned in the decade prior to the time of this writing, from work on poverty to bereavement, prenatal stress to maltreatment. A wealth of evidence shows that adversity in childhood affects the HPA axis and CRH and a small but growing body of evidence that this serves as a pathway through which early adversity affects neurobehavioral development and health. There is still a good deal that is not understood. Poverty, in and of itself, seems to be unreliably related to stress reactivity and regulation. Other types of adversity discussed here are likely mediators. Prenatal stress, but not necessarily maternal emotional state, seems to upregulate the HPA axis, decrease birth weight, and increase fearfulness. Parental loss and risky family environments also seem to upregulate the system, but in contrast, maltreatment, perhaps particularly physical and sexual abuse, downregulate the HPA axis, except possibly in those individuals who develop depression (see Depression section). Why different types of stressors have different effects, whether it is type or severity, whether there are sensitive periods and, if so, whether they are the same for different facets of the stress system are questions that must be answered to move the field forward.

TEMPERAMENT AND STRESS VULNERABILITY AND RESILIENCE

Temperamentally shy, behaviorally inhibited children are at risk for developing social anxiety disorders by adolescence, and thus much of the research on stress vulnerability and resilience has focused on this temperament dimension (see review, Fox et al., 2010; Hostinar & Gunnar,

2012). We argue that temperamental shyness increases vulnerability to both adverse childhood experiences and the normative challenges of childhood. It is associated with the affective neurobiology of fear and social phobia that, when activated, stimulates increased HPA axis activity. Furthermore, elevations in CORT can act on these systems to enhance fear memories, increase vigilance to threat, and lower thresholds for subsequent anxious reactions to socially challenging situations (Rosen & Schulkin, 1998). However, low shyness and high extroversion are not necessarily protective. The protective value of a socially outgoing temperament depends on whether extroverted children have sufficient self-regulation to manage their exuberance in appropriate ways. If not, these children are vulnerable to the stress of peer conflict and rejection, and this vulnerability may foster the development of externalizing problems (Oldehinkel, Hartman, De Winter, Veenstra, & Ormel, 2004).

As we discuss in this section, shy/inhibited children do not always activate the HPA axis in response to social challenge. Whether or not they do depends, in part, on whether they embrace or avoid the challenge. If they successfully avoid, the very behavior (i.e., inhibition of approach) that defines behavioral inhibition reduces HPA axis reactivity. If they cannot avoid or choose to approach situations they find threatening, increased HPA axis activity may be observed (Tarullo, Mliner, & Gunnar, 2011). Because of these dynamics, it is helpful to have a cumulative measure of HPA-axis activity that reveals responding over time to multiple instances of challenge, some of which can be avoided and some cannot. In monkeys, behaviorally inhibited temperament is associated with higher CORT levels assessed using hair CORT (Laudenslager, Jorgensen, Grzywa, & Fairbanks, 2011). No studies with children have examined hair CORT in relation to shyness/inhibition, but such work would be helpful. Instead, there are studies examining children's reactions to different social situations.

Shy/inhibited children tend to exhibit relatively low levels of CORT in anticipation of entering a new social group, but higher late afternoon and evening CORT levels following the social challenge (for review, see Hostinar & Gunnar, 2012; Russ et al., 2012). Thus, unlike exuberant children who mount a preparatory response and then return to baseline levels, many shy/inhibited children do not prepare physiologically for the challenge of being with peers and then fail to bring levels to baseline for hours after the encounters are over. Once in the peer group, whether or how fast CORT increases depends on the shy/inhibited

child's coping strategies. Shy/inhibited children who spend more time in solitary play show lower CORT responses to group entry (Davis & Buss, 2012). Similarly, over the course of a preschool year, shy/inhibited children who avoid social contact show stable or declining CORT levels (Tarullo et al., 2011). Of course, avoiding social contact, while it may reduce acute experiences of stress, sets children up for developing poorer social skills and experiencing continuing problems in negotiating the social landscape of childhood. This may be why mothering that is overprotective and controlling is associated with sustained inhibition throughout childhood and increased likelihood of developing anxiety disorders (Lewis-Morrarty et al., 2012).

Approaching what frightens you should activate the stress system. There is now evidence that this is what happens when shy children attempt social engagement. For example, in one study shy children who spent more time hovering and attempting to enter into peer interaction produced a more prolonged CORT response to group entry than did shy children who spent more time playing alone (Davis & Buss, 2012). Studying shy/inhibited children across a year of preschool, those who showed increases in CORT levels as the year progressed surprisingly were more socially competent, had more friends, and were better integrated socially into the classroom (Tarullo et al., 2011).

The fact that social approach and peer engagement are both stressful for shy children and essential for developing social competence points to the possibility that activation of the HPA system may, at times, be a component of resilience. What is not known is whether social competence developed at this cost will result in increases in allostatic load for these children. The allostatic load associated with social engagement for shy/inhibited children may depend on whether or not the social competence gained is sufficient to result, over time, in a reduction of anxiety about social interaction.

In addition to these data about peer interaction, stress, and shyness, there is increasing evidence that shy/inhibited children are especially vulnerable to increases in HPA-axis activity in response to adverse childhood experiences. This has been shown for interparental violence, harsh and/or less sensitive maternal care, and poorer quality childcare (Hostinar & Gunnar, 2012).

There is also increasing evidence that for shy/inhibited children, higher allostatic load and/or higher levels of CORT late in the day predicts the development of anxiety disorders and internalizing problems, perhaps most predictably for girls (K. A. Buss, Davis, & Kiel, 2011). Thus, in studying children in full-day childcare, the combination of shy/inhibited behavior and rising levels of

CORT over the childcare day predicted increasing levels of inhibition at childcare and higher internalizing problems (Gunnar, Kryzer, Van Ryzin, & Phillips, 2011). Notably, when CORT followed the normal diurnal decrease over the day in childcare, shy/inhibited children became less fearful over time and showed fewer internalizing problems relative to non-shy children. This last finding is reminiscent of the differential susceptibility and sensitivity to context hypotheses. Indeed, regarding internalizing problem scores, children lower in inhibited behavior were unaffected by whether they experienced increasing or decreasing CORT levels over the childcare day.

In work by Rothbart (Derryberry & Rothbart, 1997), shyness loads negatively on a higher-order temperament factor labeled surgency or extraversion. Children who score high on this factor seek stimulation, are impulsive, enjoy novelty, are not shy, and are high in activity. As noted earlier, such children are at risk for developing externalizing problems (Oldenhinkel et al., 2004). Although they tend to be the opposite of shy/inhibited children, highly surgent children are not necessarily stress resilient. Surgent children do tend to show habituation of the CORT response to parental fighting over time (Sturge-Apple et al., 2012). They are also less sensitive to whether they are in a childcare that produces increases or decreases in CORT over the day (Gunnar et al., 2011). However, while they do not tend to develop altered patterns of CORT or vagal tone reactions in response to harsher maternal care, they do show changes in sympathetic activity that, in turn, mediates externalizing behavior problems (Sturge-Apple et al., 2012).

Indeed, whether the surgent child experiences chronic or frequent elevations in CORT depends on whether they have the self-regulatory competencies to manage their exuberance in ways that do not create conflicts with others. For example, in a study of preschool children, surgency plus poor effortful control was associated with aggressive peer interactions that then resulted in more peer rejection and elevated CORT (Gunnar et al., 2003). For children who are social and outgoing, being isolated or ignored is emotionally distressing. Indeed, there is now evidence that social rejection activates the same circuits that process physical pain (Eisenberger, 2012). Although most surgent children show decreases in CORT over the school year, highly surgent preschoolers who were not well integrated into the social network and who had no close friendships did not show these declining CORT values (Tarullo et al., 2011).

These findings suggest that the relations between emotional temperament and stress vulnerability and resilience

depend to large measure on self-regulation. This has been shown in a large sample of 10- to 12-year-olds in the Netherlands. Among these youth, poor self-regulation increased the risk of behavior disorders later in adolescence, with temperament mediating the type of disorder: surgent temperament with externalizing, shy/inhibited temperament with internalizing (Oldenhinkel et al., 2004). In that study, self-regulation was assessed as effortful control, a construct that reflects regulation of reactive emotional dimensions of temperament (i.e., approach/impulsivity and fear/withdrawal) by corticolimbic attentional circuits (Derryberry & Rothbart, 1997). In work with Posner, Rothbart identified executive attention involving the anterior cingulate cortex (ACC) and the dlPFC, as fundamental to effortful control (Posner, Rothbart, Sheese, & Tang, 2007). Executive attention and other executive functions influence circuits in the vmPFC that can put the brake on the amygdala and hypothalamic autonomic and neuroendocrine systems. Under resting conditions, one would expect that children scoring higher on measures of effortful control would have lower basal HPA activity (Watamura, Donzella, Kertes, & Gunnar, 2004). Under conditions of cognitive challenge that require recruitment of effort, modest increases in HPA and autonomic activity should support better performance (Blair, Granger, & Razza, 2006). Finally, under conditions of emotional threat that require modulation of amygdala reactivity, higher levels of effortful control should result in reduced HPA reactivity (Slattery, Grieve, Ames, Armstrong, & Essex, 2013). Interestingly, in response to the TSST, better executive functions (in the form of working memory) predicted a smaller CORT response in nondisordered adolescents, but the opposite was found in adolescents with internalizing disorders (Slattery et al., 2013). It is not only cognitive skills but likely the uses to which they are put (adaptive coping versus ruminating) that influences stress responding. Also, as discussed earlier, elevations in CORT can impair executive functions and effortful control. Thus, there is a dynamic relationship between the cognitive abilities that support self-regulation and the activity of stress-sensitive systems.

Inputs from the vmPFC to the amygdala appear to be critical in extinction of fear responses, and perhaps as these inputs develop they may be critical in regulating the responses of temperamentally shy/inhibited children. Experience also affects the development and functioning of the vmPFC and the strength of its control over amygdalar threat processing.

In studies of adult humans and animals, those with prior experiences of control over potent stressors cope better

with subsequent threats, responding with less activation of the HPA axis and with stronger apparent expectations of being able to protect themselves from harm. There is increasing evidence that this facet of resilience reflects control-induced activation of the vmPFC (Maier & Watkins, 2010). These data add to an understanding of why overprotective parenting sustains shy/inhibited temperament as such parenting may neither allow nor promote children's experiences with manageable threat (Lewis-Morrarty et al., 2012). In addition to experiences of controllable threat, there is evidence that children's ability to regulate emotions and reduce stress is promoted by parental scaffolding, which reflects responsiveness to the child's needs and respect for the child's autonomy (Eisenberg et al., 2010).

Summary and Future Directions

Children's emotional dispositions and their ability to regulate those dispositions contribute to their stress vulnerability and resilience. Experiences affect how temperamental differences among children influence development and how self-regulatory capacities develop and modify stress vulnerability and resilience. The two reactive dimensions of temperament that were discussed, shyness/inhibition and surgency, affect the odds that children will develop internalizing and externalizing disorders. We now turn to what is known about relations between stress and psychopathology in childhood and adolescence.

DEVELOPMENTAL PSYCHOPATHOLOGY

Activity of the HPA axis has been implicated in several mental disorders. We already discussed its potential role in PTSD in the section on maltreatment. Here we focus on two disorders that emerge in childhood and adolescence: major depressive disorder and disruptive behavior disorders (DBDs). Two major questions guide our discussion of this work: (1) What is the evidence that dysregulation of the HPA axis is involved and (2) is stress experienced during development critical to the role that CORT and/or CRH play in these disorders?

Depression

Dysregulation of the HPA axis in depression is one of the most robust findings in biological psychiatry. Depression is often accompanied by a flat diurnal rhythm due to failure to

bring CORT down to low levels in the late afternoon and evening (Heim & Binder, 2012).

Depressed individuals exhibit a larger CORT elevation in response to stressors and they remain elevated for a longer period of time before returning to baseline post-stressor. In addition, they often show failure to suppress to the dexamethasone challenge test, indicating poor negative feedback regulation of the HPA axis. Both the remitted and current major depression groups exhibit a higher CAR than never-depressed individuals (Vreeburg et al., 2009). Adults with depression consistently show a blunted ACTH response to CRH challenge, possibly due to a chronic CRH drive and subsequent downregulation of pituitary responsiveness to CRH (Heim & Binder, 2012). This adult literature on depression and the HPA axis has been challenged by work on adults with depression who do and do not have histories of child abuse (Heim & Binder, 2012). Many of the findings described above appear to be characteristics of depressed adult survivors of child abuse rather than depressed adults without maltreatment histories.

Consistent with this argument, suicide victims with a history of child abuse compared with those without were found to exhibit increased methylation of the same gene in the hippocampus (i.e., NR3C1 promoter region of the GR gene) shown to be methylated in rodent studies of poor maternal care (McGowan et al., 2009). Because of the frequent comorbidity of PTSD and major depression, the association of major depression with hyperactivity of the HPA axis and PTSD with hypoactivity has long been very puzzling. If, however, trauma is associated with hyperactivity of the axis followed by downregulation in most individuals but not in those who develop major depression, then this provides a way of focusing the research question.

Specifically, why, in adult survivors with major depression, has the HPA axis up- rather than downregulated in response to frequent or chronic elevations in CORT experienced in response to maltreatment?

Treatment studies provide the most compelling evidence that the HPA system and CRH play causal roles in the induction and maintenance of major depression. For example, antidepressants reduce CRH in the cerebral spinal fluid (CSF) of healthy controls as well as in patients with major depression, indicating that antidepressants directly manipulate CRH levels rather than the reduction of CRH being a side effect of improved depressive symptoms (Wilkinson & Goodyer, 2011). Treating depression with SSRIs reduces CORT levels of depressed adults to those of nondepressed adults, and this decline is correlated with lower levels of depressive symptoms. Rodent studies

support the causal role of the axis by showing that depressive behaviors and HPA hyperactivity induced by low maternal care can be reversed in adulthood by pharmacological and dietary interventions that reverse methylation of hippocampal GR (Heim & Binder, 2012). Individuals with high CRH have the greatest risk of relapse following antidepressant treatment (Wilkinson & Goodyer, 2011). In addition, greater CORT reactivity predicts increases in depressive symptoms (Morris, Rao, & Garber, 2012) and a smaller CAR, or blunted HPA axis activity and low morning CORT predict an unfavorable psychiatric course and/or greater risk of relapse (Morris, Rao, et al., 2012; Vreeburg et al., 2009).

The role of the HPA axis in child and adolescent depression is less clear (Wilkinson & Goodyer, 2011). Although high CORT levels are often reported for depressed youth studied in outpatient settings, it has been more difficult to identify endogenous dysregulation assessed by acclimating children and adolescents to a sleep laboratory for several days, providing them with warm and supportive adult attention, and then testing them for both sleep and HPA-axis impairments (Dahl et al., 1991). It is hypothesized that children may be more resilient than adults to endogenous dysregulation and that the period of late adolescence or more chronic depression may shift individuals to greater endogenous vulnerability. The experience of depression may also have different effects on children and adults. For example, in adolescents, those studied soon after symptom onset showed elevated CORT levels, whereas those studied following more chronic symptoms showed blunted activity of the HPA axis. By contrast, adults with more chronic symptoms are, if anything, hypercortisolimic. In depressed youth, the system may still be resilient enough to downregulate following periods of prolonged activation.

HPA measures have also shown predictive power in adolescents. A higher CAR in adolescence predicted the onset of a major depressive episode 2.5 years later although it was not predictive beyond that time point (Vrshek-Schallhorn et al., 2013). In another study, higher basal CORT in the morning and afternoon predicted an increase in depressive symptoms over 2 years in boys tested initially between 10 and 14 years (Heim & Binder, 2012). Although HPA dysregulation is less common in children and adolescents with depression, these findings indicate that regulation of the HPA axis likely contributes to the onset and maintenance of depression prior to adulthood.

Some of the most persuasive evidence that abnormalities in the HPA axis precede the onset of depression come

from the study of not-yet-depressed children who are at high risk because of a family history of depression. When the depressed family member is the mother, as is often the case in these studies, alterations in the axis before the children develop depression likely reflects the interaction of both shared genetics and shared environment along with the effects of parents and children on one another. That said, offspring of postnatally depressed mothers had higher and more variable morning CORT levels over 10 days when they were 13 years old, and these levels predicted the development of depressive symptoms over the next few years (Halligan, Herbert, Goodyer, & Murray, 2007). At the transition to adolescence, girls but not boys with depressed parents showed blunted CORT responses to a psychosocial challenge (Bouma, Riese, Ormel, Verhulst, & Oldehinkel, 2011). Children with depressed mothers may also be more likely to develop dysregulated patterns of HPA axis activity when exposed to other family risk factors such as harsh parenting (Dougherty, Klein, Rose, & Laptook, 2011), high expressions of anger in the family (Essex et al., 2011), or insecure attachment (Heim & Binder, 2012). The timing of maternal depression may also matter, which suggests that more than shared genetics are involved (Dawson & Ashman, 2000).

Of course, it is not just the HPA axis that may be altered prior to symptom onset in the offspring of depressed mothers. There is at least one report that low levels of vagal tone and poor vagal regulation are observed in children of depressed mothers (Gentzler, Rottenberg, Kovacs, George, & Morey, 2012), which is consistent with evidence that low vagal tone and blunted CORT responses may co-occur with higher levels of internalizing symptoms in children (El-Sheikh, Arsikawa, Hinnant, & Erath, 2011). Thus, interactions of HPA axis anomalies with anomalies in other developing stress-mediating systems need to be examined. In addition, given the increase in depressive symptoms and the emergence of the gender bias in depression with puberty, special consideration must be given to interactions between the HPA and hypothalamic-pituitary-gonadal axes.

Researchers are actively pursuing whether genes involved in regulating the HPA system (e.g., CRHR1, GR and MR polymorphisms, FKBP5) affect the risk for depression. We have already discussed FKBP5, which seems to moderate the effect of childhood abuse on adult PTSD (Klengel et al., 2013). For depression, it may be the CRHR1 gene that moderates the effects of child maltreatment (Heim & Binder, 2012). This pattern would suggest that genes that increase the potency with which

threats can affect the pituitary-adrenal system and other fear-stress orchestrating targets of CRH increase the risk of depression, while genes that downregulate CORT effects may increase the risk of PTSD. This is highly speculative, but it does suggest the relevance of a systems neuroscience approach to understanding genes, stress, and developmental psychopathology.

Disruptive Behavior Disorders

Disruptive behavior disorders (DBDs), including conduct disorder and oppositional defiant disorder, have been associated with low basal and reactivity measures of both the HPA and ANS systems. There have been a number of reviews on this topic, which we draw on in this section (Hawes, Brennan, & Dadds, 2009; Shirtcliff et al., 2009; van Goozen et al., 2007). One study by van Goozen and colleagues (2007) proposed a neurobiological model of childhood antisocial behavior according to which genetic factors interact with childhood adversity to produce neurobiological and self-regulatory deficits, which then enhance the development of antisocial behavior. Diminished activity of the HPA axis plays an important role in this model based on evidence that, in animals, CORT interacts with serotonin receptors in the amygdala to support typical aggressive responses to threat provocations and insufficient CORT then fails to provide this input. This then leads to abnormal, hyperaggressive behavior. Studies supporting the association between CORT and DBD in children include evidence that (a) when exposed to a stressor that involves taunting and disparaging remarks made by another child, typical children respond with elevations in CORT and autonomic activity, whereas DBD children do not but do engage in more hostile retributive actions, (b) youth with lower CORT levels and reactivity respond less to interventions designed to reduce antisocial behavior, and (c) even subclinical levels of externalizing problems have been associated with lower baseline levels of CORT. Despite these arguments, a meta-analysis revealed that the association between CORT and externalizing behavior is less strong than once thought. This led Hawes and colleagues (2009) to posit two pathways to adult antisocial behavior distinguishable by whether the children display callous-unemotional traits. These traits are viewed as developmental precursors of psychopathy. One pathway to adult antisocial behavior runs through this disposition, which is associated with blunted activity of the HPA axis, whereas another runs through adverse childhood experiences, poor emotion and behavior regulation, and more

reactive stress responding. The Hawes et al. (2009) analysis is complemented by another (Shirtcliff et al., 2009) that reviewed the neuroscience research on psychopathy, callousness, and empathy and provided a rationale for why low levels of CORT and reduced HPA axis reactivity should be associated with the observed patterns of brain impairments in callous-unemotional antisocial individuals. Despite this, the empirical evidence for a relation between callous-unemotional traits and low levels of CORT activity is weak. Among boys with ADHD and DBD, blunted CORT reactivity to the TSST has been associated with callous-unemotional traits (Stadler et al., 2011). However, two other studies failed to find any association with basal CORT levels, although aggression was negatively associated with basal levels in these studies (e.g., Poustka et al., 2010). Because the relation between antisocial behavior and low sympathetic tone and reactivity is better established, it may be that a combination of low CORT and low sympathetic activity will be more consistently associated with DBDs (van Goozen et al., 2007).

Treatment studies are particularly telling. Thus, boys with DBD were found to have lower CORT levels than healthy controls before treatment and a larger increase in CORT over time, suggesting that interventions may reduce disruptive behaviors through normalization of basal CORT levels (Dorn, Kolko, Shenk, Susman, & Bukstein, 2011). Studies have also shown that DBD interventions increase HPA axis responses to a frustration stressor (van Goozen et al., 2007) and CORT levels in anticipation of peer entry in boys at risk for DBD, as discussed earlier (O'Neal et al., 2010).

Comorbidity is a problem for researchers studying DBD, as anxiety and attention disorders are often present simultaneously with DBD. Furthermore, there is evidence that, when comorbid with an anxiety disorder, the relations of DBD with CORT may invert. That is, in the absence of an anxiety disorder, children with DBD may have lower than normal levels of CORT or CORT reactivity, but when combined with an anxiety disorder, CORT levels and reactivity may be higher than in nondisordered children (van Goozen et al., 2007). Thus, variability in findings may have to do with other comorbid problems present in children with DBD.

It may also be that activity of the HPA axis is associated with an endophenotype that contributes to the development of DBD but may do so to different degrees for different children or for different subtypes of DBD. As we have discussed, callous-unemotional traits might be one such endophenotype. Another may be low sensitivity to

punishment. Low punishment sensitivity has been associated with amygdala hyporeactivity to negative events, lower CORT reactivity, altered fear conditioning, and changes in serotonin and noradrenaline regulation (Matthys, Vanderschuren, & Schutter, 2012). There is evidence that disrupted serotonergic regulation is related to low CORT levels or CORT downregulation following chronic stress, but more research is needed to understand the nature of this association. Impaired sensitivity to punishment and its accompanying physiological characteristics may disrupt children's and adolescents' abilities to pair inappropriate actions and negative consequences. Disruptions have been related to hyposensitivity to reward, which encourages adolescents to engage in sensation seeking as a compensatory behavior, and to problems with executive functioning, which impair the ability to overcome emotion-driven behaviors (Matthys et al., 2012).

Sex differences are essential to consider in research on DBD. There is evidence that boys with DBD and healthy control girls have lower basal CORT than girls with DBD and healthy control boys (Dorn et al., 2009). The timing of puberty and activity of specific systems are also important moderators of disruptive behaviors. In boys, high CORT responses to stress were related to antisocial behavior in adolescents with later onset puberty. However, in boys with earlier puberty, lower salivary alpha-amylase activity—an index of autonomic activity—was related to more antisocial behavior (Susman et al., 2010). Future research needs to consider the effects of testosterone, SNS mediators, and hormones with antiglucocorticoid properties (e.g., DHEA) in order to understand the complexities of DBD in relation to the HPA axis.

Summary and Future Directions

One of the most perplexing questions confronting neuroendocrine researchers is whether HPA-axis dysregulation precedes psychopathology or if the onset of psychopathology produces alterations in HPA functioning. Although there is growing evidence of HPA abnormalities preceding the onset of psychiatric disorders, future research must track children before any sign of disorder to determine how early alterations can be detected and whether this information can be used in preventative interventions. The role of genes in mediating HPA-axis contributions to the development of psychopathology, as well as the effects of stress in epigenetic changes contributing to psychopathology are critically important and growing areas of research.

Future models of HPA axis development must explain how the system acts to mediate the effects of experience on physical, cognitive, and socioemotional domains across time and in concert with other stress-mediating systems. These models must also describe how individual characteristics affect HPA regulation and predict who goes on to develop psychopathology. As knowledge of HPA correlates of psychological functioning accumulates, translational efforts should be made to aid the treatment of disorders. For example, should practitioners manipulate CORT levels or GR levels and sensitivity in order to prevent or treat depression? Can altering stress hormone levels affect individuals' ability to cope following a major stressor to prevent PTSD? Any such efforts should be made with the understanding that the HPA axis does not operate in isolation and that manipulation of the system may also affect susceptibility to other disorders closely related to stress system activity.

GENERAL CONCLUSIONS AND FUTURE DIRECTIONS

There is little doubt that stress plays a critical role in development and that activity of the HPA axis and CRH, in interaction with other stress mediators, is involved in many of the effects of childhood adversity on physical and mental development. Despite the broad evidence for this conclusion organized in this review, there are a number of issues that remain to be resolved.

First, are there sensitive periods for the development of stress reactivity and regulation, and if so, when are they and how are they characterized? Although there are clear sensitive periods in the rodent models that spawned this field, rodents are born with less mature neuroendocrine systems than humans are and translating the timing of sensitive periods from rats to humans is problematic. Yet there is increasing evidence that the homologous GR gene is methylated by postnatal experiences in rats and humans (McGowan et al., 2009). Nature appears to be able to accomplish similar outcomes in the infant rat and young human, though it is unknown whether they occur through the same molecular processes. Still, the issue of sensitive periods for shaping the stress system persists and is one of the more critical ones in the field.

Second, how can we move beyond analyzing each stress-mediating system separately? The dynamics of the HPA axis defy many of our attempts to do so. For example, while elevated sympathetic and suppressed HPA activity

might reflect the effects of chronic stress, it depends on the type of stressor, the context, the individual's prior history with similar stressors, and likely, the stage of development. To be useful, theoretical models of multisystem patterning need to be as nuanced and contextualized as the neurobiology and neuroendocrinology of stress.

Third, theories and research plans in the study of development have paid relatively little attention to temperament, sex differences, or gender socialization. Nonetheless, temperament has been shown repeatedly to moderate stress responses and the effects of stress on development. With regards to sex and gender, although we see few sex differences in physiological reactivity until puberty, it seems quite possible that gendered worlds of childhood will begin to affect how children weigh the threats they encounter and influence their best strategies for managing threat. No theories of stress adequately address sex differences, although the Tend-and-Befriend hypothesis (Taylor et al., 2000) might provide inspiration for how to begin examining and thinking about how gendered stress and coping emerges during development.

Fourth, we need to understand how development, and particularly puberty, affects stress physiology for children exposed to early life stressors and trauma. Time-since-trauma may explain changes in the direction and activity of stress-mediating system during adolescence, but it seems highly unlikely that this is the whole story. Puberty may open windows for reorganizing the neurobiology of stress and emotion shaped in particular ways by earlier experiences, and pubertal hormones and processes may have differential effects on this neurobiology depending on the way earlier experiences have shaped the system. Given the importance of adolescence in psychopathology, this is a critical avenue for future research.

Finally, we need to figure out how best to incorporate work on genes and epigenetics into our theories and research on stress and development. We now know of a number of polymorphisms for stress-relevant genes. Studies are beginning which, generally, ask the same question: Does this genetic polymorphism moderate the stress response? These studies are likely to yield conflicting findings. Until the field of developmental science can move beyond the simple directional hypothesis (increase or decrease the stress response), it will not reap the benefits of molecular genes. What is needed are hypotheses that take into account the nature of the stressor, the level of the system the gene should affect, the potential counterregulatory activity that may have developed to negate the effects of

the "faulty" gene and the time during the stress response that effects should be most apparent. In all of this, the developmental stage is also likely to be relevant. The same applies to epigenetics. It is necessary to move beyond asking whether the epigenome is affected by childhood experiences, although this was an important first issue, and move on to asking about specific epigenetic effects. Again, it may also be necessary to adjust predictions to the specific tissue under analysis. And again, are there sensitive periods for epigenetic programming of stress-relevant genes, and the same sensitive periods for brain, buccal, and white blood cells? These are challenging questions, but ones that will be at the forefront of research on stress and development in the coming years.

The writing of this chapter was supported by grants from the National Science Foundation (#BCS-1225620) and the Social Sciences and Humanities Research Council of Canada (SSHRC) to

X. Chen and by grants from SSHRC, the Natural Science and Engineering Council of Canada (NSERC), and the Canadian Institutes of Health Research (CIHR) to L. A. Schmidt.

Human development is a complex phenomenon involving the joint influence of individual dispositional characteristics and socioecological conditions. Children come to the world with initial temperamental biases, which provide a basis for them to interact with their environments in specific ways. Through the interaction, children increasingly develop socioemotional, behavioral, and cognitive qualities that distinguish them from one another.

This chapter is concerned with children's temperament and personality and their roles in socioemotional development. We begin by providing a brief background to the exploration of temperament and personality. We then discuss major theoretical perspectives and some assessment issues in the field. Next, we focus on the biological foundation for the development of temperament and personality. After reviewing research on links between temperament and personality and their developmental outcomes, we discuss the roles of social contexts, including the family and peers, in facilitating and undermining the development of temperament and personality characteristics and their relations with adjustment. We go on to consider how culture affects the display and the developmental significance of temperament and personality. The chapter concludes with a discussion of practical implications and future directions.

As a general framework for the chapter, we emphasize the role of social interaction in shaping children's temperament and personality from a contextual-developmental perspective (Chen & French, 2008). According to this perspective, temperament and personality need to be understood in terms of their developmental processes, and the development of temperament and personality needs to be understood in the social context. How adults and peers perceive, evaluate, and respond to specific characteristics of children in social interaction, which is guided by cultural norms and values, is a main mechanism for the development of those characteristics. Whereas biologically rooted individual biases in early disposition may be a major source of variations in temperament, personality, and socioemotional development, social interaction gives meaning to individual characteristics and determines, to a large extent, their developmental patterns and their relations with adjustment.

TEMPERAMENT AND PERSONALITY: SOME CONCEPTUAL ISSUES

Temperament and personality represent individual behavioral, emotional, and attentional characteristics that are relatively stable across situations and over time and have a pervasive impact on wide ranges of social and cognitive functions. Whereas temperament is often considered the core of personality, personality taps more specific individual traits as indicated by the patterns of behaviors, emotions, cognitions, and implicit and explicit aspects of the self that are associated with adaptive and maladaptive performance in particular domains (e.g., Rothbart, 2011). Some investigators have argued that temperament and personality have much in common (Shiner & Caspi, 2012). For example, temperament and personality both (a) are concerned with the uniqueness of individual characteristics that show consistency across situations and over time and with interpersonal differences in these characteristics, (b) involve the processes of reactivity and regulation, (c) are influenced by biological factors and experiences, and (d) interact with the environment in contributing to adjustment.

Despite their commonalities, temperament and personality may differ to varying degrees in several aspects. First, temperament has traditionally been viewed as constitutionally based emotional and behavioral characteristics of feelings, thinking, and reacting (e.g., Allport, 1937; Rothbart & Bates, 2006), and thus it is presumed to be more biologically rooted and is determined to a greater extent by heredity and maturation than personality. Second, many temperamental characteristics, such as irritability, distress proneness, soothability, and activity level, appear very early in life, as indicated by individual differences in these characteristics in newborns and infants (e.g., Rothbart, 2011). Researchers have examined the development of personality in childhood and adolescence (e.g., John, Caspi, Robins, Moffitt, & Stouthamer-Loeber, 1994; Lamb, Chuang, Wessels, Broberg, & Hwang, 2002). Whereas major personality traits, such as extraversion, agreeableness, and neuroticism, may emerge within the first 2–3 years of life and become increasingly salient with time, many of them are not well defined in early childhood. As indicated by Lamb et al. (2002), some aspects of personality may not become apparent until children experience various social situations

that allow their tendencies to be consolidated. Personality traits that are based on sophisticated social and cognitive skills, coping styles, and values are likely to appear in the later years. Third, relative to most personality traits, temperamental characteristics are concerned with more general affective and behavioral processes. Temperamental characteristics become increasingly differentiated with age and gradually integrated or merged into personality, which, as argued by Rutter (1987), may be considered the projection of temperamental tendencies into the world. Finally, according to Chess and Thomas (1986), temperament is mainly about the style of behavior (the “how,” e.g., rhythmicity, adaptability, intensity of reaction), whereas personality may include the content of thought, habits, motives, coping styles, goals, values, and beliefs (the “what”). Nevertheless, as pointed out by Rothbart and Bates (2006), the style versus content distinction makes sense at the theoretical level but is less useful in research because it is often difficult to differentiate between them in the assessment of children’s temperament.

A salient issue in the study of temperament and personality is temporal stability. Two types of stability are interesting from a developmental perspective: mean-level stability (i.e., whether the average level of a trait remains the same or changes with age) and rank-order stability (i.e., whether children maintain their relative positions on traits over time). Research has shown that levels of traits related to regulatory abilities such as effortful control and conscientiousness tend to increase from childhood to adulthood, which may reflect psychological maturity (Caspi & Shiner, 2006; Chuang, Lamb, & Hwang, 2006). Research has also revealed that the rank-order stabilities of many temperamental and personality characteristics are moderate over years, with the magnitude increasing with age (higher from middle childhood), and decline as the time interval increases, although researchers have reported long-term stabilities of some characteristics such as inhibition and undercontrolled behavior (e.g., Asendorpf, Denissen, & van Aken, 2008; Caspi et al., 2003).

Despite evidence that temperament and personality are generally stable, research projects on similar characteristics often provide inconsistent results perhaps in part because of the age-specific pattern of genetic influence and the impact of changing socializing environments. That is, it is unclear when and in what circumstances temperament and personality characteristics maintain their temporal stabilities and when and in what circumstances developmental changes in these characteristics occur. A related issue, which is important for empirical research, is how the

same characteristic is manifested in observable behaviors in different developmental periods. It is plausible that the “latent” construct of a characteristic is manifested in different behaviors over time. In order to meaningfully examine the stabilities of temperament and personality, researchers need to analyze how personal, developmental, and contextual factors are involved in the exhibition of specific characteristics and establish their observed “indicators” at different ages, although this may be a difficult task (see Thompson & Goodvin, 2005, for a review).

BRIEF HISTORY

The phenomena of temperament and personality were observed and mulled over profoundly in ancient times. However, it was not until the last century that these phenomena were explored systematically from a scientific perspective. Research on temperament and personality burgeoned exponentially from the 1980s, yielding a comprehensive understanding of their nature, structure, and developmental significance.

Ancient Times

The notion of temperament and personality in human beings appeared in early civilizations. In Chinese society, for example, Mencius (372–289 BC), one of the most famous Confucian thinkers, identified four social–moral attributes of the ideal personality: *ren* (benevolence, humanity), *yi* (righteousness), *li* (propriety, proper conduct), and *zhi* (wisdom and knowledge). He believed that these four attributes originated from four predispositions or inborn qualities of human beings that he described as “sprouts”: a feeling of commiseration, a sense of shame, a reverential attitude toward others, and a sense of right and wrong. Mencius emphasized human predispositions because he believed that external control was unlikely to improve the organization of the society without considering innate human tendencies. Nevertheless, he asserted that education and socialization in childhood and adolescence were critical to cultivating the innate goodness of the individual and preventing the development of undesirable behaviors.

The idea of temperament also appeared in *Huang Di Nei Jing* (the Emperor Huang’s Manual of Corporeal Medicine), a book written more than 2,500 years ago that had a pervasive impact on traditional Chinese medicine and cultural beliefs. According to the holistic perspective provided in this book, human physical and emotional

well-being was associated with the balance of Yin (the passive and receding aspect of nature) and Yang (the active and advancing aspect of nature). The Five Element Model, as a part of the broad Yin and Yang theory, explained how individual traits might be formed on the basis of interactions among the states of human functioning that represented the fundamental “five elements” in nature (wood, fire, earth, metal, and water). The model particularly stressed the connections among factors at the psychological and physical/biological levels. For example, five basic emotions—irritability/anger, joy, worry, sadness, and fright/fear—might be directly associated with the condition of the liver, heart, spleen, lung, and kidney, respectively. And at the same time, repeated experiences of a predominant emotion in people with a particular disposition might result in health problems related to the corresponding organ (see Chen & Swartzman, 2001).

The connection between temperament and biological functioning was also recognized in ancient Western societies. The Greek physician Hippocrates (460–370 BC) developed a four-element model that was surprisingly similar to the Chinese Five Element Model. Drawing on the basic elements of nature, earth, air, fire, and water, Hippocrates proposed that human health, emotions, and behaviors were related to body fluids or “humors”: blood, yellow bile, black bile, and phlegm, derived from the heart, liver, spleen, and head, respectively, and that the balance of the fluids determined one’s health status. Based on the combination of hot-cold and dry-wet with the four elements, Galen (AD 131–200) developed the well-known typology of temperament and attempted to link it to physiological processes. The four temperaments he identified, the sanguine (sociable, cheerful), choleric (aggressive, ambitious, full of energy), melancholic (introverted, anxious, sad), and phlegmatic (calm, rational), each represented an excess of one of the humors. Although the typology described distinct behavioral and emotional inclinations, Galen indicated that individuals differed mainly in the strength of the qualities.

The ancient views of temperament in Eastern and Western cultures have influenced the thinking of scholars and the public. For example, the typological approach has been adopted by some contemporary researchers (e.g., Kagan, Snidman, Kahn, & Towsley, 2007). Ideas about the biological origin of temperament have received support from research. In addition, the notion in both the Chinese and the Hippocrates-Galen models that temperament, health, and environmental factors such as socioecological conditions interact with each other is consistent with the

results of empirical studies (Hampson & Vollrath, 2012). Nevertheless, the ancient views have been replaced by more sophisticated and scientifically relevant modern theories and perspectives that have been refined on the basis of research findings.

Modern Temperament and Personality Theories and Research

For the first part of the 20th century, the theoretical and empirical explorations of temperament and personality were conducted mainly within the same broad frameworks of individual traits because temperament was considered the nucleus or a subdomain of personality (Allport, 1937; Gesell, 1928). As a result, the boundaries between temperament and personality were rather blurry in much of the scholarship from this period. Most of the theories and studies focused on adults but tapped developmental origins and socialization processes, which provided the intellectual and methodological foundations for developmental research on children.

Pavlov’s and Jung’s Typologies

Based on his seminal studies of dogs, Pavlov (1935) postulated the central nervous system (CNS) as a framework for different types of temperament, with a focus on excitatory and inhibitory processes. According to his theory, how excitatory and inhibitory processes function in individuals is related to the properties of their CNS including strength (the extent to which an individual endures intense and prolonged stimulation or conditioned inhibition), balance or equilibrium (how the two processes function in the system relative to each other), and mobility (how the CNS adequately responds to continuous changes in the environment). Individual differences in these properties define types of temperament (e.g., the strong, impetuous, and unbalanced; the strong, equilibrated, and lively). Among them, the weak inhibitory type, which is still interesting to temperament researchers today, characterized individuals that were particularly susceptible to stressful and challenging situations. Dogs of weak inhibitory type were easily disturbed by irregular stimuli and were likely to develop what Pavlov called experimental neurosis, which was an indicator of the disturbance of the balance between excitatory and inhibitory processes of the nervous system (Pavlov, 1935). Pavlov found that basic temperamental tendencies were inherited or conditioned since infancy by various environmental influences. Once formed, these tendencies persisted and had a long-lasting impact on behavior.

Many features of Pavlov's model are reflected in other theories, such as Jung's introverted and extroverted personality typology. According to Jung (1928), whereas extroverts were action-oriented and tended to direct their psychic energy (libido) outward toward people, objects, and activities, introverts were thought-oriented and quiet and tended to direct their energy toward internal states such as ideas and feelings. Jung (1928) described four types of individuals based on two rational or judging functions (thinking and feeling) and two irrational or perceiving functions (sensing and intuition), allowing extroverted and introverted tendencies to be expressed in different ways. Extroverted thinking, for example, characterized individuals who understood the world through abstract concepts learned from other people, whereas introverted thinking characterized individuals who interpreted the environment through subjective, internal knowledge. Although multiple extroverted and introverted functions could be present in the same person, one of them was normally more developed and dominant, existed in consciousness, and defined one's personality type, with the others repressed into a part of unconsciousness. A related notion in Jung's theory was that, besides the *personal unconscious*, which represented individual unique and private experience, the *collective unconscious*, a deeper and more fundamental part of the unconscious, influenced our behaviors and emotions. The collective unconscious, with what he called archetypes, was innate and generally universal, derived from the latent memory traces of human beings' ancestral past.

Allport's Personality Traits

According to Allport (1937), the basic unit of personality was the trait, which he defined as a neuropsychic system with motivational properties. An individual's traits guided his or her behavior and made it consistent across situations and over time. An individual might possess traits that were unique to him or her as well as traits that were shared by others to a varying extent in a culture. The existence of common traits such as sociability, submissiveness, and conformity was important because it allowed us to assess individual differences in personality.

In Allport's theory, traits within the person were interconnected to form an internally consistent and coherent system, which constituted a basis for the development of the self and a sense of identity. Thus, Allport advocated the use of the interpretive or idiographic approach to understand the unique and integrated personality profile of the individual; this approach was believed to be useful but is nonetheless rarely used in personality research today.

The Factor-Analytic Approach: Some of the Pioneers

Consistent with Allport's trait approach, psychologists have explored temperament and personality structures using analytic methods. One technique that is commonly used to pursue this task is factor analysis. As noted by Rothbart (2011), European researchers such as Webb (1915) and Burt (1937) were among the first to explore the structures of temperament and personality using early forms of factor analysis at the beginning of the 20th century. Webb (1915), for example, conducted factor analysis of items describing individual emotions and social behaviors, rated by judges on a sample of college students, and found a factor concerning the consistency of action related to deliberate volition or will. The early factor-analytic studies might have contributed to the development of Eysenck's personality model.

In Eysenck's initial two-dimensional model (Eysenck, 1947), the dimension of extraversion–introversion was concerned with the extent to which individuals needed external stimulation and directed their attention outward to other people or the environment or inward to inner experiences. This dimension was related to the balance between excitation and inhibition in the reticulocortical circuit, with introverts typically more aroused than extraverts. The other dimension, neuroticism, was characterized by emotional stability and levels of negative affect and was related to the activation threshold of the limbic system. People who had lower activation thresholds and were more vulnerable to neurotic problems were believed to be more aroused in the limbic circuit by emotion-provoking events or situations. The combination of the two dimensions in Eysenck's model formed different types of personality—the neurotic extravert (choleric in Hippocrates-Galen typology), the neurotic introvert (melancholic), the stable extravert (sanguine), and the stable introvert (phlegmatic).

In his later work, Eysenck identified another factor, psychotism, based on data obtained from individuals in mental institutions (Eysenck & Eysenck, 1976). This dimension represented the tendency to become psychotic or display problems with reality, as reflected in qualities such as recklessness, lack of empathy, and inappropriate emotional expression. Eysenck suggested that this dimension might be related to serotonergic function.

Challenges of Behaviorism

Temperament and personality theories were persistently challenged by behaviorism in the 20th century. A key assumption for the existence of personal traits is the consistency of behaviors across situations and over time. This

assumption is incompatible with the main argument of behaviorists, who emphasized learning processes and the dependence of behavior on specific contexts. In the late 1920s, as Freud elaborated his view that the superego was the moral aspect of personality, Hartshorne and May (1928) conducted a series of experiments assessing school-age children's moral behaviors in various settings with opportunities to lie, cheat, or steal; to help others or not; and to resist or yield to distractions. The results showed virtually no consistency or coherence of behaviors across situations. Although later reanalyses of the Hartshorne and May data suggested that behaviors might be more consistent than Hartshorne and May originally reported (Burton, 1963), cross-setting correlations remained weak.

The dispute over the consistency of behaviors was heightened by Mischel's (1968) argument that broad personality traits were not useful. Based on his review concluding that personality traits failed to show consistency or to predict behavioral outcomes, Mischel argued that behaviors were largely determined by specific situational factors and that it would be more interesting to analyze situation-behavior relations. Interestingly, Mischel's later work examined children's self-control, as indicated by performance on delay of gratification tasks, and its long-term effects on adjustment. Although the debate is unlikely to end as long as research findings continue to show weak to moderate consistency of behaviors, many researchers, including Mischel and his colleagues (e.g., Mischel & Shoda, 2008), now take a broader view that considers the interaction of individual traits and social contexts.

Summary

The ancient views and modern theories of temperament and personality focus largely on the identification of a few fundamental or core characteristics, in the form of either types or traits, to describe individual differences in behavioral and emotional tendencies. Several of these characteristics such as extraversion–introversion and the inhibitory process in the nervous system continue to receive intensive attention from contemporary researchers. The methods used in the early studies, such as factor analysis, continue to be used in the exploration of temperament and personality structures today.

Some major issues raised in the ancient and modern theories are still intriguing and should be examined more systematically in the future. For example, both biological functions and experiences are believed to play significant

roles in the formation of temperament and personality. However, it is still largely unknown how biological and environmental factors work together to affect temperament and personality. It will be an important task for researchers to explore this issue in the future. The Chinese Five Element model and Pavlov's system, along with others, suggest dynamic interactions among different traits or biological processes. The ideas are mostly speculative and sketchy and clearly need to be elaborated. In addition, although the ancient and modern theories tap the origins or antecedents of temperament and personality, the goal is mainly to provide explanations of adulthood characteristics without a deliberate inquiry into distinct characteristics and their changes in childhood and adolescence. To address these issues, it is necessary to use integrative frameworks and multimethod, multidisciplinary approaches. Researchers have attempted to do this over the past half century, which has led to significant progress in the development of temperament and personality theories.

MAJOR CONTEMPORARY THEORETICAL PERSPECTIVES

Researchers have proposed theories of temperament and personality from different perspectives in the past half-century. In this section, we briefly review the major theories, particularly those that address temperament and personality development in childhood and adolescence. In addition, we discuss a contextual-developmental perspective that emphasizes the role of social interactional context in the development of individual characteristics. The contextual-developmental perspective serves to guide our discussions of temperament and personality development and its relations with adjustment outcomes in different societies.

Thomas and Chess's Categories of Infant Temperament and the Concept of Goodness of Fit

Thomas, Chess, Birch, Hertzig, and Korn (1963) proposed the first systematic categorization of young children's temperament based on their New York Longitudinal Study (NYLS). The researchers observed that family environment or parenting practices could not explain children's behavioral and psychological disturbances. For example, high-power parenting might lead to anxious and submissive behaviors in some children, but defiant and antagonistic

behaviors in others. Thus, to understand the developmental origins of behavioral problems, it is necessary to consider individual characteristics in response to external and internal stimuli called *individual reaction patterns* (changed to temperament later). Examples of these characteristics include positive versus negative mood, intensity of reaction, and regularity of body activities. Based mainly on the content analysis of parental reports of infants' behaviors, Thomas and Chess identified nine dimensions of temperament: activity level, rhythmicity (regularity), approach versus withdrawal, adaptation, threshold of responsiveness, intensity of reaction, quality of mood, distractibility, and attention span/persistence. As indicated by Goldsmith et al. (1987) and Rothbart (2011), although Thomas and Chess attempted to focus on the style, not the content or motivation, of behavior, some of these dimensions, such as positive versus negative mood and the tendency to approach or withdraw from new situations, are related to what children do rather than how they do it.

Based on their work on the dimensions of temperament as well as their consideration of clinical relevance, Thomas and Chess further developed the well-known broadband categories or temperamental constellations: easy child or temperament, difficult child or temperament, and slow-to-warm-up child or temperament (Thomas et al., 1963; Thomas & Chess, 1977). Easy and difficult categories are characterized by high and low scores on regularity, approach, adaptability, mild intensity of reactions, and positive mood, and the typical features of the slow-to-warm-up child include negative mood, low intensity, and low adaptability. Despite its popularity in the academic and applied fields as well as among members of the public, this framework, particularly the labeling and the notion of "difficult" children or temperaments, has been criticized by many researchers (e.g., A. H. Buss & Plomin, 1984; Rothbart, 2011; Strelau, 1998). Indeed, whether a specific characteristic or a child with a particular temperamental profile is judged as difficult may depend on many factors including situations, age and gender of the child, and cultural norms. Moreover, the difficultness of a child's characteristics inevitably depends on parental attitudes, an issue related to the concept of goodness of fit.

Thomas and Chess's concept of goodness of fit stemmed from the fact that temperamental categories did not correspond directly to behavioral problems. According to Thomas and Chess (1977), the meanings of temperamental characteristics needed to be considered in relation to family or other environmental factors. It is the extent to which child characteristics fitted the expectations, demands,

and opportunities of the environment that determined the adjustment of the child. A particular characteristic might be regarded as desirable in one family but undesirable in another. Moreover, during development, a characteristic might be viewed as desirable at one time but undesirable at another, depending on parental expectations about their child.

The goodness of fit theory has been widely used by researchers to describe relations between temperament and environmental factors in the family, school, community, and society. However, several issues need to be clarified at the theoretical level for research and applied work. First, as pointed out by Sanson, Hemphill, Yagmurlu, and McClowry (2011), it is difficult to operationalize the concept of goodness of fit because it is unclear what "fit" exactly means. Direct match or similarity of characteristics (e.g., irritability) between the child and the socialization agent may not necessarily constitute a good fit; children and parents or teachers with different temperaments may still engage in positive interactions. Second, researchers often believe that goodness of fit is equivalent to interaction between the child's and caregiver's characteristics in their contribution to developmental outcomes (Strelau, 1998). Although child temperament and socialization undoubtedly both play crucial roles in development and their interaction has been shown in a number of studies, whether the outcomes of their combination can be understood within the goodness of fit framework is unclear. It is unclear, for example, what type of child temperament an unsupportive or rejecting parenting behavior can fit to produce positive outcomes. Similarly, it is difficult to understand why warm, sensitive, and inductive parenting would not fit either easy or difficult child temperaments. The exacerbating effect of unsupportive parenting on relations between the child's irritability and problems or the facilitating effect of supportive parenting on relations between the child's desirable characteristics and adjustment seem to be a more complicated issue than goodness of fit. Third, adult attitudes such as approval and disapproval of a child characteristic are a major criterion for the judgment of goodness of fit in the model, which makes the measurement of fit relatively viable (e.g., using parental reports). However, the value of the framework would be markedly limited if goodness of fit is equivalent to, or determined by, the degree of adult approval. Moreover, how adult attitudes toward the child (e.g., parental indulgence of an impulsive and defiant child), even if they represent a good fit, are related to adaptive or maladaptive developmental outcomes may not be straightforward.

“Big Three” and “Big Five” Models

Researchers have developed different models of child temperament and personality since the 1970s, many of which were influenced by Thomas and Chess’s work (e.g., A. H. Buss & Plomin, 1984; Goldsmith & Campos, 1982; Rothbart & Derryberry, 1981). Among them, “Big Three” and “Big Five” models appear most popular, although they may not be about the same three or five dimensions or factors. Whereas some of the models focus on temperament in childhood, others do not explicitly differentiate between temperament and personality characteristics.

Various “Big Three” Models

Consistent with their definition of temperament as a set of inherited personality traits that appear early in life, A. H. Buss and Plomin (1984) proposed that the structure of temperament consisted of three major traits that are present in early childhood and genetic in origin: sociability (preference for being with others), emotionality (tendency for emotions such as fear and anger to be aroused easily and intensely), and activity (rate and extent of movement). According to A. H. Buss and Plomin (1984), traits that are not present in infancy, such as self-regulation or effortful control, were not considered temperamental. Traits that are present in infancy but do not show continuity or have an apparent enduring impact on later development, such as rhythmicity or regularity of biological functions, were not considered temperamental either. Neither were traits that have low heritability, such as smiling.

The criteria used by A. H. Buss and Plomin to define temperamental traits have been challenged by other researchers (e.g., Goldsmith et al., 1987) or proved to be less useful in research than Buss and Plomin thought. There is little disagreement today, for example, that self-regulation, which may show relatively limited individual differences in early infancy, is one of the most important temperamental characteristics. Hinde (Goldsmith et al., 1987) also argued that genetic origin is not a satisfactory criterion for temperament because, among other reasons, (a) it is unnecessary to maintain the dichotomy of innate versus learned behavior, (b) it is impossible to specify the proportions of variance accounted for by genetic factors, given that most behavioral characteristics are partly heritable, and (c) heritability may change with age and across samples and environments. Perhaps molecular genetics research will help resolve disputes about the defining features of temperament. Despite these disputes, however, most researchers agree that temperament should appear in

the early stage of life, show at least moderate temporal stability or predict relevant developmental outcomes, and be linked to biological or genetic processes (Zentner & Bates, 2008).

Rothbart and colleagues (Rothbart & Derryberry, 1981; Rothbart & Bates, 2006) proposed a theory focusing on individual differences in two dimensions of temperament, reactivity and self-regulation, and three broad components, surgency, negative affectivity, and effortful control. Reactivity referred to the arousability of behavioral, neuroendocrine, and autonomic systems in the face of change in external and internal environments. It was indicated by threshold, latency, duration, and intensity of motor, affective, and attentional reactions, and was expressed in fear, smiling and laughter, and activity level. Self-regulation was concerned with the processes that modulate (enhance, maintain, or inhibit) reactivity such as approach, avoidance, and attentional orienting, indicated by frustration with limitations, soothability, and duration of orienting.

Each of the three temperament components or categories in Rothbart’s model consisted of several lower-level domains. Surgency, like the personality construct of extraversion, represented a dispositional tendency toward positive emotions, rapid approach to potential pleasant activities, and high activity level. Negative affectivity included anger/frustration, fear, sadness, discomfort, and difficulty recovering from distress or excitement. Finally, effortful control included attentional focusing, inhibitory control, low-intensity pleasure, and perceptual sensitivity. In Rothbart’s model, reactivity and self-regulation and the broad categories were believed to be constitutionally based and associated with neurobiological processes. Reactivity might depend on arousal in autonomic and endocrine systems; self-regulation was related to the efficiency of neurobiological networks in frontal regions of the brain that functioned to increase optimal alertness, arousal, and interpretation of information.

From a personality perspective, Block (1971) proposed a “Big Three” model to describe resilient, overcontrolled, and undercontrolled individuals. Resilient people had traits of adaptability, concentration, and self-confidence, allowing them to get along with the world. In contrast, overcontrolled and undercontrolled people had poor abilities to maintain their emotions and behaviors according to social standards and displayed anxious-introverted and impulsive-defiant behaviors, which led them to move away from or against the world. Developmental researchers have found robust evidence using various methods supporting this model in children and adolescents (e.g., Robins,

John, Caspi, Moffitt, & Stouthamer-Loeber, 1996). Links between Block's model and other researchers' temperamental models have also been found in studies of temperamental characteristics of children with resilient, overcontrolled, and undercontrolled personality types (Komsu et al., 2006).

The “Big Five” Model

Since the mid-1980s, the Big Five model, developed based on Cattell's pioneering work (Cattell, Eber, & Tatsuoka, 1970) by a number of researchers (e.g., Goldberg, 1992; Costa & McCrae, 1992), has increasingly guided research on adult personality. The five factors in the current model—Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness—were believed to represent major personality dimensions that were independent of each other. Relative to personality researchers, however, developmental researchers have been more cautious and hesitant about accepting the model in studies with children.

Developmental researchers have been reluctant to adopt the Big Five model for multiple reasons. First, the model was derived mainly from factor analysis of adults' self-report data. It is difficult to obtain meaningful self-report data from children about their own traits, especially complicated ones such as openmindedness and conscientiousness, until at least middle to late childhood. It is unclear whether other methods that are commonly used in studies with children, such as observations, parental reports, teacher ratings, and peer evaluations, are sufficiently effective to detect the personality traits and whether the data from these sources point to the same five factors. Second, developmental researchers are obviously interested in developmental patterns and processes. It is theoretically and empirically more efficient to focus on fewer traits to study their developmental patterns and processes. Thus, models with fewer dimensions are often preferred. Moreover, the Big Five model is largely nondevelopmental, with little consideration of age-specific features of children's characteristics, such as activity level, negative emotions in the forms of whining, crying, and tantrums, and reactivity to novel situations in early childhood. Despite the hesitations, researchers have examined the emergence of Big Five characteristics from early childhood (e.g., Lamb et al., 2002) and have attempted to integrate temperament models such as Rothbart's model with the Big Five model (De Pauw & Mervielde, 2010; Shiner & Caspi, 2012). The initial evidence (e.g., John et al., 1994; Kohnstamm, Halverson, Mervielde, & Havill, 1998; Lamb et al., 2002) suggests that, although some aspects of personality may

not be evident in early childhood, the Big Five model may be a useful framework for a comprehensive assessment of personality structure in children and adolescents and may help connect temperament and personality research on children and adults.

Kagan's Approach

Kagan and colleagues (e.g., García Coll, Kagan, & Reznick, 1984; Kagan et al., 2007) have focused on a single temperamental characteristic: behavioral inhibition. These researchers observed that, in response to novelty, some children tended to be vigilant and anxious, whereas others were relaxed and spontaneous and displayed relatively little distress. When presented with novel visual and auditory stimuli, inhibited infants displayed a high level of motor reactivity and negative emotions such as crying. In toddlerhood, compared with their uninhibited counterparts, inhibited children were typically more anxious and fearful in unfamiliar social and nonsocial situations, as indicated by a hesitation to interact with a stranger, retreat from unfamiliar objects, and lack of play and vocalization.

Believing that behavioral inhibition reflected a lowered threshold for amygdala reactivity, Kagan and colleagues (e.g., Kagan et al., 2007) were interested in autonomic, hormonal, and brain patterns in infants and children who exhibited highly inhibited and uninhibited reactions to novelty. Thus, behavioral observations as well as biological measures were used to assess children's temperament. The combined behavioral and biological approach helped to focus attention on constitutional factors within the child. This approach largely shifted the field from accounts of temperament that were mainly descriptive toward an appreciation of its causal underpinnings. Another feature of Kagan's approach was the identification of inhibited/high-reactive (typically 15%–20% of the sample) and uninhibited/low-reactive (15%–40% of the sample) children believed to be qualitatively different, based on aggregated behavioral and biological data. Kagan's work has considerably shaped the field of temperament over the past two decades. His colleagues and students (Fox, Henderson, Marshall, Nichols, & Ghera, 2005; Schmidt et al., 1997) have expanded the investigation of behavioral inhibition to other biological processes such as resting frontal brain activity and neuroendocrine functioning, although not all of these researchers have followed his methodology, especially with respect to the categorization of children. Moreover, adopting Kagan's conceptualization and research paradigm, researchers have explored interactions between temperament and environmental

factors such as social relationships in human development (e.g., Chen et al., 1998; Rubin, Coplan, & Bowker, 2009).

In the literature, reactivity has been viewed as a broad concept referring to behavioral, emotional, psychological, and physiological responses, positive or negative, to stimuli and their changes in the environment (Fox et al., 2005). Behavioral inhibition is a type of reactivity focusing on fearful and anxious responses to novel situations. Researchers have expanded the notion of inhibition to include anxious responses to other situations. For example, inhibition in preschool and school age children is often indexed by their reluctance to spontaneously interact with unfamiliar peers by watching others playing without joining in, whining, and nail biting (Asendorpf, 1991; Rubin et al., 2009; Stevenson-Hinde, Shouldice, & Chicot, 2011). Research has showed substantial links between early inhibition and shy, wary, and reticent behaviors (e.g., Kagan et al., 2007). Thus, researchers (e.g., Chen & French, 2008) have used the term “shyness-inhibition” to conceptualize children’s vigilant and anxious reactivity to challenging social situations (social novelty and perceived social evaluation) that indicates internal conflict

between approach and avoidance motivations (Asendorpf, 1991).

The Contextual-Developmental Perspective

Researchers have long recognized that environmental factors, particularly socialization experiences, affect temperament and personality characteristics and their significance for development (e.g., Pauli-Pott, Mertesacker, & Beckmann, 2004; Rothbart & Derryberry, 1981). The temperament-environment connection and interaction were reflected in Thomas and Chess’s goodness of fit theory. However, that theory focused on the compatibility of temperament and socialization and on caregivers’ ability to change their childrearing practices depending on children’s temperaments, with little attention paid to the contributions that children’s experiences and social-contextual factors made to temperament and personality development.

Chen and colleagues (e.g., Chen, 2012; Chen & French, 2008) have proposed a contextual-developmental perspective emphasizing social interaction as a context for the development of socioemotional characteristics (see Figure 5.1). According to this perspective, children’s

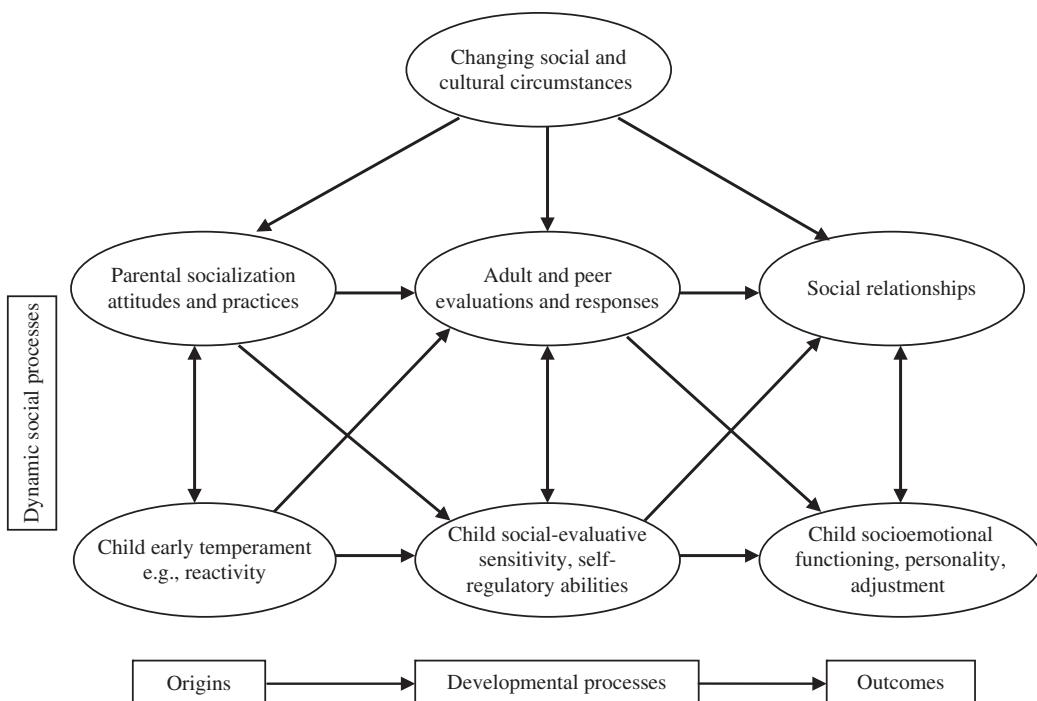

Figure 5.1 A contextual-developmental model concerning the role of social interaction in the development of temperament, personality, and socioemotional functioning.

Source: Adapted from “Peer Interactions, Relationships and Groups from a Cross-Cultural Perspective,” by X. Chen, J. Chung, and C. Hsiao, 2009, in K. H. Rubin, W. Bukowski, and B. Laursen (Eds.), *Handbook of Peer Interactions, Relationships, and Groups* (pp. 432–451), New York, NY: Guilford Press, and “Culture, Temperament, and Development,” by X. Chen, F. Yang, and R. Fu, 2012, in M. Zentner and R. Shiner (Eds.), *The Handbook of Temperament* (pp. 462–478), New York, NY: Guilford Press.

temperament and personality need to be understood from a developmental point of view, and the development of temperament and personality needs to be understood in the dynamic social context. Specifically, individual and group biases in early disposition constitute a major initial source of variations in socioemotional development. Parents and other socialization agents, particularly peers from middle childhood, may evaluate children's characteristics in manners that are consistent with social expectations in the society, community, or group. Moreover, based on their evaluations, adults and peers may respond to these characteristics and express attitudes (e.g., acceptance, rejection) toward children who display the characteristics in interactions. Social evaluations and responses during interactions, guided by changing social-cultural norms and values, in turn serve to regulate the development of the characteristics and determine, to a large extent, the children's adjustment.

The contextual-development perspective highlights the regulatory function of social interaction in temperament and personality development. Social contexts likely direct children's attention to external demands, and continuous feedback from others promotes children's awareness of social expectations and evaluations. Whereas social approval informs children that what they display is regarded as appropriate, negative evaluations from others may place pressure on them to modify their behaviors. The regulatory process of social interaction occurs gradually as children attempt to maintain or alter their behaviors or behavioral styles according to social evaluations. The need for social acceptance, intimate affect within social relationships, and a sense of belonging (Sullivan, 1953) are the main motivational forces that direct children to participate in interaction, to attend to social evaluations, and to adjust their reactions. To obtain social acceptance and affiliation, children need to understand others' attitudes and expectations and change behaviors that provoke negative social responses. For behavioral characteristics that are resistant to change, particularly those strongly influenced by genetic factors, children need to learn how to control them and how to express them in socially acceptable ways. Children with adequate social-cognitive abilities may act as others expect to improve their social relationships and adjustment status, but those who fail to do so may experience frustration, distress, and other psychological problems, which eventually lead to maladaptive outcomes.

The contextual-developmental perspective is particularly concerned with social interaction in the peer group

as a context for development. Support from the peer group, including approval and acceptance, is necessary for children to maintain socially desirable characteristics such as self-control that may be related to readiness for personal sacrifice. Group-level social processes including the establishment and modification of group norms and mutual evaluation and regulation in group activities determine, in part, the display and functional significance of temperamental and personality characteristics, although individual sensitivity to social evaluations may affect the processes by constraining or facilitating group influence. As they develop their social-cognitive abilities, children play an increasingly active role in the social processes through their reactions to social influence (e.g., compliance, resistance) and through their participation in constructing new norms for social evaluations (Chen, 2012). Thus, the social processes are transactional in nature.

Summary

Theorists and researchers have been engaging in intensive and extensive inquiry over the past 50 years about the function, structure, and development of temperament and personality in childhood and adolescence. Theories and models have been proposed from different perspectives and validated using different approaches. Although these theories and models help the field understand the major aspects of temperament and personality, researchers still know relatively little about their developmental processes, particularly the role of socialization experiences in the processes.

From the contextual-developmental perspective, social interactional processes are involved in the formation, maintenance, and change of temperament and personality. An examination of social processes may help to achieve multiple goals such as the delineation of temperament and personality structures. Information about adult and peer interpretations and evaluations of, and responses to, specific characteristics that children display during interaction allows for a better understanding of the distinct functions of the characteristics in social contexts. In addition, children's temperament and personality need to be examined from a developmental perspective. Findings about similar and different developmental origins, patterns, and outcomes of child characteristics, such as reactivity to novelty, frustration, and excitement, may help clarify issues related to the constructs and provide insight into the general and domain-specific nature of temperament and personality characteristics.

ASSESSMENT ISSUES

Over the past several decades, researchers have debated how to assess temperament and personality (e.g., Kagan, 1998; Rothbart & Bates, 2006). Depending on their theoretical considerations (e.g., focus on coherent patterns of behaviors and emotions across contexts versus reactions to specific stimuli or situations) and practical constraints, researchers may choose particular methods to assess individual characteristics. Three types of assessment approaches often used by researchers in the field are subjective reports, direct observations of behavior, and physiological measures. Each of these approaches has particular strengths and limitations.

Subjective Reports

Of the three approaches to assessing temperament and personality, subjective reports have been the most common. Ease of administration is the main factor in the growth of studies using questionnaires. However, the real advantage of subjective measures lies in the richness of the data generated. Parents and caregivers are in a unique position to assess how their children behave in a wide variety of situations and across multiple contexts. Rothbart and colleagues have developed a series of parent- and self-report measures of temperament that tap similar temperamental dimensions from infancy to early adulthood (e.g., Evans & Rothbart, 2007; Putnam, Gartstein, & Rothbart, 2006; Rothbart, Ahadi, Hershey, & Fisher, 2001). For example, the Infant Behavior Questionnaire (IBQ) asks parents to rate how often in the last week their 3- to 12-month-old cooed and vocalized for 5 minutes or longer. The Early Childhood Behavior Questionnaire (ECBQ) asks parents of toddlers between 18 and 36 months of age to indicate their child's activity level, attention-shifting and focusing, and other temperamental characteristics. The Children's Behavior Questionnaire (CBQ), used to measure temperament in children aged 3 to 7 years, produces three factors: negative affectivity, surgency/extraversion, and effortful control (see Rothbart & Bates, 2006). The Colorado Child Temperament Inventory (CCTI; A. H. Buss & Plomin, 1984) measures temperament at ages similar to those in the CBQ and yields temperament dimensions of shyness, sociability, emotionality, soothability, activity level, and attention.

Researchers have also attempted to measure children's personality using self-reports. For example, Corulla (1990) developed a "junior" version of the Eysenck Personality

Questionnaire to assess personality dimensions of extraversion, neuroticism, and psychoticism in children and youth. Others have developed self-report measures to index the Big Five dimensions, which have been demonstrated in adulthood, to see if similar constructs can be reliably identified in childhood (e.g., Kohnstamm et al., 1998).

A major difficulty with the use of subjective reports is that parents and teachers are vulnerable to biases such as contrast effects. For example, behavioral characteristics of a child may be amplified or attenuated in the parent's mind when the child is compared with another child in the family. Teachers are susceptible to similar biases in which they have a tendency to rate bright and well-behaved children more positively than less bright and disruptive children. Other problems affecting informant accuracy include memory biases, inadequate attention to instructions, social desirability considerations, and any interpretations of a behavior. Accordingly, agreement between subjective reports and laboratory observations is typically low. Whether parental responses reflect the child's behavior or characteristics of the parent also remains an important issue to be addressed by researchers. This situation can be improved by aggregating responses from multiple raters (e.g., teachers, caregivers, parents, and the child) to achieve convergence. Subjective questionnaires also tend to avoid asking invasive personal questions and use selected vocabulary that can be understood by a majority of, but not all, respondents. The reasons for these choices are obvious, but they have the unintended effect of limiting what can be measured by the questionnaires. This issue is important because investigators' conclusions are often based on factor analyses of item responses so excluding some items necessarily influences the number and type of factors generated. Finally, many of the temperament and personality questionnaires have not been normed on diverse ethnic and cultural groups, but rather reflect primarily middle-class North American values. This is a concern because particular traits may be more valued in one culture than in another. Investigators are beginning to address this issue by creating and norming measures that can be used across nations and cultures. For example, Rothbart's questionnaires (e.g., IBQ-R and ECBQ) have been translated into multiple European and Asian languages.

Behavioral Observations

One of the most objective measures is information garnered from direct observation of behavior in laboratory or

naturalistic settings. Laboratory assessments allow for relatively high levels of control of the experimental parameters. The data collected are unbiased by parental perceptions or the child's relationship with the parent or teacher. Behavioral measures are then quantified in terms of rate or frequency, duration, and intensity of response. Because laboratory assessments are expensive and time-consuming, their use is often restricted to one or two visits. As a result, such assessments provide only a brief sample of a child's behavior in an unusually controlled environment. As well, laboratory measures are often obtained in contrived settings that may not reflect the child's everyday environment and may constrain some behaviors that would be observed in non-laboratory settings.

Other measures may be derived from observations of the child in naturalistic settings (e.g., playground) or everyday environments (e.g., home) that are familiar to the child. A familiar environment provides high ecological validity. However, one limitation with everyday environments is that the setting and sequence of events are not standardized. This limitation may introduce confounds between the features of child behavior and features of the home or school. Aggregating naturalistic observations across multiple sessions over time may offset this limitation and provide the most reliable information about the child's behavior.

Physiological Measures

The measurement of physiological processes involved in temperament and personality development provides another piece of information that can be used in conjunction with behavioral and subjective assessments. Physiological measures provide additional evidence about the underlying state of a child, which enables researchers to make inferences about motivation and intention. Different noninvasive measures are used with children to assess electrocortical, autonomic, and neuroendocrine functioning.

Electrocortical Measures

One measure that has been used to index functioning of the central nervous system is electroencephalographic (EEG) activity. Researchers can measure patterns of electric activity generated by thousands of synchronously firing brain cells by using electrodes attached to the surface of the scalp. The electrical oscillations produced by these brain cells may be measured as tonic levels of firing in resting conditions or phasic changes in firing during information processing and state-related processing. The magnitude

of spectral power, computed as the amount of electrical energy in specific frequency bandwidths of the signal, reflects underlying brain activation in a given brain region during a particular task/condition. Activity in these EEG frequency bands is presumed to reflect different functions as well as psychological and motivational processes. For example, the pattern of frontal EEG alpha activity at rest has been linked to individual differences in temperamental reactivity (Fox et al., 2005).

Investigators also use electrocortical measures to index event-related brain reactions to sensory stimuli to effectively track real-time brain processing. Event-related potentials (ERPs) are short (typically < 1,000 ms) epochs of EEG activity that are time-locked to discrete stimuli or responses. Although the use of ERPs in temperament studies is relatively limited, researchers have found that the way the brain processes information may reflect temperamental characteristics (McDermott et al., 2009).

There are limitations associated with the use of brain electrical activity measures. One limitation is related to the difficulties involved in recording sensitive electrical signals from children. Another limitation is the fact that information from adult studies is used as a guide to understand children's EEG and ERP components, even though the child's brain may not be fully mature. A third limitation is that the source of the EEG signal measured at the surface of the scalp is unknown. The source may originate at subcortical and cortical levels and their interactions. Thus, investigators should be cautious in drawing inferences from electrocortical measures without support from behavioral observation and/or self-report data. However, if these caveats are addressed, electrocortical measures can provide invaluable and unique information about brain processing and novel insights about brain processes underlying temperament and personality functioning.

Autonomic Measures

Individual differences in autonomic reactivity are of interest to developmental researchers because of links between heart rate control and temperamental inhibition. To assess cardiac autonomic control, researchers collect continuous cardiac electrical signals over a period of minutes while the child is relaxed or attending to a visual and/or auditory stimulus. Measures of heart rate and heart rate variability, such as respiratory sinus arrhythmia (RSA), are then usually calculated offline. At rest, cardiac output is dominated by activity in the parasympathetic division of the autonomic system through the vagus nerve, which is the 10th cranial nerve. When psychological or physical demands

increase, parasympathetic outflow is withdrawn, reducing RSA and allowing heart rate to increase. The ability to successfully disengage and reengage the “vagal brake” at an early age in response to changing psychological and physical stressors is associated with emotional regulation (see Porges, 1995, 2007). High levels of resting RSA and greater RSA reactivity in infants have been found to be associated with social engagement, preschool adjustment, and fewer behavior problems (Porges, Doussard-Roosevelt, Portales, & Greenspan, 1996).

It is important to note that inferences about psychological and motivational states such as behavioral inhibition cannot be made from high RSA alone. As with other psychophysiological indexes, converging evidence from different sources is needed to create a reliable physiological profile that may be related to a given psychological or motivational state.

Neuroendocrine Measures

Cortisol is a stress hormone that is produced by the hypothalamic-pituitary-adrenocortical (HPA) system (see Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume). The brain stimulates the adrenal glands to increase cortisol production and secretes cortisol into the blood, increasing blood sugar levels and blood pressure to prepare the body for fight or flight. Cortisol is assayed from samples of saliva, plasma, or urine and measured as the difference between some basal or baseline level and the level obtained in conjunction with a psychological stressor. Temperamentally inhibited children are known to have higher basal levels of cortisol activity as well as higher resting heart rates than uninhibited children (Kagan, Reznick, & Snidman, 1988). However, Schmidt, Santesso, Schuklin, and Segalowitz (2007) found that baseline salivary cortisol levels varied significantly among inhibited children, indicating that a temperament of inhibition is a necessary, but not sufficient, condition for high cortisol production. Gunnar and her colleagues (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; see also Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume) reported that early caregiving might moderate the relation between inhibition and cortisol reactivity. Inhibited toddlers who were insecurely attached exhibited higher levels of cortisol stress reactivity than inhibited toddlers who were securely attached.

Over time, environmental factors can influence cortisol levels. Under conditions of chronic stress, the HPA system may downregulate its activity. Early chronic stress may lead to low cortisol in which morning cortisol production

is markedly suppressed and cortisol reactivity is dampened as a result of downregulation (e.g., Beaton, Schmidt, Schuklin, & Hall, 2013). One of the main challenges in studying the HPA system lies in the difficulty of activating this system within the context of controlled laboratory settings. Psychological stimuli in the laboratory are often not potent enough to elicit significant cortisol production. As well, cortisol is highly susceptible to time of day, diet, medications, and a range of daily life events. It is difficult to control for all of these factors.

Summary

Three commonly used types of assessment tools for understanding temperament and personality are subjective report, behavioral observation, and physiological measures. Researchers need to weigh the time, cost, and feasibility of these methods in relation to their questions when designing studies. Each of these methods has advantages and disadvantages. For example, although biological measures are often viewed as “objective” and privileged relative to subjective reports, presumably making the science more rigorous, the psychometric qualities of many biological measures have not been assessed. In addition, although biological measures often account for unique variance in predicting temperament, personality, and socioemotional outcomes, effect sizes using these measures are typically smaller than behavioral and self-report measures. The strongest approach is one that combines multiple methods and measures as this enables researchers to investigate the phenomena on multiple levels of analysis. Future research should consider the use of multiassessment tools in longitudinal designs in order to establish convergent evidence over time regarding the developmental phenomena under investigation.

BIOLOGICAL FOUNDATIONS

The search for a physiological basis of temperament in the modern era began with Pavlov (1927). Pavlov theorized that individual variation in nervous system functioning was important for understanding the degree of adaptation to various environmental stimuli. Pavlovian concepts and ideas exerted a considerable influence on subsequent generations of Soviet and Eastern European scientists studying biological aspects of temperament in adults. Investigators such as Teplov, Nebylitsyn, and Strelau made important contributions to the study of individual differences in

temperament by applying Pavlovian ideas of nervous system functioning to humans.

Certain concepts investigated by the Soviet and Eastern European researchers were revisited and elaborated by Eysenck and Gray in the adult personality literature. For example, the balance between neural excitation and inhibition was central to Eysenck's (1947) theory. For Eysenck, extraversion reflected the degree of arousal in the brainstem reticulocortical activating loop, and neuroticism was mainly related to a low threshold for excitability in the limbic lobes of the brain. Along the same lines, Gray's (1994) approach/withdrawal model extended basic notions of threshold sensitivity in the brain as mediating factors in a behavioral activation system (BAS) and a behavioral inhibition system (BIS). Cloninger, Svrakic, and Przybeck (1993) and Zuckerman (2005) extended the "biochemical bases of individuality" proposed by Nebylitsyn many years earlier by relating the activity of diffuse neurotransmitter systems to individual differences in novelty seeking (dopamine) and harm avoidance (serotonin).

In research on individual differences in temperament, specifically temperamental inhibition, Kagan (1998) speculated that infant reactivity to novelty might be linked to sensitivity in forebrain circuits involved in the processing and regulation of emotion. Children who become easily distressed during the presentation of novel stimuli may have a lower threshold for arousal in forebrain areas, particularly the central nucleus of the amygdala. This hypothesis was based largely on findings from studies of species in which the amygdala plays an important role in the regulation and maintenance of conditioned fear (see LeDoux, 1996). The amygdala sensitivity hypothesis in temperamental inhibition was tested and supported in empirical studies (e.g., Schmidt & Fox, 1998; Schwartz, Wright, Shin, Kagan, & Rauch, 2003).

In this section, we review theories and research concerning biological foundations for temperament and personality development. We limit our review to the major biological systems. Although other biological measures have been used to index children's temperament and personality (e.g., skin conductance reactivity, autonomic preejection period, startle EMG, fMRI), given their relatively limited use in the field, we do not review studies using these measures.

Brain Electrical Activity and Temperament and Personality

The link between brain physiology and individual differences in temperament and personality development is

supported by at least two types of evidence: EEG asymmetry and power and ERP studies. In this section, we describe some of the theoretical framework and empirical evidence related to the studies.

Studies of Frontal Brain Asymmetry and Power

One long-standing, and perhaps the most widely used, theoretical framework to understand the biological foundations of temperament and personality development is the model developed by Davidson (2000) and Fox (1991). Davidson and Fox described a frontal activation model of emotion, in which they argued that emotions are organized around approach-withdrawal motivational tendencies, which are differentially lateralized at the level of the cerebral cortex. The left frontal cortical area is involved in approach-related emotions (e.g., happiness, joy, interest). The right frontal cortical area is involved in the withdrawal-related emotions (e.g., fear, sadness, disgust). Using regional measures of brain electrical activity (EEG) to index brain responses during the concurrent presentation of affective stimuli, Davidson and Fox found greater relative right frontal EEG activity during the presentation of visual stimuli used to induce negative emotion, and greater relative left frontal EEG activity during the presentation of visual stimuli used to induce positive emotion. These same basic patterns of frontal EEG responses to affective stimuli have been noted across different sensory modalities and different ages (Schmidt, 1999).

Davidson and Fox also theorized that patterns of resting or "tonic" lateralized alpha activity in the frontal hemispheres were predictive of dispositional mood and affective reactivity (Davidson, 2000; Fox, 1991). Individual differences in the patterns of resting frontal activity are presumed to reflect differences in excitability of forebrain limbic circuitry involved in the regulation of emotion.

The neurocircuitry underlying affective reactivity with respect to approach- and withdrawal-related motivational systems has been intensively investigated. The frontal regions, particularly regions of the prefrontal cortex, are believed to be involved in the regulation of subcortical sites, such as the amygdala, a region known to be intimately involved with withdrawal-related negative affect (LeDoux, 1996). More specifically, left-sided activation of the prefrontal cortex may exert an inhibitory effect on the activation of the amygdala, thereby dampening the duration of negative affect in response to negatively valenced stimuli (Davidson, 2000). Individual differences in patterns of prefrontal activity at rest may mediate the regulation of the time course of emotional responding, such that individuals

showing greater relative left prefrontal activity recover more rapidly from negative affect than those individuals with greater relative right prefrontal activity (Davidson, 2000).

In a series of studies with typically developing infants and children, Fox and colleagues (2005) reported that inhibited infants at 4 months of age exhibited greater relative right frontal EEG activity at 9 months and 4 years of age. As well, children classified at Age 4 as either socially anxious-reticent or solitary-passive during play with same-sex and same-age peers exhibited greater relative right frontal EEG activity at rest than socially outgoing children. Schmidt and colleagues (e.g., Theall-Honey & Schmidt, 2006) reported differences in state-related changes in frontal EEG activity in shy children. For example, shy children displayed greater relative right central EEG activity at rest and during the presentation of a fear-eliciting video clip than non-shy children at Age 4. Shy children also displayed greater increases in right, but not left, frontal EEG activity in anticipation of a self-presentation compared to their non-shy counterparts at Age 7 (Schmidt, Fox, Schukin, & Gold, 1999). Associations between right frontal EEG activity and infants' and children's social withdrawal-related behaviors and temperamental fear were reported in others studies (e.g., K. A. Buss et al., 2003). In addition, the pattern of right frontal EEG asymmetry characterizes some other personality styles in childhood. For example, Santesso, Reker, Schmidt, and Segalowitz (2006) reported a relation between right frontal EEG asymmetry at rest and disinhibited behaviors in 10-year-olds. Accordingly, right frontal asymmetry at rest might reflect emotion regulatory problems underlying inhibited and disinhibited temperaments in childhood.

Although the frontal brain asymmetry model for understanding temperament has garnered considerable traction over the years, it has a number of limitations. The salient limitations include (a) the assumption of localization of emotion and temperament, which is somewhat antiquated as it is now known that they are distributed brain processes, (b) the assumption of emotional experience as static, which is inconsistent with evidence for the blending of emotional experience (Kreibig, Samson, & Gross, 2013), (c) unclear causal relations between frontal asymmetry and behavior, (d) inadequate explanations of the meaning of brain asymmetry function, (e) lack of information about the source of brain activity because the signal's origin gets distorted by the time it reaches the scalp, and (f) failure of many studies to replicate basic right-left differences in relation to temperament and personality.

Some general suggestions may be offered for future research. First, researchers should develop alternative models about the frontal brain asymmetry. For example, the frontal asymmetry may be considered to indicate a static or dynamic *endogenous environmental condition* that varies from the left side (related to tendency of approach in social settings) to the right side (related to avoidance or hesitant behavior) and interacts with some genes to promote particular outcomes (Schmidt & Miskovic, 2013). The argument about gene X environment (e.g., resting brain activity) interaction is consistent with the notion in other biological disciplines that have long emphasized the importance of the internal environment for gene expression and the development of different genotypes. Second, in brain asymmetry models, alpha activity is traditionally considered the dominant frequency band related to temperament and personality characteristics. Nonhuman and human and evolutionary evidence indicates that slow-wave brain activity (e.g., delta) originating in deep cortical/subcortical structures is related to arousal while fast-wave brain activity (e.g., beta) originating in the neocortical mantle is associated with higher cognitive and regulatory functions. Delta-beta EEG spectral power coupling or correlation may reflect cortico-subcortical cross-talk. Thus, it is possible to use continuous EEG power measures to examine the degree of correlated activity in frequency ranges to approximate connectivity and cross-talk among distinct brain levels and distributed neural processes in understanding individual differences in temperament (see Miskovic et al., 2010). It is necessary to move beyond the single frequency band notions that are central to the frontal asymmetry model to more distributed and brain network models. Such an approach allows deeper insights into how the brain communicates among particular brain regions and which circuits underlie temperament and personality variations.

Event-Related Potentials

The interface of the work of Posner and Rothbart (2000, 2009) provides the framework for ERP studies of temperament and personality in children. Rothbart, Ahadi, and Evans (2000) argued that regulation or effortful control and other basic dimensions are biologically based. Posner's work on executive attention and the putative neural substrates and attentional networks that underlie self-regulation provides a basis for ERP studies of broad executive processes (e.g., Posner, Rothbart, Sheese, & Voelker, 2014).

There is an emerging literature on the ERP study of executive attention processes and networks involved in children's emotion regulation. P. J. Marshall, Reeb, and Fox (2009) found that children who were classified as inhibited as infants exhibited increased amplitude of a positive slow wave in the ERP response to deviant tones compared with standard tones at 9 months. Bar-Haim, Marshall, Fox, Schorr, and Gordon-Salant (2003) also found that, at Age 4, shy children had smaller mismatched negative amplitude and longer mismatched negativity (MMN) latencies than non-shy children. In addition, McDermott et al. (2009) reported that adolescents classified as inhibited as children displayed enhanced response monitoring, manifest as large error-related negativities (ERNs), ERP components linked to response monitoring that appear approximately 100 ms after an error. In a study of affect processing in 7-year-olds, Perez-Edgar and Fox (2007) noted that children rated high in soothability and attentional control showed slower behavioral responses to social words with a negative valence. Children low in attentional control displayed enhanced amplitudes in the later, more cognitive ERP components (i.e., a P3 component, which is linked to cognitive and attentional processing) in response to both positive and negative affective words.

Using different ERP components, researchers have examined relations between temperament and personality traits and information processing. Some of these studies have used the N2 response, an ERP component linked to cognitive inhibitory and attentional control. For example, K. A. Buss, Dennis, Brooker, and Sippel (2011) found that increases in the N2 response were associated with less efficient executive attention and lower temperamental effortful control in 6-year-olds. Lamm, Granic, Zelazo, and Lewis (2011) examined the N2 response temporally (200–500 ms) during a go/no-go task in a group of children aged 8 to 12 who were classified as anxious and aggressive. Anxious aggressive children exhibited high ventral prefrontal activation in the early N2 window, and nonanxious aggressive children displayed high ventral prefrontal activation in the late N2 window. Henderson (2010) reported that shyness and the N2 response interacted to predict social adjustment in 9- to 13-year-old children. Shyness was related to poor outcomes among children with relatively large N2 brain responses.

Still other investigators have used the ERN to examine different temperament and personality styles in children and youth. For example, Brooker, Buss, and Dennis (2011) found that enhanced ERN and Pe (error-related positivity response following the ERN) responses were

related to better orienting and greater attentional focusing, respectively, in 4- to 8-year-olds. Greater Pe was also associated with less observed boldness in the children. Santesso, Segalowitz, and Schmidt (2006) found that 10-year-old children who scored high on the CBCL measure of obsessive-compulsive behaviors exhibited greater ERN responses to errors made on a visual flanker task than children scoring low on this CBCL measure. The pattern of ERN response was interpreted to mean that the children with obsessive-compulsive tendencies may have been more concerned with making errors than children scoring low on the CBCL measure. Santesso and Segalowitz (2009) also found that risk propensity (risk taking, sensation seeking, and sensitivity to reward) and empathy were associated with the ERN amplitude, negatively and positively, respectively, in a sample of boys in late adolescence. In another study, Segalowitz et al. (2012) reported an interaction between temperament and context on the feedback-related negativity (FRN) component in response to an impending simulated car crash in a group of typically developing 15-year-olds. The FRN amplitude was reduced as a function of (a) the presence of peers during the driving task stimulus and (b) high trait surgency; these findings suggest that the FRN is sensitive to both context and temperament.

ERP measures suffer from some of the same methodological issues as continuous EEG asymmetry and power measures, including source, volume conduction, as well as the lack of normative data, which is of critical importance as more and more ERP studies are being used to parse and categorize problem temperaments. It should also be noted that, although ERP studies are concerned with dynamic brain processing, the presentation of hundreds of trials in a sterile laboratory environment may not accurately capture how the brain actually processes sensory information in the real world. Researchers need to find ways to assess the activities of the brain that extract meaning from far fewer trials that are usually not repeated with the same temporal course. One approach, for example, would be to examine event-related brain oscillations allowing for the interplay of time and frequency activity and single trial analyses.

Autonomic Activity and Temperament and Personality

The autonomic nervous system and measures that index peripheral physiology have also been used to illustrate the biological foundation of temperament and personality in children. There are at least three measures that have been used at rest and in response to affective stress to assess temperamental reactivity: heart period (inverse of heart rate),

heart period variability (standard deviation of heart period), and cardiac vagal tone, which is a measure of heart rate variability due to respiration (e.g., Porges, 1995). In general, a high and stable heart rate reflects emotion dysregulation, while high vagal tone reflects more optimal emotion regulation abilities than low vagal tone.

Kagan and colleagues (1988) found that inhibited preschoolers exhibited high and stable resting heart rates. Schmidt and colleagues reported a relation between high resting heart rate and shyness in 7-year-olds. State-related changes have also been found in shy children, with increases in heart rate and reductions in heart rate variability during self-presentation (Schmidt et al., 1999).

Fox (1989) found that infants with higher vagal tone were more reactive to positive and negative events at 5 months and more sociable at 14 months than infants with lower vagal tone. By contrast, low resting vagal tone has been related to frustration, fear, and distress in neonates, infants, and toddlers (Gunnar, Porter, Wolf, Rigatuso, & Larson, 1995).

Despite a number of studies using cardiovascular measures to understand stress and anxiety, there is still little consensus about how peripheral measures index central states. Arousal is often the key link to negative emotions, yet hyperarousal characterizes some forms of aggression as well as sociability in children. Future studies should examine a combination of psychophysiological measures that index central and peripheral levels during different affective challenges. Because central-level measures provide more information in distinguishing emotions, this multilevel approach may help delineate the relative contributions of general arousal and emotional valence from arousal to temperament and personality development.

Neuroendocrine Activity and Temperament and Personality

In the study of the neuroendocrine system, cortisol, a stress hormone, has been examined in relation to individual differences in temperament and personality. Overall, high basal and baseline cortisol characterizes fearful, inhibited, and anxious profiles, although some studies have shown that these profiles are also characterized by low levels, a result that has been hypothesized as reflecting a recalibration of the HPA involved in regulating cortisol.

Kagan and his colleagues (1998) reported that inhibited children exhibited higher morning basal cortisol levels than their uninhibited peers. Schmidt and colleagues

(1997) replicated the morning basal cortisol finding in shy preschoolers at Age 4 and reported increased cortisol reactivity in shy children at Age 7 in response to self-presentation (Schmidt et al., 1999). Gunnar, Mangelsdorf, Larson, and Hertsgaard (1989) reported that infants who were identified as temperamentally distressed from 9 to 13 months of age exhibited increases in adrenocortical activity during the presentation of laboratory vignettes. Gunnar's group also noted that inhibited children who were in insecure attachment relationships exhibited greater increases in salivary cortisol in fear-eliciting conditions than uninhibited and securely attached children (Nachmias et al., 1996).

There appears to be a developmental pattern between temperament and personality and cortisol responses. Schmidt et al. (2007) found that, although shy preschoolers had high morning salivary cortisol levels, shyness predicted high and low salivary cortisol levels in middle and late childhood. Other findings indicated that younger and older children diagnosed with clinical anxiety exhibited different patterns of cortisol responses to self-presentation. Across the sample, the direction of cortisol reactivity to a speech task differed by age groups; in younger children (<9.75 years) this task elicited a slight decline between baseline and the speech stressor, whereas in older children (>9.75 years) cortisol increased (Mathewson et al., 2012).

Despite the burgeoning use of cortisol as an index and the HPA axis as a theoretical framework for understanding temperament and personality over the last several decades, the field is still left with many unanswered questions. A major concern surrounds the role of cortisol in the maintenance of temperament. For example, although high cortisol levels are usually characteristic of anxious personality, high cortisol levels occur in bold and exuberant children as well (see Schmidt et al., 1997). This apparent paradox may inform how researchers should view cortisol and behavior. For example, rather than conceptualizing cortisol as a molecule of fear, it may make more sense to view it as an indicator of energy metabolism (that is, energy to be fearful and hypervigilant to the environment as well as to be bold and exuberant). In addition, cortisol levels are highly variable and sensitive to time of day, stress, diet, and other factors. Repeated measurement of cortisol throughout the day is necessary to capture its diurnal pattern within an individual. At the same time, it is important to ensure the reliability of the data by measuring cortisol levels across days and contexts before inferring their psychological significance.

Genetic Basis of Temperament and Personality

The idea that there may be a genetic basis to individual differences in temperament can be traced to evidence produced by three disparate sources: inbred nonhuman animal strains, twin studies, and molecular genetics. The first source of evidence involves studies of domesticated and laboratory animals. Researchers have known for years that nonhuman animals can be bred to produce highly fearful, defensive, aggressive, and subdued temperaments. As well, a long and substantial nonhuman animal literature demonstrates a susceptibility to stress-reactivity among some inbred animal strains. Strain differences in physiological and behavioral reactivity have been found in rodents (Blizard, 1989).

A second body of evidence for a genetic basis of temperament comes from findings of long-standing behavioral genetics studies of human twins (Gagne, Vendlinski, & Goldsmith, 2009). Overall, researchers have shown that identical (i.e., monozygotic) twins appear more similar in temperament and personality than fraternal (i.e., dizygotic) twins and adopted children. For example, Matheny (1989) reported genetic influences on inhibited and timid behavior in 12- to 30-month-old children, with changes and stability in behavior being more concordant in monozygotic twins than in dizygotic twins. Robinson, Kagan, Reznick, and Corley (1992) assessed a longitudinal sample of same-sex twin pairs at 14, 20, and 24 months on observed laboratory behaviors of fear and wariness, and found high internal consistency at all ages, suggesting that these behaviors are heritable. In a later study of 24-month-old twin pairs, DiLalla, Kagan, and Reznick (1994) reported that monozygotic twins showed stronger intraclass correlations of inhibited and fearful behavior to unfamiliar stimuli than dizygotic twins and non-twin siblings.

A third source of evidence for a genetic basis of temperament and personality comes from the rapidly emerging field of molecular genetics in the study of human personality. Researchers who are interested in the molecular genetic basis of temperament and personality have studied, among others, the functional polymorphism in the dopamine D4 receptor gene (DRD4) and the serotonin transporter gene (5-HTT) (e.g., Benjamin, Patterson, Greenberg, Murphy, & Hamer, 1996; Lesch et al., 1996). Dopamine has been implicated as a major neuromodulator of novelty seeking because of the role it plays in inducing euphoria in humans and approach behavior in animals. The longer alleles code for a receptor that is apparently less efficient in binding dopamine than the shorter alleles. Serotonin

has been implicated as a major neurotransmitter of anxiety and withdrawal because of its effects on regulating mood and emotional states. The short allele of 5-HTT reduces efficiency of serotonin promotion and results in reduced serotonin expression.

Two initial studies (LaHoste et al., 1996; Swanson et al., 1998) reported an association between the DRD4 receptor gene and attention deficit hyperactivity disorder (ADHD). The 7-repeat form of the DRD4 appeared more frequently in children with ADHD than in the control group. Another study reported a gene-gene interaction in predicting neonatal temperament (Ebstein et al., 1998). Neonates with a short 5-HTT allele and who lacked a long form of the DRD4 had lower orientation scores on the Brazelton neonatal assessment scale than other neonates. Other studies with children have linked the DRD4 long allele gene to reactivity and regulation and problem behaviors maintained by reactivity and regulation across a range of measures and ages, including attention problems and aggression in children (Schmidt, Fox, Perez-Edgar, Hu, & Hamer, 2001; Schmidt, Fox, Rubin, Hu, & Hamer, 2002).

Lesch et al. (1996) initially found that adults with one or two copies of a short allele in the serotonin transporter gene self-reported higher levels of neuroticism, anxiety, and depression than adults with two copies of a long allele. Auerbach, Faroy, Ebstein, Kahana, and Levine (2001) reported that infants who were homozygotic for the short allele (i.e., s/s) of the 5-HTT gene exhibited less fearful distress to stranger approach and less pleasure in a structured play situation than infants who were homozygotic for the long allele (i.e., l/l) or heterozygotic (i.e., l/s) for this gene. Battaglia et al. (2005) and Hayden et al. (2007) found that children who were homozygotic for the short allele were significantly shyer than children with at least one copy of the long allele of the 5-HTT gene. Others reported that the long form of the 5-HTT gene was associated with shyness in 7-year-olds as measured using questionnaires (Arbelle et al., 2003). However, Schmidt et al. (2002) failed to find an association between the 5-HTT gene (short or long form) and observed shyness in preschoolers.

Other studies have extended prior work on the main effects of genes on behavior to examine the interaction of genes with particular environments. For example, Kochanska, Philibert, and Barry (2009) found that children who carried at least one short 5-HTT allele (i.e., s/s or s/l) and who were in insecurely attached mother-child relationships developed poor regulatory capacities. However, children who were in securely attached relationships developed as good regulatory capacities as children who

were homozygotic for the long allele. Sheese, Voelker, Rothbart, and Posner (2007) found that children who were carriers of the DRD4 7-repeat (long allele) and experienced lower quality parenting had higher levels of sensation seeking. The authors also reported that there were no associations between the DRD4 gene and children's self-regulation as assessed using an effortful control measure.

Schmidt, Fox, Perez-Edgar, and Hamer (2009) reported evidence for a gene-“endoenvironment” interaction in which the environment was conceptualized as dynamic activity within the individual. This interaction predicted children's temperament related to self-regulation and effortful control. Importantly, the internal environment was conceptually and empirically orthogonal to the candidate gene of interest. Children who were carriers of the DRD4 long allele exhibited the highest and lowest levels of soothability at 48 months, depending on whether they also had greater relative left or right frontal EEG activation asymmetry, respectively, at 9 months.

It is important to note that many studies have failed to replicate findings regarding the molecular genetics of complex traits. There is growing evidence that the initial findings of particular candidate genes underlying complex traits are not as informative as they first appeared. As well, the mechanistic approaches of gene \times environment interactions have been questioned. The field now views gene \times environment interactions as probabilistic rather than deterministic. What we have learned is that gene expression is quite dynamic rather than static (Charney, 2012). Today, the science of epigenetics is beginning to inform our understanding of complex traits. Epigenetics involves changes in gene expression, but not the underlying chemical structure of the DNA sequence. These changes are affected by a range of internal and external environmental influences. Epigenetics provides new opportunities for understanding human development (van IJzendoorn, Bakermans-Kranenburg, & Ebstein, 2011).

Summary

Theoretical and methodological advances in the area of neuroscience have spawned much interest in how researchers come to understand complex traits in children. Although much remains to be discovered, there have been significant advances in the understanding of brain-behavior relations, the biological origins of complex traits, and the neural processes that may maintain them. For example, it is now known that brain functions and structures are

not fixed after the early school-age years and that early experience plays a key role in shaping brain-behavior relations. Developmental changes can occur across the life span.

Nevertheless, it is important that methodological advances do not trump theoretical and research questions. Some methods that fuel excitement in the field come and go, but the fundamental questions about what makes people unique transcend time. Among the questions concerning the biological processes of temperament and personality, for example, it is important to examine how biological systems are malleable to environmental input, what environmental conditions influence change, and whether there are sensitive periods for change. Caution is recommended when inferring the psychological significance of biological states and measures. Further theoretically driven developmental research is required to achieve a better understanding of biological data.

THE DEVELOPMENT OF TEMPERAMENT OR PERSONALITY AND ADJUSTMENT

Given the general belief about the significance of dispositional characteristics for development, it makes sense that researchers are interested in links between early temperament and later personality and their contributions to socioemotional and behavioral adjustment. In this section, we review major findings in this area. We also review the literature on trait \times trait interaction in development. Our review and discussion focus mainly on the two dimensions of child reactivity to stressful and provocative situations and self-regulation or self-control.

Temperament Development in Early Childhood

Newborns show clear individual differences in levels of arousal and emotionality, such as alertness, calmness, activity, irritability, and distress proneness (e.g., Korner, 1972). There is also evidence indicating variations among newborns in soothability, an initial indication of regulatory abilities (e.g., Crockenberg & Smith, 1982). Within the first half-year of life, individual patterns of reactivity, such as the expressivity of positive and negative emotions in different situations, become increasingly distinct and stabilized. A temperamental characteristic in infants that has received heightened attention from researchers is reactivity to novel stimuli. Kagan and colleagues (e.g., García Coll et al., 1984) have found that infants at 4 months displayed

different reactions to unfamiliar visual and auditory stimuli. Inhibited infants are anxious and distressed, displaying high levels of physiological arousal, whereas uninhibited infants are spontaneous and exhibit little distress. Findings from different projects, including those based on extremely inhibited and uninhibited groups, indicate that behavioral inhibition is moderately stable in childhood (Fox et al., 2005). However, it is unclear how inhibition changes in form or level among normative or extremely inhibited children, although reactivity to novel situations in early childhood is associated with anxiety in social-evaluative situations from middle childhood (e.g., Rubin et al., 2009).

Compared to reactivity, more evident normative progressive “phases” are observed in self-regulation in early and middle childhood, likely in response to the rapid development of neurocognitive abilities. Initial regulation, largely automatic, in infants’ sleeping, eating, and orienting gradually becomes more sophisticated as reflected in parent–child coordinated daily activities, such as dressing and feeding and in infants’ initiation and control in social interactions (Rothbart, 2011). At 4 to 6 months, some infants show signs of controlling their attention and using the control to help them regulate their emotions, such as looking away from distressing or frightening objects (Crockenberg, Leerkes, & Jó, 2008; White, Helfinstein, Reeb-Sutherland, Degnan, & Fox, 2009). Toward the end of the first year, children start to display some forms of goal-directed, internally driven self-regulation largely due to the maturation of the frontal lobe and associated executive function.

Research has shown that at least from the second year, there are reliable and meaningful individual differences in effortful control, the ability to inhibit dominant responses to perform subdominant ones (Rothbart & Bates, 2006). Kochanska, Murray, and Harlan (2000) have found that children’s performance on effortful control tasks, such as snack delay, latency to look at gift upon request, and slowing down motor activity, considerably improves from 22 months to 33 months. Similar results have been reported in other studies (e.g., Chuang et al., 2006). Girls often outperform boys on control tasks during early childhood (Chen et al., 2003; Kochanska et al., 2000). Self-regulation or control is maintained mainly by external adults’ directions and demands in early childhood, but, with age, becomes increasingly mediated by internal factors such as spontaneous and voluntary pursuit of goals. Voluntary internalized control is indicated by children’s willingness to initiate, maintain, or modify particular actions and to

delay or inhibit certain behaviors without adult intervention (Kochanska et al., 2000).

The development of self-regulation is likely to affect other aspects of temperament and socioemotional functioning in children and adolescents, such as emotional expressivity in social settings. Researchers have found that children’s expressivity of positive and negative emotions and intensity of emotions steadily decline from middle childhood to early adolescence (Sallquist et al., 2009; Weinstein, Mermelstein, Hankin, Hedeker, & Flay, 2007). As children develop more mature regulatory skills, they may become more competent in managing their emotional reactions, particularly of a high intensity, to function more appropriately in social interactions (Sallquist et al., 2009). It remains to be examined to what extent self-regulation serves as a driving force of temperament and personality development.

Links Between Temperament and Later Personality

Because temperament is considered the dispositional core of personality, it is reasonable to expect conceptual and empirical links between temperament in the early years and later personality. Several scholars (De Pauw & Mervielde, 2010; Shiner & Caspi, 2012) have made great efforts to build connections, mostly at the conceptual level, between major temperament and personality traits. For example, based on their analysis of similarities in structure and content of traits in the literature, Shiner and Caspi (2012) proposed that temperament and personality in children and adults might be organized within the Big Five framework, with traits of Positive Emotionality/Extraversion, Negative Emotionality/Neuroticism, Effortful Control/Conscientiousness, Agreeableness, and Openness to Experience/Intellect. The work on the integration of the two fields, however, has drawn some concerns and criticisms including, among others, (a) unclear forms of expression of some traits (e.g., agreeableness and openness to experience in young children) at different developmental periods, (b) weak and inconsistent empirical evidence regarding some of the hypothesized links, and (c) the lack of specification of the developmental processes linking traits in childhood and adulthood (e.g., Wachs & Bates, 2010).

Despite these concerns, researchers have found that major temperamental characteristics in early childhood, such as behavioral inhibition, self-regulation, and positive emotionality, predict personality traits in the later years (Rothbart, Ahadi, & Evans, 2000). In a longitudinal study

with a large sample in Dunedin, New Zealand, Caspi and colleagues (2003) assessed temperament at Age 3 years based on ratings of observed behaviors as well as personality profiles at the ages of 18 and 26 years based on self-reports and reports of other people who knew the participants. The researchers found that undercontrolled children who were rated irritable and impulsive in early childhood became easily upset, antagonistic, and anti-social, with high scores on negative emotionality and neuroticism and lower scores on agreeableness and conscientiousness in adulthood. In contrast, inhibited children who were shy and fearful at 3 years developed an over-controlled and nonassertive personality style, with high scores on harm avoidance and constraint and low scores on extraversion, social potency, and positive emotionality in adulthood. Relative to undercontrolled and inhibited children, the personality profiles of other groups were less clear in adulthood. Some patterns emerged indicating that confident and outgoing children were more extraverted, socially more active, and more open to experience than others in the later years.

Results of other, mostly cross-sectional and short-term longitudinal studies also indicated associations between sociability/approach tendency and extraversion and agreeableness, between negative emotionality/fear and neuroticism, and between self-control/persistence and conscientiousness (Komsu et al., 2006; also see Deal, Halverson, Havill, & Martin, 2005). The magnitudes of the associations varied from weak to moderate, depending on a number of factors such as the length of interval (weaker with a longer interval), the developmental period (e.g., weaker from infancy to toddlerhood than from adolescence to adulthood), the domain of traits (e.g., stronger between irritability/anger and defiance than between approach and agreeableness), and research methods (e.g., stronger when assessments completely relied on self-reports than when observations were used) (Shiner & Caspi, 2012).

Temperament, Personality, and Adjustment Outcomes

Relations between temperament and later personality represent one aspect of trait development. A broader issue is how temperament and personality predict later adjustment in various domains. Researchers have found that temperament and personality characteristics such as positive emotionality, irritability, and extraversion–introversion have implications for individual adaptive and maladaptive social, cognitive, and psychological development. Positive

emotionality, for example, is positively associated with social competence as well as social-behavioral problems (e.g., Eisenberg et al., 2009). Anger or irritability is associated with externalizing problems such as aggression and defiance (Eisenberg et al., 2009; Lengua, 2006; Oldehinkel, Hartman, Ferdinand, Verhulst, & Ormel, 2007). We focus on the two fundamental dimensions, reactivity and self-regulation, in the following section because longitudinal research has demonstrated that they have relatively extensive and enduring effects on individual adjustment in socioemotional areas.

Reactivity/Inhibition and Adjustment

Cumulative evidence indicates that early reactivity or inhibition is associated with, and predictive of, socioemotional difficulties (e.g., Asendorpf, 1991; Fox et al., 2005). Moreover, when reactive or inhibited children realize their difficulties in social situations, they may develop anxiety, depression, negative self-perceptions, and other internalizing problems (Coplan, Prakash, O’Neil, & Armer, 2004; Kagan et al., 2007), although the findings are sometimes inconsistent with each other (Asendorpf & van Aken, 1994). Thus, it has been argued that high reactivity or inhibition is a major risk factor for maladaptive development (Rubin et al., 2009).

Kagan and colleagues (e.g., García Coll et al., 1984; Kagan et al., 2007) conducted one of the most systematic explorations of the later correlates of early reactivity. Based on physiological and behavioral assessments, groups of children were identified at 4 months and 24 months of age as high-reactive and low-reactive. Follow-up studies revealed that, relative to those who were identified as low-reactive, infants who had been high-reactive tended to be less sociable, quieter, and more socially avoidant in interactions with unfamiliar peers and adults from middle childhood to adolescence. Adolescents who were high-reactive in toddlerhood displayed higher levels of social anxiety than those who were low-reactive (Schwartz, Snidman, & Kagan, 1999). In addition, compared with adolescents who were low-reactive in infancy, adolescents who were former high-reactives described themselves as less happy and more morose and nervous, worrying about interpersonal relationships (Kagan et al., 2007).

Gest (1997) examined links between inhibition in middle childhood (Ages 8–12) and adjustment in early adulthood (Ages 17–24). Longitudinal analyses, with the stability effects controlled, revealed that childhood inhibition, rated by interviewers in interview and test sessions, negatively predicted the quality of social life

including peer relationships for both men and women, and positively predicted emotional distress for men. Moreover, inhibited children were less likely than uninhibited children to move out of the family-of-origin home in early adulthood. Similarly, Caspi, Elder, and Bem (1988) found that shyness-inhibition in boys, assessed at 8 to 10 years through clinical interviews, was associated with delays in career establishment, poor occupational performance, and marital instability at 30 and 40 years, although shyness-inhibition in girls was not associated with adulthood problems. Caspi et al. (2003) also found in the Dunedin longitudinal study that inhibited children displayed more internalizing problems, such as low social interest and engagement and lack of pleasure in life, at Ages 18 and 26. In a 19-year longitudinal study in a German sample, Asendorpf et al. (2008) found that both inhibited boys and inhibited girls showed a delayed transition into major social and life roles, such as romantic partnerships and full-time jobs. Moreover, extremely inhibited children displayed internalizing problems such as neuroticism and low self-esteem.

Taken together, several large-scale longitudinal projects have provided convergent evidence that highly reactive and shy-inhibited children are likely to develop internalizing socioemotional problems, such as social anxiety and life dissatisfaction, in adolescence and adulthood. Moreover, these children, particularly boys, tend to experience difficulties in later social relationships and life adjustment. The more salient problems of highly reactive and shy-inhibited boys may be related to gender-stereotypical ideologies. Relative to girls, boys are often expected to be more autonomous and assertive in social situations in most societies (Rubin et al., 2009). As a result, reactive and inhibited behaviors are viewed as more negative and less acceptable in boys, which may create obstacles for highly reactive and inhibited boys to achieve success in social interactions and life adjustment.

Self-Regulation/Control and Adjustment

Self-regulation involves processes in which individuals control behaviors, emotions, and cognitive activities (e.g., attention focusing or shifting) to achieve certain goals. Temperamental regulation, often represented by effortful control in the literature, is concerned with the ability to manage one's responses in order to complete tasks. It is conceivable that the ability to willfully and effectively control one's own behaviors or emotions helps children concentrate on their work, cope with negative experiences such as frustration and distress, and behave appropriately

in social situations (Eisenberg et al., 2009; Kochanska et al., 2000).

Longitudinal research has shown that self-regulation or control in early childhood may have prolonged effects on social-behavioral, academic, and life adjustment (Eisenberg et al., 2009; Olson, Sameroff, Kerr, Lopez, & Wellman, 2005). Crockenberg et al. (2008) found that infants' ineffective regulation, such as attention to frustrating events, positively predicted later aggressive behavior, whereas effective regulation, such as looking away from frustrating events, negatively predicted later aggressive behavior, particularly in girls. Kochanska and Knaack (2003) assessed effortful control in early childhood using behavioral observations on tasks, such as delaying, slowing down motor activities, suppressing or initiating activity to signals ("Go-No Go" tasks), and lowering voice, and conscience and externalizing problems in middle childhood using interview with the child, maternal ratings, and observations. The researchers found that children with higher effortful control at 22 to 45 months developed higher levels of conscience at 56 months and fewer externalizing problems at 73 months.

Hill, Degnan, Calkins, and Keane (2006) identified groups of children with different developmental trajectories of externalizing problems from 2 to 5 years and found that children's emotion regulation on frustration tasks and mother-rated inattention at 2 years differentiated the groups. Specifically, poor attentional control predicted high and stable externalizing problems in both boys and girls. Poor emotion regulation predicted such problems in girls. Eisenberg et al. (2009) found that parent and teacher ratings of low attentional (maintaining or shifting attentional focus according to the task) and low inhibitory (suppressing inappropriate responses) control were associated with externalizing problems in middle childhood. Moreover, low effortful control was associated with an increase in externalizing problems over time. In their longitudinal projects, Caspi and colleagues studied how children with control problems adjusted in adulthood. In the Berkeley study (Caspi, Elder, & Bem, 1987), explosive, irritable, and undercontrolled temperament in childhood was associated with the progressive deterioration of socioeconomic status, work instability, divorce, and ill-tempered parenting at 30 and 40 years. Similarly, in the Dunedin study (Caspi et al., 2003), undercontrolled children displayed social and behavioral problems, such as perceived alienation from the world and aggression, in adulthood.

Researchers have speculated about the processes by which early self-regulation or control contributes to

development (e.g., Wachs & Bates, 2010). However, there is relatively little research on the processes. Zalewski, Lengua, Wilson, Trancik, and Bazinet (2011) assessed children's physiological, behavioral, and self-reported reactions to frustration and social evaluation, and found that, whereas the overall lack of regulation of negative emotions in the frustration situation was a main mediator of the relation between low effortful control and conduct problems, the poor ability to regulate subjective experience of frustration appeared to mediate the relation between low effortful control and depression. According to Zalewski et al. (2011), the contributions of effortful control to adjustment and problems may operate through children's emotional response and regulation in challenging or provocative situations. Moffitt et al. (2011) found in the Dunedin sample that low self-control from 3 to 11 years, based on adult ratings of multiple behaviors such as inattention, hyperactivity, and lack of persistence, positively predicted health problems, depression, substance use, financial struggles, and criminal convictions at 32 years. The longitudinal associations were mediated, in part, by "mistakes" the participants made in adolescence, such as smoking, becoming an unplanned teenaged parent, and dropping out of high school. These mistakes during the critical period of development trapped them in adverse lifestyles.

Self-control is consistently associated with academic achievement (Blair & Diamond, 2008; Ponitz, McClelland, Matthews, & Morrison, 2009). It is understandable that behavioral and emotional control is necessary for children to maintain their motivation for learning, focus on classroom activities, and make sustained efforts to complete assignments. Adequate control helps children organize their actions toward long-term goals and facilitate the execution of problem-solving strategies. In longitudinal studies with middle school students, Duckworth, Quinn, and Tsukayama (2012) found that, whereas IQ predicted changes in standardized achievement test scores over time, self-control, rated by parents, teachers, and students, mainly predicted later report-card grades. More importantly, the effects of self-control on grades were mediated by teacher-rated homework completion and classroom conduct, such as mastery of skills and knowledge taught in class, class participation, school attitudes and effort, and prompt and reliable class attendance.

Valiente et al. (2011) tested whether children's social functioning (social competence and externalizing problems) mediated relations between effortful control and academic achievement. The results indicated that children's

effortful control was positively associated with later academic achievement. The associations were fully mediated by social functioning. Chen, Zhang, Chen, and Li (2012) found in a Chinese sample that children's behavior on delay tasks at 2 years positively predicted school adjustment and negatively predicted learning problems in adolescence and that social competence mediated the predictive relations. Apparently, self-control or regulation helps children attend to others' needs and interests, which is conducive to the engagement of positive social interactions. The favorable experiences that well-controlled children obtain may enhance their positive attitudes about the school milieu and motivate them to display their competencies and to maintain their behaviors according to social standards.

The Moderating Effects of Self-Regulation on Relations Between Reactivity and Socioemotional Functioning: An Example of Trait × Trait Interaction

If self-regulation represents the process that modulates reactivity to events and their changes in the environment, it is reasonable to expect that self-regulation moderates the effects of reactivity. The moderating role of regulation has been explored from both temperamental and personality perspectives (e.g., Muris, 2006). In general, the literature suggests that self-regulation, particularly effortful control, moderates the effects of reactivity to (a) novelty or stressful situations (inhibition, fearfulness) in predicting internalizing problems such as anxiety, depression, and other negative emotions, and (b) frustration or limitation (irritability, anger) in predicting externalizing problems such as aggression, noncompliance, and disruptive behaviors (e.g., Olson et al., 2005). In addition, regulation and reactivity may interact in other ways, such as high negative emotionality and low control exacerbating the effects of each other in predicting poor socioemotional and social-cognitive skills (Belsky, Friedman, & Hsieh, 2001; Eisenberg et al., 1995; Ursache, Blair, Stifter, & Voegtle, 2013).

Several studies have been conducted to examine the moderating effects of attentional and behavioral control on the relations between inhibition and internalizing problems. White, McDermott, Degnan, Henderson, and Fox (2011) examined children's abilities to shift attention and suppress prepotent responses using cognitive regulatory tasks (e.g., Dimensional Change Card Sort, Day-Night Stroop) and maternal reports, and found that observed inhibition positively predicted later parental ratings of anxiety for children with low scores, but not for children with high scores, on attention shifting. Similarly, Sportel,

Nauta, de Hullu, de Jong, and Hartman (2011) found, in a sample of adolescents in the Netherlands, that attentional control moderated the associations between inhibition and a series of internalizing symptoms, such as generalized anxiety disorder, social phobia, and major depressive disorder. High behavioral inhibition was associated with internalizing problems only for adolescents who were low on attentional control. Although inhibited children tend to be highly vigilant in threatening situations, the ability to flexibly shift their attention away from these situations reduces their vulnerability to negative emotions.

Regulation or effortful control seems to moderate the effects of personality traits that are similar to behavioral inhibition on internalizing problems. Muris (2006) analyzed interactions between neuroticism and effortful control in predicting psychopathological symptoms such as depression and anxiety in a sample of adolescents in the Netherlands. The results showed that neuroticism was positively associated with internalizing problems, but the associations were weaker for adolescents with higher effortful control. Similarly, Oldehinkel et al. (2007) found in a sample of Dutch young adolescents that effortful control attenuated the effects of fearfulness on internalizing problems.

Consistent with its moderating effects on internalizing problems, regulation may affect relations between reactivity to frustration and externalizing symptoms. Stifter, Spinrad, and Braungart-Rieker (1999) observed 5- to 18-month-old infants' reactivity to frustration (arm restraint and toy removal) and regulation (orientation to mother, toy, or other objects, avoidance, communicative behaviors, self-comforting) and examined how they jointly predicted compliant and noncompliant behaviors on toy clean-up and other tasks at 30 months. The results showed that reactivity at 5 months predicted high levels of noncompliance and defiance more strongly for infants with lower regulation, although the patterns of interaction were more complex at 10 and 18 months. Degnan, Calkins, Keane, and Hill-Soderlund (2008) found similar frustration reactivity by physiological regulation interactions. These researchers observed children's reactions to frustration tasks and measured their vagal tone activities during the baseline and frustration episodes. The results showed that reactivity to frustration as indexed by vagal tone activities at 2 years was positively associated with maternal reports of disruptive behavior at 4 and 5 years for children with low regulation whereas the pattern was opposite for children with high regulation. Thus, high physiological regulation

was a protective factor that reduced the risk for children who displayed high levels of emotional reactivity, whereas low capacity to regulate emotional reactions to frustration placed these children at higher risk for developing disruptive behavior. Consistent with the findings in early childhood, Oldehinkel et al. (2007) reported that effortful control served to weaken the effects of frustration on externalizing problems in adolescence.

Reactivity and regulation may also interact in predicting children's social competence. Eisenberg and colleagues (1995) found that school-age children who were irritable and anxious as well as weak in regulation were more likely than others to become socially incompetent and experience difficulties in peer interactions. Belsky et al. (2001) found, in a longitudinal study of children of 15 months to 3 years of age, that high levels of negative emotionality displayed in stressful laboratory episodes were associated with low levels of mother-rated social competence, but only for children who had low scores on attentional persistence in a free play session. Finally, regulation may interact with other temperamental characteristics in development. Dollar and Stifter (2012), for example, found in a longitudinal sample (4–5 years to 6–7 years) that self-regulation moderated relations between surgency and later aggression and social wariness. Highly surgent children tended to develop more problems than others when they were low on regulation but fewer problems than others when they were high on regulation.

Summary

Newborns and infants show initial biases in their emotional, attentional, and behavioral responses to the environment, which constitute the dispositional foundations for socioemotional functioning. During the first 2 to 3 years, due to biological maturation, the growth of social-cognitive capacities, and socialization experiences, children display increasingly distinct reactivity to different situations, socially oriented and internally driven regulation, and more generally, individualized and coherent temperament profiles. Early temperamental characteristics predict, often to a modest or moderate extent, relevant personality traits and adjustment outcomes in adolescence and adulthood. Among these characteristics, reactivity or inhibition and effortful control show relatively robust and long-term effects on socioemotional functioning.

The interaction between reactivity and regulation in their contributions to social and psychological adjustment has

received increasing attention in developmental research. Researchers interpret the interaction mainly in terms of how high regulation or control serves to mitigate the development of problems or low regulation or control serves to exacerbate maladaptive development in highly reactive children. Nevertheless, some of the findings do not support this model. For example, in White et al.'s study (2011), inhibition positively predicted later anxiety for children with low scores, not for children with high scores, on attention shifting. However, a closer inspection revealed that, whereas among high-inhibited children, those low on attention shifting were more anxious than those high on attention shifting, among low-inhibited children, those low on attention shifting were less anxious than those high on attention shifting. In Stifter et al.'s study (1999), among highly reactive children at 5 months, those low on regulation were more defiant later than those high on regulation; however, the pattern was virtually opposite for highly reactive children at 18 months—those high on regulation tended to be more noncompliant than those low on regulation. Therefore, the processes of interaction between reactivity and regulation remain to be investigated, perhaps with different models, in future research. Research on trait \times trait interactions has focused on the moderating effects of regulation or control. It will be interesting to explore interactions among other traits such as positive emotionality and irritability in socioemotional development. Moreover, the contributions of temperament and personality characteristics to development take place in social environments. It is essential to consider social factors such as the socialization practices of parents and peers when studying the development of temperament and personality.

PARENTS AND PEERS AND THE DEVELOPMENT OF TEMPERAMENT AND PERSONALITY: THE ROLE OF SOCIALIZATION

Although traditional conceptualizations of temperament and personality tend to emphasize their biologically rooted dispositional features and temporal and cross-setting stabilities, researchers have been aware of the role of the environment in temperament and personality development (Rothbart & Derryberry, 1981). Findings from research programs have indicated that environmental factors are associated with the development of temperament and personality and may modify their relations

with adjustment outcomes (e.g., Eisenberg et al., 2007). Based on a reanalysis of the NYLS data that indicated weak to moderate stabilities of difficult temperament, Partridge and Lerner (2007) argued that temperament was an "emergent property of a dynamic interaction between a child's physiological and behavioral capacities and the constraints and contingencies placed on that child by his or her ecological context" (p. 263). Moreover, researchers believe that child characteristics and the environment may contribute independently as well as interactively to social and psychological adjustment (Lahey et al., 2008).

Nevertheless, a number of issues exist concerning how child characteristics and environments, particularly socialization practices, are associated with each other and how they interact in predicting adjustment outcomes. Researchers disagree, for example, about the causal direction between child characteristics and socialization practices. The main arguments include that (a) the manifestation of temperament and personality elicits particular patterns of social reactions of adults and peers, which in turn form an environment for the child, (b) environmental factors such as parenting trigger the exhibition of temperament and personality characteristics and facilitate or hinder their development, and (c) child characteristics and socialization practices reciprocally affect each other, although the effects may or may not be balanced. Different models of temperament \times environment interaction have also been proposed. In general, the contributions of child characteristics and environments to adjustment may occur in (a) an additive manner in which they make unique and independent contributions to adjustment, and (b) an interactive manner in which the contribution of one depends on the other. Concerning the interaction between child characteristics and environments, it may occur in two major fashions: (1) environmental factors exacerbate or buffer against the adverse effects of undesirable child characteristics, such as difficult temperament, that are considered risk factors, and (2) environmental factors reinforce or "potentiate" the strengths of children with desirable characteristics, such as high self-control, and enhance further adaptive development. Finally, from a different perspective, it has been suggested that child characteristics, such as emotionality and compliance, may represent personal susceptibility to environment influences (e.g., Belsky & Pluess, 2009). Individual differences in susceptibility to adversity and environmental support are likely to predict different development outcomes.

Relations Between Temperament and Personality

Characteristics and Parenting: The Issue of Directionality

As the most important socialization agent in the early years, the family, particularly parents, has received heightened attention in empirical studies of temperament and personality development. Although a lack of relations has been found in some studies (see Wachs & Bates, 2010), evidence from a number of studies indicates that parenting and parent-child relationships are associated with child characteristics (Kiel & Buss, 2011; Pauli-Pott et al., 2004; Schofield et al., 2012). The associations in some of the studies, particularly correlational and cross-sectional, may be contributed partially or completely by the “third” variable, such as genetic similarity between parents and their children, family conditions, and shared method variances if the data are collected from the same source of information. However, the results of more rigorously designed and controlled longitudinal and interventional studies (e.g., Pauli-Pott et al., 2004) suggest that the links are unlikely to be spurious.

Nevertheless, the direction of causality in the links is not clear. Researchers have reported results indicating both parent-to-child (Eisenberg et al., 2007; Pauli-Pott et al., 2004; Schofield et al., 2012) and child-to-parent (Kiel & Buss, 2011; Rubin, Nelson, Hastings, & Asendorpf, 1999) effects. The impact of temperament on parenting and parent-child relationships tends to be more evident in the first several years, although family influence on child characteristics becomes stronger in the later years (Lengua & Kovacs, 2005). It appears that, in general, child temperament or personality and family relationships affect each other in a reciprocal manner. Indeed, results from some longitudinal studies have supported the bidirectional model. Lengua and Kovacs (2005), for example, found that child irritability and parental inconsistent discipline predicted each other. Eisenberg et al. (1999) found that children’s poor regulation at 6 to 8 years of age predicted parental punitive reactions at 8 to 10 years and that parental punitive reactions at 8 to 10 years predicted low regulation at 10 to 12 years. Despite the evidence, further investigation is needed to clarify the causal processes in the relations between specific child characteristics and family socialization practices.

Parenting and Reactivity

Rubin and colleagues (2009) have argued that parental oversolicitousness and overprotection are developmental origins of children’s reactive and shy-inhibited behavior

because directive and overprotective parenting may lead to dependence on parents and a lack of exploration of the environment, which ultimately weakens children’s ability to develop coping strategies to overcome anxious reactions to novelty and challenging social situations. According to this argument, helping children to avoid stressful situations may not help them to develop social competencies. Consistent with the argument, Pauli-Pott et al. (2004) found that maternal sensitivity as observed at home significantly predicted infants’ negative emotionality, such as irritability and fear, that was observed in the laboratory and reported by parents. Hudson, Dodd, Lyneham, and Bovopoulous (2011) also found in a sample of 4-year-old children that maternal high involvement in mother-child interactions was significantly and positively associated with later increased behavioral inhibition in peer interaction settings.

It should be noted that the behavioral manifestations of parental high involvement, overprotection, and solicitousness may be similar to those of parental warmth and support. However, parental warm and supportive behavior may be beneficial for children to acquire feelings of security and confidence in exploring the environment and thus alleviate children’s reactivity and social anxiety (L. Murray, Creswell, & Cooper, 2009). A major issue in these studies is the failure to examine whether parental involvement and warmth are intended to guide children to engage in social activities or to impede their activities. In the future, researchers should consider the goal of parental behaviors in the study of their relations with children’s reactivity or inhibition.

In addition, it is possible that children’s reactive and anxious behavior elicits parental involvement and overprotection. Anticipating or viewing their children’s anxiety and fear in challenging situations is likely to produce feelings of concern and unease. As a result, parents may attempt to provide their support and assistance by displaying overprotective and controlling behaviors such as directly telling the child what to do and how to do it (Rubin et al. 1999). Kiel and Buss (2011) found in a longitudinal study that the association between child fearful temperament and later maternal protective behavior was strengthened by maternal accuracy in predicting children’s distress reactions to novel situations. In other words, child fearfulness appeared to elicit more protective behaviors in mothers when they anticipated correctly their children’s fearful reactions. According to Dadds and Roth (2001) and Rubin et al. (2009), child reactive and fearful temperament and parental protective and involving behavior may form an anxious-coercive cycle, in which anxious children seek attention and protection from the parents in stressful

settings and in turn parental protective responses reinforce children's behavior.

Parenting and Regulation

Relations between parenting and child regulation appear more unidirectional than those between parenting and reactivity. According to Eisenberg et al. (2007), children's regulatory abilities develop in the context of social interactions and relationships, particularly with their parents. Parents may affect children's regulatory abilities in several ways, including (a) serving as models in managing stress and controlling negative emotions and behaviors; (b) approving or disapproving children's expression of emotions and behaviors, which facilitates or undermines children's regulation; and (c) providing warmth and support in parent-child interaction that are beneficial to the development of secure parent-child relationships, compliance to adults' requests, and internalization of adults' goals. In addition, Eisenberg et al. (2007) suggest that parental responsiveness to children's emotions is important for the socialization of effortful control. When parents are sensitive to children's emotions such as distress, children may not become overaroused in distressing situations. In contrast, parental insensitivity and unsupportive reactions may induce aroused and dysregulated emotions in children.

Empirical results have consistently indicated that infants and toddlers of parents who are warm, sensitive, and responsive to child emotions tend to develop competent regulatory skills and express their emotions and behaviors appropriately in various situations (e.g., Kochanska, Aksan, Prisco, & Adams, 2008). Studies of parenting and conscientiousness or self-control in older children and adolescents provided similar results. Schofield and colleagues (2012), for example, reported that supportive parenting (e.g., warmth and respect for the child, as rated by observers during home visits) of both mothers and fathers positively predicted adolescent alpha personality, which was formed by lower-order traits of conscientiousness, agreeableness, and emotional stability, two years later with the stability of personality controlled in the analysis. The effects of parenting of mothers and fathers on adolescent personality were virtually identical and modest.

Parenting and Parent-Child Relationships as a Moderator of Relations Between Child Characteristics and Adjustment

The notion of interaction between temperament and parenting is consistent with the goodness of fit theory (Thomas & Chess, 1977). However, the goodness of fit theory may not

be particularly useful for making predictions in empirical research because of the judgmental nature of fit, which often results in circular reasoning about the appropriateness of parenting and adjustment outcomes. In the study of interactions between child characteristics and parenting or other environmental factors, many researchers use other models, such as the stress-buffering model (Cohen & Wills, 1985). According to the stress-buffering model, undesirable characteristics such as behavioral inhibition or irritability represent risk factors in development. Supportive parenting or favorable family conditions may serve as a protective factor that reduces the risk and protects children with those characteristics from developing maladaptive outcomes, whereas unsupportive parenting or unfavorable family conditions serve as an exacerbating factor that makes temperamentally at-risk children particularly susceptible to adjustment problems. As a result, children with undesirable characteristics in supportive and unsupportive families may have different developmental outcomes.

The stress-buffering model has been supported by findings from a number of studies. Williams et al. (2009), for example, assessed infants' inhibited behavior in laboratory observations and parenting styles and child behavioral problems based on maternal reports. The results showed that, whereas inhibited infants displayed more internalizing problems at Age 4 years than uninhibited infants when their mothers used permissive parenting styles, inhibited infants did not differ from their uninhibited counterparts when they were not exposed to permissive parenting. Similar buffering effects were found in other studies with young children, such as those involving parental positive control and child impulsivity in predicting externalizing problems (e.g., Lahey et al., 2008) and parental sensitivity or control and child difficult temperament in predicting internalizing and externalizing problems (e.g., van Aken et al., 2007).

Researchers have also examined the buffering function of parenting in relations between temperament and personality characteristics and adjustment beyond early childhood. Van Leeuwen, Mervielde, De Clercq, and De Fruyt (2007) studied parenting \times personality interaction in predicting adjustment problems among school-age children, using parent-report data. The results showed that low levels of agreeableness and conscientiousness were associated with externalizing problems for children with high scores on negative parenting (e.g., harsh discipline and punishment) or low scores on positive parenting (e.g., positive parental behavior, teaching rules, and autonomy), but not for children with low scores on negative parenting or high scores on positive parenting. Apparently, warm and

supportive parenting styles served to protect children who had antagonistic tendencies and poor control abilities.

Although researchers have widely used the stress-buffering model, child characteristics may interact with parenting in other ways. A conceptual model that is an alternative to the stress-buffering model is the resource-potentiating model (Kupersmidt, Griesler, DeRosier, Patterson, & Davis, 1995), which focuses on the context of low risk or high resources (e.g., child positive emotionality, self-control). According to this model, supportive parenting or favorable conditions facilitate the strengths of children with desirable characteristics. The potentiating effect ensures that favorable conditions promote positive developmental outcomes whereas unfavorable conditions hinder or constrain positive development. The resource-potentiating model is theoretically interesting and can help achieve a further understanding of the person \times environment interaction processes, given that many temperament and personality characteristics, such as positive emotionality, sociability, and self-regulation, likely contribute to adaptive development in supportive social conditions.

Not all research findings support the moderating or interactive model. Hudson et al. (2011), for example, found that behavioral inhibition and parenting as assessed in observations predicted maternal reports of child anxiety in an additive, rather than an interactive, manner. Lengua and Kovacs (2005) measured child temperament, parenting, and adjustment problems based on maternal and child reports, and found that temperamental characteristics, such as irritability, and maternal parenting, such as acceptance and inconsistent discipline, contributed uniquely and independently to the prediction of children's externalizing and internalizing adjustment problems. In a later 3-year longitudinal study, Lengua (2006) further found that increases in child fear and irritability during development were associated with high levels of internalizing and externalizing problems, over and above the effects of parenting, whereas increases in maternal rejection and inconsistent discipline were associated with high levels of externalizing problems when child temperament was controlled. These results supported the additive model.

The Role of Peer Interactions and Relationships in Temperament and Personality Development

With age, children engage in more social activities outside the home, and peer interactions become an increasingly important socialization context. Researchers who are

interested in peer interactions and relationships often focus on peer acceptance and rejection, dyadic relationships with friends, and peer groups. Experiences of these three aspects of peer relationships all seem to have significant implications for the development of temperament and personality.

As an illustration of the role of peer relationships in temperament and personality development, researchers examined the associations between peer exclusion and anxious withdrawal or solitude, a type of solitary behavior due to internal social anxiety or fear. Using a longitudinal data set from 10 to 13 years of age, Oh and colleagues (2008) and Booth-LaForce and colleagues (2012) identified three trajectories of anxious-withdrawn children (low-stable, increasing, and decreasing), based on peer nominations, and examined self-reported peer experiences associated with these trajectories. The results showed that children who initially had unstable friendships or lacked mutual best friends were likely to be in the increasing group, where anxious withdrawal became higher with time. In contrast, children with low levels of peer exclusion and victimization after the transition from elementary to middle school (11 years of age) were likely to be in the decreasing group, where anxious withdrawal was initially high but gradually decreased over time. Apparently, these children might have an opportunity to reduce their anxious-withdrawn behavior in a new school where they could engage in relatively normal peer interactions without being excluded.

In a longitudinal study with children from 5 to 9 years of age, Gazelle and Ladd (2003) examined children's peer relationships and anxious solitude using teacher reports and peer nominations. Anxious-solitary children who experienced peer exclusion after school entry displayed stable anxious solitude from 5 to 9 years of age. In contrast, anxious-solitary children who did not experience significant peer exclusion early on displayed decreased anxious solitude over time. Gazelle and Ladd (2003) argued that, compared with their counterparts who experienced peer exclusion, anxious-solitary children who did not might find it easier to overcome their social fear because it had not been confirmed by their social experiences. The experience of peer exclusion was likely to confirm and perhaps intensify social fear of anxious-solitary children.

Gazelle and Ladd (2003) also examined in this study how anxious solitude and peer exclusion jointly contributed to the risk for depressive symptoms. The results indicated that anxious solitude in combination with interpersonal adversity predicted elevated depression symptoms over time. Thus, whereas anxious-solitary children who

experienced high levels of early peer exclusion displayed sustained or increased depressive symptoms, anxious-solitary children without the experience of early peer exclusion did not differ from other children on initial depression and, more importantly, displayed a declining trajectory of depressive symptoms during the period of study. According to the authors, peer exclusion might have provoked negative self-schemata and feelings of helplessness that were linked to depression in anxious-solitary children.

The impact of peer relationships on temperament and personality characteristics and on their relations with adjustment is also demonstrated by developmental changes in children who are affiliated with peer groups with distinct group norms. Van Zalk, van Zalk, and Kerr (2011) investigated self-reported affiliation with crowd groups and individual social anxiety in Swedish adolescents. The researchers found that, in radical crowds (punks and goths) comprising adolescents who were shy and socially fearful, members became more anxious through group interactions with time. In these groups, members reinforced one another's anxious behavior by approving of the behavior in situations that elicit social fear. Similarly, Prinstein (2007) assessed group experiences and internalizing symptoms using adolescent and peer reports, and found that experiences in active groups, such as the "Populars" and "Jocks," led to declined shy-anxious behavior whereas experiences in academically oriented groups, such as the "Brains," led to increased social anxiety from childhood to adolescence. Moreover, increases in social anxiety were associated with greater susceptibility to peer influence, particularly among girls. In addition, the effects of peer groups were stronger on peripheral than nuclear members of the group, perhaps because peripheral members faced greater pressure to conform to the group norm (Conway, Rancourt, Adelman, Burk, & Prinstein, 2011).

Dishion and colleagues' work (Boislard, Poulin, Kiesner, & Dishion, 2009; Dishion, McCord, & Poulin, 1999) has shown peer group influences on self-control or control-based behaviors. When adolescents discussed topics such as planning a joint activity and solving a problem, adolescents who displayed deviant, undercontrolled, or delinquent behaviors were more likely than others to engage in talk about rule-breaking and to express contingent positive reactions, such as laughter, to deviant talk. Moreover, interactions among adolescents, including talk about rule-breaking and positive reactions to the talk, led to increased problems including violence, substance use, and high-risk sexual behavior in subsequent years. As argued

by Dishion and Dodge (2005), the grouping or aggregation of adolescents with behavioral problems provided a context that facilitated the development of their undercontrolled and defiant behaviors. Personal and contextual factors may moderate peer group effects. For example, the salience of the group norm, the uniformity of norm-based social evaluations, and affective and attitudinal processes in interactions such as mutual responsiveness may affect peer influences on the development of behavioral characteristics. In addition, group influence seems to be more evident for members who are more discrepant from their peers (Boxer, Guerra, Huesmann, & Morales, 2005).

Child Temperament and Personality as a Sensitivity Factor

Trait \times environment interactions can be understood from different perspectives. Although researchers have traditionally focused on the moderating effects of parent-child and peer relationships on relations between child characteristics and adjustment, it may be equally valid, from both theoretical and analytical perspectives, to view child characteristics as moderators of environmental influences on adjustment.

Several relatively broad frameworks may be useful for exploring the moderating effects of child temperament and personality. In their chapter on socialization and parent-child interaction in the *Handbook of Child Psychology*, Maccoby and Martin (1983) argued that researchers should consider child compliance, receptiveness, or readiness in the study of family socialization, particularly parenting styles. Parental socialization efforts such as guidance may lead to expected developmental outcomes among children who are compliant with parents and "ready" for socialization, but such efforts may be less successful for children who resist parenting attempts. In other words, parental support and guidance may elicit cooperation or reduce problem behavior in children who are responsive but not in children who display disobedient and defiant reactions to parental requests and demands. Maccoby and Martin (1983) and other researchers (e.g., Kochanska et al., 2008) have focused on the mutual contributions of compliance and parenting or the mediating role of compliance in relations between parenting and adjustment. However, the conceptualization of child compliance, or broadly regulation, as an indication of receptiveness to socialization implies the moderating function of this trait and perhaps other related personal traits such as conscientiousness and social sensitivity in the link between social experiences and development.

Another model of the moderating role of personal characteristics, which is commonly used in the field of psychopathology, is the vulnerability or diathesis-stress model (e.g., Rutter, 2006; Zuckerman, 1999). According to this model, children with certain undesirable characteristics such as a difficult temperament may be more vulnerable than others to adverse environmental influence, which leads these children to develop more adjustment problems. In this process, adverse environmental factors or experiences may trigger destructive reactions in vulnerable, but not resilient, children; individual vulnerability and environmental stressors represent a dual-risk for maladaptive development. Thus, relative to children with easy temperaments, children with difficult temperaments are more likely to suffer in adverse environments, although they are not more likely than others to benefit from supportive rearing conditions. The vulnerability or diathesis-stress model, which is virtually equivalent to the stress-buffering model that focuses on environmental factors as a moderator, has been supported by findings from numerous studies (e.g., Lengua & Wachs, 2012). De Haan, Prinzie, and Deković (2010), for example, examined relations among personality, parenting, and behavioral problems in a Flemish sample of 6- to 15-year-olds based on teacher and parent reports. The results indicated that personality moderated the relations between coercive or overreactive parenting (criticism, yelling) and the development of delinquency and aggression; coercive parenting was related to higher and more stable delinquency and aggression for less extraverted, benevolent, and conscientious children.

As an extension of the diathesis-stress model, Belsky, Ellis, and colleagues (Belsky & Pluess, 2009; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011) have proposed a differential susceptibility model that treats temperament as susceptibility to the influence of childrearing environments. This model includes the aspect of resource-potentiation in the resource-potentiating (Kupersmidt et al., 1995) and vantage sensitivity (Manuck, 2011) models. All these models recognize that children with certain temperamental characteristics or genes may be particularly sensitive to the influence of environmental conditions. However, the differential susceptibility model explicitly emphasizes that individual susceptibility may be directed toward both positive and negative influences, which can lead to corresponding adaptive and maladaptive outcomes. The same characteristic, such as negative emotionality, fear, or difficult temperament, may predict problems when it is combined with a detrimental

environment but positive outcomes when it is combined with a supportive environment. In other words, children with a high level of susceptibility are vulnerable in stressful settings, but, at the same time, are more likely than others to benefit from supportive environmental conditions (Belsky & Pluess, 2009). Individual sensitivity to environmental influence is rooted in an evolutionary framework. According to Ellis and Boyce (2008), a strategy for survival and reproduction may promote success in some environments but failure in others. "Selection pressures therefore tend to favor *adaptive phenotypic plasticity*, the capacity of a single genotype to support a range of phenotypes in response to particular ecological conditions that recurrently influenced fitness during a species' evolutionary history" (p. 183).

Pluess and Belsky (2010) tested the differential susceptibility theory using a longitudinal data set from a large sample in multiple locations in the United States. In the study, mothers rated children's difficult temperament at 6 months, and maternal parenting and childcare quality were assessed by semistructured play and observation at 6, 15, 24, 36, and 54 months. Children's cognitive-academic competence and socioemotional adjustment outcomes were assessed repeatedly over time from 5 to 11 years of age using standardized tests and teacher reports. The results partially supported the differential susceptibility model. Children with high temperamental negativity had clearly lower scores on later academic performance, including in reading, math, and picture vocabulary, when they experienced insensitive and unsupportive parenting, but children with the same temperament did not display obviously higher academic competence when their parents were sensitive and supportive, a result that supported the diathesis-stress model. On the other hand, consistent with the differential susceptibility model, children with a difficult temperament had lower scores on social skills and higher scores on problems in the context of low-quality parenting or childcare but had higher scores on social skills and lower scores on problems in the context of high-quality parenting or childcare.

Essex, Armstrong, Burk, Goldsmith, and Boyce (2011) tested the differential susceptibility hypothesis in a longitudinal study of children from 7 to 13 years of age. The researchers measured reactivity with biological (e.g., slope of mean arterial pressure across a 20- to 30-minute stress protocol) and behavioral (inhibition/disinhibition) assessments, and teacher-child relationships and externalizing and internalizing problems through teacher, parent, and child reports. The results indicated that, compared with

their counterparts low in biological sensitivity, biologically sensitive children were more susceptible to adverse teacher-child relationships, but were not more susceptible to supportive teacher-child relationships, which supported the diathesis-stress model. The results about behavioral reactivity appeared to be consistent with the differential susceptibility hypothesis. However, the pattern of interactions between temperament and teacher-child relationships were not straightforward in predicting later problems; whereas highly inhibited children were more susceptible to the influence of teacher-child conflict, highly disinhibited children were more susceptible to teacher-child closeness.

Mixed findings were also reported by Lengua and colleagues in a series of studies (e.g., Lengua, 2008) of child characteristics, including fear, anxiety, frustration, and effortful control, as moderators of relations between parenting or neighborhood environment and adjustment in childhood. In general, different child characteristics appeared to operate differently depending on the parenting or neighborhood dimension and the adjustment outcome. For example, Lengua (2008) found that maternal rejection was associated with greater increases in externalizing problems for children high in frustration, relative to children low in frustration, which was consistent with the differential susceptibility hypothesis. However, many other interactions in these studies were complex and did not show a coherent pattern.

Stronger support for the differential susceptibility model came from some other research programs. Boyce, O'Neill-Wagner, Price, Haines, and Suomi (1998) found that high-reactive rhesus monkeys who were exposed to a high-stress living condition had the highest number of injury incidents over a 12-month period, whereas high-reactive monkeys who were exposed to a low-stress living condition had the fewest injury incidents during this time period. The low-reactive monkeys had a mid-level number of injuries during the same time regardless of whether they were exposed to high- or low-stress environments. Bakermans-Kranenburg and van IJzendoorn (2006) found that children with the DRD4 7R allele, which is related to a range of reward-seeking and approach-related behaviors such as sensation seeking, impulsivity, and risk taking, exhibited the least and most externalizing behaviors, depending on whether they experienced high or low quality caregiving. Thus, the DRD4 7R allele may not be a risk allele per se, but may confer heightened sensitivity to environmental influences, regardless of whether these influences are positive or negative.

In several longitudinal studies using various observational laboratory paradigms, Kochanska and colleagues (e.g., Kim & Kochanska, 2012) showed that parenting, particularly by mothers, had significant effects on developmental outcomes for children high in fearfulness or negative emotionality, but not for children low in fearfulness or negative emotionality. Moreover, the patterns of interactions suggested that children high in fearfulness or negative emotionality often displayed regulatory behaviors in the presence of low-power parenting and positive mother-child relationships, but had lower scores on regulation when mothers used more power-assertive parenting and mother-child relationships were less desirable. Similarly, using data collected from observations and maternal and teacher reports, Bradley and Corwyn (2008) found that parenting variables were more strongly associated with behavioral problems for children with difficult temperaments than for children with easy temperaments. Whereas children with difficult temperaments had fewer problems when their parents were sensitive and supportive but more problems when their parents used insensitive and harsh parenting practices, the trends were weaker or nonsignificant for children with easy temperaments.

In short, researchers have interpreted interactions between temperament and personality traits and environment factors in terms of individual vulnerability to adverse environmental influences. The differential susceptibility model (Belsky & Pluess, 2009) provides a useful alternative perspective that is receiving increased attention. Research findings supporting this model have generally been mixed. Clearly, children vary in their sensitivity to external influences, either positive or negative, perhaps due to the features of their nervous or other biological systems (Ellis et al., 2011). However, it is unclear (a) what child characteristics (e.g., anxiety, fearfulness, difficult temperament, frustration) reflect sensitivity or susceptibility, (b) whether children with a high level of sensitivity react to different environmental influences (e.g., parental support, control, childcare settings) to the same extent or in the same manner, and (c) whether children's sensitivity is manifested similarly or differently in terms of developmental outcomes (e.g., externalizing problems, internalizing problems, regulatory behavior). It will be important to clarify these issues, which will allow researchers to formulate more explicit hypotheses (e.g., whether a particular characteristic is a vulnerability, resource-potentiating, or sensitivity factor) and make more meaningful interpretations of findings. At the same time, researchers should continue to explore how individual characteristics and

environmental factors contribute to adjustment from different perspectives. Different frameworks and models, such as those focusing on socialization receptiveness and vulnerability, may be complementary when addressing development of temperament and personality in different domains.

Summary

Research has shown that temperamental and personality characteristics are associated with parenting and peer relationships, although the directions and processes of causality underlying the associations remain largely unclear. There is empirical support for each of the arguments about child temperament and personality eliciting reactions from parents and peers, parent and peer socialization leading to change in child characteristics, and reciprocal influence between child characteristics and social relationships. Research has also revealed joint and interactive contributions of child characteristics and environmental factors in predicting adjustment outcomes. To achieve a more in-depth understanding of trait \times environment interactions beyond the statistical representations (e.g., simple slope analysis) that have been provided in most studies, researchers need to explore, perhaps using strategies such as experimental or quasi-experimental, intervention, and multiwave longitudinal designs, the processes by which specific socialization factors buffer or potentiate the effects of child desirable or undesirable characteristics and the processes by which specific characteristics make children vulnerable or sensitive to the influence of rearing conditions.

The associations between child characteristics and socialization and their contributions to adjustment occur in broader socioecological settings (Bronfenbrenner & Morris, 2006). Factors such as family socioeconomic status (SES), immigration and ethnic minority status, parental mental health, and community conditions may be involved in the processes. Paulussen-Hoogeboom, Stams, Hermanns, and Peetsma (2007), for example, found that child negative emotionality was negatively associated with parental support, but the association was stronger in families from lower socioeconomic and ethnic minority backgrounds. The results suggest that child negative emotionality is likely to gradually elicit unsupportive parenting from parents with low-SES and ethnic minority backgrounds. However, parents from resourceful, middle- to high-SES, and European American families may be more

sensitive to their children's characteristics and more capable of adjusting their parenting behavior to children with difficult temperaments. Therefore, another future direction is to study how SES and other macro-level socioecological factors affect relations and interactions between child characteristics and parenting or peer relationships.

CULTURE AND THE DEVELOPMENT OF TEMPERAMENT AND PERSONALITY

The influence of culture on personality has been an interesting topic in anthropology, psychology, sociology, and other behavioral sciences. In the history of culture and personality studies, cultural anthropologists such as Benedict (1934) and Mead (1928) had a major impact on theoretical and empirical work. However, the culture and personality school or movement that emerged in the first half of the 20th century was highly controversial and was eventually abandoned by researchers, due to a number of factors including the strong criticisms of its assumptions about homogeneous personality types within cultures, stereotype-related national character studies, and simplistic explanations of the relation between culture and personality (e.g., G. Marshall, 1998).

In the developmental field, interest in how cultural factors influence children's and adolescents' temperament and personality has been growing rapidly, with little connection to the traditional culture and personality school. Using a variety of research strategies, including behavioral observations in naturalistic (e.g., home and school) and controlled laboratory settings, surveys, narrative interviews, and longitudinal analysis, researchers have investigated the role of culture in the development of emotionality, self-control, and other characteristics. Although cross-cultural comparisons have been made, most studies are concerned with similarities and differences among children in different societies or communities on specific characteristics and their development rather than with identifying "national characters" or "modal personality types" as in the culture and personality school. Moreover, researchers are generally aware that (a) enormous variations exist in any society or community; (b) group differences in temperament and personality are associated with specific social, economic, and ecological circumstances, lifestyles, and values that are constantly changing; (c) sociocultural conditions may affect the display as well as the meaning of temperament and personality characteristics; and (d) it is important to examine the processes by which sociocultural factors are

involved in individual development (Chen & French, 2008; García Coll, Akerman, & Cicchetti, 2000).

The issues of cultural influence on human development, including temperament and personality development, have been discussed mainly from two broad perspectives—the sociocultural perspective (Vygotsky, 1978) and the socioecological perspective (Bronfenbrenner & Morris, 2006). The sociocultural theory emphasizes the internalization of external symbolic systems, such as language and signs, from the interpersonal level to the intrapersonal level. During development, after mastering these systems, human beings can use them to perform psychological processes and manipulate the environment. Social practices or activities of human beings are an important part of cultural influence on development, and changes in sociocultural structures and related social practices are likely to result in reorganization of mental processes and the formation of new psychological functions (Rogoff, 2003). From a different perspective, the socioecological theory indicates that culture, as a part of the ecological environment, affects individual attitudes, emotions, and behaviors mainly through a series of more proximal systems. The cultural beliefs and values endorsed in a society or community may serve to organize other ecological settings, such as community services, school and daycare arrangements, and family interaction patterns, which in turn shape individual development (Super & Harkness, 1986).

Consistent with the sociocultural and socioecological perspectives, researchers have argued that different societies and communities may place different values on children's characteristics such as emotion expressivity, obedience, and independence (García Coll et al., 2000; Rogoff, 2003). According to Chen and French (2008), two major dimensions of socioemotional functioning, social initiative and self-control, are reflected in most of these values. Social initiative represents the tendency to initiate and maintain social participation, which may be indicated by reactivity in challenging social situations, whereas self-control is concerned with the ability to modulate behavioral and emotional reactivity in social interactions. In Western self-oriented societies, in which acquiring personal autonomy and assertiveness is considered a major socialization goal, social initiative is viewed as an important aspect of competence. Although self-control is considered necessary to achieve personal goals, children are encouraged to maintain a balance between the needs of the self and those of others (Maccoby & Martin, 1983); both under- and overcontrol are regarded as maladaptive. In group-oriented societies, on the other hand, social

initiative may not be highly valued because it may cause disturbance to, or interfere with, interpersonal and group harmony. To maintain interpersonal relationships and group harmony, however, children are encouraged to restrain personal desires in order to address the needs of others. Therefore, self-control, particularly effortful control, is strongly emphasized in these societies (Chen, Yang, & Fu, 2012).

Cultural values regarding social initiative and self-control provide a frame of reference for social judgments about temperamental and personality characteristics such as sociability-agreeableness (active social initiative with effective control), defiance-impulsivity (high social initiative and low control), and shyness-inhibition (low social initiative and adequate control to constrain behaviors and emotions toward self) (Chen & French, 2008). Thus, when adults and peers evaluate and respond to the characteristics that children display in social settings, culture serves as a guideline for social evaluations and responses. Through social evaluation and response processes in interactions, culture plays a role in determining the display and development of temperament and personality.

Culture and the Display of Temperament and Personality Characteristics

Numerous findings have been reported concerning cross-cultural similarities and differences in children's and adolescents' temperamental and personality characteristics. For example, researchers have found that children in some Asian societies are less expressive of both positive and negative emotions than children in Western societies (Camras, Chen, Bakeman, Norris, & Cain, 2006; Gartstein et al., 2006). Indian, Kenyan, Korean, Mayan, and Mexican children tend to be less sociable and to engage in less self-expressive activities than Western children (Edwards, 2000; Farver, Kim, & Lee, 1995). Adolescents and young adults in some African (e.g., Nigeria, South Africa), Asian (e.g., China, Korea, Japan), and South American (e.g., Costa Rica) societies seem to be less extraverted and more introverted than their Western counterparts (e.g., Lee, Okazaki, & Yoo, 2006; Oakland, Pretorius, & Lee, 2008). Whereas cross-cultural differences in aspects of temperament and personality such as emotionality or expressivity are interesting, in the sections that follow, we focus mainly on children's reactivity or social initiative and self-control, which may systematically reflect the influence of cultural values on individual characteristics.

Reactivity to Challenging Situations

Cross-cultural research has revealed that Asian children may differ from Western children on negative reactivity to stressful or challenging situations in the early years. According to parental reports, for example, relative to their American counterparts, Japanese, mainland Chinese, Taiwanese, and Vietnamese infants and toddlers tend to display greater negative reactivity, as indicated by higher intensity, irritability, fear, and reluctance to approach in unfamiliar situations (e.g., Gartstein et al., 2006). Austin and Chorpita (2004) also found that Chinese American, Philipino American, and Japanese American children displayed higher levels of social anxiety than their European-American counterparts. Huntsinger and Jose (2006) found similar results, indicating that second-generation Chinese American adolescents scored higher on sensitivity and withdrawal, and lower on emotional stability, excitability, and cheerfulness than European-American adolescents. When the scores were aggregated to form higher-order personality factors, Chinese American adolescents were clearly lower on extraversion and independence. Interestingly, in a follow-up study that was conducted 5 years later, most of the group differences disappeared. Chinese American adolescents differed from European American adolescents on only two dimensions: cheerfulness and boldness; Chinese American adolescents were less cheerful and less bold. Huntsinger and Jose (2006) argued that increased similarity in personality might be related to some universal developmental processes and acculturation.

Consistent with the findings based on parental reports and self-reports, researchers have found differences between Asian and Western children on reactivity to stressful situations in observations. Farver et al. (1995), for example, found that Korean American children displayed more shy behavior than European American children in peer interactions in preschool settings. Chen et al. (1998) found that Chinese toddlers were generally more reactive and inhibited than Canadian toddlers in novel laboratory situations. Compared with Canadian toddlers, Chinese toddlers stayed closer to their mothers and were less likely to explore the environment in mother-child free play sessions. Chinese toddlers also displayed more anxious and fearful behaviors in interaction with strangers, as indicated by their higher scores on the latency to approach strangers and to touch toys when they were encouraged to do so. In a later analysis of data from multiple samples, Rubin et al. (2006) found that Korean and Chinese toddlers exhibited

higher levels of inhibition than Australian, Canadian, and Italian toddlers in multiple stressful episodes.

It should be noted that, although researchers have generally found Asian children to be higher on reactivity than Western children, different results have been reported in several studies. Kagan et al. (1994), for example, found that Chinese infants were less active, irritable, and vocal than American infants. The lower levels of activity and vocalization in Asian infants may be understandable considering their greater anxiety and wariness in challenging situations. The expression of less explosive emotions such as irritability in Asian children may be related to their higher levels of self-control, either automatic or effortful, over the emotions.

Relatively little research has been conducted on reactivity with non-Asian children in non-Western cultures. Gudiño and Lau (2010) investigated acculturation and shyness among Hispanic/Latino American children. The results indicated that parental familiarity with, and endorsement of, American culture were associated with lower levels of shyness as reported by parents and children. Researchers have examined specific types of reactivity in stressful social situations such as social anxiety in Hispanic/Latino youth, but the findings are largely mixed. Hispanic/Latino and European American children and adolescents differed on social anxiety in some studies (e.g., Pina & Siverman, 2004), but not in others (e.g., Schreier et al., 2010). When cultural or ethnic differences were found, however, Hispanic/Latino youths tended to display greater social anxiety (Pina & Siverman, 2004; Varela et al., 2004). Polo and López (2009) argued that, as in many East Asian societies, collectivistic values such as group harmony and interdependence endorsed in Latino societies might facilitate the development of sensitivity to social evaluations and vulnerability to social anxiety. On the other hand, according to Schreier et al. (2010), Latino cultures stress sociability, self-expression, and avoidance of criticizing and rejecting others, which may reduce, rather than enhance, anxious behavior in social situations.

Finally, researchers found that, compared with European Americans, more African Americans showed high social anxiety in some studies (e.g., Neal & Turner, 1991), but not in others (e.g., Ferrell, Beidel, & Turner, 2004). Moreover, it was reported that, relative to their European American counterparts, African American youths tended to have lower levels of social anxiety (e.g., Compton, Nelson, & March, 2000). A major problem in the previous studies is the reliance on self-report data such as those from questionnaires, which may be confounded with methodological

issues such as culturally specific response styles and the reference group effects. Clearly, research using more rigorous methods is needed to obtain a better understanding of cultural differences.

Self-Control

Parents in Chinese and some other East Asian societies often rate their children as more persistent in orienting than do parents in the West, and the differences appear to increase with age (Gartstein et al., 2006). Consistent with parental ratings, Chen et al. (2003) found in an observational study that, compared with Canadian toddlers, Chinese toddlers were more likely to display compliant behaviors without adult intervention during a clean-up session, indicating internalized control. Chinese toddlers also waited longer on a brief delay task in which the experimenter told the child to wait to play with a packet of attractive crayons until she returned to the room. Compared with their counterparts in the West, Chinese, Korean, and Japanese children and adolescents also showed higher levels of control, persistence, and conscientiousness in other studies including those concerned with executive function and personality (e.g., Oh & Lewis, 2008). It has been argued that the Asian cultural values of group orientation and behavioral restraint promote the socialization of self-control (Chen & French, 2008).

Findings concerning self-control of children in other cultures are less evident and coherent than those based on Asian and Western children. Galindo and Fuller (2010) found that, according to ratings by kindergarten teachers, Latino American children had lower scores than European American and Asian American children on self-control (e.g., controlling temper, responding appropriately to peer pressure). Among the Latino children, however, substantial subgroup differences were found: Children of Cuban and South American heritages were significantly higher on self-control than children of Mexican and Puerto Rican origins. Socioeconomic class was related to self-control; whereas children in economically poor Latino American families were rated lower on self-control than children in European American and Asian American families, children growing up in middle-class Latino families did not differ from other ethnic groups.

Gartstein and colleagues (e.g., Gartstein, Peleg, Young, & Slobodskaya, 2009) examined parental perceptions of infant temperament in Russian and other cultures, and found the influence of cultural context on parental perceptions of infants' control abilities. Russian infants in Israel were described by their parents as displaying

greater regulation, such as requiring a shorter time to recover from distress, than Russian infants in the United States. According to the authors, it is important to learn to effectively cope with daily life stress in Israel because recovery from distress is critical to adjustment in the environment. This argument was consistent with the finding that, among the Russian immigrants in Israel, parental involvement in the Israeli (host) culture was positively associated with infants' regulatory capacity, such as the duration of orienting/persistence of attention.

Culturally Directed Social Attitudes Toward Children's Characteristics

An important part of the cultural belief system is how people view desirable and undesirable characteristics of children. In Western societies that value personal autonomy and self-realization as major socialization goals, people typically hold positive views about stable and positive mood, sociability, and adaptability in children. But these characteristics may not be viewed as ideal in some non-Western societies that emphasize group harmony and interdependence (Klein, 1991). Cultural beliefs and values, particularly those related to socialization goals, affect adult and peer attitudes toward children's characteristics, which constitute distinct social environments for temperament and personality development.

Parental Attitudes

Parental attitudes toward children's characteristics are determined in large part by societal values. In a multi-national study of child temperament, Super et al. (2008) found that low approach and adaptability were associated with parental perceptions of "difficulty" more strongly in an Italian sample than in samples from other countries such as Australia, Spain, and Sweden. The results, as argued by the researchers, were consistent with the model of parenting in the Italian culture that encourages children to be active in exploring social situations while maintaining close relationships with parents.

Relative to parents in Italy and some other Western countries, parents in China have more positive attitudes toward children's shy-inhibited behavior. Chen and colleagues (1998) found that, whereas in Canada inhibition in toddlerhood was positively associated with mothers' negative attitudes such as rejection and punishment orientation, in China inhibition was positively associated with warm and accepting maternal attitudes. Positive parental attitudes toward shy-inhibited behavior were also found in older

children in China. Several studies showed that shyness in Chinese school-age children was positively associated with parental acceptance and negatively associated with parental rejection and power assertion (e.g., Chen, Rubin, & Li, 1997).

Cross-cultural differences have also been found in parental attitudes toward children's self-control. Kohnstamm et al. (1998) noticed that, when the researcher asked parents to describe their children, relative to parents in Western countries including Belgium, Greece, Holland, Poland, and the United States, Chinese parents focused more on child conscientiousness (careless or diligent) and were more concerned about the lack of control in their children. Cole, Tamang, and Shrestha (2006) examined parental attitudes in two villages in Nepal occupied by Brahmins and Tamangs. Brahmins are high-caste Hindus who value power and hierarchy, and Tamangs value social equality and compassion. Consistent with the cultural orientations, Tamang parents were more likely than Brahman parents to criticize angry children, indicating their disapproval of anger and undercontrol.

Keller and colleagues (2004) studied parent-child interactions that might reflect parental attitudes toward children's self-regulation in Cameroonian Nso, Costa Rican, and Greek cultures. The researchers found that, on a proximal parenting style such as body contact and body stimulation, Cameroonian Nso mothers were higher than Costa Rican mothers, who were higher than middle class Greek mothers. Nso mothers were also more likely to engage in body contact than German mothers (Kärtner, Keller, & Yovsi, 2010). According to the researchers, the early experience of body contact or proximal parenting is conducive to the development of self-regulation and compliance. Thus, higher levels of body contact in Nso mothers indicate their greater tendency to socialize their children to be self-regulated and compliant.

Peer Attitudes

Cultural norms and values may affect peer attitudes, such as social evaluations and responses in peer interactions. In a study of peer interactions among 4-year-olds, Chen, DeSouza, Chen, and Wang (2006) found that shy-inhibited children received different reactions from peers in China and Canada. In Canada, when shy children tried to initiate social interaction, peers were likely to make negative responses such as overt refusal, disagreement, and intentional ignoring of the initiation. However, in China peers responded in a more positive manner by controlling their negative actions and by showing support. The passive and wary behaviors that shy children displayed were perceived

by peers as incompetent in Canada, but appropriate in China. Peers in China tended to view these behaviors as indicating courtesy and a desire for social engagement. The observations of peers' voluntary initiations indicated that peers were forceful in Canada but more supportive and cooperative in China in their interactions with shy-inhibited children.

Overall peer acceptance and rejection may also reflect cultural evaluations of temperament and personality characteristics. In a study with Indonesian school-age children, Eisenberg, Pidada, and Liew (2001) found that shyness was negatively associated with peer nominations of dislike, which was different from what is typically found in the West. Chen and colleagues (e.g., Chen, Rubin, & Sun, 1992) found that shyness was associated with peer rejection in Canadian children, but with peer acceptance in Chinese children in the early 1990s. As urban Chinese society became competitive and individualistic during the transformation to a market-oriented system, however, children's shyness was associated with increasingly negative peer attitudes (Chen, Cen, Li, & He, 2005; Chen, Wang, & Wang, 2009).

Rapee and colleagues (Heinrichs et al., 2006; Rapee et al., 2011) conducted several studies of peer attitudes toward social anxiety that included shyness-inhibition. This group found that youth in East Asian countries including China, Japan, and Korea reported greater levels of social anxiety and fear of blushing than youth in Western countries including Australia, Canada, Germany, the Netherlands, and the United States. Moreover, youth in East Asian countries were more accepting of socially reticent and unassertive behaviors than their counterparts in Western countries. In these studies, for example, the participants were presented with vignettes describing individuals who displayed shy and reserved behaviors or outgoing behaviors and were then asked to indicate the extent to which they would expect the individuals in the vignettes to be socially liked and to succeed in their careers. Compared to Western youths, East Asian youths perceived smaller differences between shy and outgoing vignettes in their social and career impact. The researchers argued that cultural norms concerning social anxiety and inhibition determined, in part, social judgments of the characteristics.

Culture and the Significance of Temperament and Personality for Adjustment

According to a revised goodness of fit view (e.g., Lerner & Lerner, 1983), the adjustment of children depends

on how their temperament and personality fit specific environmental conditions, including opportunities, demands, and cultural expectations in the society. The role of socioecological conditions may be illustrated by DeVries's (1984) striking findings concerning the adaptive nature of "difficult" infant temperament in East Africa. In the Western literature (e.g., Thomas & Chess, 1977), difficult temperament, such as high negativity and irregularity, represents a risk factor in maladaptive development. However, DeVries (1984) found that difficult temperament was associated with lower infant mortality among the Masai people of East Africa during a famine. In a harsh environment such as the sub-Saharan region during the drought that occurred in 1974, infants with a difficult temperament got more parental attention because of their fussiness, which increased their chances of survival.

From the contextual-development perspective (Chen, 2012), culture may affect the development of children's characteristics through social interaction processes. When children display culturally valued characteristics, adults and peers likely provide approval and support. This favorable experience in turn strengthens the maintenance and development of the characteristics and at the same time helps children develop self-confidence and positive self-feelings. On the other hand, children who display characteristics that are inconsistent with cultural norms may receive negative feedback in social interactions, which places a pressure on them to change or suppress those characteristics. Those who are unable or unwilling to do so may develop negative emotions such as frustration and distress, which may lead to externalizing problems such as antisocial behaviors if directed toward others, internalizing problems such as negative self-feelings and depression if directed toward the self, or both. Children in certain contexts such as socially deviant groups and dysfunctional families may receive approval and support for the exhibition of characteristics that are incompatible with the general cultural norms in the society. In the long run, however, the socialization processes in these contexts may eventually lead to adjustment problems in the larger social environment.

Shyness-Inhibition and Adjustment Outcomes Across Cultures

Increasing evidence indicates that shyness-inhibition is associated with less problematic outcomes in societies where social initiative and assertiveness are not highly valued. For example, Eisenberg et al. (2001) found that shyness in Indonesian children was negatively associated with behavioral and emotional problems. In a longitudinal

study of the outcomes of shyness in Swedish society, Kerr, Lambert, and Bem (1996) followed a sample of children born in a suburb of Stockholm in the mid-1950s and found that, although shyness predicted later marriage and parenthood, it did not predict adulthood career stability, education, or income among Swedish men; this result is different from what was found in the United States (e.g., Caspi et al., 1988). According to Kerr et al. (1996), shy-reserved behavior was less maladaptive in Sweden because the social welfare and support systems based on the egalitarian cultural values assured people that they did not need to be highly competitive or assertive to achieve success.

Chen, Chen, Li, and Wang (2009) examined in a Chinese sample how behavioral inhibition in toddlerhood as observed in the laboratory predicted social and school adjustment 5 years later. The results indicated that early inhibition predicted cooperative behavior, peer liking, perceived social integration, positive school attitudes, and school competence; inhibited Chinese toddlers displayed more socially desirable behaviors and were better adjusted socially and psychologically than others in middle childhood. The relations between shyness-inhibition in childhood and later adjustment in Chinese children were also found in other studies (e.g., Chen, Rubin, Li, & Li, 1999). For example, shyness, as assessed through peer nominations, in elementary school children in China positively predicted teacher-assessed competence, academic achievement, and perceived general self-worth in adolescence. Shy Chinese children were likely to achieve leadership status in the school and to perform well in academic and socioemotional areas. Recent studies showed that, although shy children in urban areas of China started to experience learning difficulties, depression, and other adjustment problems as a result of social change (e.g., Chen et al., 2005), shy children in rural areas were still well adjusted in social, academic, and psychological areas (Chen, Wang, & Cao, 2011).

The results of studies with Chinese, Indonesian, North American, and Swedish children suggest that different social experiences of shy-inhibited children are likely to lead to different developmental outcomes. The difficulties that shy-inhibited children in North America experience in social activities may foster negative emotional reactions and psychopathological symptoms. In contrast, peer interactions that shy-inhibited children in some other societies engage in provide the opportunity for them to learn the skills needed to function appropriately in social situations. Moreover, the supportive relationships that shy-inhibited children in these societies establish with others help them

develop self-confidence and motivation to achieve success in life.

Self-Control and Adjustment Outcomes Across Cultures

Children's self-control or regulation in most cultures is associated with positive social and behavioral outcomes. Eisenberg, Zhou, Liew, Champion, and Pidada (2006) found that high levels of self-control were associated with adjustment in social relationships and other domains in Chinese, French, and Indonesian children. Researchers have also found robust links between low self-control and externalizing behaviors among children in North American and other societies (e.g., Olson et al., 2005). Zhou, Lengua, and Wang (2009) reported that low control and high anger-irritability were associated with high externalizing problems in both American and Chinese children, although the associations were stronger in the Chinese children. As argued by Eisenberg et al. (2006), cross-cultural similarities in self-control and adjustment may be due to the fact that control involves the executive system, which is likely to have similar functions for most children in any culture. Moreover, there are situations in most societies (e.g., completing tasks in the home and school) in which children are expected to modulate (e.g., suppress or strengthen) their behaviors, and children's self-control abilities are necessary for the achievement of individual and group goals.

Nevertheless, children's self-control is associated with different developmental outcomes across cultures in some socioemotional domains. Research findings concerning relations between self-control and internalizing problems in American children have been generally mixed. Whereas some studies found virtually no associations between self-control and internalizing problems, other studies revealed that self-control was positively associated with internalizing problems (e.g., K. T. Murray & Kochanska, 2002). Unlike the results based on American children, Eisenberg et al. (2007) found, based on teacher and parent reports, that behavioral control was negatively associated with fearfulness and anxiety in Chinese school-age children. Similarly, Chen, Zhang, et al. (2012) found in China that self-control as assessed by performance on delay tasks at 2 years positively predicted perceived self-worth and negatively predicted self-reported loneliness and depression at 11 years. Apparently, self-control abilities help children display compliant and cooperative behaviors, which are highly valued in the Chinese society. In this context, social approval and support that well-controlled children acquire may enhance positive self-perceptions and

impede the development of negative self-feelings. Children who are poor in self-control may experience great pressure and stress, which in turn may contribute to maladaptive development.

Consistent with the results of Eisenberg et al. (2007) and Chen, Zhang et al. (2012), Cheung and Park (2010) found that anger suppression was positively and more strongly associated with depression in European Americans than in Asian Americans. Moreover, an interdependent self-construal reduced the magnitude of association between anger suppression and depressive symptoms. Cheung and Park (2010) argued that emotional control or suppression mainly served a self-protective function for individuals holding Western values but helped to achieve social engagement and prosocial goals for individuals who hold more Asian values.

Summary

Research has revealed substantial cross-cultural differences in the display and developmental significance of temperament and personality characteristics such as reactivity to challenging situations and self-control among children and adolescents. Culture plays a central role in organizing the development of temperament and personality by facilitating or constraining the exhibition of specific characteristics, by regulating their developmental processes, and by moderating their relations with adjustment outcomes. Thus, research findings based on children and adolescents in particular societies such as European American societies cannot be assumed to be universal without considering distinct cultural circumstances that may affect the meaning and development of the relevant characteristics.

A major task is to understand how cultural beliefs and values are involved in temperament and personality development. Traditional approaches that rely on Western-based theoretical models and focus on comparing mean scores of self-report measures among youth and adults in different cultures without considering the social contexts are likely to provide limited information about the processes by which culture affects temperament and personality.

Developmental researchers have started to explore in different societies how socialization practices and social interactions are related to aspects or dimensions of child temperament. The results suggest that cultural norms and values guide social evaluations and responses in interactions, which in turn regulate the display and development of individual characteristics. These results have shed some

light on the social processes bridging culture and temperament and personality development. Nevertheless, the role of social processes in mediating cultural influences has not received adequate consideration in research, especially outside East Asia and North America. It will be important to examine how cultural norms and values are involved in social processes in adult-child and peer interactions and how social processes regulate individual development in other societies.

THE PERSON IN CONTEXT: CONCLUSIONS, IMPLICATIONS, AND FUTURE DIRECTIONS

The study of temperament and personality waxed and waned from the 1920s in North America and Europe, with learning theory and the cognitive revolution achieving prominence in psychology for most of the period. Although the zeitgeist began to shift in the 1960s with the work of Thomas and Chess, the systematic investigation of child temperament has grown substantially only after Buss and Plomin, Kagan, Rothbart, and other researchers developed their conceptual frameworks in the early 1980s. Nevertheless, research on children's and adolescents' temperament and personality in the past several decades has led to a comprehensive understanding of human dispositions.

As indicated by research findings, infants differ considerably on basic dimensions of temperament such as reactivity and regulation, and individual tendencies on these dimensions become increasingly discernible and stable within the first several years. The dimensions or aspects of temperament also become more coherently organized with age, which allows for identification of children with distinct temperamental profiles. The development of temperament and personality involves major biological systems, including the frontal brain networks, the autonomic nervous system, and the neuroendocrine system. Child characteristics such as irritability/anger, inhibition/fear, and regulatory behavior in the early years may independently or interactively predict later personality and adjustment outcomes. However, the development of temperament and personality and their contributions to adjustment are constrained by experiences and socialization factors. Parenting practices, peer relationships, and other rearing conditions may interact with temperament and personality during development, and they jointly determine adjustment outcomes. Finally, cultural norms and values direct social evaluations and responses in interactions, which in turn attribute meanings to individual

characteristics and, at the same time, regulate the display and development of the characteristics.

Research on temperament and personality has many noticeable implications for education and applied work. For example, individual differences in dispositional tendencies to react to life experiences and self-regulatory abilities suggest that some children are inevitably more vulnerable than others to the development of psychopathological symptoms (Strelau, 1998; Rothbart & Bates, 2006). Researchers have consistently found that reactivity to stressful situations and neuroticism predict internalizing problems such as anxiety and depression and that irritability and behavioral undercontrol predict externalizing problems such as aggression and antisocial behaviors in Western and some other societies (e.g., Asendorpf et al., 2008; Caspi et al., 2003). Detecting temperament and personality tendencies in childhood that represent risk for maladaptive development is an important first step for prevention and intervention.

Findings concerning temperament \times environment interactions, however, indicate that whether children possessing a "risk" disposition eventually develop problems depends on their socialization experiences and other environmental conditions. Highly reactive children may be susceptible to stress in undesirable conditions, leading to maladaptive behavior, but become adaptive in desirable conditions. Thus, it is critical to provide a supportive environment, particularly positive social relationships in the family, school, and community, for children who show high reactivity. It may also be a useful strategy to help these children develop self-regulatory skills to handle their negative emotions such as fear and frustration in challenging situations. Moreover, as suggested by the contextual-developmental perspective, social interaction processes are involved in maintaining and modifying the development of temperament and personality characteristics. Thus, parents, educators, and professionals should consider social interaction context such as the peer group in designing programs for children who are at risk for maladaptive development. In addition, because adaptive and maladaptive characteristics are determined, in part, by cultural norms and values, researchers and professionals need to be sensitive to the cultural interpretations of temperamental and personality characteristics of children from different backgrounds when making assessments and judgments. It is important to take into consideration how specific characteristics are perceived and evaluated in the society or community in order to develop culturally effective and appropriate prevention and intervention programs.

We conclude this chapter with several suggestions for future exploration, based on our review and discussion of the theoretical and empirical work in the field. First, one of the major issues that theorists and researchers have been exploring over the past century concerns the structures of temperament and personality in childhood and adulthood. The identification of dimensions or components of temperament and personality often relies on theoretical considerations and the factor analysis of self-report and observational data. To obtain a more complete understanding of temperament and personality structures as well as of their connections, researchers should examine relevant characteristics from a developmental perspective. As indicated earlier, findings about the similar and different developmental origins, patterns, and outcomes associated with children's and adolescents' characteristics will help us understand the underlying constructs and their general and domain-specific nature at a higher level.

Second, a related issue is the lack of adequate efforts to explore developmental processes. For example, researchers have conducted a number of studies concerning relations between early temperamental characteristics (e.g., behavioral inhibition and effortful control) and adjustment outcomes (e.g., anxiety and delinquency). However, it is unclear how temperamental characteristics contribute to the development of adjustment and maladjustment. The contributions inevitably occur in social contexts with multiple factors exerting mediating and moderating effects. According to the cascade model (e.g., Masten & Cicchetti, 2010), for example, the influence of early temperament may spread to various domains of individual functioning progressively over time. The progressive dynamic cascade process may be reflected in both direct and indirect or mediated effects of temperament on adjustment. Moreover, the process may be domain-specific and developmentally variant. Analyses of cascading and other transactional processes in the relations among various temperament characteristics, contexts, and adjustment outcomes across different developmental periods will likely help us achieve an in-depth understanding of the issues in the area.

Third, given the strengths and weaknesses of each of the major methods used to assess temperament and personality (e.g., self-reports, observations, and physiological measures), a multimethod approach is obviously ideal if relatively accurate information is to be obtained. Perhaps due to practical difficulties, this approach has not been common. This is particularly the case in personality research, which relies heavily on self-reports. With technological and methodological advances in conducting observational and

physiological assessments, researchers should combine different methods, and this may help clarify confusions and inconsistencies in the literature.

Fourth, the past several decades have witnessed an exponential increase in the use of biological measures to understand complex human behavior and traits, which has led to important new insights and discoveries. However, a cautionary note is warranted. A common perception is that the use of biological measures somehow makes the science more rigorous and legitimate, and with this perception comes the tendency to collect data on phenomena in the absence of good theory and research questions. Biological methods and measures help researchers to explore processes underlying complex behavior, but the data are likely sterile without theoretically driven questions.

Fifth, there needs to be a broader conceptualization of the environment in the study of temperament and personality development. Much of the work highlighted in this chapter, and on human development in general, defines the environment in terms of influences residing outside of the individual (e.g., peers, parents, communities). Researchers need to consider endogenous environmental influences that affect gene expression and their interaction with other biological factors in shaping brain-behavior relations in development (e.g., physiology, electrochemical states, neural dynamics; see Fortier et al., 2014; Schmidt et al., 2009; Schmidt & Miskovic, 2013). Findings from other disciplines studying biological phenomena have indicated that the consideration of these proximal internal influences may help develop more complete models of human temperament and personality.

Sixth, in this chapter, we have focused mainly on reactivity and regulation in the discussion of the development of temperament and personality. Relative to these two fundamental dimensions, other important dimensions or aspects, such as surgency/agreeableness, empathy, activity, and openness to experience, have been studied less systematically, especially in longitudinal projects. As a result, little is known about their developmental origins, processes, and outcomes, or about factors that affect their development. Researchers should pay more attention to these dimensions or aspects in the future.

Seventh, researchers have proposed a number of models from different perspectives about the influences of parents and peers on temperament and personality and about interactions between socialization forces and child characteristics in predicting developmental outcomes. Mixed results have often been reported. Moreover, because most of the studies are correlational and cross-sectional

with insufficient control for confounding factors, it may be difficult to discern causal directions of influence. Longitudinal, experimental or quasi-experimental, and interventional studies are needed to clarify the associations and to provide information that helps better understand the models.

Eighth, researchers who study cultural influences on human development are often interested in comparing children in Western self-oriented societies with those in other more group-oriented societies. The framework focusing on broad categories has been criticized for its inadequacy in describing the complex cultural systems, the substantial within-culture heterogeneity, and differences between cultures that are assumed to be extreme. Moreover, extensive and intensive cultural interactions due to international migration and communication across nations over the past decades have resulted in the coexistence and integration of different values. It will be important to investigate how children with different temperamental and personality characteristics adjust to diverse and integrated cultural environments. It will also be interesting to examine whether these environments provide opportunities for children to develop sophisticated qualities that allow them to function effectively in different circumstances.

Finally, it has been argued that children play an increasingly active role in development with age through participating in socialization and constructing the environment for their activities (e.g., Chen, 2012; Corsaro & Nelson, 2003). This argument is consistent with the findings concerning the mutual influences of child characteristics and parenting and the moderating effects of self-regulation on relations between reactivity and adjustment. In general, however, the active role of children has been largely neglected in the conceptualization and study of temperament and personality. Therefore, it is crucial to engage in continuous exploration of this issue in order to achieve a more thorough understanding of the person in context.

Relationships and regulation. Throughout the history of developmental science, these terms have been in frequent juxtaposition. Classic developmental theories have underscored the regulatory influence of parent–child relationships, for example, in the context of socialization. Viewed from different theoretical perspectives, relational regulation arises from the security experienced by the infant, the child’s identification with the parent, the parent’s use of rewards and sanctions, the influence of discipline strategies, and many other processes. The purpose of the parent’s regulatory influence is to help organize and guide developing behavioral systems, but with the expectation that it will be progressively replaced by the child’s growing competence at self-regulation according to individual needs, family values, and cultural practices. Other relationships, such as with peers and teachers, also have regulatory influence, but parent–child relationships have received preeminent attention because of their early, enduring, and wide-ranging influence.

Over the years, this general model has been criticized in several ways. Culturally oriented developmental scientists, many working from a neo-Vygotskian perspective, have noted that socialization processes and goals vary

according to the developmental outcomes valued by the culture (e.g., Rogoff, 1991). Bell’s (1968) famous critique of the unidirectional socialization model was one of the earliest arguments for the importance of understanding child effects on parents. A more trenchant critique from developmental behavioral genetics claimed that most alleged parenting effects were actually derived from the shared genetic characteristics of family members, leading some to argue that peer, not parental, relationships are the more significant developmental influence (e.g., J. R. Harris, 1998). These critiques have altered developmental theory and productively broadened empirical inquiry into parent–child relationships even as this topic remains one of the most vigorous in developmental research.

The task of this chapter is to provide a perspective on early parent–child relationships and the development of self-regulation. This is a different goal from the previous edition of this *Handbook*, in which my chapter focused on early developing social understanding, parent–child attachments, the growth of conscience and self-awareness in considering the “development of the person” (Thompson, 2006). These topics remain important, and themes from these research literatures can be found

in the discussion that follows. But in the context of other excellent reviews of the research literature on parent–child relationships and socialization (see especially Grusec & Hastings, *in press*), a comprehensive review of research in this area is not really needed (or possible, given the length of this chapter). Rather, the goal is to do something new by focusing primarily on two research literatures that have grown significantly since the previous edition of this *Handbook*. These research fields present new opportunities for understanding the nature of parent–child relationships and their influence on the development of self-regulation.

The first concerns the biological consequences of the quality of parental care. Beginning with the expanding literature in developmental neuroscience, researchers have broadened their attention to the influence of early experience on other developing biological systems, including stress neurobiology, immune system functioning, and gene expression. Because the most relevant aspect of early experience is the quality of parental care, these research literatures together underscore the significance of parent–child relationships for the organization of biological systems that affect reactivity and self-regulation. These experiential influences begin prenatally, have potential multigenerational consequences, and have important implications for intervention and for classic developmental issues such as our understanding of nature and nurture.

The second concerns the representational consequences of parent–child relationships. Building on the rich work on theory of mind, researchers have been examining its foundations in the social representations of infants and toddlers. Their findings are drawing attention to the importance of young children’s first-hand interactions with social partners from which they construct understandings of goal-oriented agency, shared intentionality, helpful and harmful actions, and other early social-cognitive achievements relevant to developing theory of mind. These generic representations of human behavior develop at the same time that young children are also constructing representations of the specific propensities of their attachment figures, and together contribute to developing capacities for cooperation and prosocial conduct, an emergent premoral sense, and other constituents of self-regulation. These relational influences on developing social representation begin early, have implications for intervention, and address classic developmental issues related to the construction of core knowledge in the social domain.

An expanding understanding of relational influences on developing biology and representation complements but significantly extends traditional understanding of

socialization processes in the parent–child relationship. It provides an opportunity, for example, to reconceptualize the characteristics of parental care that have consequences for young children by including biological and representational outcomes as well as behavior. It encourages developmentalists to explore in greater depth how parental practices affect not only behavioral development but also its representational correlates and, for some children, its biological correlates as well. For children in poverty, for instance, it requires inquiring into how heightened stress reactivity deriving from early economic insecurity affects developing representations of the social world. And for the study of developing self-regulation, it suggests that studying the association of relationships and regulation must be conducted in a multilevel manner involving transactional influences between developing behavior, representation, and biological functioning. This is important because research in this area also highlights the contributions of the child to developing self-regulation, both in the powerful capacities for learning from social experience and in the influence of developing temperamental individuality. For this reason, a developmental systems perspective is well-suited to exploring these multilevel interactions. The final section of this chapter draws these ideas together as they are applied to an understanding of the early development of emotion regulation in children.

Before proceeding further, however, it is important to establish a general framework of thinking about the nature of early parent–child relationships and their developmental influence. The relationships between parents and their young children constitute one of the most enduring and iconic research topics in developmental science, occupying a central place in virtually every theory of social and personality development. Infants and young children live in a social world, but they develop in an environment of relationships that has singular importance. Central are their relationships with parents.

A relationship can be characterized as an integrated network of enduring emotional ties, mental representations, and behaviors that psychologically connect one person to another over time and across space. A young child’s interactions with relational partners are distinct from interactions with other social partners in several ways. First, they are ubiquitous in early experience, enabling repeated shared experiences that compound the developmental influences of relational partners. This is one reason that relational partners afford security, buffer stress, or generate expectations in a manner that other social figures do not. Second, extensive shared experience enables familiarity.

It is the experience of knowing and being known by another person that contributes to central socioemotional achievements of the early years because familiarity facilitates the kind of statistical learning by which first-person experience generates an understanding of people's behavior, intentions, feelings, and other mental states. Third, relational interactions are mutual and reciprocal and involve continuous coaction over time between partners that enables interactions to be fine-tuned to the individual characteristics of the child. Importantly, relationships are characterized both by interactive synchrony (involving collaborative goals, joint attention, mutual imitation, and responsiveness) and dyssynchrony (entailing divergent intentions, expectations, and other mental states), and both provoke early social and personality growth. Finally, relationships are infused with emotion that influence young children's appraisals, motivate their social engagement, influence their own emotions and other mental states, and contribute to their self-regulation. Indeed, relationships become affectively colored as sources of assurance, protection, stress, or threat that constitute, in a sense, the prior probabilities that are generalized to other social partners, and by which relationships themselves acquire regulatory influence.

Relational experience begins early as infants recognize and develop expectations for familiar people (although some would argue that fetal experience prepares infants for this), and becomes increasingly mutual and bidirectional with the growth of social skills and mental representations. Traditionally, researchers have emphasized parental characteristics as the primary influences on relational quality. The most notable example is the emphasis of attachment researchers on parental sensitivity as a key determinant of attachment security, with sensitivity viewed as a characteristic that accommodates to differences in infant temperament and other attributes. In a similar vein, researchers have focused on parental warmth, emotional communication, contingent responsiveness—and at older ages, coaching and rational discipline methods—as definitive of relational quality (see Laible, Thompson, & Froimson, in press). This general focus on parental attributes is based, in part, on the view that a young child's confidence in parental solicitude is a central foundation for healthy socioemotional development, and that parental investment in the child's well-being, which is biologically mandated for early survival, is manifested in these attributes of parental care.

However, a number of alternative formulations have emerged. Kochanska (2002; Kochanska, Aksan, Prisco, & Adams, 2008) is one of several developmentalists who

characterize early parent-child relationships dyadically, such as by assessing their "mutually responsive orientation" on the basis of their joint cooperation, harmonious communication, coordinated routines, and emotional ambiance. A mutually responsive orientation contributes, in her view, to the child's self-motivated compliance and adoption of the parent's values and expectations. Another interactionist perspective draws from self-determination theory and emphasizes the young child's need for autonomy, or the need to take initiative and to be self-directed. From this perspective, Grodnick and Pomerantz (2009) have distinguished parental control that is autonomy supportive—which they call "structure"—from "control" that is intrusive or coercive. A different dyadic approach is to examine episodes of parent-child conflict as critical forums for socialization. Viewing conflict episodes as important opportunities for understanding conflicting desires and goals, for example, Laible and Thompson (2002) reported that the ways in which disputes between mothers and their 2½-year-olds were discussed and resolved predicted critical aspects of children's socioemotional development at the age of 3.

Besides their greater attention to the mutual influences of mothers and children, perspectives such as these also share a broadened view of what early parent-child relationships are meant to provide for young children. Confidence in parental solicitude is certainly important, but may not be all. The most detailed articulation of this view is Grusec and Davidov's (2010) domain perspective on parent-child relationships. In this view, parental practices are best understood as functioning within multiple interconnected socialization domains, each incorporated into parent-child relationships by the time a child is the age of 2. The domains are *protection* (which promotes child coping, empathy, and cooperation), *mutual reciprocity* (fostering children's receptive compliance), *control* (promoting internalized moral conduct and respect for authority), *guided learning* (encouraging knowledge and skill acquisition), and *group participation* (fostering children's conformity to group expectations and ingroup-outgroup differentiation). Grusec and Davidov argue that such an analysis sharpens understanding of parental influences by recognizing that certain parental practices have domain-specific influence and that some practices (such as sensitivity) serve different functions as they are manifested in contexts relevant to different domains (see, e.g., Leerkes, Weaver, & O'Brien, 2012).

Grusec and Davidov argue that children are biologically prepared to acquire skills relevant to each domain

because of the importance of each domain to social functioning (see also Bugental, 2000). Thus they claim that these domains are universal, although they may be differentially emphasized in different cultural systems that require different constellations of skills and knowledge. Such a view articulates a basic dynamic in the study of early parent–child relationships between recognizing the biologically adaptive processes that have fostered our species’ reproductive success and the diversity of cultural practices relevant to early care. Infants require protection, nurturance, positive social interaction, instruction, and other species-typical requirements in order to survive and develop into competent persons suited to group living. Yet there is considerable cultural diversity in how infants and young children receive care, including the extent of holding, touching, and proximity to one or many caregivers; cosleeping and breastfeeding practices; promptness of response to infant crying; biological parenting or alloparenting; and manner of teaching (see, e.g., Hewlett, 1996; Hewlett & Lamb, 2005; Keller, 2007). These alternative cultural practices are adapted to the biological, ecological, and historical conditions in which they function yet they must also address the species-typical requirements of early care. The crucial and interesting question for developmental analysis is, how do alternative cultural practices affect the nature and timing of core achievements in behavioral development and also in biological self-regulation and representational growth? This chapter addresses this question where limited data permit reasonable inferences concerning the developmental processes discussed. The data required for evaluating claims of universal socialization domains or species-typical conceptual accomplishments are complex, however, involving theoretically guided, culturally comparative research (and, in some cases, studies of early care of other primates), and thus constitutes an important research agenda for the field.

There is another manner in which questions about how the social and relational context addresses early developmental needs are considered, and this is with respect to young children living in conditions of psychosocial risk. With child poverty rates rising significantly during the Great Recession beginning in 2008 and, as of this writing, more than 1 in 5 of the youngest children in the United States living in families in poverty (along with many children worldwide), researchers have been especially interested in the developmental consequences of early poverty. On this issue, as well, a broadened view of parenting to include biological and representational influences is valuable. In the next section, for example, the multiple

levels of biological systems affected by family conditions associated with poverty is discussed, along with how positive relational influences can buffer some of these stressors. These findings help to extend other literatures addressing the multilevel consequences of psychosocial risk factors, and also have implications for early intervention.

The longstanding interest of developmental scholars in parent–child relationships and their regulatory influence has broadened considerably, therefore, to encompass the mutual influences of parents and offspring, the diverse contexts in which they interact, the diverse developmental outcomes (beyond security) that relationships influence, and the multifaceted characteristics of parenting practices that contribute to these outcomes. This chapter underscores the advances that derive from considering parental influences not only for their behavioral outcomes, but also affecting the organization of developing biological processes and representational capacities relevant to self-regulation.

In the next section, research on fetal programming, developing stress neurobiology, gene–environment interaction, and epigenetics is profiled to understand the nature of relational influences on developing biological systems that shape emergent reactivity and self-regulation. In the section that follows, relational influences on developing representations of the social world—both the generic characteristics of people and the specific attributes of their attachment figures—are profiled to understand further the catalysts to developing self-regulation through early understandings of human agency, cooperation, helping and hurting interactions, and the emergence of a premoral sensibility. In the fourth section, these relational perspectives on developing self-regulation are reintegrated in a discussion of the growth of early emotion regulation. A final concluding section identifies themes for future research.

BIOLOGY

From ancient Platonic beliefs and Confucian thought through Enlightenment philosophy to the present, the tension between nature and nurture has defined Western and Eastern thinking about human behavior. This tension was later incorporated into psychological thinking, especially research on human development. In the early 20th century, for example, the debate between Watson’s environmentalism and Gesell’s maturationism helped to define nature versus nurture as a central developmental theme. The view that developmental outcomes should be attributed either to the child’s intrinsic tendencies or to

social (especially parental) influences set up a dichotomy in thinking about human origins that endured, despite the efforts of each generation of developmentalists to argue that such a dichotomy was unnecessary and misleading.

The nature versus nurture debate has been a particular problem in thinking about parent–child relationships. Developmentalists inherited from their philosophical forebears ideas about the importance of early nurturance, education, and social opportunity, and these ideas were incorporated into psychological theories that (with few exceptions) devoted little attention to biological influences. Later, developmental behavioral geneticists moved to the opposite extreme, arguing that parental nurturance is primarily a setting for the unfolding of the child’s genetic individuality, and using heritability estimates as quantitative indicators of the proportion of phenotypic variance attributable to nature and nurture. As much as developmental scholars have argued that the nature–nurture distinction is scientifically misleading, they have persisted in reinstating it.

Throughout this period, to be sure, researchers and theorists were proposing more complex and interesting portrayals of the interaction of biology and experience. From the primatology literature (see Clancy, Hinde, & Rutherford, 2013, for a review), elegant experimental studies of gene \times environment interaction and the experiential canalization of biological and behavioral phenotypes have equipped human developmentalists with provocative models of these processes. Evolutionary/ecological systems theory has also offered developmentalists theoretical portrayals of the biologically adaptive processes that influence human growth and that function in concert with environmental experience.

Some of the strongest evidence for complex portrayals of the interaction of biology and experience has come from research on human brain development. When the National Academy of Sciences committee that wrote *From Neurons to Neighborhoods* (National Research Council and Institute of Medicine, 2000) concluded that the debate over nature versus nurture was “overly simplistic and scientifically obsolete” (p. 6), they devoted considerable attention to the interaction of experience with maturation in the developing brain to show how this was true. As is now well known, neurobiological development is a function of experience-expectant and experience-dependent processes that incorporate environmental exposure into structural and functional capacities of the developing brain. This has been shown most clearly in cases of experiential deprivation or adversity, and implicates the quality of parental care as an

essential, multidimensional component of the experiences that the brain biologically “expects” as part of its normative growth.

Other ways of portraying the complex interaction of biology and experience have emerged from allied fields of developmental study. Taken together, they offer the genuine prospect of a sustained confirmation of the conclusion of the authors of *From Neurons to Neighborhoods*. Equally important, they are leading scientists to a new understanding of behavioral and biological development in which distinctions between “nature” and “nurture” are obscured in favor of a more biologically dynamic, experientially based understanding of human growth. Besides the work in developmental neuroscience, these research literatures focus on the influence of the prenatal environment on the developmental “programming” of biological and behavioral functioning, the experiential shaping of stress neurobiology and behavior, new work on molecular gene \times environment interaction, and the emergence of epigenetic models of behavioral development. Together, they show how early experience “gets under the skin” to influence behavior through its effects on multiple biological systems.

The purpose of this section is not to provide a comprehensive review of these important advances (which are discussed more fully in other chapters of this *Handbook*), but rather to highlight the ideas they introduce and, in particular, how they are changing understanding of the nature of parenting and of the influence of parent–child relationships on the development of self-regulation. Why do these research literatures have implications for parent–child relationships? Stated simply, the quality of parental care is the most important element of the functional environment that influences gene expression, fetal programming, and developing stress neurobiology, and differences in the quality of care are operationally what is most often measured in studies of experiential influences on developmental neurobiology and gene \times environment interaction. As a result, these studies underscore that the quality of parental care (and, by extension, the quality of parent–child relationships) has biological as well as behavioral consequences, that these influences begin very early in development, and that they potentially have multigenerational consequences that are psychobiological in nature. Contrary to the view that parenting is merely the setting in which biologically based characteristics of offspring emerge, it now appears that neglect of the significance of parenting processes as fundamental influences on developing biological systems may lead to an underestimation of their importance. Beyond this, because they also address the

development of stress responding and regulation, emotional arousal and coping, social buffering of stress reactivity, and the experiential moderation of biological regulatory systems, these studies have important implications for thinking about the early biological foundations for developing self-regulation. It is not possible at present to identify the new theoretical model(s) that will emerge from these advances in understanding human development, but it is possible to begin to outline how they are changing our understanding of the developmental impact of early parenting and relationships, and their implications for the development of self-regulation.

Fetal “Programming”

During World War II, the German military occupying the Netherlands imposed a blockade of food transports in reprisal for a strike on the Dutch railways in support of the Allied invasion. As a result, official rations for the adult population fell abruptly to 400 to 800 calories daily from December 1944 to April 1945, when the Allied liberation of the Netherlands began to succeed and nutritional adequacy was quickly restored. These tragic circumstances created a unique opportunity for researchers to subsequently examine the effects of a specific period of maternal malnutrition and subsequent nutritional adequacy on immediate and long-term developmental outcomes for offspring. Although malnutrition was accompanied by maternal stress and other hardships (the winter was unusually severe), scientists could examine its effects during a time-delimited period with a sample that had been previously well-nourished, who had received adequate medical care, and who were quickly restored to adequate nutritional status. The children born to the cohort of women who were pregnant during the Dutch famine have been followed into late adulthood. The findings from this large research literature indicate that although many of the immediate effects of maternal malnutrition on newborns (such as birth weight) were not strongly predictive of later outcomes, there were important latent effects of time-delimited nutritional inadequacy. In adulthood these children exhibited significantly heightened risk for a variety of health and mental health problems, including adult obesity, heart disease, and schizophrenic disorders, compared with children of different gestational age or same-sex sibling controls (see Lumey et al., 2007, for a review).

These findings are consistent with other studies in a variety of fields that have also documented long-term associations between prenatal risks and poorer adult health

and well-being using normative datasets, research on early deprivation, and experimental studies with animals (see reviews by Almond & Currie, 2011; Hodgson & Coe, 2006). Viewed in the context of research on the enduring developmental effects of maternal smoking, fetal alcohol exposure, environmental pollutants, and other teratogens, they point to the prenatal period as especially sensitive to environmental challenges, particularly those associated with the quality of nutrition, stress, and other aspects of maternal care. These hazards have been found to pose risks to healthy development because of their threats to placental functioning, CNS integrity, and fetal organ system development during critical stages of prenatal growth (Barker, Eriksson, Forsén, & Osmond, 2002).

An important mediator between fetal adversity and later health and well-being is maternal stress. There is considerable evidence in the animal literature, including experimental studies, showing that significant prenatal maternal stress predicts later deficits in stress regulation and emotional and cognitive functioning in offspring (Weinstock, 2008). Demonstrating such associations in humans is challenging, however: The gestational timing of stress, its intensity and duration, and careful measurement of stress and its hypothesized developmental outcomes complicate nonexperimental human research on this issue (DiPietro, 2012).

Nevertheless, a clearer but complex picture of the consequences of fetal stress exposure is beginning to emerge. Elevated and extended prenatal exposure to maternal cortisol is associated with a larger neonatal cortisol response and slower recovery (E. P. Davis, Glynn, Waffarn, & Sandman, 2011). But gestational timing and stress severity are important in predicting longer-term effects. Davis and Sandman (2010) reported, for example, that elevated exposure to maternal cortisol *early* in gestation was associated with a slower growth rate and lower mental development scores on the Bayley Scales at 12 months, but elevated cortisol exposure *late* in gestation was associated with accelerated cognitive growth and higher scores at 12 months. Similarly, DiPietro, Novak, Costigan, Atella, and Reusing (2006) found that maternal reports of moderate anxiety and stress mid-pregnancy were positively associated with postnatal Bayley mental and physical development scores, even with control for postnatal maternal anxiety and stress. At 7 years, maternal cortisol early in gestation was associated with higher maternal-report Child Behavior Checklist (CBCL) scores reflecting affective difficulties, and this association was mediated by larger right amygdala volume in girls (Buss et al., 2012). These associations with prenatal stress exposure are modest, but they

have been found for a variety of developmental outcomes extending to middle childhood, and are consistent with the view that heightened stress exposure, especially early in gestation, may influence the development and functioning of several developing biological systems, including the hypothalamic-pituitary-adrenocortical (HPA) axis (see, e.g., Oberlander et al., 2008).

Taken together, the findings concerning the effects of maternal stress, malnutrition, and other aspects of fetal adversity on long-term developmental outcomes underscore the sensitivity of prenatal development to environmental challenge. To some, they also reflect biologically adaptive processes. According to the *predictive adaptive response model*, these prenatal conditions allow early detection of characteristics of the environment after birth to which developing organisms must adapt (Gluckman & Hanson, 2005). Viewed in this light, for example, heightened maternal prenatal stress signals postnatal environmental adversity for which upregulation of the developing HPA axis may prepare human young for these conditions after birth (Sandman, Davis, & Glynn, 2012). Likewise, fetal malnutrition causes changes in energy metabolism and growth rate that potentially have long-term benefits for living in an environment of food scarcity. Biological and behavioral adaptations like these can render the child better capable of coping with these environmental conditions and enhance chances of long-term survival if those conditions endure. If they do not, however, then deleterious developmental outcomes may ensue. In the case of the survivors of the Dutch famine whose prenatal experience prepared them for a life of food scarcity, for example, growing up instead in conditions of plenty for which they were biologically unprepared may have contributed to their later health and mental health outcomes (e.g., adult metabolic disorder).

These studies indicate that biological and behavioral self-regulation begins to take shape prenatally in response to the conditions affecting fetal development, and that individual differences in self-regulatory processes can be influenced by prenatal exposures. The prenatal stress literature, in particular, suggests that differences in early temperament, stress-related coping, and other characteristics have origins in maternal stressors as they are mediated by prenatal cortisol exposure (e.g., DiPietro, Ghera, & Costigan, 2008). Early developing emotionality and self-regulation at birth, therefore, already reflect an experiential history based on the characteristics of prenatal care, and these characteristics may be associated with broader external conditions like family income and poverty.

Experiential Guidance of Developing Stress Neurobiology

The view that early adversity and environmental exposures calibrate developing biological systems extends beyond the prenatal period to characterize considerable research on the effects of early life experience. This is because developing biological systems mature slowly during the postnatal period, rendering them vulnerable to stress and challenge, and experiences during this time may also provide significant guidance concerning the life conditions to which these systems must adapt to promote long-term survival. Whereas research on fetal programming focuses on intrauterine exposure to maternal stress hormones, research on the experiential shaping of stress neurobiology emphasizes the child's direct experience of stressful circumstances. And whereas the research on fetal programming highlights the quality of maternal care as the primary mediator of fetal adversity, the work on developing stress neurobiology underscores parental care as a stressor or stress buffer.

Much of the research in this area has focused on the development of the HPA axis, one of several stress-relevant neurobiological systems that develop significantly during the initial postnatal years (Loman & Gunnar, 2010; see also Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume). The HPA response matures over an extended period in the early years, with the emergence of an adult-like circadian rhythm not apparent until after the pubertal transition (Wiik & Gunnar, 2009). During this period, experience has considerable influence on the development of HPA responsivity, which is most apparent in studies of the impact of severe, chronic stress on the functioning of the HPA system, and in research on the social buffering of stress reactivity.

In ordinary circumstances, the brain's detection of threat-related stimuli provokes acute activation of the HPA axis, which has many consequences including the production of cortisol that contributes to the mobilization of energy, suppression of immune functioning, enhanced cardiovascular tone, and other critical components of the stress response. In addition, basal levels of HPA functioning, following a circadian clock, are important to ongoing cortisol output that helps to maintain self-regulation and coping capacities. Chronic stress, however, alters HPA functioning over time by altering the neurocircuitry underlying the regulation of stress responsiveness. This occurs as repeated exposure to stressors changes the sensitivity of the HPA system, in part through its effects on the limbic

and cortical regulators of HPA activity (Ulrich-Lai & Herman, 2009). These biological changes have behavioral consequences.

In some cases, the organism becomes *hyperreactive* to stress owing to the effects of repeated shocks to the stress system, such as in prior experiences of physical abuse or threat. Higher basal cortisol levels have been found, for example, in maltreated children exhibiting internalizing symptomatology compared with nonmaltreated children (Cicchetti & Rogosch, 2001), in infants and toddlers in poverty (Blair et al., 2008; Blair et al., 2011), and in young children of chronically depressed mothers (Essex, Klein, Cho, & Kalin, 2002). In other cases, prior exposure to stress results in the organism's *hyporesponsiveness* to stress owing, it appears, to the deprivation or withdrawal of social support. Diminished cortisol levels have been found, for example, in young children who have lived in deprived institutional care (Carlson & Earls, 1997), neglected children placed in foster care (Dozier, Manni, et al., 2006), and young children living in homes characterized by domestic violence and/or maternal emotional unavailability (Sturge-Apple, Davies, Cicchetti, & Manning, 2012).

This delineation of hyperreactive and hyporeactive response profiles remains provisional because there is considerable variability in the patterns of HPA reactivity and regulation identified in studies of children and adults experiencing chronic stress (Gunnar & Vazquez, 2006; G. E. Miller, Chen, & Zhou, 2007). For children in foster care, for example, basal cortisol levels vary depending on whether children had primarily experienced physical neglect (low basal levels) or emotional maltreatment (high basal levels) (Bruce, Fisher, Pears, & Levine, 2009). Similarly, Essex and her colleagues report that patterns of hypercortisolism and hypocortisolism were each apparent in their sample depending on the nature, duration, and severity of early life stress (Essex et al., 2011). The important conclusion, however, is that significant deviations from developmentally normative patterns of stress responding result from chronic early stress exposure, and may be risk factors for long-term biological and behavioral functioning. Moreover, contrary to prevalent concepts of "toxic stress," dysregulated stress functioning in children may arise not only from chronic threat but also from the deprivation of nurturant care.

These risk factors arise, in part, because of the effects of persistent HPA activity on other biological systems (Bruce, Gunnar, Pears, & Fisher, 2013). Chronic cortisol output alters the functioning of cortical and limbic regulators of HPA functioning (e.g., hippocampus, hypothalamus,

amygdala, medial prefrontal cortex) and, through these, contribute to some of the behavioral correlates of persistent stress including heightened vigilance, self-regulatory deficits, and learning and memory problems (Ulrich-Lai & Herman, 2009). Stress is associated with acute increases in autonomic nervous system activity, including elevated blood pressure and other sequelae (El-Sheikh & Erath, 2011). Chronic stress also alters immune system functioning by increasing sensitivity to infectious challenges, increasing cytokine response, and embedding "proinflammatory tendencies" into biological responding in other ways (G. E. Miller, Chen, & Parker, 2011). Taken together, these attributes of chronic stress are consistent with the portrayal of "allostatic load," an index of the progressive "wear and tear" on biological systems attributable to the long-term effects of chronic stress activation (Danese & McEwen, 2012).

The predictive adaptive response model would regard some of these biological and behavioral responses as adaptations to promote survival in an aversive environment. For young children who are maltreated, for example, biological reactions that foster rapid responding to perceptions of threat, allocation of attentional and cognitive resources to threat vigilance, and altered immune response render children better prepared to cope with a home environment that may persistently pose unexpected, severe dangers (Pollak, 2012). But these behavioral adaptations are poorly suited to social environments outside the home, such as school and peer settings. When considered together with the biological costs of chronic neuroendocrine, nervous system, and immunological activation, it is more appropriate to view these adaptations as double-edged swords that purchase immediate coping advantages at the cost of longer-term health and mental health (Blair & Raver, 2012; Repetti, Robles, & Reynolds, 2011).

Because of these health and mental health consequences, there has been growing interest in the social buffering of stress reactivity. Several studies indicate that early emerging HPA system dysregulation can be altered by planned interventions, and in these studies the quality of relational support is central to intervention design. In one such program, Fisher and colleagues designed an intervention to ease young children's transition to new foster care placements and enhance continuity of care through individualized sessions with child therapists, weekly playgroup sessions, and support for foster parents (Fisher, Stoolmiller, Gunnar, & Burraston, 2007; Fisher, Van Ryzin, & Gunnar, 2011). Compared with children assigned to regular foster care placements, who showed

the pattern of HPA hyporesponsiveness earlier described, children in the intervention group showed patterns of HPA reactivity that progressively resembled the normal patterns of a nonabused community comparison group over the course of 6 to 12 months of treatment. Reductions in foster parent stress were directly implicated in these changes in young children's HPA function recovery (Fisher & Stoolmiller, 2008). Consistent with these findings, Dozier and colleagues (Dozier, Peloso, et al., 2006; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008) have reported that following a 10-week intervention based on attachment theory, infants and toddlers in foster care showed more typical diurnal patterns of HPA activity and lower cortisol reactivity in the Strange Situation.

As these findings suggest, caregiver support can alter acute HPA reactivity to immediate stressors as well as normalizing basal cortisol levels (Gunnar & Donzella, 2002). In a study of families living in rural poverty, one research group found that toddlers' chronic exposure to domestic violence was associated with elevated cortisol reactions to challenge tasks at 24 months. However, when mothers had been observed to respond sensitively to their children in observations at 7, 15, and 24 months, this buffered the effects of partner violence on cortisol reactivity at 24 months (Hibel, Granger, Blair, Cox, and the Family Life Project Key Investigators, 2011). These findings underscore the plasticity of developing neuroendocrine and other biological systems, even when their development has been subject to chronic and severe stress. They also highlight the importance of relational support as a stress buffer. Plasticity and recovery are bounded, however, even in childhood. In their study of a sample of children rescued from profoundly depriving Romanian institutions, for example, Gunnar, Morison, Chisholm and Schuder (2001) found that after 6½ years of supportive adoptive care, the basal cortisol levels of children who had been early adopted (less than 4 months in the institution) resembled those of typically reared comparison children. However, children who had lived 8 or more months at the orphanage did not show such recovery, and evidence of enduring cortisol dysregulation was greater the longer that children had been in institutional care.

Studies of experiential dysregulation and social buffering of stress reactivity highlight the significant influence of caregiving experience on biological regulation and the need for multilevel examination of the processes by which this occurs (Hostinar, Sullivan, & Gunnar, 2014). This research draws attention to the effects of psychosocial stress on early developing stress reactivity and regulation and the

importance of caregiving support on the social buffering of stress, and these influences may also have potentially enduring influences on other developing biological systems. Luby and colleagues (2013) found, for example, that early childhood poverty was associated with smaller hippocampus volume, and that this association derived from the impact of stressful life events in childhood and hostile parenting. There is also emerging evidence of broader neurobiological outcomes from maternal support, such as increased hippocampal volume at school age (see Luby et al., 2012). These studies also highlight how these processes are likely to be associated with broader economic and social factors that affect caregiver functioning. In such a multilevel system, the interaction of early experience with dynamic biological growth is centered on the parent-child relationship.

Molecular Gene-Environment Interaction

The idea that developing biological systems are environmentally sensitive has long been incorporated into concepts of sensitive periods and developmental canalization that underscore the dynamic, environmentally responsive qualities of developing biological systems. By contrast, genes have traditionally been viewed as conferring biologically stable organization to developing systems. Experience does not alter structural DNA, and consequently genetic influences have been regarded as functioning interactively with environmental influences but not being altered by them.

Developmental behavioral genetics researchers have long recognized, however, that genetic influences might have different behavioral manifestations based on experience. Gene-environment interaction indicates that genetic characteristics may increase or decrease an individual's sensitivity to specific environmental influences—and that environmental conditions affect how genetic influences are manifested. Unfortunately, the research methods of twin or adoption studies do not provide powerful tools for examining gene-environment interaction and, indeed, their interaction is often unmeasured in developmental behavioral genetics research (Rutter, Moffitt, & Caspi, 2006). Molecular genetics research, however, provides better understanding of environmental moderation of genetic effects because specific gene alleles and environmental influences can be identified. The clearest examples of these can be found in research with animals because of the greater control over genetic and environmental characteristics, but research with humans also illustrates the significance of conditions of parental care for gene \times environment interaction.

Three gene polymorphisms have been of particular interest in research with humans and nonhuman primates. First, a specific “short” allele in the promoter region of the serotonin transporter (5-HTT) gene confers low transcriptional efficiency compared with the “long” allele, and is thus a risk factor for decreased serotonergic function and its behavioral correlates, such as depression and anxiety. Second, a functional polymorphism in the promoter region of the monoamine oxidase A (MAOA) gene, an X-linked gene, produces high or low levels of the MAOA enzyme that metabolizes serotonin, norepinephrine, and dopamine, rendering them inactive. The behavioral correlates of low MAOA activity include proneness to aggression and antisocial behavior. Third, a polymorphism of the dopamine receptor D4 (DRD4) gene is based on the number of 48-base-pair tandem repeats in exon III; the 7-repeat allele is associated with low dopaminergic efficiency and its behavioral correlates, including novelty-seeking and conduct problems. These polymorphisms have been the focus of research attention because findings related to their behavioral consequences have been replicated across different samples and because some of the intermediary biological processes between gene expression and behavioral functioning are understood.

In research with nonhuman primates, extreme differences in raising conditions—such as maternal care versus peer group raising—have been found to moderate genotypic expression. Studies with rhesus macaques (reviewed by Suomi, 2011) indicate, for example, that peer-raised monkeys with a homologous short 5-HTT allele show higher levels of aggression as juveniles than mother-raised monkeys or peer-raised monkeys with the long allele. The quality of care moderates, in other words, expression of a genotype conferring risk for behavior problems. Kinnally and colleagues (2010) extended these findings by documenting an interaction between the effects of the 5-HTT polymorphism and the MAOA polymorphism that was particularly evident for monkeys living in nursery raising conditions without their mothers (Kinnally et al., 2010). Living with the mother in a free-range condition (typical for monkey colonies) buffered these associations. This study is noteworthy because gene \times gene interactions of this kind are likely to be typical, especially in the development of complex behavioral phenotypes.

Research with human children fortunately does not compare such extreme differences in rearing conditions. Many developmentalists were introduced to the significance of molecular gene \times environment interactions in a highly publicized study by Caspi and colleagues (2002), who analyzed

data from the large Dunedin longitudinal study to find that, although indicators of harsh or negative parenting in childhood (indexed as maltreatment risk) predicted multiple measures of young adult antisocial behavior, this was moderated by a significant interaction between maltreatment risk and the MAOA gene. Males with low levels of MAOA activity were the most antisocial if they had also been at high risk for maltreatment in childhood; for those with high MAOA activity, the effect of childhood maltreatment risk was much smaller or nonsignificant (Caspi et al., 2002). This study has been replicated by several others (Kim-Cohen et al., 2006), and is consistent with a growing research literature examining candidate gene \times environment interactions in the prediction of developmental psychopathology (for reviews, see Dodge & Rutter, 2011; Rutter et al., 2006).

Gene \times environment interactions have further been noted in studies of personality development. Bakermans-Kranenburg and van IJzendoorn (2006) observed maternal sensitivity when infants were 10 months old and measured externalizing problems at 39 months. Maternal insensitivity was significantly associated with later externalizing, but only for children with the DRD4 7-repeat polymorphism; for children without this polymorphism, earlier maternal insensitivity was unpredictive. An intervention study subsequently enlisted this gene \times environment interaction in an effort to improve developmental outcomes (Bakermans-Kranenburg, van IJzendoorn, Pijlman, Mesman, & Juffer, 2008). A video-feedback parenting program was provided to a sample of mothers who had rated their toddlers high on externalizing behavior on the CBCL. A posttest after 1 year revealed that the parenting program succeeded in improving positive disciplinary practices. In a follow-up assessment 1 year later, the children of the intervention group showed less externalizing behavior, but this was significant only for children with the DRD4 7-repeat polymorphism. There were no intervention program-related changes for children without the 7-repeat allele.

The results of this intervention highlight the need for thoughtful interpretation of the findings of gene \times environment studies related to developmental outcomes. It is possible, indeed likely, that some genotypes function not only as risk alleles in contexts of environmental adversity (consistent with diathesis-stress models), but also as “beneficial” alleles in contexts of environmental support, consistent with differential susceptibility and biological sensitivity to context models (Belsky & Pluess, 2009; Boyce & Ellis, 2005; see also Ellis, Boyce, Belsky,

Bakermans-Kranenburg, & van IJzendoorn, 2011). In much of the research reviewed here, in fact, children with a specific genotype not only functioned more poorly in contexts of harsh or negative parenting, but they also showed more positive outcomes (although not as strongly) in contexts of sensitive, supportive care (see Bakermans-Kranenburg & van IJzendoorn, 2011 for relevant meta-analytic findings). How environmental conditions interact with the biochemical processes associated with gene expression thus requires considerably further thought and research. Environmental conditions can be contextual triggers that alter genetic susceptibility when conditions change above or below a particular set-point; they can impose constraints on the behavioral manifestations of gene expression; they can foster or inhibit competing behavioral (or biological) tendencies—these and other mechanisms of gene \times environment interaction can be envisioned.

In this research, the functional environment of gene \times environment interaction is parental care. The quality of parenting moderates gene expression (and, conversely, gene expression moderates the effects of parenting quality) such that children with the same allele manifest different phenotypical characteristics based on the quality of care they receive. Moreover, the phenotypes of interest primarily concern developing self-regulation: Behavioral impulsivity, antisocial conduct, and externalizing problems illustrate the outcomes of interest, especially when the quality of parental care is poor, owing in part to the focus of researchers on genetic moderators of dopaminergic and serotonergic systems. By contrast, some research suggests that when parental care is supportive, the same genotypes are more likely to result in diminished rates of behavioral problems (other positive indicators of self-regulatory competence are rarely measured in these studies) (Bakermans-Kranenburg & van IJzendoorn, 2011; Belsky & Pluess, 2009). Together, this research illustrates the significance of parent-child interaction to the behavioral manifestation of genotypical tendencies related to the growth of self-regulation.

The quality of parenting in this literature is, however, operationalized broadly. In the primate studies, it consists of the distinction between maternal deprivation, various forms of species-atypical peer raising, and normal maternal contact. In the human studies, parenting quality ranges from harsh, abusive practices to sensitive caregiving. These broad-brush distinctions raise important questions about the particular characteristics of parental care that function to moderate genetic risk. For a young child with a genetic tendency to low dopaminergic efficiency, for example,

is the central feature of supportive care the provision or deprivation of emotional warmth? Positive responsiveness? Consistency in rewards? Are the same qualities most relevant to a child with risk for decreased serotonergic functioning? Or is the presence or absence of threat-related cues or conflict management more important? Further consideration of such questions would be helpful in moving the field beyond broad characterizations of parenting quality and might have practical applications when tailoring parenting interventions to the genetic characteristics of offspring.

As this research has implications for developmental theory and intervention, it also faces significant challenges. Prominent among these is the “missing heritability” problem (Plomin, 2013; Turkheimer, 2011). Simply stated, the problem is that there is a substantial gap between the large heritability estimates for many human characteristics derived from behavioral genetics methods and the small proportions of variance explained in these characteristics by molecular genetics methods. As of this writing the problem is unresolved, but potential avenues for attacking it include (a) reconsidering the size of heritability estimates derived from quantitative genetic methods, (b) the likelihood that complex human characteristics have many, many genetic contributions of very small effect size, (c) elucidating the potential importance of gene \times environment interactions for genetic effect size estimates, and (d) consideration of epigenetic processes profiled below. A full discussion of these considerations is beyond the scope of this chapter, except to note that the missing heritability problem and its possible solutions have significant implications for how developmental scientists may think in the future about the nature of genetic influences on the complex phenotypes of interest to them.

A second related problem is the unreliability of findings from small-scale genetically informed studies that are often underpowered in relation to their models. Future research will require much larger samples to yield reliable results. The frequent failure to replicate molecular genetics effects in human studies using small samples typical of developmental research has raised questions about the small effect sizes of the genetic effects reported and their meaning as well as their reliability (see, e.g., Roisman, Booth-Laforce, Belsky, Burt, & Groh, 2013). These issues also have yet to be resolved, but they are at the heart of this research literature.

Taken together, therefore, the challenges in studying molecular genetic effects and gene \times environment interaction in human research are substantial. But this work is also

contributing to an understanding of the environmentally responsive, dynamic quality of gene expression in which early parental care moderates the behavioral manifestation of genetic characteristics associated with self-regulation.

Behavioral Epigenetics

Epigenetics is the study of potentially heritable changes in gene expression that occur without changes in DNA sequence. For gene expression to occur, gene transcription must be activated—it does not occur automatically. How genes are activated or deactivated results from the activity of the epigenome, which is a complex biochemical regulatory system that can activate, silence, or change the transcriptional activity of genes without changing the DNA sequence itself. This is accomplished through chemical processes that change the chromatin, or the protein structure surrounding the DNA molecule, to alter transcription, such as through DNA methylation, acetylation of histone proteins, or other processes. While many epigenetic modifications of the genome are stable throughout life, such as those contributing to cellular differentiation, others are environmentally responsive. In a sense, epigenetics is another way of understanding gene \times environment interaction, because some epigenetic changes in gene expression incorporate the experience and history of the organism into the phenotype.

Epigenetics has long been studied in plants and animals, and research has documented changes in gene expression associated with exposure to environmental toxins, disease, stress, diet, and other influences. In recent years, behavioral scientists have begun to appreciate the potential significance of epigenetic processes through the elegant research of Meaney and his colleagues, who have systematically conducted multilevel work documenting epigenetic processes associated with maternal care in rodents (see Meaney, 2010, for a review). They have shown that differences in maternal licking and grooming (LG) are associated with enduring differences in stress reactivity in pups, with the offspring of low-LG mothers showing heightened behavioral and neuroendocrine responses to stress compared to the offspring of high-LG mothers. Cross-fostering studies indicate that these cross-generational influences arise through early experience. Meaney and his colleagues (e.g., Weaver et al., 2004) have documented the chemical processes by which maternal LG changes the chromatin that regulates glucocorticoid receptor gene expression in hippocampal neurons through DNA methylation and histone acetylation, which in turn moderates HPA activity.

These epigenetic “marks” on genes are preserved under ordinary circumstances every time genes are copied to create enduring effects on HPA activity, contributing to the behavioral differences in stress reactivity observed in the offspring of high-LG and low-LG mothers.

This research has also documented other phenotypical consequences of epigenetic processes in rat pups deriving from high and low levels of maternal LG. For example, the offspring of high-LG mothers also show increased synaptic density and greater synaptic plasticity in the hippocampus that is related to diminished methylation of glucocorticoid receptors. This is associated with their stronger performance on measures of learning and memory in low-stress contexts compared to the offspring of low-LG mothers. By contrast, the offspring of low-LG mothers show better learning in high-stress contexts of fear conditioning, perhaps owing to their greater HPA activation, consistent with their generally stress-reactive, threat-vigilant phenotype (Champagne et al., 2008). Epigenetic processes, particularly those associated with histone acetylation, may thus be very important to processes of learning and memory (Roth & Sweatt, 2011). There is also evidence for epigenetic influences on pubertal age and reproductive activity, with the offspring of low-LG mothers showing early pubertal maturation, greater sexual receptivity, and high fecundity (consistent with a *r*-selection strategy) and offspring of high-LG mothers investing in high maternal care, consistent with a *K*-selection strategy (Cameron et al., 2008). These studies show, therefore, that differential rates of maternal LG stimulated epigenetic changes in various aspects of the genome that had effects on stress reactivity, neurocognitive responding, reproductive functioning, and other behavior in offspring.

Meaney and his group have also documented some of the processes underlying the intergenerational effects of early experience of maternal care (see Meaney, 2010). Epigenetic changes can be inherited, of course, as a result of epigenetic markers in the germline being transmitted to offspring. But there are also behavioral processes of intergenerational transmission. Low maternal LG results, for female offspring, in greater methylation of estrogen receptor gene expression in the hypothalamus, decreased oxytocin levels, and lower activation of dopamine release during nursing bouts that together contribute to their lower LG activity with their own pups (Champagne, 2011). Thus low-LG mothers have pups that grow up to become low-LG mothers because of epigenetic changes in maternal neurobiology evoked by earlier levels of maternal licking and grooming when they were pups.

Because these intergenerational influences on gene expression are experience-dependent, they can also sometimes be changed experientially. If the offspring of low-LG mothers are raised in conditions of social enrichment, for example, they subsequently engage in high levels of LG, and it is the high-LG phenotype that is transmitted to their own offspring. Similarly, if the offspring of high-LG mothers develop in conditions of social isolation, they engage in low levels of LG and it is this phenotype that is passed on to their offspring (Champagne & Meaney, 2007).

These epigenetic processes have been elegantly worked out in Meaney's lab with Long-Evans rats (and replicated by other groups; see e.g., Roth & Sweatt, 2011), but generalization to other species (and even other rat strains) must be considered cautiously. Homologous neuroendocrine and behavioral patterns across species must be balanced against different adaptive pressures and developmental processes pertinent to each species. Research studies with humans and nonhuman primates are, however, beginning to yield findings that are consistent with this account of behavioral epigenetics. In a whole-genome study of children experiencing institutional care compared with those reared by their biological parents, for example, Naumova and colleagues (2012) reported greater DNA methylation in the institutionalized group, including in genes associated with brain development and functioning, stress reactivity, and immune functioning, consistent with predictions and with the research discussed earlier (Naumova et al., 2012). Radtke and colleagues (2011) reported that children and adolescents born to women who reported intimate partner violence while pregnant exhibited enhanced methylation of the glucocorticoid receptor gene. There was no association with methylation in offspring when mothers experienced partner violence either before pregnancy or after the child's birth (Radtke et al., 2011).

Epigenetic processes may, in fact, help to account for some of the experiential influences on developing biological systems earlier discussed, such as the effects of fetal programming. Oberlander and colleagues (2008) assessed maternal depressive symptomatology during late pregnancy and found that higher levels of maternal depression were associated with increased neonatal methylation of a specific site of the glucocorticoid receptor gene. They also found that methylation of this region predicted heightened cortisol levels when infants were observed in an information-processing task at 3 months, suggesting an association between maternal prenatal stress and infants' HPA dysregulation through epigenetic mediation. Heijmans and colleagues (2008) studied adults who were

exposed prenatally to the Dutch famine of World War II and found that, compared to unexposed same-sex siblings, these adults had diminished methylation of the insulin-like growth factor II (IGF2) gene six decades later. This epigenetic effect may help to account for some of the metabolic and health problems that developed in this sample (Lumey et al., 2007). And in a prospective longitudinal study, Essex and colleagues (2013) reported that differences in adolescents' DNA methylation were predicted by maternal reports of stress in the child's infancy and paternal stress when children were preschoolers.

As these findings suggest, stress in caregiving conditions has been reliably associated with changes in DNA methylation, particularly of the glucocorticoid receptor gene. This would be consistent with the view that epigenetics is a mechanism by which phenotypic plasticity adapts to the environmental conditions signaled by caregiving quality to promote long-term behavioral adaptation. In light of research indicating that more than 900 genes in the rat are stably regulated by maternal care (Weaver, Meaney, & Szyf, 2006), however, it seems likely that a far broader range of regulatory processes are subject to epigenetic modification, as the findings earlier summarized seem to suggest. More generally, early care may have to be seen in a new light: as an important influence on gene expression with effects that are potentially heritable, and which may also be altered through subsequent caregiving experience. The quality of early care contributes, in other words, to heritable differences in phenotype that are not genetic, but rather epigenetic. And many of these phenotypic differences are associated with the regulation of stress reactivity, as well as of learning and memory, and parenting of the next generation.

Epigenetics is the best-known but only one of several significant scientific challenges to conventional thinking in genetics. Potentially equally significant are discoveries related to the structural variation of the human genome, such as the influence of transposable elements (especially retrotransposons), copy number variations, and somatic and chromosomal mosaicism (see Charney, 2012; Zhang et al., 2013). The significance of these discoveries for research on human development has not been fully worked out, but Charney (2012), among others, argues that it has significant implications for our understanding of the genetic and epigenetic similarities and differences between MZ and DZ twin pairs, how heritability is calculated and its meaning, the nature of the shared and nonshared environment, and other core elements of developmental behavioral genetics and developmental theory.

Interim Conclusion

It is clear, then, that the conventional distinction between nature and nurture is untenable. Are conduct problems observed in young adult males with a history of harsh parenting—but only when they have low MAOA gene activity—an example of nature or nurture? Is the association of fetal stress, glucocorticoid receptor gene methylation, and stress reactivity in offspring an example of nature or nurture? The answer to each question underscores, once again, the fruitlessness of partitioning phenotypic variance into nature and nurture components.

As part of the recognition that development is a biologically dynamic, experience-driven process, researchers must also begin to reconceptualize the biological and behavioral consequences of early care. Early parenting, and the quality of parent–child relationships, influences the regulation of developing neuroendocrine, immunological, neurological, and other systems through processes that include experientially instigated epigenetic modification of gene expression and the effects of experience-dependent influences on the developing brain. Many of these influences occur through the effects of early stress, experienced prenatally or early in life, that ranges in severity in this literature from the profound deprivation of institutional care to daily experience with a depressed and emotionally unavailable caregiver. The biological effects of positive caregiving qualities, such as sensitivity and support, are also observed in the social buffering of stress reactivity, the remediation of HPA dysregulation in foster children, and the positive behavioral outcomes of children with “risk alleles” who receive supportive care. Experience of stress and support are both important, and there are indications in these studies that although they impact common systems, their effects are also mediated by different neuroendocrine and gene \times environment processes. One important task for future research is to elucidate these biological mediators of the effects of different attributes of parental care, with special attention to mediators of positive behavioral outcomes that have been less well examined, such as the oxytocinergic system in human young (Hostinar et al., 2014; see also Feldman et al., 2012). In so doing, researchers should also unpack variability in the quality of parental care that is biologically influential, moving beyond global characterizations of aversive and sensitive parenting to better specify and measure what it is about parental conduct that is important to the organization of biological regulatory systems.

These biological influences of caregiving quality are important because of their behavioral consequences.

Although the connections between experiential influences, biological remodeling, and behavioral outcomes are still being worked out, researchers are establishing pathways between HPA system dysregulation and emotional reactivity, threat vigilance, and other self-regulatory problems, with downstream implications for cognitive functioning owing, in part, to the impact of cortisol on cortical and limbic systems. Similarly, some researchers are documenting associations between stress and the biological embedding of “proinflammatory tendencies” that impair physical and behavioral health (G. E. Miller et al., 2011), while others are elucidating the social buffering of stress reactivity through the impact of positive caregiver responsiveness on neuroendocrine, limbic, and prefrontal systems that regulate HPA activity (Hostinar et al., 2014). What makes these efforts so interesting is that their multilevel analysis is both theoretically integrative and generative of new hypotheses about the connections between early caregiving experience, developing biological systems, and behavioral functioning in the early years. The field is ready for more contributions like these.

The view that relationships are biological regulators hearkens to Hofer’s (2006) enduring ideas about the “hidden regulators” of early psychobiological organization in young organisms. These regulators are no longer so hidden, but they do cast a different light on the association of relationships with regulation. In addition to the behavioral embedding of self-regulatory skill in parental socialization, these studies shed light on the biological embedding of self-regulatory capability in the setting conditions created by parental care. A multilevel analysis invites questions about the interaction between, and perhaps the dependency between, different levels of regulation involved in parent–child relationships.

The focus of several of these research programs on children in poverty illustrates how these developmental influences interact with broader social processes (Thompson, 2014). This is illustrated by Blair and Raver’s (2012) experiential canalization model of the effects of poverty on children’s biological and behavioral self-regulation (see also Evans & Kim, 2007). As they note, children in poverty experience a variety of stressors deriving from economic hardship, including parents’ depression and distress, poor and crowded housing conditions, neighborhood violence, and poor schools. Consistent with the literatures reviewed here, they show how these hardships have biological effects on stress neurobiology, immune function, and cortical and limbic systems with behavioral consequences that include heightened emotional reactivity,

impaired executive function, and poorer self-regulation. Importantly, Raver has enlisted this multilevel analysis into the design of an intervention program to support the development of self-regulatory skills in at-risk young children in Head Start (Raver et al., 2009). Like the foster care interventions of Fisher and Dozier discussed earlier, this effort draws on an understanding of the biological and behavioral consequences of aversive early life experience to try to benefit young children (Thompson & Haskins, 2014).

Translational research of this kind is more likely in the future, and it is another welcomed direction for future work. Fortunately, researchers in this field have used a variety of research populations, including children and families in different socio-demographic groups, at-risk children in challenging ecologies, animal populations that permit greater experimental control and research simulations of human adversity, and even historical studies. (Despite the focus of this review on mothers, moreover, paternal influences have also been examined in several human studies on the social regulation of stress neurobiology.) This attention to diverse populations has enabled researchers to better understand the biological and behavioral difficulties of at-risk children and ask how this understanding might change thinking about assisting children at risk. Beyond contributing to the design of intervention strategies, for example, this research might prompt more searching inquiry into why some interventions seem to be more effective than others (e.g., does beginning home visiting prenatally, as the Nurse Family Partnership model does, provide opportunities related to averting fetal stress that postnatal visitation programs do not?). Furthermore, research in this field highlights the potential value of using biomarkers as well as behavioral measures of intervention outcome. As one illustration, Fernald and Gunnar (2009) showed that after 3½ years of participation in a conditional cash-transfer antipoverty program in Mexico, preschool children showed lower basal cortisol levels, and this was partly moderated by maternal depression, with children of mothers with high depressive symptomatology showing the greatest program benefit. As another, O’Neal and colleagues (2010) reported that the effectiveness of an intervention program for at-risk 4-year-olds to reduce later aggression was mediated by the intervention effect on cortisol response. These and other translational questions also await further research advances in this field.

Finally, it is noteworthy what is missing from this multi-level analysis thus far. Children’s representations of their experience do not figure into these innovative studies of early life experience. Consideration of this omission raises

interesting and potentially important questions about how representational processes contribute to and potentially moderate some of the behavioral and biological outcomes discussed in this section. How much is the social buffering of stress reactivity a function of how children interpret the meaning of parental solicitude (such as in relation to attachment security)? How might early stresses, and the experience of chronic HPA reactivity, affect young children’s developing social representations, such as their inferences of others’ emotions, or emergent concepts of fairness? These questions provide the transition to another kind of relational regulation through the effects of parent-child interaction on developing representations of the social world.

REPRESENTATION

The influence of social experience is moderated by how it is represented. In adults, the importance of social representation can be seen in the influence of self-schemas, relational expectations, stereotypes, attributional biases, and many other ways that the interpretations of others affect how people respond. With children, these representations are developmentally evolving and relationally guided. Children construe social experience in increasingly complex and nuanced ways as they cognitively mature, and throughout this process their beliefs and expectations are influenced by social experience, particularly with caregivers. The development of social representation is important as a means by which social experience “goes underground” to influence developmental outcomes, as a foundation for individual differences in adult beliefs and attitudes, as an important source of developmental continuity from childhood to later years, and as another means by which relationships contribute to self-regulation (Dweck & London, 2004; Thompson, 2000).

To illustrate, consider two examples. First, in a classic analysis, Grusec and Goodnow (1994) reinterpreted longstanding research on parent discipline practices and children’s internalization of values by considering the mental processes mediating children’s internalization. They summarized research showing how internalization is influenced by the accuracy with which children perceive and understand parental messages, their judgments of the appropriateness of parental intervention, the consistency of the parents’ messages with the child’s other beliefs, the affect associated with the parent’s behavior, and many other factors. Their analysis provided less insight,

however, into the *origins* of individual differences in these mental processes because there was much less research at the time relevant to understanding their development. Since then, however, there has emerged an expanding research literature into these and other aspects of developing social cognition (see, e.g., Banaji & Gelman, 2013; Hughes, 2011). Researchers have documented how the child's response to the parents' messages is influenced by the mutuality and warmth of the parent–child relationship (Kochanska, 2002), the extent to which parental practices are perceived as normative for the community (Gershoff et al., 2010), children's evaluations of the parents' veracity (P. L. Harris, 2012), social domain judgments (Lagattuta, Nucci, & Bosacki, 2010), and many other social-cognitive processes.

Second, using violation of expectancy procedures with preverbal infants, Johnson and her colleagues (2010) documented what they describe as evidence for emergent internal working models associated with the security of attachment (Johnson et al., 2010). Twelve-month-olds were habituated to a video scene in which a large red orb and a smaller blue orb were together at the bottom of an incline. Subsequently the red orb moved away from the other and up the incline, after which the sound of a baby cry was heard while the smaller orb pulsed and changed color. After habituation, two test trials were presented in counterbalanced order, each beginning as the habituation scene had ended, with the sound of the baby cry and the smaller, pulsing orb. In one, the red orb reversed course to rejoin the smaller one; in the other, the red orb moved farther up the incline and away from the other. Johnson and her colleagues (2010) reported that infants who were securely attached (based on the Strange Situation) looked longer at the trial in which the red orb moved away, while insecurely attached infants looked longer at the trial in which the red orb returned to the smaller one. In each case, the authors concluded, their visual behavior reflected surprise at the scenario that was most inconsistent with their attachment history: Secure infants were surprised when “the caregiver ignored the infant's cries,” and insecure infants were surprised at outcomes “in which the caregiver responded” (p. 813). There were no differences between insecure-avoidant and insecure-resistant infants.

The juxtaposition of these papers illustrates two themes of this section: how relational representations moderate the influence of social experience, and how relational experience contributes to the development of social representation. Discussing these dual themes requires surveying and integrating two research literatures that have developed

in a surprisingly independent fashion. One literature is the rapidly growing research on early developmental social cognition. Contemporary social-cognitive researchers portray the growth of early social representation as a continuous interaction between the young child's powerful inductive capacities (whether interpreted with reference to naïve theory construction, statistical learning, teleological reasoning, innate systems of core knowledge, or other processes) and the social experiences that provide data for these inductions. But the relevance of social experience has not been well specified in this experimental literature, so one of the goals of this research review is to better identify its nature and importance. The other literature is the work on social representations arising from early relationships, much of it conducted by attachment researchers. In this view, social experience shapes the mental “working models” that influence other relationships, but the representational processes by which this occurs have also not been well specified. The task of this section is to create bridges between these two approaches to early social representation, and to urge further work on their integration.

The central argument is that, through the development and influence of these early social representations, relationships contribute to the development of self-regulation in the early years. As young children are developing the neurobiological and cognitive foundations for self-control, they are enlisting understanding of what people are like and what motivates them, the implicit rules for interacting with them, the social obligations people share, and other forms of developing social awareness that guides their emerging self-regulatory efforts. This developing understanding is fundamentally constituted by early social experience. Both the developmental social-cognition literature and the attachment literature speak to these issues but in very different ways, suggesting that greater dialogue between researchers in each field would be mutually rewarding.

This section begins with a discussion of the early foundations for developing social cognition in the core knowledge or conceptual primitives that might exist at birth. Next is a selective review of research on social-cognitive growth, highlighting the social influences on these developing competencies in the early years, with a particular focus on developing understanding of intentionality, the growth of shared intentionality, and emerging judgments of observed third-party actions, as well as the role of language in these early achievements. This is followed by consideration of studies that have focused on individual differences in the quality of parent–child relationships and

their representational implications. Central conclusions from these reviews are considered in a final section.

Early Foundations

What do infants know, and when do they know it? More important, why do they know it? In the study of cognitive development, longstanding interest in the conceptual primitives or core knowledge underlying cognitive growth has inspired considerable research and provoked debate over the rich or lean interpretation of research findings. This has been important for addressing fundamental questions about whether young infants possess innate or very early developing representations that guide reasoning in critical domains of experience. The field of social-cognitive development is a latecomer to this debate, but several studies have suggested remarkable early capacities for social representation in infancy. Thomsen, Frankenhuys, Ingold-Smith, and Carey (2011), for example, report that 10- to 12-month-olds represent events in terms of social dominance and acquiescence; Hamlin, Wynn, and Bloom (2007) indicate that 10-month-olds prefer actors who help others and avoid those who are antisocial; Luo (2011) reports that 3-month-olds attribute goals and dispositions even to a self-propelled box; Powell and Spelke (reported by Spelke, Bernier, & Skerry, 2013) indicate that 8-month-olds expect actors to conform to the behaviors of their group.

These and related studies share several characteristics in common. First, each uses a violation of expectancy procedure which, like the Johnson et al. (2010) study described above, habituates (or familiarizes) infants to a standard set of events and then presents them with test trials, one of which is consistent with the expectations hypothesized to be generated by the standard, and one of which is inconsistent. Second, looking time to the test trials is the primary dependent measure (with younger children, choice preference is sometimes used as an alternative dependent measure; see Hamlin, Wynn, & Bloom, 2010, for an example with 3-month-olds). Consistent with typical habituation procedures, differences in looking time are interpreted to reflect a discrimination between the test trials, and enhanced looking is often viewed as an indication of surprise at an unexpected or inconsistent event. Third, these procedures use moving objects—orbs, blocks, triangles, sometimes with eyes, that are animated in human-like ways—as actors in these scenarios presented on a puppet stage or on video. Finally, the findings of these studies are often taken to reflect innate representational biases

originating in human evolution to provide a foundation for group cooperation, morality, or other social capacities. Infants' behaviors, in other words, are interpreted to reflect species evolution, not early developmental influences.

Because this research literature is small and relatively new, well-designed replication studies are necessary to better characterize the nature of the discriminations that these studies reveal and to eliminate competing explanations (see, e.g., Scarf, Imuta, Colombo, & Hayne, 2012, and reply). As has been true in the cognitive literature (e.g., Aslin, 2007), some argue that the reliance on looking time in these studies is interpretively challenging, as considerable research has shown that responses to these measures are multidetermined. As a consequence, even when infants discriminate between test trials, it can be difficult to know why.

To illustrate, compare the following well-known studies. Hamlin et al. (2007) habituated 10-month-olds to scenes in which a red ball appeared to try to move up an incline and was either (a) pushed uphill by a yellow triangle or (b) pushed downhill by a blue square. On the subsequent test trials, infants looked significantly longer when the red ball moved to rest alongside the blue square than when it rested alongside the yellow triangle. From these results, the authors concluded that 10-month-olds expected actors to affiliate with those who were helpful, not unhelpful, because they looked longer (reflecting surprise) when the red ball acted in the opposite manner. Kuhlmeier, Wynn, and Bloom (2003) used computer animations but a very similar procedure in which 12-month-olds were habituated to scenes involving a circle trying to move up an incline that was similarly “helped” (by a triangle) and “hindered” (by a square), and then saw test trials in which the circle moved to rest alongside either the triangle or the square. This time, infants looked significantly longer when the circle rested alongside the triangle, which was interpreted as reflecting the infant's preference for a coherent continuation of the habituated scene. The looking time results were the opposite of each other, but interpreted to reflect the same preference for helpers over hinderers. These studies indicate that infants discriminate between the test events, but it is unclear on what basis (see Wynn, 2007, for further discussion of these studies).

There is a long way to go, therefore, before researchers can characterize the core knowledge underlying early social representations, and further research using multiple convergent and well-validated methods will be required. Three-month-olds may discriminate “helpful” from “hurtful” actions (Hamlin, 2013) and toddlers may

offer instrumental assistance to a stranger (Warneken & Tomasello, 2009), but without further knowledge of the meaning of these responses or their developmental origins, researchers are wise not to rush to inferences of innate morality or altruism.

It is, however, likely that certain early conceptual primitives facilitate emergent social representations. These enable very young children to represent social phenomena in unique ways, preparing them for social relations on which their survival depends. As children mature cognitively, it is likely that these conceptual primitives become supplanted by broader, more flexible representational systems (a similar view has been advanced by students of cognitive development such as Apperly and Butterfill, 2009). If core knowledge underlies early social representations, what might these foundational conceptual primitives consist of? Here are some possibilities.

Contingency perception is one candidate. Newborns are sensitive to contingent responses to their behavior and are particularly attuned to perfect contingencies that are likely to reflect self-generated outcomes (Gergely & Watson, 1999; Watson, 2001). High (but imperfect) contingencies also elicit the infant's attention because they are often associated with social interaction. As early as 8 months, infants seem to represent even inanimate objects as agentic—visually following their apparent attentional focus much as they do with human partners—but only when objects had previously responded contingently to the infant's behavior (Deligianni, Senju, Gergely, & Csibra, 2011). By the end of the first year, infants make similar attributions to inanimate objects after observing their contingent third-party interaction with an experimenter, but only if the interaction has the attributes of sociability, characterized by the experimenter's attentional and affective reciprocity with the object (Beier & Carey, 2014; Meltzoff, Brooks, Shon, & Rao, 2010). In addition to contributing to basic forms of self-awareness, therefore, contingency perception may be important to early attributions of social agency.

Contingency perception is important to other kinds of social cognition. In the development of person-specific social expectations, infants are especially attentive to the contingency of others' responses to their signals. The statistical learning involved in early "distress-relief sequences" (Lamb, 1981) depends on baseline levels of infant distress and adult remediation as well as the strength of the association between them (Watson, 2001). By 6 months, infants act in ways suggesting that they have begun to perceive such contingencies, such as by quieting

in anticipation to the sound of mother's approaching footsteps and protesting if she approaches but does not pick them up (Gekoski, Rovee-Collier, & Carulli-Rabinowitz, 1983; Lamb & Malkin, 1986). Similar responses can be observed at the same age in infants' expectations for adult responses to their nondistress vocalizations (Goldstein, Schwade, & Bornstein, 2009). Findings such as these help to explain why contingent responsiveness to infant signals figures prominently in theoretical views of the origins of parent–infant relational quality. They underscore the sensitivity of young infants to the reliability of the association of their behavior with others' responses in developing person-specific social expectations.

A second candidate is the capacity to represent others' actions self-referentially. An early emerging capacity for social imitation, which can be observed in chimpanzee and rhesus neonates as well as human newborns, possibly draws on delegated neurobiological systems (such as the mirror neuron system) and may have evolved to support rudimentary learning and social engagement of the caregiver (Paukner, Ferrari, & Suomi, 2013). In human infants, neonatal imitation may also provide a bridge to later, more complex forms of imitative social activity that enable infants to interact intersubjectively with adults and denote correspondences between self-initiated and other-initiated activity. This has been described as a "like me" orientation (Meltzoff, 2010), although this is a rich characterization of the conceptual primitive present at birth. Meltzoff (2007, 2010) argues that self-referential action representation leading to newborn imitation provides a foundation for later inferences concerning others' intentionality, perception, desire, and referentiality because of the toddler's capacity to generalize between personal experience and interpretations of others' behavior. In this respect, self-referential action representation early in infancy may provide a basis for the development of more sophisticated understanding of self–other correspondence that follows later.

A third candidate is the infant's attentional and affective engagement with human faces and voices. More specifically, infants are highly sensitive to eye contact with another person, and to infant-directed speech (characterized by exaggerated prosody, repetition, and simple syntax) from birth. Indeed, when these occur in the context of socially contingent interaction, Csibra and Gergely (2011; Csibra, 2010) argue that they constitute signals of ostensive communicative acts from which infants are innately prepared to learn. Wherever this "natural pedagogy" leads, it underscores how this suite of social

orientation biases in young infants, long viewed as supporting developing social interaction and attachment, may also be enlisted for early generic learning.

There may be other forms of core knowledge associated with emergent social representation, but three observations about these candidate capacities warrant note. First, these are sparse rather than rich primitives to enable foundational inferences of human agency and action and to permit early interaction and social learning. More may not be needed to construct more sophisticated representations of the social world from direct social experience. Second, each of these conceptual primitives—contingency perception, self-referential action representation, and privileged orientation to human faces and voices—facilitates social interaction and social-cognitive understanding. This suggests the possibility that they function to support social representational development *through* facilitating experiences of social interaction, especially with relational partners whose familiarity and ubiquity provide compounding catalysts to social-cognitive growth. Finally, these elements of core knowledge underscore the importance of first-person experience in developing social representation. It is, in other words, not only an infant's observations of others' behavior that is important, but essentially the child's direct experiences of social *interaction* that underlie social representational development.

Understanding Goals and Intentions

Contingency perception is important to early attributions of agency to human actors. But contingency perception is just the beginning of infants' understanding that people act intentionally, and considerable conceptual growth is required before young children can make more sophisticated inferences of what actors intend and why. Nevertheless, this process begins early. Studies using visual habituation indicate that as early as 5 to 6 months, infants represent others' behavior in terms of the goals of their actions rather than representing physical movement alone (see review by Woodward, 2013). At about the same age, infants selectively imitate only the behavior of actors whose actions are goal-oriented (rather than goal-ambiguous), adding convergent evidence to the visual habituation studies (Hamlin, Hallinan, & Woodward, 2008). Infants in the second half of the first year use a variety of behaviors—such as the actor's focused attention, grasping, pointing, and even emotional expression (i.e., smiling toward an object)—to predict the actor's interest in and subsequent behavior toward the object.

It is no accident that these behaviors by which infants interpret adult activity as goal-directed are the same behaviors that infants are beginning to enlist into their own goal-directed efforts. By 6 months, infants are familiar with the sight of their own hand reaching toward an object, and thus may be prepared to interpret others' object-directed reaches as similarly goal-oriented. During the months that follow, infants use pointing, gaze-following, gesturing, and other actions to infer others' goal-orientation at about the same time as they become competent in using these behaviors to accomplish their own goals. Experimental studies support the association between infants' first-person experience of goal-directedness and their interpretation of the goal-orientation of others' actions. Sommerville, Woodward, and Needham (2005) showed, for example, that when 3-month-olds were provided first-hand experience with picking up toys using Velcro-equipped mittens it resulted in greater amounts of visually guided reaching, and their subsequent performance in a habituation study revealed greater sensitivity to the actor's goal-orientation compared to infants without this experience (see also Brune & Woodward, 2007). During the second half of the first year, as infants are becoming more competently agentic, they increasingly interpret others' actions in goal-oriented ways. By 10 to 11 months, for example, infants become proficient at parsing the ongoing stream of human behavior they observe into meaningful segments based on their inferences of the actor's goals (Saylor, Baldwin, Baird, & LaBounty, 2007).

During this time, of course, infants have other kinds of first-person social experience that supports developing understanding of intentionality. This includes parent-infant face-to-face play at 2 to 6 months of age, characterized by mutual gazing, contingent responsiveness, proto-conversational turn-taking of vocalizing, and sharing emotional expressions (Hobson, 2002; Stern, 1985). Social experience of this kind, in different relational and cultural contexts, likely extends the "like me" orientation to shared (or mirrored) emotions, mutual (later referential) gazing, shared (or reciprocal) movement, and kinesthetics. [Moreover, an equally important internal awareness of "not like me" is also likely to emerge in the comparably frequent experiences of interactional dyssynchrony that characterize early social play, motivating both partners to reestablished shared goals, visual orientation, and coordinated activity again.] Most important to the organization of shared activity is the adult's structuring of play (or its repair) around the maintenance of positive emotion in the infant by responding appropriately and contingently to the

child's interests, expressions, and other behavior—and, in doing so, strengthening the infant's experience of agency and intentionality.

Later in the first year, infants and parents also engage in cooperative games, such as rolling a ball back and forth, or taking turns putting objects into a bin or stacking blocks. This shared activity is more complex than adults simply responding to the child's initiatives because now it involves coordinated activity in which each partner has intersecting roles. This cooperative social interaction also contributes to developing representations of human goal-orientation. Henderson, Wang, Matz, and Woodward (2013) showed that 10-month-olds who had personal experience with collaborative activity (i.e., jointly retrieving a ball from a box with an adult) subsequently represented the actions of two other adults they observed in terms of their collaborative goal, whereas infants without this first-hand experience did not comparably interpret the adults' behavior as collaborative. Direct experience with social cooperation was essential; simply observing other people engaged in cooperative activity was insufficient.

In play and other contexts, adults often interpret the infant's behavior as goal-oriented and they respond accordingly (Kaye, 1982). They react to the infant's directed gaze or reach by retrieving the object of interest; they imitate the infant's emotional expressions or gestures; they applaud the child's effortful accomplishments; they query and talk to the preverbal child about intentions and goals. Notably, caregivers also intervene to deter the infant's goal-directed efforts, such as by removing a prohibited object before the child reaches it, or removing the child from a potentially hazardous activity, and thus respond to the infant's intentionality in these ways also. In each case, adults are acting from a mentalistic interpretation of the infant's behavior in terms of underlying internal states.

One reason that infants have considerable first-person experience with goal-oriented agency, therefore, is that caregivers are responding to the infant as a intentional, agentic person. This adult characteristic has been described as "mind-mindedness" (Meins, 1997), which can be defined as an adult's interpretation and response to the infant's behavior in terms of underlying intentions, goals, feelings, desires, and other mental states. The concept of mind-mindedness is based on mentalizing theory, which argues that the development of psychological self-awareness derives, in part, from the organization of the parent's behavior toward the infant around these mental states (Fonagy, Gergely, & Target, 2007). According to this view, when the parent responds consistently with the

infant's intentions, feelings, and desires, especially when mirroring the infant's emotions, it contributes to the infant's developing self-awareness of these internal states and the growth of a sense of agency (see also Kaye, 1982). Studies of mind-mindedness show, for example, that infants whose mothers frequently comment on the infant's mental states during play later show stronger performance on theory of mind tasks (Laranjo, Bernier, Meins, & Carlson, 2010; Meins et al., 2002).

Research on parental mentalization typically relies on verbal assessments through interview protocols to elucidate adults' interpretations of the child's behavior. The important question, however, concerns how mentalization is manifested in interaction with the infant in a manner that contributes to the infant's developing representations of the self and others. Shai and Belsky (2011) have argued that parental responsiveness of this kind can be observed in the adult's expressive, kinesthetic, and nonlanguage vocal responses (see also Stern, 1985). When a parent responds with a questioning vocal sound or word, together with gaze-following and moving closer to the baby in response to the child's directed reach to an object of interest, for example, a mentalized interpretation of the infant's gesture is conveyed that reinforces the infant's intentionality and also supports the infant's communicative efficacy. In a related vein, Brand, Baldwin, and Ashburn (2002) have reported that parent–infant interaction during the second half of the first year is structured in a way to enhance awareness of the intentionality and goal-structure of each partner's behavior. They call this characteristic "motionese" as a counterpart to the well-documented "parentese" that facilitates language acquisition. "Motionese," they conclude, facilitates infants' interpretation of social behavior in terms of its intentional structure.

These studies suggest, then, that parental responsiveness to infants' goal-directed behavior in the first year contributes the child's developing awareness of intentionality. Parental behavior, especially when it is coordinated with the child's actions, also contributes to the infant's awareness of the intentionality of other people. Interestingly, this period is also when the security of attachment develops in response to the sensitivity of parental care. Parental mental state awareness is incorporated into classic definitions of sensitivity (i.e., noticing the baby's signals, interpreting them accurately, and responding to them appropriately and promptly) that is the basis for a secure attachment. Sensitivity that is organized around responsiveness to perceived intentions and goals, especially as the infant is becoming a more competent and

self-aware agentic being, contributes to the security of attachment. If the infant is better representing parent activity as intentional and goal-directed at the same time, it may conceptually imbue the child's interpretation of the meaning of the parent's solicitude in security-relevant ways: that is, as an adult who *intends* support.

Shared Intentionality

A major advance in understanding intentional human activity occurs in the second year with advances in "shared intentionality" (Tomasello, Carpenter, Call, Behne, & Moll, 2005). Shared intentionality is not just the coordinated interaction of infant and adult but their doing so in a manner that shares mental states, especially shared goals and intentions. "Shared mental states" hearkens back to the reciprocal exchange of emotional expressions and the emergence of joint attention in the first year, of course, but what is different about shared intentionality in the second year are the mutual intentions encompassed in this sharing. The toddler's ability to enter into another's behavior in terms of that person's goals and plans for accomplishing them is distinctive about shared intentionality. Examples of shared intentionality can be observed in toddlers' cooperative problem solving and social games, especially when shared intentions are reflected in the child prompting an adult who fails to continue participating (Brownell, 2011; Warneken, Chen, & Tomasello, 2006). Shared intentionality can also be observed in toddlers' participation in activities that involve reversing roles with the adult (Carpenter, Tomasello, & Striano, 2005), and assisting the adult with simple prosocial acts (Warneken & Tomasello, 2006). Tomasello and his colleagues (2005) argue that owing to this sharing of mental states, shared intentionality provides the conceptual foundation for language acquisition and other forms of cultural learning.

Sharing intentional states with another is predicated on earlier forms of mental and emotional sharing in the first year. Once infants have developed a salient awareness of their own goal-directed intentionality and have incorporated intentionality into their interpretation of others' behavior, entering into another's intentional stance becomes a valuable means of understanding another's actions. Shared intentionality also permits better coordinated, complex, and more emotionally engaging social interaction. This may be why toddlers seek the participation of another in collaborative activity even when that person's involvement is not necessary for the activity to succeed (Warneken, Gräfenhain, & Tomasello, 2012).

Shared intentionality thus derives from an interaction between the young child's expanding understanding of the intentional origins of human action with social experiences that stimulate and support these inferences in developmentally evolving ways. As it develops, furthermore, the capacity to enter into and share another's intentional stance contributes to other advances in social understanding. Imitative behavior changes, for example, as toddlers respond on the basis of their inferences of the adult's goals even if the adult's observed actions failed to accomplish them (Carpenter, Call, & Tomasello, 2005; Gergely, Bekkering, & Kiraly, 2002). Shared intentionality may also be associated with the development of desire psychology as young children begin to understand the association between intention, desire, and emotion: People are happy when they get what they want or accomplish their goals, but they are unhappy when they do not. Because these goals and intentions are often shared with another person, toddlers' shared emotions in joint activity provide opportunities to comprehend the connections between these mental states. Finally, the growth of shared intentionality may also transform the impact of parental sensitivity, causing the toddler to interpret the adult's responsiveness as entering into and supporting the child's intended activity. As the child generalizes the adult's example, it may provide a foundation for early prosociality and contribute to the development of the mutually responsive orientation toward the parent that Kochanska (2002) views as a basis for conscience development.

Interpreting and Responding to Third-Party Actions

As these examples illustrate, shared intentionality provides toddlers with greater conceptual flexibility in understanding the mental origins of human activity. In particular, it provides them with a "bird's-eye view" of social interaction involving both first-person and third-person perspectives incorporated into the child's representation of events (Tomasello, 2007). What happens, then, when children of this age observe someone else cooperating with another person, or preventing them from accomplishing their goals? If shared intentionality derives from young children understanding the goals of others' behavior and being able to enter into their intentional stance, then this might also influence their appraisal of third-party actions.

There is growing evidence that this is so for children in their second year. Using puppets, for example, Hamlin, Wynn, Bloom, and Mahajan (2011) showed that 19- to 23-month-olds were more likely to provide rewards

to a puppet who was previously observed as helpful to another puppet (i.e., retrieving a ball the other puppet had dropped), and to take rewards from a puppet who had previously acted harmfully to another (i.e., taking away the dropped ball). It is noteworthy that in these situations, young children's responses could not directly address the consequences to the "victim" of what was done. Instead, children provided benefits to the victim, or denied them to the perpetrator, in response to observing the effects of a third party's actions on an actor's intentions and desires.

A similar conclusion derives from a study involving children's direct participation in a social drama (Vaish, Carpenter, & Tomasello, 2009). Toddlers aged 18 to 24 months watched as one adult either stole or damaged the possessions of a second adult (experimental condition) or took or damaged comparable items that did not belong to the second adult (control). After moving to another room, toddlers were given two balloons and the second adult only one, and subsequently the latter's balloon was lost. Young children who had previously witnessed that adult being victimized by another in the experimental condition were significantly more likely to help that person, such as by giving her a balloon, hugging or patting the adult, or making suggestions for retrieving the balloon, than children in the control condition. Toddlers appeared to be responding, as in the Hamlin study, to the harm previously caused by the third party's actions to the recipient's goals. Toddlers responded comparably even when one adult only intended, but failed, to harm the interests of another (Vaish, Carpenter, & Tomasello, 2010).

At somewhat older ages, children make comparable judgments in more complex circumstances. In a study using doll play, 3½-year-olds showed that they believed that a protagonist would prefer to give rewards to another doll who had previously helped her compared to one who had not (Olson & Spelke, 2008). In a reflection of indirect reciprocity, moreover, they also indicated that a protagonist would prefer to give rewards to a doll who had previously been generous to another doll compared to one who had not. Another study showed that children of this age not only assist the victim of harm that they have witnessed, but also protest the harmful act and tattle on the perpetrator (Vaish, Missana, & Tomasello, 2011). Taken together, shared intentionality means that toddlers not only can share another person's goal-directed intentionality, but can use their understanding of another's goals to appraise the conduct of third parties and respond appropriately.

What evaluations of third-party actions account for these responses by young children? Judgments of other

people as "nice" or "mean" figure prominently in the spontaneous comments of young children about the people they observe, and such judgments derive from how the actions of one person affect another's goals, feelings, or welfare (Wright & Bartsch, 2008). Intuitive judgments of "fairness," which also appear early, may also be influential. Children of 3½ years were more likely to share undeserved rewards with a peer partner, for example, when rewards were derived from a collaborative task than when they received undeserved rewards from a noncollaborative task (Hamann, Bender, & Tomasello, 2014). When children of this age were shown a story about two girls who started baking cookies, but only one completed the task, three-quarters of the children judged that the child who contributed more should receive more of the cookies (Baumard, Mascaro, & Chevallier, 2012).

Taken together, these studies suggest that one of the consequences of shared intentionality is young children's sensitivity to the effect of third-party actions on another's goals, which may result in person-centered evaluations and motivate efforts to restore fairness by rewarding those who assist another, punishing those who hinder, offering assistance to those who were previously victimized by a hinderer, and ensuring that benefits are distributed fairly among all parties. Although the experimental studies described here—conducted with puppets, stories, and emotionally impassive experimenters—are designed to minimize the influence of emotion, in everyday experience emotion is likely to be important to how young children appraise the actions of helpers, hinderers, and victims, especially in light of their developing understanding of the associations between the fulfillment of intentions, goals, and desires, and positive or negative feelings.

The importance of emotion in representations of third-party action is particularly apparent when considering that children of these ages have substantial first-hand experience with these concerns in family contexts. Rewarding those who are helpful, sanctioning those who are harmful, comforting or compensating those who have been harmed, concerns about the fair allocation of shared resources or rewards, and drawing attention to another's wrongdoing are familiar experiences for toddlers, especially those growing up with siblings (Dunn, 1988, 2006; Dunn & Munn, 1985). Indeed, the stories enacted by puppets or experimenters in these studies seem very similar to everyday family dramas. What is equally remarkable in these findings, moreover, is the unexamined variability in children's responding that may also be associated with prior family experience. Baumard and colleagues (2012)

reported, for example, that most of the children in their sample initially preferred allocating resources equally rather than differentially according to effort, but some later settled on differential allocation after planned follow-up questioning. Likewise, in the Vaish et al. (2009) study, more than a third of the control condition children helped or shared with the experimenter even though the adult had experienced no prior harm. Further exploration of the bases for variability in children's responding, especially in light of their own first-person experience in the family, seems warranted.

The rewarding, punishing, compensating, comforting, protesting, prosocial, and even tattling behaviors documented in these studies have a moral cast, but are they moral conduct? Thompson (2012, 2015) has argued that these responses by young children reflect a premoral sensibility derived from their capacities to understand the association of goals with emotions and desires, represent these in terms of first- and third-person perspectives, and derive intuitive evaluations of "nice," "mean," and "fair" on this basis. But these capacities become incorporated into a more explicitly moral perspective through relational experience. Mothers' coaching of care for others' needs increases linearly from 1 to 4 years to parallel these social-cognitive achievements, and helps to connect children's actions with another's goals and feelings (Gralinski & Kopp, 1993). At times, maternal socialization messages related to others' welfare are emotionally powerful communications, explicitly linking another's emotions with causal attributions and intentions, even if the child was just a bystander (e.g., Zahn-Waxler, Radke-Yarrow, & King, 1979). This may explain why parent-child discourse about people's feelings and needs—but not about rules and consequences—is a predictor of conscience development in preschoolers (Laible & Thompson, 2000, 2002). According to Smetana (1989), mothers justify their enforcement of moral rules to their 2- to 3-year-olds on the basis of people's needs or welfare, but justify social conventional rules instead in terms of social order and regulation. Consequently, by 3 to 4 years of age, young children view moral violations as more serious and less revocable than violations of other domain rules, justifying their judgments in terms of unfairness and the harm to others entailed in moral violations (Nucci & Weber, 1995; Smetana, 1989). In this relational context, therefore, a young child's premoral sensibility becomes enlisted into a broader system of values as caregivers build on children's intuitive judgments of human conduct in their moral socialization (see, e.g., Schmidt, Rakoczy, & Tomasello,

2012). In this manner, early social representations assume self-regulatory significance.

Simply stated, family relationships provide first-person experiences that enable young children to integrate their intuitive appraisals of human conduct into a system of values. If this conclusion is warranted, however, it requires a broader reconsideration of early moral development. First, by contrast with traditional moral development theories that portray young children as externalized and consequentialist until they internalize moral values, this view suggests that the primary incentives for moral behavior are internal from the beginning. Early developing appraisals of human conduct in relation to people's goals and feelings are foundational to the values orientation that caregivers subsequently build into their moral socialization efforts (Thompson, 2012). Indeed, external sanctions and incentives may impede, not facilitate, the cooperation, helping, and sharing that emerges from this premoral orientation (Warneken & Tomasello, 2008). Second, the emergence of an early premoral sensibility in young children is a developmental process that does not require assumptions of innate and universal sociomoral norms as core knowledge (cf. Sloane, Baillargeon, & Premack, 2012). Instead, moral awareness develops in a similar manner to other complex cognitive skills through the interaction of the young child's powerful inductive capacities (in this case, appraisals of human conduct based on consequences for others' goals, desires, and feelings) and the data provided by social experience (in this case, values socialization through family interaction).

Further Advances in Social Cognition

As young children proceed to more advanced social-cognitive achievements, the influence of social and relational experience remains significant (see, e.g., Astington & Baird, 2005; Carpendale & Lewis, 2004; Hughes, 2011). Developmentalists have studied a variety of social influences (e.g., parent-child discourse; culture and socio-economic differences; family size; attachment security) in relation to a broadening range of later social-cognitive achievements (e.g., false-belief understanding; ingroup-outgroup differentiation), and a comprehensive review of these influences is beyond the scope of this discussion. One aspect of this literature that merits further consideration, however, relates to the influence of adult mental state language on developing social representation.

There is a large research literature documenting a substantial predictive association between adults' use of

mental state language and central features of preschoolers' social understanding, especially false belief and emotion understanding (see Hughes, 2011; Milligan, Astington, & Dack, 2007; Thompson, 2006, for reviews). The more important, and interesting, question concerns *why* adult mental state language might have such influence. There are several alternative views, each of which may be influential (see Astington & Baird, 2005; P. L. Harris, de Rosnay, & Pons, 2005).

First, exposure to adult mental state language "lexicalizes" young children's preverbal conceptions of emotional and psychological states. In this semantic view, acquiring words like "know," "sad," and other mental state terms provides children with explicit referents for mental concepts that can then be the object of shared discourse. Second, exposure to adult mental state language may also sensitize young children to mental states through the ways in which language is structured (de Villiers & de Villiers, 2000). In this syntactic view, certain language constructions convey the open-ended characteristics of mental states, such as the use of sentential complements ("Mary thought that her father was arriving this morning.") and embedded propositional phrases referring to the objects of mental activity ("I don't know whether it's a dog or a cat.").

Third, exposure to adult mental state language may be important in the context of shared discourse in which mental concepts are incorporated into representations of the child's direct experience. In this pragmatic view, it is not the number of mental state terms that is important, but rather their enlistment into conversation about everyday events that reveal different points of view, conflicting interpretations, portrayals of emotion or desire, communication of beliefs, and other mental state references. From this perspective, therefore, young children develop an understanding of mental events through their engagement in discourse in which references to these mental events are incorporated into the narrative structure and causal attributions. Such a view is consistent with a Vygotskian portrayal of the internalization of linguistically mediated interaction with others to create "dialogic" cognitive representations (see Fernyhough, 2005).

A complementary approach to this pragmatic view comes from Fivush and her colleagues, who argue that the content and quality of an adult's verbal representations of the child's experiences contributes to developing understanding of mental states (Fivush, Haden, & Reese, 2006). To these researchers, maternal *elaborative* speech—a style characterized by the use of open-ended questions, statements, and evaluations that add new information to a shared

representation of the child's experience—contributes significantly to the quality of children's autobiographical narratives about past events. Their focus on autobiographical narratives is based on the view that, in constructing a shared representation of the past, a child's memory, sense of self, and social-cognitive understanding internalize the content and form of parent-child discourse and also the beliefs and values of the culture. From this neo-Vygotskian perspective, therefore, a developing awareness of mental states is dialogically scaffolded.

There is research evidence (reviewed by Fivush et al., 2006) that a maternal elaborative style of parent-child conversation is associated with greater mental state understanding (especially emotion understanding) in young children. Other research indicates that language in the context of social-relational interaction has this influence. A training study showed, for example, that preschool children who were engaged in discussion about deceptive experiences improved on theory of mind tasks, especially when discussions incorporated sentential complements that made reference to open-ended mental states as illustrated above (Lohmann & Tomasello, 2003). Ensor and Hughes (2008) reported that not only mothers' mental state references but their incorporation into her "connected" conversational turns with the child (i.e., building on the child's previous utterance) predicted a suite of measures of children's social understanding. Other studies indicate that *causal* language related to people's emotional or other mental states is associated with more advanced understanding of mental states in children (see Thompson, 2006, for a review; see also Hughes, 2011).

It is important to note that the influence of mental state language on developing social understanding is not limited to parent-child relationships. Indeed, researchers have shown that in interactions with siblings and peers, preschoolers talk about mental states more frequently than they do with their mothers (Brown, Donelan-McCall, & Dunn, 1996). It is not difficult to understand why. Conversations with other children typically involve comparisons and conflicts about feelings and intentions, negotiating goals and desires, discussions about differing preferences or viewpoints, explicit contrastive statements, and many other elements of mental state discourse. Mental state discourse with siblings and peers, whether focused on cognitive or emotional dimensions, also predicts children's social understanding (e.g., Hughes, Lecce, & Wilson, 2007; see Hughes, 2011, for a review).

Whether parents, siblings, or peers are concerned, the influence of mental state language on developing social

understanding underscores the importance of language in the context of relationships. In relationships, shared experiences are discussed, different perspectives matter and are compared and resolved, emotions are recognized and understood, conflicting intentions and desires are recognized and resolved, group membership is identified, and other mental states are explored by young children. These experiences of mental state discourse assume meaning because talking about them is one way that relationships develop and grow stronger as children become better known by, and better know, another person. As the content and quality of shared discourse in relational contexts influence children's developing representations of the social world, moreover, it also provides an avenue by which the parent's causal attribution biases, moral judgments, trait attributions, and other interpretive biases are also conveyed intergenerationally. Stated differently, parent-child discourse shapes the beliefs, values, and goals that underlie children's developing self-regulation.

Individual Differences in Relational Experience

Humans are biologically adapted to develop in the context of social relationships. But these relationships differ in quality, and humans are also selected to be sensitive to differences in the quality of relationships early in life because of their relevance to survival and well-being. Life history theory and other viewpoints (such as the predictive adaptive response model) argue that the quality of early social experience provides implicit cues concerning the broader environmental conditions to which human young must adapt. Viewed in this light, therefore, early social representations must comprehend not only generic human characteristics but also individual differences in these characteristics, especially between adult caregivers. In this respect they are different from representations of objects, number, geometry, and other core domains. Infants are neither likely to encounter nor are biologically prepared to adapt to significant variability in the functioning of other ontological domains because gravitational, geometric, quantitative, and other processes function fairly consistently in experience. But this is not true for social functioning, in which individual differences in others' behavioral propensities and the representations that derive from them are relevant to biological survival and psychological adjustment.

Thus we should expect that, in addition to generalizable representations of mental states discussed above, young children would also develop differentiated representations

based on their social experiences with specific partners. The literature on developmental social cognition has been much more concerned with generic knowledge than person-specific representations, although there is room in this research for serious consideration of the latter. Infants develop differentiated social expectations, for example, based on statistical regularities in the responsiveness of caregivers. Securely attached children have a better grasp of false belief in their mothers than do insecurely attached children, and they also have a more discriminating view of the veracity of her claims. Variations in social experience also affect the quality and timing by which generic advances in social cognition occur. Young children vary in their development of false-belief based on how much caregivers respond mentalistically to the infant as a psychologically motivated being (e.g., "mind-mindedness"). Preschoolers' emotion understanding is affected by variations in maternal use of mental state language in conversation with the child. Viewed more broadly, variations in cultural practices influence the timing and sequence of these early social-cognitive milestones even though they do not result in fundamental differences in their nature or acquisition (see, e.g., Callaghan et al., 2011; Liu, Wellman, Tardif, & Sabbaugh, 2008; Wellman, Cross, & Watson, 2001).

Differences in early relational experience and their representational correlates are important, therefore, for expanding understanding of how relationships influence children's understanding of themselves, their social partners, and their broader social ecology. They are also important for understanding how these representations mediate children's social experience. Two research programs illustrate these contributions.

First, based on the ideas of emotional security theory, Cummings and Davies (2010) and their colleagues have studied the behavioral, emotional, and representational consequences of young children's exposure to marital conflict and their mediation of later internalizing and externalizing problems. One of the outcomes of marital conflict is children's insecure representations of the marital relationship, which is typically assessed using the MacArthur Story Stem Battery in which children's responses to family-related story stems are scored for themes of marital conflict, parental caregiving, and overall emotional insecurity. When 6-year-olds' representations of the marital relationship were assessed in this manner, insecure representations mediated between children's exposure to marital conflict in the home and their subsequent poorer school adjustment (Sturge-Apple, Davies,

Winter, Cummings, & Schermerhorn, 2008). There was also evidence that parents' depressive symptomatology was comparably associated with children's behavioral problems through children's representational insecurity (Cummings, Schermerhorn, Keller, & Davies, 2008). As a further illustration of the moderating influence of these representations on other social experiences, children's insecurity in the marital relationship affected their representations of peer relationships which, in turn, also contributed to problems in school adjustment (Bascoe, Davies, Sturge-Apple, & Cummings, 2009).

Second, the work of Pollak and his colleagues has focused on more extreme family stresses associated with child maltreatment and their association with representations of emotion and relationships (Pollak, 2008). When children were asked to identify pictures of adult facial expressions of emotion that had been progressively "morphed" from one prototypical expression (e.g., sadness) to another (e.g., anger), maltreated children were more likely to identify blended expressions involving anger elements as angry than were nonmaltreated children (Pollak & Kistler, 2002). They did not, however, misidentify other emotion blends. Maltreated children exhibited a lower attentional threshold for detecting anger in the vocal expressions of their mothers (Shackman & Pollak, 2005), and had more difficulty attentionally disengaging from perceived angry cues (Pollak & Tolley-Schell, 2003). They also misattributed hypothetical situations as likely to evoke anger and sadness that children without a maltreatment history better distinguished (Perlman, Kalish, & Pollak, 2008). Together, these findings are consistent with the view that maltreated children are sensitized to signals of adult anger as the result of their family experiences, perhaps because doing so enables them better to anticipate and prepare for aversive encounters with an adult who has abused them in the past. However, as noted earlier, hypersensitivity to anger expressions and aggressive cues may also contribute to the social problems of maltreated children in out-of-home settings involving peers and adults, and further contribute to the dysregulation of neurobiological stress responding.

Several characteristics of these research programs, and others that also examine the representational correlates of variations in family experience, warrant note. First, the nature of the representations are similar to, but also different from, those of the developmental social-cognitive literature. Emotion understanding is studied, for example, but with an added focus on misrepresentations arising from a history of abuse or insecure attachment. Representations

of "helpers" and "hinderers" are captured with reference to specific family members in the context of family experience. Second, representations are studied with respect to the particular vulnerabilities (or benefits) hypothesized to derive from specific kinds of relational experience. The differential approach of this literature sharpens predictions to later behavior, which is part of the purpose of this research, but can make it more hazardous to generalize conclusions to the development of social representations in other circumstances. Finally, methodology is comparably diverse, with researchers using semi-projective story stems, measures of preattentive processing, coding of verbal discourse in parent-child conversation, and other approaches in addition to carefully designed experimental probes. These and other differences in approach and orientation can make it difficult to appreciate that individual differences in these relational representations must draw on comparable processes of social representation to those profiled in the social cognition literature. Integrating these approaches is a necessary and desirable goal.

Mental Working Models of Attachment Relationships

The attachment literature is the most enduring and theoretically sophisticated effort to understand the representational correlates of individual differences in early relational experience (see Cassidy & Shaver, 2008, for a general overview). As such, it exemplifies both the strengths and weaknesses of this approach to social-cognitive development.

Attachment theorists argue that, in addition to the other influences on socioemotional development derived from secure or insecure parent-child attachments, young children develop mental working models (or "internal working models" [IWMs]) of themselves, significant partners, and relational interaction from their experience with caregivers (Thompson, 2008a). These mental models change developmentally and with experience (hence "working"). IWMs are hypothesized to bridge the security of attachment and other aspects of social and personality development, such that young children with secure attachments develop different self-referential beliefs, relationship schemas, and personality organization compared to children with insecure attachments. These representational processes constitute, in turn, interpretive filters through which children choose new social partners and interpret their social experiences with them in ways that are consistent with past experiences and expectations arising from secure or insecure attachments. Insecurely attached children may,

for example, so anticipate another's unfriendliness that they remain distant and unengaged and, in so doing, evoke the responses they expect. By contrast, securely attached children, guided by different IWMs to expect people to respond warmly to them, act in such a positive manner as to create more affirming, intimate relationships with them.

In portraying mental working models in this way, attachment theorists articulate three functions of these mental working models. IWMs enable the *prediction* of the behavior of attachment figures, which is especially (but not exclusively) apparent early in life when children are most dependent on the reliable responsiveness of their caregivers. IWMs also assist in the *interpretation* of social behavior of attachment figures and others. Finally, IWMs underlie the *self-regulation* of relational responding in accordance with these interpretations. These multiple functions of IWMs help to explain their influence on the development of new relationships, social construal, and personality.

The concept of internal working models is simultaneously used by attachment theorists to refer to the initial representations in infancy leading to a secure or insecure attachment, the representations deriving from that attachment in childhood and adolescence, and even the relational representations that adults enlist in their romantic partnerships and parenting. Herein is one of the strengths and liabilities of the IWM concept. It is a richly inclusive theoretical construct describing relational representations that are dynamic and emotionally colored, but the breadth and inclusiveness of the IWM construct undermines specificity in its conceptualization and measurement.

With respect to conceptualization, attachment theorists have struggled to mine the rich potential of this theoretical idea by specifying more clearly its defining features. Some theorists have focused on the *content* of the mental working models deriving from parent-child attachment. Thompson and his colleagues (Thompson, 2008b; Thompson, Laible, & Ontai, 2003), for example, have argued that the relational experiences associated with secure attachments, particularly the more candid communication shared by parents and children, provides children with enhanced social understanding and better social problem-solving skills. There is considerable research supporting this view. A number of studies have shown that the mothers of securely attached preschoolers are more elaborate in their conversational style with their children, which may contribute to their enhanced mental state understanding (see Fivush et al., 2006, for a review). As reviewed by Thompson (2008b), securely attached children have greater

emotion understanding, exhibit more positive expectations for peer behavior, show greater compliance, cooperation, and other indicators of emergent conscience, have a more positive self-concept, and exhibit enhanced emotion regulation when compared with insecurely attached children. With respect to the self-regulatory function of mental working models, Raikes and Thompson (2008a) found that securely attached children were more likely to identify socially competent and relevant solutions to social problem-solving tasks, were less likely to attribute negative social motivations to peers, and were less lonely than were insecurely attached children. These social problem-solving skills may help to account for the greater peer social competence of securely attached children. In this formulation of IWMs, one can see aspects of developing social cognition studied by researchers outside of the attachment framework reviewed above, suggesting that something in secure relationships—perhaps in the positive dialogic construction of understanding—facilitates developing social cognition.

Other attachment theorists have focused on the influence of IWMs on the *processing* of social information (Dykas & Cassidy, 2011). Drawing on classic concepts of defensive exclusion, they propose that securely attached children are biased to process in a relatively open manner a broad range of positive and negative social information relevant to attachment concerns, and to do so in a positively biased manner. By contrast, insecurely attached children are biased to process social information, particularly negative information, much differently. On one hand, they are expected to defensively exclude from awareness negative information that is likely to cause them psychological pain. On the other hand, they are expected to process information that will not cause them pain in a negatively biased manner, consistent with their attachment history. Studying these formulations in children requires assessing selective attention to and memory for social information, and there is some evidence for these processing biases in children in a manner that is consistent with studies of attachment in adolescents and adults (see Dykas & Cassidy, 2011; Thompson, 2008b, for reviews). Few researchers outside of attachment theory study these kinds of defensive influences in children, but one can see in this formulation elements of social-cognitive research in adults, such as the confirmation bias, the self-fulfilling prophecy, and processes of constructive memory.

In light of these different formulations of the nature and functioning of IWMs, it is understandable that there is methodological pluralism as well. In addition to the

kinds of measures described above, attachment researchers use semi-projective doll play, story stems, drawings, or picture cards to elicit children's representations of family experience, as well as direct interviews about children's experiences with family members (Solomon & George, 2008). In some respects, this methodological diversity makes sense in light of the complexity of the construct that researchers are seeking to capture, especially within the neoanalytic orientation of attachment theory. On the other hand, as others have argued, the lack of theoretical clarity of the IWM construct is an impediment to articulate methods development as well as to its appropriate conceptual application to research findings (Belsky & Cassidy, 1994).

Despite these drawbacks, the attachment research based on the IWM concept has been uniquely generative in establishing reliable associations between early relational experience and the development of social representations that influence self-regulation and predict later behavior. Together with research outside of attachment theory, it provides some of the strongest evidence to date for how representations, drawn from previous relational experience, moderate subsequent social relations and contribute to developing self-regulation.

Interim Conclusion

The developmental account that emerges from this research is that, in the early months and years of life, young children are learning both about the generic characteristics of people and the specific propensities of those they live with. They are rapidly acquiring understanding of the goal-directed quality of human action at the same time that they are developing specific expectations for the intentional behavior of people toward them. They are evaluating the influence of actors on the goals and desires of other actors at the same time that they are having first-hand experience with helping and hindering behavior among family members. At the same time that language contributes to children's understanding of false belief and emotion, the quality and content of parent-child conversation is shaping children's representations of themselves, their experiences, and the characteristics of specific people. Relational experience is central to the social influences from which young children derive this understanding, and these representations influence their subsequent social interactions, emotion regulation, and behavior management.

In this manner, the representations derived from relational experience contribute to the development of self-regulation. Representations of the intentions, desires,

and feelings of other people become incorporated into cooperative conduct as well as a premoral sensibility that contributes to children's judgments of fairness, their developing capacities for cooperation and helping, and other manifestations of shared intentionality, especially as it is enlisted into a values orientation through relational guidance. Representations of the self and other people acquired dialogically through parent-child conversation contribute to a developing network of beliefs, values, and goals that guide how young children respond to social partners. The relational security inspired by sensitive care contributes to the growth of mental models of people, the self, and relationships that become incorporated into how children regulate their interactions with attachment figures and other partners.

The research literatures surveyed in this discussion each contribute to this account with complementary but different orientations that underscore the potential value of creating bridges between them. On one hand, the insightfully descriptive yield of developmental social cognition research, based on carefully designed experimental studies, better portrays the young child as embedded in a collection of social figures than in a relational network of affective significance. On the other hand, the research based on attachment theory has shown how relational representations predict later behavior but without clarity concerning the nature of those representations or their assessment. Each research field addresses common issues related to the nature of early social representations and the influence of social experience on their development, and greater connections between them would be mutually informative.

There have been several efforts to bridge these perspectives. Repacholi and Trapolini (2004), using a false belief task focused on the mother's beliefs, reported that securely attached children performed better than insecurely attached children, with avoidant children showing the greatest difficulty understanding maternal false beliefs compared with those of an unfamiliar adult. Building on the research literature on children's trust in testimony (P. L. Harris, 2012), Corriveau et al. (2009) reported that securely attached children generally preferred to believe their mothers when evaluating the veracity of her claims, but wisely did not do so when the evidence warranted disbelief. By contrast, insecure-avoidant children showed less reliance on their mother's claims, while insecure-resistant children displayed more. Not everything has to be associated with the security of attachment, however. Forman and Kochanska (2001) examined individual differences in toddlers' propensity to imitate their mothers, and found that it was

associated with other measures of children's receptiveness to the parent's socialization initiatives, and these differences in responsive imitation also predicted later measures of conscience development (see also Forman, Aksan, & Kochanska, 2004). Taken together, studies like these indicate that examining variability in children's performance on assessments of social-cognitive understanding may yield informative understanding of individual differences related to children's prior relational experience.

Other kinds of research directions are required to move deeper toward understanding relational influences on developing social representation. It is important to better understand, for example, the everyday social experiences shared by young children with their parents that provide data for the social representations that develop so rapidly and easily in the early years. How are a parent's mentalizing interpretations of an infant's behavior manifested in response to the child's initiatives and expressions? How do parents and toddlers engage in cooperative social interactions that derive from, and foster, the growth of shared intentionality? What sorts of verbal messages accompany parents' evaluations of young children's behavior, and how do these messages relate to the mental constructions children are developing with respect to third-person responsibility for helping or harming another (see Thompson & Winer, 2014)?

Theoretically driven, culturally comparative investigations may contribute to addressing such questions. Although studies comparing the performance of children from different nationalities are a good start, what the field really needs are hypothesis-testing efforts that predict variations in children's social-cognitive skills from assessments of parent belief systems and the organization of everyday social relations between young children and their caregivers. In cultures where parents think it is nonsensical to talk to infants until they are capable of language (e.g., Richman, Miller, & Levine, 1992), for example, how does this influence parental responses to infants' goal-directed efforts and does this result in significant differences in developing shared intentionality? Such efforts would contribute to understanding the extent to which processes of early interaction observed in Western societies (on which most research on social development is based) are broadly generalizable. But equally importantly, such research would help to clarify the extent to which such differences, when observed, result primarily in variations in the timing or sequence of developmental milestones, or instead in more significant variations in the organization of early social-cognitive development. Advancing this kind of research might also help to reveal how different patterns

of social interaction in Western and non-Western cultures contribute to common social-cognitive achievements through different means. Keller (2007) offers a useful model of such inquiry with respect to the development of self in infancy.

Understanding relational influences on the development of social representation would also benefit from theory development. In particular, the concept of "internal working models" within attachment theory lives up to the criticism that it can constitute a "catch-all, post hoc explanation" (Belsky & Cassidy, 1994) for any research linking attachment security to other behavior. Besides the vagueness of this concept, it is applied to a developmentally wide range of attachment-related processes without a coherent theory to explain how IWMs themselves change with development. The idea of dynamic, integrative, affectively endowed mental working models is a powerful conceptual tool for understanding the representational dimensions of early relationships, but as Bowlby (1969/1982) himself recognized, the general idea of mental working models is only the beginning of the systematic theoretical work required to make this idea a meaningful theoretical construct. One way of addressing this challenge is to unpack the concept of mental working models to specify the specific components that emerge developmentally in relational experience. This discussion has identified a number of candidate elements of developing social cognition that must be encompassed within the general rubric of IWMs, and other research literatures in social psychology offer additional candidates that might be particularly relevant to adult attachment. Only when this occurs will it be possible to understand how IWMs are associated with the initial development of secure or insecure attachments in infancy, how IWMs change or remain stable with increasing age and the relational influences that are relevant to their consistency, and how the nature of attachment security developmentally evolves as the IWMs on which it is based also change developmentally.

In the end, the importance of this work derives not just from its significance for developmental theory and research. Understanding relational influences on developing social representations and their impact on self-regulation is also important for its applications to improving early developmental outcomes, especially when caregiving relationships go awry. An intervention study highlights the potential value of efforts to change the representations that young children derive from living with an abusive or depressed caregiver, and also tests some of the ideas discussed in this section. In Preschooler-Parent

Psychotherapy, an attachment-based program, the intervention focused on helping mothers achieve insight into their own representations of the child and self. Mothers were encouraged to reflect on how these representations derived from past experience and their influence on parent-child interaction and, in sessions involving the child, therapists helped mothers develop healthier patterns of caregiving behavior. In one evaluation of this program, Toth, Maughan, Manly, Spagnola, and Cicchetti (2002) reported that preschoolers' representations of the mother and the mother-child relationship, as well as of the self (assessed using story-stem narratives), became more positive from intake to follow-up and were better at outcome than those of a non-maltreating comparison group. Other comparable interventions with maltreating mothers (Moss et al., 2011) and depressed mothers (Toth, Rogosch, Manly, & Cicchetti, 2006) have improved rates of secure attachment in intervention group children from intake to follow-up using similar procedures. In light of concerns about the intergenerational transmission of psychological risk mediated through the representational processes that derive from disordered parent-child relationships, further exploration of these kinds of representation-based interventions seems warranted.

TOWARD SELF-REGULATION

Development proceeds from external regulation to self-regulation in most behavioral domains. External regulation is needed to provide protection and support to guide the growth of behavioral systems. But for development to proceed optimally, external regulation is never meant to endure alone. Rather, the child's maturing self-regulatory capacities should progressively interact with and eventually supplant regulation from outside. In this manner, children become competently autonomous.

Portrayed in this simple manner, however, the development of self-regulation is complex. Whether considered with respect to the growth of cognitive self-control, moral conduct, emotion regulation, social competence, or other domains, the development of self-regulation integrates multiple developmental processes from within and outside the child. These include the maturation of many biological systems, most notably in the developing brain, relevant to the development of reactivity and self-control. They include diverse developing cognitive skills for enlisting self-regulatory procedures to effect behavioral change. They include a developing sense of self that motivates

self-regulatory efforts in order to achieve desired results. They include parents' socialization strategies, framed by personal beliefs and goals, to guide children's conduct according to expectations for mature conduct. They include cultural values that are influential in defining those expectations, as well as establishing a system of practices in a social ecology that includes the child. These developmental processes are integrated into a network of reciprocal influences that, over time, not only enable children to be competently self-regulating but to do so adaptively within their social contexts.

The development of emotion regulation illustrates these complex, integrated processes of self-regulation. Developmental scientists have devoted considerable attention to emotion regulation because it contributes significantly to social and behavioral competence and because emotion dysregulation is viewed as a risk factor for affective psychopathology. Scientific interest in emotion regulation is also consistent with cultural beliefs about the value of self-control and theoretical interest in functionalist theories of emotion. This section proposes that understanding the growth of emotion regulation—and self-regulation generally—as a multilevel system involving continuous interaction between biological, representational, and social processes is necessary to comprehend its development and its implications for behavioral competence. This multilevel orientation makes developmental systems theory a useful theoretical context for studying emotion regulation (e.g., Gottlieb, Wahlsten, & Lickliter, 2006; Thompson, 2011). The portrayal by systems theory of the multidirectional interactions between influences at different system levels is one contribution of this perspective. Additional contributions are its emphasis on coaction between different levels of developmental systems and the portrayal of these levels of influence as embedded in a richly complex social context.

One illustration of the value of a systems perspective is the neurobiological organization of emotion regulation. Emotion regulation is believed, according to many accounts, to modulate the intensity of emotion activation through the imposition of cognitive controls (such as response inhibition) or cortical controls (such as prefrontal regulation) on emotional arousal. This view is important and influential, but it captures only part of the model generated by research on the neurobiology of emotion. This literature shows that responses to emotional stimuli activate complex neural networks that are widely distributed throughout the brain, integrating areas typically regarded as relevant to emotion activation (including the amygdala,

hypothalamus, brainstem, and striatum) and those viewed as relevant to emotion regulation (including the lateral and medial prefrontal cortex and anterior cingulate). There is increasing evidence from neuroimaging research that these multilevel emotion-relevant areas are *coactive* in response to emotion stimuli rather than functioning primarily in activation-inhibition associations (Kober et al., 2008; Ochsner et al., 2009; see also Ulrich-Lai & Herman, 2009). Stated differently, emotion regulation can function in a conventional “top-down” fashion (such as how prefrontal processes regulate amygdala function) or in a “bottom-up” fashion (such as how conditioned fear arising from limbic processes alters higher-level threat detection). Regulatory influences can occur at different levels of the system throughout the process of emotional responding.

The orientation of developmental systems theory to multilevel processes with continuous coaction between different system levels is consistent with this neurobiological account, and also offers new ways of thinking about the development of emotion regulation. It inquires, as earlier sections of this chapter have done, how experiences of parental care influence the development of biological systems underlying emotional reactivity and self-regulation. It poses questions about how the child’s representations of emotions and their management are affected by differences in biological reactivity and parent socialization, as well as cultural values, and how these representations influence emotion management. It asks how the parents’ representational systems, shaped by cultural values as well as personal experience, influence their guidance for developing emotional self-control. It explores how the child’s biological reactivity affects parents’ socialization strategies and their effectiveness. And with respect to risk for affective psychopathology, the contextualism of developmental systems theory inquires how processes of emotion regulation that are dysfunctional in certain social contexts may have developed because they are most adaptive in the contexts in which children are at greatest risk, presenting an inherent trade-off in strategies of emotion regulation because of inconsistent contextual demands. These are potentially important questions to ask of the development of emotion regulation, although addressing them well requires considerably more research than currently exists.

Development of Emotion Regulation

It is customary to begin a discussion of the development of emotion regulation with birth. But the fetal programming

research indicates that individual differences in stress reactivity and self-regulation begin to develop prenatally owing to the biological effects of prenatal care. These prenatal influences contribute to differences in children’s reactivity to postnatal environmental events and stress regulation.

Experiential influences on developing biological systems continue after birth in children’s exposure to adversity or receipt of support, especially as these experiences are mediated by the quality of care. In interaction with the child’s genetic characteristics (and, in certain circumstances, affecting their expression), these experiences influence the development of biological systems underlying emotional reactivity and self-regulation and, as earlier noted, affect other systems related to immunological functioning, autonomic reactivity, and cognitive functioning. These biological changes have behavioral consequences for many aspects of developing individuality, including temperament (e.g., DiPietro et al., 2008). More broadly, they also contribute to the development of individual differences in susceptibility to environmental stresses and support that moderate children’s reactivity and self-regulation in response to challenge (Ellis et al., 2011). Owing in part to the effects of early experiences, in other words, some children become more sensitive to environmental conditions than others.

The neurobiological systems associated with reactivity and self-regulation have a fairly extended maturational course. The HPA axis and prefrontal areas associated with emotion, for example, continue to develop into adolescence (Casey, Giedd, & Thomas, 2000), which is one reason why the development of emotion regulation has such an extended timeline. This long maturational period is also why these systems remain amenable to experiential influences for so long. Throughout this period, for example, individual differences in autonomic functioning and parasympathetic regulation are influenced by the quality of parental care, including parental sensitivity and the effects of family conflict (El-Sheikh & Erath, 2011; Propper & Moore, 2006).

This makes the caregiver’s responsiveness to the infant’s emotions important, especially before capacities for self-control are well developed. Young infants possess a small repertoire of behaviors that can manage their arousal, including attentional redirection, behavioral withdrawal, self-soothing, social signaling, and later using motor actions to move toward or away from arousing events. Caregiver sensitivity and responsiveness are important to supporting this rudimentary self-regulatory repertoire and providing external regulation of the infant’s arousal.

Sensitive responding to a young infant is not an easy task, however, because recurrent bouts of unexplained fussiness (e.g., colic) and unpredictable changes in behavioral state can make it difficult to understand, predict, or regulate arousal states, causing some parents to approach early care as ministering to the needs of an inexplicably energized organism (Robson & Moss, 1970). This difficulty in managing early arousal also explains why so much of parents' external emotion regulation is proactive (or antecedent) in nature. Parents manage the daily routine to reduce upsetting events as much as possible, they promptly avert fussiness before it escalates by soothing, redirecting attention, or other means, they seek to induce positive affect by modeling, entertaining, or otherwise stimulating the baby, and they analyze the infant's cues to discern the causes of distress (for which their own capacities for mentalization or "mind-mindedness" can be helpful).

These parental efforts are not always successful, but they cumulatively contribute to the infant's emotion management. Consistent with the research on physiological stress buffering, for example, Braungart-Rieker, Hill-Soderlund, and Karrass (2010) found that although infant fear and anger reactivity generally increased from 4 to 18 months, sensitive mothers had infants who showed more modest increments in fear than infants with less sensitive mothers. Besides the immediate impact of nurturant contact on soothing infant distress, sensitive care may also be influential by lowering the threshold for distress-incompatible responses, such as attentional focusing elicited by the adult's touch or voice, or positive affect through emotional contagion. Parental practices become more effective as the infant becomes capable of representing experiences of care in more complex ways. Over the course of the first year, as earlier noted, distressed infants increasingly respond with anticipatory quieting to the sound of the adult's approach (Gekoski et al., 1983; Lamb & Malkin, 1986), and social expectations in these circumstances regulate distress. The relief of distress in situations like these provides further opportunities for associating the caregiver's presence and characteristics (voice, face, quality of touch) with soothing and reassurance. The development of these early social representations, especially as adult responses are encoded as intentional conduct by the infant, are likely to be important contributors to secure attachment.

With increasing age, young children acquire more active strategies of emotion regulation deriving from their growing understanding of the causes and consequences of emotion (see Thompson, 1990, 1994). Understanding the

association between perceptual processes and emotional arousal, for example, young children leave situations that they find distressing, cover their eyes or ears, or restrict perceptual access in other ways. Their developing comprehension of the referentiality of emotional expressions contributes to their use of social referencing in uncertain situations to receive reassurance or a cautionary alert. Their experience with caregivers teaches them the value of seeking nurturant assistance for managing emotions, or even using reassuring self-talk. Not all of these advances in representing emotion contribute to better emotion regulation. Toddlers' knowledge of the association between sadness and unfulfilled desire may cause them to be insistent on getting what they want before they can feel better. In general, however, these advances in emotion understanding contribute to the development of behavioral strategies for managing emotion that rely on young children's actions to change their exposure to emotionally arousing events or access to social support.

This account is incomplete, however, because of increasing evidence that young children also recognize the value of mentalistic strategies of emotion regulation. E. L. Davis, Levine, Lench, and Quas (2010) and Dennis and Kelemen (2009) each used short story vignettes to probe preschoolers' understanding of the efficacy of different strategies for managing negative emotions, and each reported surprising sophistication in young children's endorsement of mentalistic strategies such as cognitive reappraisal, deliberate distraction, and goal substitution. The major difference in strategy endorsement between younger and older children in these studies was the continued reliance of younger children on relatively ineffective means of managing emotion. Several research groups have also noted that young children evaluate the efficacy of alternative emotion regulation strategies on an emotion-specific basis, describing problem-solving approaches as most effective for anger, emotion-focused strategies (such as seeking social support) as most useful for sadness, and altering thinking (especially emotion-relevant interpretations) as most suitable for fear (see Sayfan & Lagattuta, 2009, and Waters & Thompson, 2014).

The realization that children as young as age 3 recognize the value of mentalistic strategies for managing emotion raises the question of why there is so little evidence that young children use these strategies in everyday circumstances. There are several potential explanations, including the obvious difference in task requirements between responding to short story vignettes and enacting self-regulatory strategies in personal circumstances. But

this discrepancy between emotion representations and emotion regulation also suggests that something more is necessary to bridge understanding and application. To many developmentalists, that “something more” consists of the development of executive functions.

Executive functions consist of higher cognitive capacities that enable self-regulation by managing more basic mental and behavioral processes. Zelazo and Cunningham (2007) distinguish “hot” executive functions that are motivationally significant from “cool” executive functions that are not on the basis of different brain areas and processing characteristics, and emotion regulation is clearly more closely associated with “hot” executive functions. Executive functions relevant to emotion regulation include inhibition, focused or sustained attention, cognitive flexibility (including switching perspectives, goals, or mental focus), self-monitoring, error detection, manipulating information in working memory, and reappraising the meaning of events. It is not difficult to see the significance of these executive functions for emotion regulation. Inhibition is crucial to resisting the inclination to respond in an emotionally impulsive manner and instead enlist self-regulatory efforts. Working memory is important to recognizing multiple considerations relevant to emotional responding, including the nature of the provoking event, the social context, one’s goals, the emotional reactions of others, and other factors. Reappraisal is a means of managing emotion by reinterpreting circumstances to yield more emotionally satisfying responses. Cognitive flexibility is necessary for reappraisal and for anticipating the probable outcomes of an emotional response. In some definitions of emotion regulation (Thompson, 1994), self-monitoring of one’s feelings is important to managing them.

Executive functions have an extended developmental course, but the most significant advances occur between the ages of 3 and 5 (Best & Miller, 2010). Subsequently children can be observed using more strategic, cognitively sophisticated strategies for managing their emotions, such as cognitive reappraisal, substituting goals, mental distraction, and other approaches (Thompson, 1990). Their greater understanding of the association between thinking and feeling also enables older children to better appreciate the value of positive thinking, even in difficult circumstances, and the detriments of ruminating on the negative (Bamford & Lagattuta, 2012). Children of this age also recognize how the anticipation of feeling good can be a motivator for moral compliance, even in circumstances when compliance requires doing what you do not want to do (Lagattuta et al., 2010). These developing cognitive

competencies are important to the growth and flexibility in emotion self-regulation.

There are further advances in the development of emotion regulation that have been less studied but are also important. These include

- Increasing breadth, sophistication, and flexibility in the use of different emotion regulation strategies, substituting effective for ineffective approaches, and using multiple strategies when necessary;
- Growing skill in understanding and enlisting emotion regulation skills appropriate to the interpersonal context, such as knowing about differences in suitable emotion regulation strategies for use with peers versus adults (Thompson & Waters, 2010);
- Increasing use of emotion-specific self-regulatory strategies as well as emotion-general strategies;
- Growing sophistication in the social and personal goals motivating self-regulatory efforts, including enlisting emotion regulation for managing social relations, protecting self-esteem, and facilitating cognitive functioning, consistent with cultural expectations; and
- Developing a consistent individual style of emotion regulation focused on personal goals and preferred strategies, consistent with developing personality organization.

These developing competencies are co-constructed by children and parents, with parents at the leading edge of fostering children’s emotional self-control. It is in parents’ interest to foster children’s emotion regulation, of course, and they are also motivated by their developmental expectations for children’s self-control. A national survey in the United States showed that nearly half the parents with very young children reported that 3-year-olds could control their emotions when frustrated, and most thought that children of this age could competently share and take turns with other children (Newton & Thompson, 2010). These expectations may explain why parents are so concerted in their efforts to foster young children’s emotional self-management, and why they become frustrated when children are not self-controlling in circumstances where parents believe they should be capable of doing so.

Parents’ beliefs about children’s emotions and emotion regulation are thus important to how they respond. Wong, McElwain, and Halberstadt (2009) reported, for example, that parents who believed that young children’s negative emotions should be accepted were less likely to report responding nonsupportively to children’s distress.

With a middle childhood sample, Ramsden and Hubbard (2002) likewise found that mothers' acceptance of children's negative emotions, together with low negative family expressiveness, together predicted teacher ratings of children's emotion regulation.

Not surprisingly, parent beliefs incorporate cultural values concerning the appropriate expression of emotion. In a culturally comparative study, Cole, Tamang, and Shrestha (2006) observed mothers with their preschool-age children from Tamang and Brahman ethnic groups in Nepal and interviewed village elders about characteristics of the competent child. Consistent with cultural values concerning these emotions, Tamang mothers were observed teasing or rebuking their angry children but responding with nurturance when children were ashamed, while Brahman mothers were more likely to respond with nurturance and teaching to an angry child but ignore children when they were ashamed. Consistent with these practices, Tamang children in an independent study indicated that they did not respond angrily to situations that angered children from the other cultural groups (Tamang elders indicated that competent children did not get angry when things did not go their way) but instead felt shame. Brahman children admitted feeling angry while shame was not a salient emotional experience for them (Cole, Bruschi, & Tamang, 2002).

Parental beliefs about children's emotions are thus important. So also is how parents represent emotion in their own experience. Consistent with the concept of mentalization, parents who are better able to regard their own emotional experiences with acceptance and insight may be more capable of doing so with respect to the feelings of their children. Meyer and her colleagues found that mothers' beliefs in attending to and accepting emotions, along with their endorsement of the value of emotion management, together predicted their reports of children's competence in emotion regulation. This association was mediated by mothers' constructive emotion socialization practices, such as problem- and emotion-focused responses to children's expressions (Meyer, Raikes, Virmani, Waters, & Thompson, 2014). One reason that parents' emotion representations are influential is that they affect how adults interpret how children feel. Prior research indicates that parents can be surprisingly discrepant from children's self-reports in their retrospective descriptions of how their children felt during shared experiences. Sometimes this occurs because adults and children perceive their shared experience with different goals, expectations, and interests (Levine, Stein, & Liwag, 1999). A study by

Waters et al. (2010) likewise found that when mothers and children independently reported on what children were feeling during an emotion regulation probe earlier in the research session, mothers were much less concordant with children's self-reports than were independent observers, with fewer than 50% reporting that their children felt mad or sad when their children reported those feelings about themselves. However, mothers who responded most consistently with children's self-reports were higher in their own beliefs that emotions should receive attention and be accepted, and they also had secure attachments with their children (Waters et al., 2010).

These findings are consistent with Gottman, Katz, and Hooven's (1997) concept of a parental "meta-emotion philosophy" that guides their emotion socialization of children. A meta-emotion philosophy incorporates the adult's awareness of her or his own emotions, an understanding and acceptance of children's emotions, and the parent's approach to managing the child's feelings. Gottman and his colleagues (1997) have distinguished two kinds of philosophies based on interviews of parents in the United States. Emotion-coaching parents are attentive to their own feelings and those of their child, consider the child's emotional expressions as teaching opportunities, and offer support and guidance for managing feelings. Emotion-dismissing parents tend to ignore their own emotions or belittle their importance, may not constructively attend to their children's feelings, and view emotions (especially negative ones) as potentially harmful, and thus they see themselves as responsible for subduing negative outbursts in their children.

An extensive interview is typically used to distinguish emotion-coaching from emotion-dismissing parents, and studies based on this formulation have yielded supportive results (Katz, Maliken, & Stettler, 2012). The view that parents' emotion socialization practices are guided by a meta-emotion philosophy is heuristically powerful. Much more research is needed to unpack this formulation, however, and to identify relevant elements of parents' socialization practices, clarify the nature of their emotion coaching, and examine its association with parents' emotion-related beliefs and children's emotion regulation.

With respect to parent socialization, for example, there are many ways that family experience affects emotional development and emotion regulation (Morris, Silk, Steinberg, Myers, & Robinson, 2007; Thompson, 2013). The importance of sensitive responding and proactive interventions were considered earlier. In addition, parents' modeling of emotional reactivity and self-control are

likely to be influential in the context of the family's general emotional expressiveness (see, e.g., Denham, Mitchell-Copeland, Strandberg, Auerbach, & Blair, 1997). In a series of studies, for example, Eisenberg showed that preschoolers' social competence was affected by how constructively mothers conveyed positive or negative feelings in the home, and this association was mediated by differences in children's self-regulatory behavior (e.g., Eisenberg et al., 2001; Eisenberg et al., 2003). These and other studies suggest that moderate to high amounts of positive emotion among family members contributes to children's self-regulatory competence, while the effects of the expression of negative emotions depends on their frequency, intensity, and threat to the child (Thompson, 2013). Consistent with Gottman's formulations, moreover, parental dismissal of children's emotions tends to be associated with poorer emotion coping than problem-focused responses (Eisenberg, Fabes, & Murphy, 1996; Meyer et al., 2014). Much more remains to be understood about how these and other socialization practices coincide to guide children's emotional development. Developmental changes in the nature of these influences also merit further study.

With respect to emotion coaching, there are many direct and indirect ways that parents prompt children's emotion regulation efforts. In one example, Morris and her colleagues found that mothers' prompting the use of cognitive reframing or attention refocusing when their young children received a disappointing gift was associated with lower-intensity expressions of anger and sadness (Morris et al., 2011). Emotion coaching can also occur during conversations about past emotional experiences. In one study, for example, mothers and their preschool children talked together about recent experiences that had provoked the child's sadness or anger, and 88% of the mothers spontaneously talked about different means of managing emotion in these situations. Many mothers explicitly commented about the effectiveness of these strategies for making one feel better (Thompson, Virmani, Waters, Raikes, & Meyer, 2013). In such conversational contexts, knowledge of emotion regulation can be integrated with broader emotion understanding and cultural beliefs about emotional expression and its management. Our research group has also observed that emotion self-regulatory strategies are sometimes prompted by mothers in conversations about anticipated future events that may be upsetting to the child, such as a visit to the dentist. In doing so, mothers often make reference to strategies in the past that have proven effective for the child.

Finally, it is important to frame the study of parents' emotion philosophy and socialization practices in a broader cultural context. Cultural and subcultural groups differ in their beliefs about emotional expressivity in children, the emotional characteristics of an admirable child, the use of emotion in socialization practices (such as shame in moral socialization), how emotions are acceptably conveyed, and the role of the parent in emotion socialization (see Parker et al., 2012, for an analysis). Supporting children's emotional expressiveness and validating their feelings are not necessarily universal values. In general, considerable work remains to better understand the socialization practices relevant to developing emotion regulation in children.

The same could be said for understanding emotion regulation and the security of attachment. There is a reliable association between secure attachment and competence in emotion regulation in studies with infants, preschoolers, grade-schoolers, and adolescents (see Thompson, 2008b, for a review). The foregoing discussion indicates several reasons that this would be so. Sensitive responding to distress, which is foundational to developing a secure attachment, is also likely to alter infants' implicit representations of distress and its management. This is consistent with the lower HPA reactivity of secure infants (compared to insecure infants) observed with their mothers in situations that were challenging to them (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). Securely attached young children are also more advanced in emotion understanding (especially of negative emotions) than are insecurely attached children, which may provide them with greater insight into the causes of emotion and its regulation. The mothers of secure infants may contribute to emotion understanding through their more elaborative style of talking with children about their experiences, including experiences involving heightened emotion. Mothers in secure relationships are more consistent with their children in their understanding of what the child is feeling (Waters et al., 2010) and their conversational style also incorporates greater validation of the child's feelings and constructive emotion regulation coaching (Thompson et al., 2013; Waters et al., 2010; see also Raikes & Thompson, 2008b). Taken together, these aspects of secure attachment relationships contribute to their characterization as a "psychological secure base" for young children to learn about their emotions and how they can best be managed.

One of the disadvantages of an inclusive construct like the security of attachment is that it enfolds many aspects of relational variability into a single concept that is then

used as a predictor of diverse components of psychological development. This undermines the ability to identify the specific features of relational experience that are most influential to the behavioral differences associated with the security of attachment, such as emotion regulation. On the other hand, if the different features of relational experience associated with secure attachment—sensitive responding, elaborative emotion-related discourse, validation of the child's feelings, emotion coaching—have been independently confirmed as positive influences on the development of emotion regulation, then their combined influence in the context of a secure attachment may be theoretically informative. Developing competence in emotion regulation is a multifaceted, multilevel process involving responsiveness to children's emotional expressions, guidance of children's representations of emotion and its management, constructive practical assistance in managing emotions, and other processes that affect the biological and psychological dimensions of emotion and its regulation.

The studies of emotion regulation and attachment also illustrate the multilevel influences of relational experience on emotional reactivity and its management, which range from the effects of caregiver responsiveness on biological stress regulation to the effects of parent-child conversation on representations of emotion. To some attachment researchers, differences in attachment security are primarily differences in the relational management of emotion. In light of this, it is striking how little is known about the representational, biological, and behavioral characteristics of children in the three insecure groups relative to emotion regulation. To even the casual observer of infants or preschoolers in the Strange Situation, these differences in emotion and its management between the insecure groups are striking, and they constitute fertile ground for further research into the development of emotion regulation. Such work would be especially informative for understanding how relational experience defines the socioemotional context to which skills of emotion regulation become adapted.

Emotion Regulation and Behavioral Competence

Research on the development of emotion regulation is motivated by the view that it contributes to social competence, emotional adjustment, and even cognitive functioning. From this perspective, self-regulatory processes help to ensure that emotional arousal—which has the potential to undermine behavioral organization—is enlisted effectively into the child's ongoing transactions, and to avoid

problems such as aggression and social withdrawal that are associated with emotional dysregulation.

Yet the foregoing analysis shows that competence in emotion regulation is also context specific. Well-regulated Tamang children acknowledge feeling shame rather than anger, while Brahman children respond in the opposite manner to similar circumstances, and children in the United States seek ways to express their anger acceptably (Cole et al., 2002). Children understand that some ways of responding emotionally may be more appropriate when parents are present than with peers (Thompson & Waters, 2010). Children who are maltreated maintain heightened vigilance for signs of adult anger that may foreshadow further abuse, and thus have a lower threshold for distress (Pollak, 2008). Although some approaches to managing emotion improve the chances for constructive behavioral outcomes, these and other findings caution that strategies of emotion regulation are rarely inherently optimal or maladaptive. They contribute to behavioral competence in the contexts in which they develop, consistent with a developmental systems perspective. They may or may not function comparably in other contexts.

Further evidence for this view comes from studies of children at risk for affective disorders. Young children with a genetic vulnerability to anxiety disorders show hyper-vigilance in situations associated with fearful events, attentional orienting to anxiety-provoking stimuli, and a tendency to construe benign situations as disproportionately threatening (Fox, Henderson, Marshall, Nichols, & Ghera, 2005). These appraisal and preappraisal processes develop to accomplish the immediate goal of avoiding anxiety-provoking events despite their broader dysfunctional consequences. Children in families characterized by frequent marital conflict engage in strategies to preserve a sense of security in their parents' relationship but which also render them more vulnerable to affective problems. These strategies include trying to mediate, comfort, or pacify parents, aggressing against one or both parents, and maintaining perceptual vigilance to cues of impending conflict, each of which can cost further enmeshment in parental conflict (Davies & Woitach, 2008). In circumstances like these, children's emotion regulatory strategies involve inherent trade-offs that purchase immediate coping at the price of long-term difficulty, and which may ultimately increase rather than diminish their emotional vulnerability. Emotion regulation for these children is a double-edged sword.

This functionalist analysis is sharpened by the recognition that in the contexts in which children seek to manage

the emotions generated by these conditions, there may be multiple goals they are seeking to accomplish with different immediate and long-term consequences. Maintaining vigilance for the angry outburst of a maltreating or maritally conflicted parent helps in preparing for an aversive encounter, but exacts continuing costs to the child's emotional security. Avoiding exposure to adult anger may support a sense of well-being at the cost of unpreparedness. In each case, these self-regulatory strategies are likely to be dysfunctional outside of the contexts in which they develop, contributing to hypersensitivity to threat that can lead to aggressive encounters with peers (Cicchetti & Toth, 1995), difficulties in school adjustment (Sturge-Apple et al., 2008), and other problems. When mothers in an urban working-class neighborhood coached their young children on strategies for expressing anger that would serve them well in challenging situations, the tactics of aggression and intimidation that children learned might have been adaptive in a potentially dangerous neighborhood, but not necessarily in the neighborhood school (P. Miller & Sperry, 1987).

The value of examining emotion regulation within this functionalist context is that it encourages developmental researchers to consider the contextual demands to which self-regulatory strategies are adapted. This is important both for developmental analysis and for research in developmental psychopathology. In each case, broad characterizations of individuals as emotionally dysregulated should be only the beginning of an incisive analysis of the contextual demands to which individuals are responding, the emotion goals to be accomplished by observed self-regulatory strategies, the trade-offs that might be involved in how emotion is managed, and their relevance to other social contexts in which individuals must emotionally function. For developmental study, this kind of analysis can sensitize researchers to the ways that children's emotion goals change with age along with their strategies of emotion management. For developmental psychopathology, this analysis causes researchers to confront whether and how more optimal means of emotion regulation are possible in the circumstances in which these children live.

Interim Conclusion

The development of emotion regulation, whether in typical circumstances or conditions of risk, illustrates the multi-level analysis required of the study of self-regulatory growth. The social ecology, especially conditions of care, affects the development of biological systems of

stress reactivity and regulation depending on whether that ecology is aversive or supportive. In these conditions, children develop representations of their experiences, parental responsiveness, emotion, and the self that contribute to their efforts to manage emotion in ways that are adapted to these life circumstances and their emotion goals. As the research described above indicates, these biological and representational processes are important mediators of the behavioral outcomes that are associated with self-regulatory differences.

Within this multilevel system, furthermore, not just children's representations but also the belief systems of parents are important contributors to the development of emotion regulation because those beliefs are manifested in socialization practices, evaluations of children's emotionality, and their coaching of adaptive self-regulation. Indeed, parents' representations may also be crucial to their social buffering of children's stress that has biological as well as representational consequences. The heuristic value of a parental "meta-emotion philosophy" underscores the importance of the parental beliefs underlying their responsiveness to the child: beliefs about the self and the parenting role, inferences about children's understanding and feelings, cultural values and expectations, representations of the admirable child, and other implicit and explicit beliefs also merit study as influences on developing self-regulation in children.

Finally, the study of emotion regulation highlights the importance of context, which is also important to self-regulation in general. Children develop skills in managing their emotions to accomplish their goals in response to the emotion challenges they face, and how they do so is influenced by whether they are with adults or peers, their socioeconomic and cultural identity, the behavior and values of other family members, as well as individuality in temperament and self-concept. Future study of the development of emotion regulation would benefit from greater attention to the contextual demands to which these skills become adapted, and to children's negotiation of different contexts requiring different goals and skills for self-regulation.

CONCLUSION

The themes of this chapter—developing biology, social representation, emotion regulation, early relationships—are some of the most vigorous research fields of contemporary developmental science, and there is every reason to expect that this will continue. In light of this, a central

goal of this discussion is to underscore how biology, representation, and relationships are interconnected in early development and, in particular, how relationships contribute to self-regulation through their influences on developing biological systems and social representations. This approach to parent-child relationships significantly broadens understanding of the impact of the quality of care on children's development, has important practical applications, and addresses classic theoretical issues in developmental science.

By contrast with some formulations that emphasize children's self-initiated self-regulatory strategies, the term "regulation" is used broadly here to refer to implicit as well as deliberate self-regulatory processes arising from outside as well as within the child. This choice recognizes that long before young children become capably self-regulating, their abilities and dispositions have already been shaped by experiences that affect how they respond to events, how they think about those events, and what they expect will happen when they respond. Considering the development of self-regulation without respect to these influences risks entering the developmental process well after it has begun. It is arguable that such a broad conception of "regulation" encompasses so much that regulation becomes simply one aspect of behavioral functioning, but that is also the point. Regulatory influences are incorporated into behavioral functioning on many levels and in most behavioral and biological domains, and although this means that "unregulated" behavior, biology, or thought is a theoretical fiction, this recognition constrains neither theoretical analysis nor empirical inquiry (cf. Campos, Frankel, & Camras, 2004).

In each section, future research directions have been identified, but several general themes also emerge from this chapter. First, context is missing from many of these research areas, particularly developmental social cognition research, and greater understanding of the influence of the large and narrow social context would complicate theory and enliven research on developing self-regulation. Concerning social-cognitive development especially, it would be valuable for more researchers to consider more deeply the first-person experiences that contribute to the early development of social understanding. The elegant experimental studies of this literature appropriately divorce young children from confounding social influences, but it sometimes appears as if young children are theoretically viewed as inhabiting comparably barren social worlds. Yet the findings from several groups that direct social experiences are important to these social-cognitive advances should spur

more researchers to consider their influence further. Young children inhabit an environment of relationships of affective significance, and it would be astonishing if relational experiences (and variations therein) were not influential to developing generic social-cognitive achievements as well as relationship-specific representations.

Second, researchers need a richer characterization of early relational experience on which to build this understanding of context. Following the discovery of the "competent infant" in the 1970s, students of social development embarked on the intensive study of parent-infant interaction in the first year that informed attachment research, temperament theory, and other fields. There is no comparably rich database concerning parent-child interaction beyond infancy and its relevance to emergent understanding of shared intentionality, collaboration, fairness and reciprocity, prosocial motivation, and other elements of a developing premoral sensibility. Our understanding of relational influences on other constituents of developing self-regulation, such as emotion regulation, is comparably impoverished. What occurs in the structure of social interchange and the nature of social discourse to provide very young children with first-hand experiences that contribute to their developing social representations or their developing skills of emotional control?

Third, culturally informed investigations could potentially be a useful contribution to addressing this question. The most useful culturally comparative studies would be hypothesis-testing efforts that predict variations in children's social-cognitive skills or behavioral outcomes from direct assessments of parent belief systems and study of the organization of everyday social interactions between parents and children. The goal is not simply the documentation of cultural variability but the determination of its meaning in relation to important developmental outcomes, some of which are likely to be species typical. Stated differently, do variations in cultural practices achieve comparable developmental outcomes (perhaps with variations in their timing) or contribute to significantly different outcomes adapted to different social ecologies?

Fourth, there are formidable challenges to future research on the biology of developing self-regulation, including the missing heritability problem, the potential unreliability of small sample studies of genetic influences, and other issues (see Dennis, Buss, & Hastings, 2012, for an overview). If these can be resolved, however, there is hope for the potential yield of further multilevel studies in this area that integrate attention to context (such as poverty and family stress), measurement of biological

reactivity and regulation, developing behavioral outcomes in children, and implications for intervention. Particularly promising are efforts to complement studies of stress reactivity and regulation with stress-buffering influences deriving from relational experience (see, e.g., Hostinar et al., 2013). Such efforts provide further insight into the biological effects of relational experience, and have implications for the design of interventions to strengthen buffers in the experience of children in stressful conditions.

Finally, the research literatures reviewed here are beginning to provide a more multifaceted, multidimensional portrayal of the nature of early parenting. Studies of developing biological systems emphasize the importance of early relationships for buffering stress and moderating adversity and highlight how genotype moderates the nature of these influences. Research on developing social representations suggests that embedded into everyday parent-child interactions are implicit lessons on human agency, intentionality, mutuality, self-other correspondence, and other building blocks for generic social understanding and the development of social expectations. Work in developing emotion regulation draws attention to what caregivers say, how they say it, and the implicit understanding of the child's characteristics and feelings that make conversational discourse meaningful to developing self-regulation. Although much more remains to be understood, as noted earlier, these literatures encourage developmentalists to move beyond global characterizations of parental sensitivity (or aversiveness) to develop theoretical portrayals of why specific parenting practices are important to what early developmental outcomes, and how.

Developmental science has a longstanding (perhaps necessary) habit of parcelling the developing child. Yet building bridges between different orientations to the developmental process has always proven fruitful. Developmental science is on the verge of resolving some of its past conceptual pitfalls and moving toward a biologically dynamic, experience-based understanding of development integrating developing biology, representation, behavior, and relationships. Our capacities as research scientists to see the developing child as a coherent, integrated being underlies our capacities to imagine the developmental process for all of its complexity, scope, and vitality.

Since the 1970s, developmental science has seen incremental increases in research on the construct of resilience: *A dynamic process reflecting positive child adjustment despite significant risk or adversity* (Garmezy, 1971; Luthar & Zigler, 1991; Masten, Best, & Garmezy, 1990; Rutter, 1987; Werner & Smith, 1982; 1992). The 1990s through the 2000s witnessed an eightfold increase in references to resilience in the scholarly literature (Ager, 2013), testifying to its salience in developmental science.

The objectives underlying this chapter are to describe the major developments in the field of resilience across the span of almost six decades. The chapter is organized in four sections, the first one presenting a brief history of work on resilience. In the second section, we describe critical

This chapter was prepared when all authors were at Columbia University's Teachers College; Luthar and Small are currently at Arizona State University. The authors gratefully acknowledge funding from the National Institutes of Health (DA10726 and DA14385), and help with background research by members of our research lab at Teachers College.

features of research on this construct, highlighting definitions of major terms and distinctions between resilience and related constructs (e.g., competence and ego-resiliency); the operationalization and measurement of vulnerability and protective processes; and statistical approaches used to illuminate major risk-modifiers.

In the third section of the chapter, we describe major research findings on vulnerability and protective factors across different at-risk populations. These are discussed in terms of the specific factors found to modify risk within three broad categories, that is, attributes of the family, community, and child. The fourth and final section includes major considerations for future work on resilience among at-risk children and families, including directions for both research and interventions.

HISTORICAL OVERVIEW OF CHILDHOOD RESILIENCE RESEARCH

The roots of resilience research can be traced back to the 1970s, with pioneering research on positive adaptation

among children of schizophrenics. Whereas these children as a group are at high risk for psychopathology, Garmezy and Rutter, along with Anthony and Koupnik, found that a subset of them manifested surprisingly healthy adjustment (for a fuller description of these early studies and citations, please see Luthar & Zigler, 1991; Masten et al., 1990). Their scientific focus on the positive outcomes of these children reflected a substantive departure from the illness-based medical models of the time.

Shortly after, Werner published the first of many reports on a cohort born in Hawaii (Werner & Smith, 1982, 1992), and the 1980s and early 1990s marked substantive changes in conceptualizations of resilience, two of which were especially salient. The first concerned perspectives on the roots of resilience. In early studies, the focus was largely on positive personal qualities of manifestly resilient children, such as autonomy or charisma. As work in the area evolved, however, scientists noted that resilient adaptation often could stem from forces external to the child. Thus, three sets of factors came to be commonly cited as implicated in resilience: attributes of the children themselves, characteristics of their families, and influences from their wider social environments (Garmezy & Masten, 1986; Rutter, 1987; Werner & Smith, 1982).

The second change involved acknowledgement that resilience fluctuates over time, as opposed to being fixed. In some early writings, terms such as “invulnerable” were used for children who functioned well in spite of multiple risks. Recognizing that this risk-evasion was not absolute and unchanging, researchers began to use the more qualified term “resilience” instead. Implicit in this change of labels was cognizance that positive adaptation despite adversity is never permanent; rather, it is a developmental progression, with new strengths and vulnerabilities emerging with shifting life circumstances (Garmezy & Masten, 1986; Werner & Smith, 1992).

A related qualifier was explicit recognition that resilience is never an across-the-board phenomenon, with uniformly positive adjustment across diverse domains. Just as children in general do not manifest consistently positive (or negative) adaptation across different spheres of adjustment, it was clear that at-risk children, too, could display remarkable strengths in some areas while showing significant deficits in others (Luthar, Doernberger, & Zigler, 1993). Most important, children under stress could appear resilient in terms of their behaviors while still experiencing considerable covert distress in the form of depression or anxiety (Farber & Egeland, 1987; Luthar, 1991). Recognizing such variability in adjustment levels across

domains, researchers now tend to use more specific terms that indicate the domains of manifest resilience, referring, for example, to academic resilience (Obradović et al., 2009), emotional resilience (Jain, Buka, Subramanian, & Molnar, 2012), or external (behavioral) resilience (Yates & Grey, 2012).

RESEARCH ON RESILIENCE: CENTRAL CONSTRUCTS

Reviews of research on resilience reflect converging definitions of the core constructs within this area (see Cicchetti, 2013; Luthar, Cicchetti, & Becker, 2000; Masten & Narayan, 2012; Rutter, 2012; Ungar, Ghazinour, & Richter, 2013; Vanderbilt-Adriance & Shaw, 2008): resilience, adversity, and positive adaptation. As noted at the outset of this chapter, resilience is a phenomenon or process reflecting relatively positive adaptation despite significant adversity or trauma. Because it is a superordinate construct subsuming two distinct dimensions—*adversity* and *positive adaptation*—resilience is never directly measured, but instead is indirectly inferred based on evidence of the two subsumed constructs.

Adversity, in developmental science research on resilience, is defined in terms of statistical probabilities: A high-risk condition is one that carries high odds for measured maladjustment in critical domains. Exposure to maternal depression or community violence, for example, constitutes high risk because children experiencing each of these manifest significantly greater maladjustment than those who do not. Aside from discrete risk dimensions such as parent psychopathology, researchers have also examined composites of multiple risk indices, such as parents’ low income and education, histories of mental illness, and disorganization in neighborhoods (Sameroff, Seifer, Zax, & Barcas, 1987). When risks such as these coexist (as they often do, in the real world), effects tend to be synergistic, with child outcomes being far poorer than when any of these risks exists in isolation.

Positive adaptation, the second component in the construct of resilience, refers to adjustment that is much better than what would be expected, given exposure to the risk condition under study. In studies of resilience in childhood, this construct is most commonly operationalized in terms of behaviorally manifested social competence, or success at meeting stage-salient developmental tasks (Luthar, 2006; Masten & Tellegen, 2012). To illustrate, competence is often operationally defined in terms of observed secure

attachment behaviors among young children, and in terms of positive relationships with peers and teachers, as well as good academic grades, among older children and adolescents.

In addition to being developmentally appropriate, indicators used to operationalize “positive adaptation” must be of high conceptual relevance to the particular risk condition examined, in terms of both domains assessed, and stringency of criteria used. When communities carry many risks for antisocial problems, for example, it is logical to assess children’s maintenance of socially conforming behaviors (Jain et al., 2012), whereas among offspring of depressed parents, the absence of depressive problems would be of special significance (Beardslee, Gladstone, & O’Connor, 2012). With regard to stringency of criteria, similarly, decisions must depend on the seriousness of the risks being studied. In research on children facing major traumas, it is appropriate to define risk-evasion in terms of the absence of serious psychopathology rather than excellence in everyday adaptation (Luthar et al., 2000; Rutter, 2012). Finally, positive child adaptation must be considered across multiple adjustment spheres; overly narrow foci on particular behaviors can be misleading in suggesting that risk-evasion has in fact occurred.

In some instances, competence is most appropriately operationalized in terms of better-than-expected functioning of families or communities, rather than of the children themselves. Toddlers, for example, are still too young to be judged as reliably manifesting resilience because their functioning is largely regulated by caregivers; it makes more sense, therefore, to operationalize positive adjustment in terms of the parent-child dyad or family unit. In parallel, the label of “resilience” can be most appropriate for communities of at-risk youth who are functioning well. To illustrate, some low-income urban neighborhoods reflect far higher levels of organization, cohesiveness, and social efficacy than do others (Jain et al., 2012), with the potential, therefore, to minimize the negative effects of poverty on children.

Given that positive adaptation fluctuates over time rather than being immutably fixed, an important area of resilience research concerns those who “bounce back” from earlier dysfunction. Long-term prospective studies have been invaluable in identifying critical turning points not just in childhood and adolescence, but also later in adulthood, illuminating instances where negative adjustment trajectories were transformed into positive, healthy ones (Hauser, Allen, & Golden, 2006; Laub & Sampson, 2003; Vaillant, 2012; Werner & Smith, 1992).

Competence and ego-resiliency are two constructs that are each related to resilience, but differ in substantive ways. Competence and resilience both represent positive adaptation, but there are four major differences. First, resilience presupposes risk but competence does not. Second, resilience encompasses both positive and negative adjustment indices (presence of health and absence of disorder), whereas competence reflects the former. Third, resilient adaptation is defined in terms of both behavioral and emotional indices, whereas competence typically involves only manifest, observable behaviors. Finally, resilience is a superordinate construct that subsumes dimensions of competence (along with exposure to risk).

Ego-resiliency is a personal trait reflecting general resourcefulness, sturdiness of character, and flexibility in response to environmental circumstances (Block & Block, 1980); like resilience, this involves positive adaptation. Differences are that (a) only resilience presupposes conditions of adversity and (b) resilience is not a personality trait, but is a process or phenomenon. Finally, just as competence is subsumed within the definition of resilience, ego-resiliency is among the personal attributes that can foster resilient adaptation, mitigating the negative effects of stressful life experiences (e.g., Cicchetti & Rogosch, 2007).

It is critical that scientists proactively guard against suggestions that resilience is a personal trait, as this can foster perspectives that blame the victim (Luthar & Brown, 2007; Ungar, 2013). Toward this end, several precautions have been noted (Luthar et al., 2000). Most important, all reports must include clear definitions of resilience, unequivocally clarifying that this refers to a process or phenomenon and *not* a trait. Second, it is preferable to avoid using the term *resiliency*, which carries the connotation of a personal attribute even more so than does *resilience*. Furthermore, it is best to avoid using the term resilient as an adjective for children and apply it instead to trajectories or profiles, because phrases such as “resilient adaptation” carry no implication of who (the child or others) might be responsible for manifest risk-evasion.

Vulnerability and Protective Processes: Operationalization and Measurement

The central objective of resilience researchers is to identify *vulnerability* and *protective factors* that might *modify* the negative effects of adverse life circumstances, and then, to identify *mechanisms* or *processes* that might underlie associations found. Vulnerability factors or markers are indices that exacerbate the negative effects of the adverse condition

(e.g., poverty) on children, such as parent mental illness or alienation from peers. Promotive or protective factors are assets that modify the effects of risk in a positive direction, such as support from informal mentors and good coping skills.

Quantitative studies of resilience have entailed two major statistical approaches in identifying protective or vulnerability factors (risk-modifiers), that is, variable-based and person-based analyses. Variable-based analyses such as multivariate regressions allow researchers to look at how adjustment is predicted by continuous scales of risk-modifiers and risk indices, examining how the former are directly related to outcomes (as main effects), and in interaction effects with the latter. An early illustration of this variable-based approach was the ground-breaking paper by Garmezy, Masten, and Tellegen (1984), in which high IQ was shown to be protective: Intelligent children seemed to be far less affected by increasing levels of life stress than did their low-IQ counterparts. Person-based analyses in resilience research, by contrast, involve comparisons between groups categorized according to their risk exposure and adjustment profiles. For example, comparisons of two groups of risk-exposed youth, manifesting positive and negative adjustment respectively, can illuminate critical factors that protect against adversity.

In variable and person-based analyses, a hallmark of the current generation of resilience research is attention to underlying processes; this is essential for guiding effective interventions. In working with at-risk groups of children, it is far more prudent to promote positive adjustment early in development than to treat disorders after they have already crystallized, and knowledge of processes potent in specific at-risk circumstances can be critical in pinpointing issues that most urgently warrant attention. To illustrate, maternal depression can affect children through various environmental processes including high family conflict, children's modeling of ineffective coping styles, and negative parenting behaviors ranging from inattentiveness to enmeshment (Valdez, Mills, Barrueco, Leis, & Riley, 2011). With regard to protective processes, similarly, supportive relationships with caregivers can benefit children through multiple pathways, including feelings of being cherished as an individual and a strong set of personal values (Werner & Smith, 1992).

Interpreting Findings: Main Effects and Interaction Terms

In variable-based analyses, a complication with interpretation has to do with whether significant main effect

associations imply that low levels of the hypothesized asset imply unusually poor adjustment, that high levels imply excellence in functioning, or both. There are, admittedly, a few "pure" vulnerability indices that can only create disorder when present but not excellence when absent, such as child maltreatment, whereas others can be beneficial when present without conferring vulnerability when absent, such as artistic or musical talents. Many, if not most, indices, however, are bipolar in nature, with the potential for effects at both extremes. For example, a significant main effect involving social skills could imply either that high levels lead to exceptional competence (protection), or that low levels lead children to unusual maladjustment (vulnerability).

Although researchers have often used these terms interchangeably, choosing somewhat arbitrarily between labels of vulnerability or protection for such "bipolar" variables, it can be useful to examine the distribution of scores to guide choices in this regard (see Luthar & Latendresse, 2005). To continue with the same example, this could be done by demarcating, for interpretive purposes, groups that are high and low on social skills (e.g., defined by the top and bottom tertiles). Depending on the degree to which the mean competence scores of these two groups each deviate from the sample mean, this could illuminate whether low social skills connote significant vulnerability (with competence scores much poorer than average), or whether high social skills reflect protection (competence well above the sample average). A more statistically sophisticated method to address issues such as this has been elucidated by Roisman and colleagues (2012). These authors suggest that researchers apply a Regions of Significance (RoS) test (Dearing & Hamilton, 2006) to determine if Y (the outcome variable) and Z (the risk-modifier) are correlated both at the high and low ends of the distribution of X (levels of stress), bounded by a conventional range of interest that is $+2$ standard deviations from the mean of X .

Although there has been some lack of clarity about main effect findings, there has, historically, been more confusion about interaction effects, wherein, for example, the presence of a particular attribute (e.g., peer support) conferred stable, adaptive functioning despite increasing stress, whereas low levels of this variable connote maladjustment. In the 1980s and 1990s, such interaction effects were viewed as being at the crux of research on resilience, sometimes emphasized as more important for inferring protection than were direct, main effects (see Luthar et al., 2000).

At this time, however, there is consensus that researchers are centrally concerned with illuminating constructs that

distinguish between well- and poorly functioning youth *within* a given risk condition, and with substantial effect sizes (what occurs in the absence of risk is not of central concern). Interaction terms typically have very small effect sizes and thus are notoriously unstable, and when researchers include multiple interaction terms in predictive models, this can greatly constrain the detection of potentially important *main effect* links, due to a loss of degrees of freedom in statistical models (Luthar et al., 2000).

VULNERABILITY AND PROTECTIVE PROCESSES: SUMMARIZING EXTANT EVIDENCE

This section of the chapter encompasses major findings from over 60 years of research on resilience. While describing the forces that modify effects of high-risk life circumstances, we discuss the categories of risk-modifiers in order of relative salience in conferring positive adaptation despite risk exposure. Resilience researchers have been criticized for producing lists of sundry protective and vulnerability factors (see Luthar et al., 2000); such lists are of limited practical value because all items (ranging from parents' intelligence, to neighborhood safety, to children's social skills) can never be addressed in a given intervention. From a pragmatic standpoint, therefore, what is needed is conceptual prioritization of domains in terms of overall likelihood of yielding substantial benefits.

Accordingly, organization of this section is based on the following considerations. In general, primacy in discussions is given to the most *influential* risk-modifiers, that is, those whose effects are relatively enduring, robust, or hard to overcome by others. Second, more emphasis is placed on *modifiable modifiers*. Whereas personal characteristics like gender or race certainly can affect outcomes, these are afforded less prominence than are those that are more amenable to change, such as parental discipline or teacher support. Third, we prioritize constructs that are *broadly deterministic*, that is, those with high potential to generate other assets (or vulnerabilities, as the case may be), in what Rutter (1987) called "chain reactions."

With these considerations in mind, our discussions focus, in sequence, on vulnerability and protective forces in the domains of the family, the community, and the children themselves (see Luthar, 2006). The family is not only the most proximal of children's external environments but also the most enduring; it is logical, therefore, to focus first on families in the triad of influences. The community,

in turn, affects children both directly as well as indirectly through their parents, so that modifying aspects of the wider environment can have benefits through both routes. With regard to children's own attributes, these obviously do play a major role in resilient adaptation, but many "child attributes" (such as self-efficacy or even intelligence) are themselves shaped by forces in the environment (Hanson & Gottesman, 2012; Luthar, 2006; Ungar, 2012). These are therefore discussed third in the sequence.

Rather than describing findings of individual studies in the research literature, our emphasis, in this section, is on summarizing major themes that have emerged regarding salient vulnerability and protective processes with selected investigations described for illustrative purposes. Along with empirical evidence on the three sets of risk-modifiers, relevant evidence from intervention efforts is also considered; data from interventions can provide valuable lessons for science by showing, for example, whether targeting hypothesized protective factors does in fact predicate resilient adaptation (Cicchetti & Hinshaw, 2002; Luthar & Cicchetti, 2000).

Family Relationships

As the key context for early development, the family environment has been the focus of much of the literature on resilience. In this section, we begin by addressing findings on resilience in the face of an especially potent vulnerability familial factor, maltreatment by caregivers. Following this, we review evidence on protective family processes, with particular attention to malleable aspects of relationships that hold the strongest implications for future interventions.

Effects of Maltreatment

Of the many processes that affect the adjustment of at-risk children, among the most powerful is maltreatment by primary caregivers. Maltreatment co-occurs with many high-risk circumstances including poverty, community violence, parental conflict, and parent mental illness (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume), thus operating as a rampant vulnerability factor. Maltreated children show deficits spanning multiple domains, with functioning disrupted in interrelated areas over time; this is unsurprising, as maltreatment entails serious perturbations in the most proximal level of the child's environment (for a full discussion of the developmental impact of maltreatment, see Cicchetti & Toth, Chapter 13, this *Handbook*, this volume).

Long-term, multidomain resilience is rare among maltreated children—as seen in diverse adult health problems linked with child maltreatment (Felitti & Anda, 2010)—but profiles of adjustment are, obviously, not homogeneous (Cicchetti, 2013). Forces that can mitigate vulnerability to some degree include positive relationships with others. As will be described fully later, good quality of caregiving is the single most robust of protective factors for children exposed to various adversities, so that positive relationships with alternate caregivers could serve protective functions for maltreated youth (Lawler, Shaver, & Goodman, 2011). Unfortunately, experiences of maltreatment also thwart access to these potentially beneficial influences, as maltreated youth struggle more than others to establish close relationships with alternative adult caregivers (Cicchetti, 2013). Furthermore, the protective function of social support can vary with the seriousness of maltreatment, with buffering effects diminishing, for example, with increases in the number of maltreatment subtypes experienced and chronicity across developmental periods over time (Cicchetti, 2013).

Beyond caregiver-child bonds, support from other relationships may be protective. Potential in this regard is seen in Bolger and Patterson's (2003) longitudinal research showing that among chronically maltreated children, having a positive, reciprocal friendship was associated with an increase in self-esteem over time. Mediating processes implicated might include improved social skills, changes in working models of attachment, increases in perceived acceptance, and decreases in felt loneliness.

Personality factors can also make a difference. Cicchetti and Rogosch (2007) found that ego-resiliency and ego-overcontrol predicted relatively competent functioning in maltreated children, as Bolger and Patterson (2003) found that maltreated children with higher internal locus of control manifested lower levels of symptoms than others. As with access to alternative supportive caregivers, however, the experience of maltreatment also compromises the very personal attributes that could confer protection. As Cicchetti (2013) has noted, maltreated children as a group show many deficits in emotional regulation, either showing excessive amounts of negative affect or blunted affect with little positive or negative emotion. Given their difficulty in effectively modulating physiological arousal, they also have trouble coping with emotionally stressful situations, particularly in the case of early-onset maltreatment. In summary, then, repeated developmental disruptions of a maltreating environment not only directly increase risk for maladjustment, but, in addition, work against positive

attributes that could have served protective functions (see Cicchetti & Toth, Chapter 13, this *Handbook*, this volume).

Acknowledging the breadth of processes affected, there have been calls for multilevel examinations of social-ecological pathways affecting outcomes among maltreated children (see Luthar & Brown, 2007). For example, Ungar (2013) has argued that for children who have been maltreated, individual attributes will be protective to the extent that they enable engagement with available resources, from community and mental health services, to features of the physical environment. In this case, analyses that consider the quality and availability of resources and services, alongside children's individual characteristics, may provide a more nuanced understanding of variations in adaptation among samples of maltreated children.

Protective Family Forces: Attachment, Nurturance, and Support

Whereas maltreatment is pernicious, child abuse is obviously not inevitable among families facing major life adversities, and positive relationships with adults can be powerful in promoting resilience among children confronting diverse risks. The critical importance of strong family relationships has long been emphasized by child development theorists from diverse perspectives. This theme is at the core of classic psychodynamic perspectives ranging from Freud's stages of psychosexual development and Mahler's notion of human symbiosis to Bowlby's attachment theory and Erikson's emphasis on trust versus mistrust. Besides psychodynamic viewpoints, Havighurst's earliest developmental tasks—learning to walk, talk, and relate age-appropriately to others—presuppose the presence of an attentive adult to foster mastery of these tasks. Similarly, learning theorists such as Bandura and Skinner emphasized the power of parents' reinforcement patterns as well as modeling behaviors in shaping the child's personality.

Consistent with these classic theories of child development, the earliest studies of resilience established that the presence of a close relationship with at least one parent figure was highly protective across a range of risks, ranging from chronic family poverty and early institutionalization to serious parent mental illness and multiple coexisting adversities (for summaries, see Luthar & Zigler, 1991; Masten et al., 1990). Recurrent reviews of the literature, similarly, have consistently pointed to responsive and supportive parenting as being the single most robust predictor of resilient adaptation in the face of diverse adversities

(Crnic & Neece, Chapter 8, this *Handbook*, this volume; Luthar & Brown, 2007; Masten, 2011; Vanderbilt-Adriance & Shaw, 2008).

Particularly important in shaping long-term resilient trajectories are early family relationships. In Shonkoff and colleagues' (2012) call to action to combat toxic stress in early childhood (with its long-term effects on the individual's stress response system), nurturing relationships with significant adults are afforded top priority, listed beside children's most basic needs for survival including adequate nutrition and safe physical environments. The critical role of early relationships is seen in longitudinal evidence that early experience places people on probabilistic trajectories of relatively good or poor adaptation, shaping the lens through which they view subsequent relationships, as well as their capacities to utilize support resources in the environment (Sroufe, Coffino, & Carlson, 2010). Thus, when early attachments are insecure in nature, at-risk children come to anticipate negative reactions from others and can eventually elicit these; experiences of rejection, in turn, further increase feelings of insecurity. Conversely, at-risk children with at least one positive relationship are able to draw upon nurturant others with whom they interact subsequently in development (Shonkoff & Phillips, 2000; Sroufe et al., 2010).

Biological research has also pointed to sensitive periods in early attachments. Across various animal species, separation from the mother after birth can lead to permanent changes in neurochemistry, endocrine responsivity, and problem behaviors (for a summary, see Luthar & Brown, 2007). Powerful evidence in this regard is seen in studies with rhesus monkeys by Suomi and his colleagues (see Suomi, 2006). After an initial month in a neonatal nursery, these monkeys were raised for 6 months away from their biological mothers, but in the presence of three to four other infants. These peer-only raised monkeys came to display several maladaptive behaviors including greater aggression, greater consumption of alcohol during "happy hour" situations, and greater biological stress reactivity (Suomi, 2006).

In humans, Gunnar and her colleagues have demonstrated that secure attachments to caregivers can prevent elevations of stress hormones in situations that typically elicit distress in infants (see Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume). In contrast, children with insecure attachments usually react to threatening situations with increased levels of the stress hormone, cortisol. Reviewing research on the ontogeny of the stress system, comprising the limbic-hypothalamic-pituitary-

adrenocortical (L-HPA) and sympathetic-adrenomedullary (SAM) systems, Gunnar and Quevedo (2007) concluded that (a) individual differences in the regulation and reactivity of both systems are related not only to temperamental characteristics but also to quality of caregiving, and importantly, that (b) the impact of the former may indeed be best understood in the context of the latter.

Among older children as well, competent parenting plays a critical role in promoting child well-being over and above the effects of contextual factors such as family poverty (Werner & Smith, 1982, 1992). Adolescent perceptions of maternal warmth, for example, are related to diverse positive outcomes including better personal adjustment and academic achievement (Suizzo et al., 2012; Walton & Flouri, 2010).

Even when risk factors stem from within the family—as when one parent has a mental illness—a strong relationship with the other parent can be substantially protective. In families affected by parental depression, for instance, Beardslee (2002) underscored the importance of strong, supportive relationships with at least one parent for resilient adaptation. Similarly, Edwards, Eiden, and Leonard (2006) found that, among young children of alcoholic fathers, a secure attachment to mothers could protect against the development of externalizing symptoms, and in a longitudinal sample of children of alcoholics, Werner and Johnson (2004) reported that the presence of a supportive, nonalcoholic mother was a critical protective factor among those who functioned well in young adulthood.

The protective potential of strong relationships has been demonstrated not only for mothers but also for fathers and father-figures. In low-income, African American families, warm, stimulating paternal behavior during early childhood was found to benefit children's academic skills in middle childhood, irrespective of whether fathers lived with their children, and independent of maternal characteristics (Coley, Lewin-Bizen & Carrano, 2011). In the Iowa Youth and Families Project, strong emotional ties to fathers were associated with resilient adaptation among youth, whereas their absence contributed to vulnerability (Elder & Conger, 2000). Indirect effects of nonresident fathers' involvement have also been shown, predicting to fewer child behavior problems via improvements in the mother's parenting, and the quality of mother-father interactions (Choi & Jackson, 2011).

Whereas close involvement with fathers can yield several benefits, it has also been found, in some cases, to be linked with relatively poor child outcomes (see Coley, 2001). Negative effects may derive from elevated conflict

between highly involved fathers and mothers, resulting, for example, from disagreements about disciplinary practices for their young children. Additionally, problem behaviors in some children of highly involved low-socioeconomic status (SES) fathers may stem from exposure to high levels of paternal antisocial behaviors (Coley, Carrano, & Lewin-Bizan, 2011). As Carlson and Magnuson (2011) note, there remains a need for more studies on the impact of low-income fathers in particular, with careful consideration of the many contextual variations in which fathering takes place (e.g., according to culture, ethnicity, child age and gender, and family living arrangements). In parallel, Luthar, Barkin, and Crossman (2013) underscore the need for more research on fathers in upper-middle-class families, given their high-stress, demanding careers and frequent absences from the home and family.

Still insufficiently explored are the benefits—or in some cases, the costs—of “social fathering” a phenomenon common in low-income, ethnic minority groups wherein men other than biological fathers fulfill the father-figure role (Coley, 2001). At this time, the existing literature on social fathering appears inconclusive, with some studies showing benefits for children, and others reporting outcomes that are no better than for children living in single-parent families (Carlson & Magnuson, 2011).

Apart from parents, siblings can also help modify the effects of high-risk circumstances. In research on rural African American families, older siblings’ competent behaviors at school were linked with increases in younger siblings’ competence over time, through the intervening variable of younger siblings’ self-regulation (Brody, 2004). By the same token, siblings can exacerbate vulnerability within at-risk families. This might occur through bullying, through modeling of negative behaviors that are emulated by younger siblings, or through mutual collusion to undermine adult caregivers (Bullock & Dishion, 2002; Fosco, Stormshak, Dishion, & Winter, 2012).

A potentially critical source of support to at-risk children lies in extended kin, with the beneficial effects occurring, directly as well as indirectly, via their parents’ adjustment (Elder & Conger, 2000). Grandmother involvement in childrearing, in particular, can serve critical buffering functions for children, moderating against the negative effects of mothers’ depressive problems and their harsh parenting behaviors (Barnett, Scaramella, Neppl, Ontai, & Conger, 2010; Silverstein & Ruiz, 2006). Indirect effects are evident in findings that kin support can bolster parents’ feelings of well-being and competence, as well as their positive parenting behaviors and involvement in

children’s schools, benefits which in turn, lead to positive child adaptation (Oberlander, Black, & Starr, 2007; Parent, Jones, Forehand, Cuellar, & Shoulberg, 2013).

Can Subsequent Good Relationships Compensate for Lack of Parental Nurturance?

Early relationships are critical in shaping the lens through which people view their subsequent interactions, but “faulty lenses” can be corrected to some degree. As noted earlier, developmental psychopathologists contend that there is generally continuity and coherence in development, such that positive adaptation in the early years predicts, in probabilistic rather than deterministic fashion, likely success at later stages (Sroufe et al., 2010). At the same time, lawful discontinuities often do occur and in the context of attachment status, these changes derive from alterations in the caregiving environment (Aikins, Howes, & Hamilton, 2009; Van Ryzin, Carlson, & Sroufe, 2011).

Such lawful discontinuities are exemplified by findings that children show shifts from secure to insecure patterns if the availability of the parent becomes reduced because of circumstances such as chronic mental or physical illness, or life events such as divorce (Moss, Cyr, Bureau, Tarabulsky & Dubois-Comtois, 2005; Pinquart, Feussner, & Ahnert, 2013). In longitudinal research, preschool children who moved from a secure classification at Age 3, to disorganization at Age 5, were more likely to have experienced decreases in the quality of mother-child interactions as well as negative family events such as the hospitalization of parents (Moss et al., 2005). Similar effects were found in prospective research spanning infancy through late adolescence. Individuals’ insecure attachment at the age of 19 years was not related to insecure status at 1 year, but it was related to more frequent maternal reports of high life stress, and lower-quality observed family interactions in early adolescence (Weinfield, Whaley, & Egeland, 2004).

In parallel, lawful discontinuities in shifts from insecure to secure attachment status occur with improvements in the primary caregiver’s well-being. A study of low-income rural children revealed that nearly half of those who were classified as insecure at 15 months were securely attached by the age of 4, changes that were associated with factors such as stability of primary caregiver and higher maternal social support (Fish, 2004). Similarly, among low-income children with insecure and avoidant patterns of early attachment, several came to show secure attachments by adulthood, manifesting close relationships with romantic partners and good parenting behaviors themselves

(Roisman, Padrón, Sroufe, & Egeland, 2002). Again, changes in attachment status were seen as deriving from positive experiences with caregivers through the later childhood and adolescent years.

Intervention studies provide consistent evidence that attachment status can be responsive to improvements in caregiving. Among mothers and children in maltreating families, positive changes in attachment status have been achieved via home-based interventions that are based on psychoeducational and psychotherapeutic frameworks, targeting improvements in maternal sensitivity (see Cicchetti & Toth, Chapter 13, this *Handbook*, this volume). Similar benefits have been seen following interventions for low-income families (Heinicke, Rineiman, Ponce, & Guthrie, 2001), and for young children of depressed mothers (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume).

Consistent evidence is seen among children who received good quality foster care experiences following significant early disruptions in relationships with caregivers. Dozier and her colleagues have shown that insecure early attachments were somewhat remediated among children by intervention services and foster caregivers' positive qualities, including responsiveness, nurturance and their own attachment states of mind (Dozier, Albus, Fisher, & Sepulveda, 2002).

The ameliorative potential of strong relationships is not restricted to childhood, as seen in long-term prospective studies. Rutter (1987) showed that, among women who had been institutionalized as young children, those who had good marital relationships as adults—characterized by harmony and a warm, supportive spouse—fared much better than others in the quality of their own parenting behaviors. Similarly, among delinquent adolescent boys followed through the age of 70 years, Laub and Sampson (2003) found that changes in rates of crime over time were strongly linked with adult transitions to marriage, with this variable alone explaining as much as a 40% reduction in rates of crime (see also Vaillant, 2012). Similar reversals of negative trajectories have been associated with enrollment in the army (and with relocation out of high-crime, low-income neighborhoods), ostensibly deriving from the structure and positive socializing influences in the new social contexts (Laub & Sampson, 2003; Ludwig et al., 2012; Werner & Smith, 1992).

Obviously, the reversibility of early insecure attachments depends on the duration and severity of early deprivation, as seen in longitudinal research on children adopted into UK families following early severe deprivation in

Romanian orphanages. At Age 6, dose-response associations were found between length and intensity of early deprivation and psychological functioning, but this relationship weakened somewhat by Age 11, suggesting the reversibility of early attachment problems (Rutter, Sonuga-Barke, & Castle, 2010). Research by Gunnar and colleagues (see Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume) has shown similar dose-response effects with levels of the stress hormone, cortisol, as the outcome of interest. A meta-analysis of attachment patterns in adopted children (van den Dries, Juffer, van IJzendoorn, & Bakermans-Kranenburg, 2009) showed a trend for those adopted before the age of 12 months to be as securely attached as nonadopted children, while those adopted at older ages were less likely than comparison peers to be securely attached.

Over a longer developmental period, dose-response associations are evident in findings on ramifications of family climate during early childhood, middle childhood, and early adolescence, for intergenerational relationships between participants at Age 26 years and their parents (Belsky, Jaffee, Hsieh, & Silva, 2001). Results showed that unsupportive childrearing during one of the three developmental periods could be offset if family relations in the other two periods were relatively supportive. Such amelioration was not found if two of the three periods reflected disruptions.

It is unclear, however, whether the required potency of "corrective" nurturing relationships is comparable to that experienced by well-functioning individuals who did not face early deprivation. In a study comparing children who were adopted from international institutions to those who were raised by their biological parents, researchers found that caregiver emotional availability at 18 months benefited emotional understanding and indiscriminant friendliness at 30 months for postinstitutionalized children, suggesting that emotional availability potentially moderates the ill-effects of early deprivation (Garvin, Tarullo, Van Ryzin, & Gunnar, 2012). At the same time, parents of these adopted children tended to be less structured and more intrusive in their care, indicating that "parents of children adopted from conditions of deprivation may need to provide even more supportive care than is needed for nondeprived children in order to enhance their social development" (Garvin et al., 2012, p. 46).

In parallel, it is not clear that positive adoptive environments entirely expunge the ill-effects of early disturbances in attachment. Among the previously mentioned children in Romanian orphanages, Rutter and colleagues (2010)

found that, at the age of 6 years, most showed social and cognitive functioning in the normal range after being adopted into British families. Follow-up assessments, however, revealed that a substantial minority manifested major persistent deficits, both at 6 and 11 years old. Persisting psychological problems in this subgroup were interpreted as suggesting some form of early biological programming or neural damage stemming from severe institutional deprivation (Rutter et al., 2010). Similarly, among adults with secure attachments in current partner relationships, those who had insecure attachment representations based on early relationships were more reactive to stress than were those who had secure attachments in their early relationships as well (Treboux, Crowell, & Waters, 2004).

Protective Parenting: Discipline and Monitoring

Aside from dimensions of attachment and warmth, another broad parenting construct critical for resilient adaptation falls in the broad domain of discipline: limit-setting and monitoring. Limit-setting—which refers to the use of appropriate rules and expectations and consistent rule-enforcement—is critical in shaping future compliance and socially desirable behavior in children (Schneider, Cavell, & Hughes, 2003).

When discipline is inappropriately harsh, this exacerbates vulnerability to maladaptive behaviors. Patterson's Social Coercion Theory (Patterson, Reid, & Dishion, 1992) maintains that if parents typically respond to young children's annoying behaviors in ways that are based on power assertion, children tend to escalate their own aversive behaviors in attempts to control the parents. Thus, the frequent use of physical discipline leads children to become more noncompliant and hostile, and as the children's aversive behaviors increase in intensity and frequency, parents sometimes acquiesce, thereby reinforcing the maladaptive behaviors.

Strong support for Patterson's coercion theory is seen in Shaw and colleagues' Pitt Mother-Child Project (PMCP; Shaw, Bell, & Gilliom, 2000), involving 310 low-income families with boys first assessed at 18 months, and tracked until Age 17. The researchers postulated that when mothers were unresponsive to infants' continued bids for attention, this would lead to later coercive exchanges between mother and child by Age 2, which in turn would be linked with elevated risk for externalizing behavior problems. Results at 3 years of age were consistent with expectations (Shaw et al., 2000), and subsequent follow-up research pointed to long-term detrimental effects. Unresponsive patterns of parenting documented during early childhood were

associated with juvenile court involvement and increased risk for clinical depression during the boys' adolescent years (Shaw, Hyde, & Brennan, 2012).

In other studies, the focus has been not on maternal unresponsiveness, but on hostility. Noting toddlers' tendencies to evoke frustration from caregivers (e.g., because of their increase in mobility and assertion of "independence"), a critical developmental task for mothers is the maintenance of a nonhostile, relatively positive approach while shaping their children's behaviors. Negative mother-child interactions during toddlerhood, as well as maternal hostility and frustration, were significantly associated with conduct problems at 5 to 6 years of age (Lorber & Egeland, 2011). Similarly, assessments of the PMCP cohort between the ages of 10 and 15 years showed that mother-reported physical discipline in a given year predicted child ratings of antisocial behavior in the next year (Lansford et al., 2011). When such rejecting, overcontrolling behaviors reflect a general parenting approach, children show escalated risk for conduct problems not only at home but also at school, with such effects documented during the preteen years and adolescence (Shaw et al., 2012).

Interpretation of hostile parenting (in the form of verbal and physical discipline) is based somewhat in cultural context, and can vary by gender (Evans, Simons, & Simons, 2012). In a study of 10-year-olds and their mothers from China, India, the Philippines, and Thailand, Lansford and colleagues (2010) demonstrated that the effects of harsh verbal discipline by mothers were more severe when children viewed these behaviors as nonnormative, as opposed to normative, within their own cultural contexts.

Related to limit-setting and also important for resilience is parental monitoring, a "set of correlated parenting behaviors involving attention to and tracking of the child's whereabouts, activities, and adaptations" (Dishion & McMahon, 1998, p. 61). The benefits of consistent parental monitoring are particularly pronounced among preadolescents and adolescents, who have increasing independence from parents, and thus growing exposure to a host of risks in the peer and community environments. Studies have shown that when their parents tend to know of their daily activities and associations, adolescents are less likely to engage in delinquent behavior, alcohol and drug use, and risky behaviors involving sex or online exchanges while using social media (Luthar et al., 2013; Piko & Eszter, 2010; Rosen, Cheever, & Carrier, 2008; Shaw et al., 2012). Consistent parental supervision also significantly aids adolescents with delinquent histories to desist from offending, over and above the effects of high housing quality

and parent stress (Walker, Bowen, & Brown, 2013). Even in areas of armed conflict, parental monitoring has been shown to be protective, leading to more positive mental health outcomes for adolescents exposed to violence (Tol, Song, & Jordans, 2013).

Links between parent monitoring and adolescent adjustment are not always simple linear ones; they can be curvilinear, and they can vary with coexisting risks in the community. To illustrate, O'Donnell, Richards, Pearce, and Romero (2012) suggested that the influence of parental monitoring on delinquency depends on environmental factors such as peer groups, as well as on the child's gender. In a high-risk sample of low-income urban African American youth, these authors found that parental monitoring was associated with boys' delinquent behavior, while peer groups had a stronger relation to delinquency in girls, possibly because adolescent females tend to be highly sensitive to close interpersonal relationships.

Importantly, effective monitoring necessitates not just parents' efforts to know about their children's whereabouts, but also the latter's willingness to disclose to their parents, and each can have independent effects. Positive adjustment outcomes such as academic effort, for example, are related to both adolescent disclosure and parental solicitation, whereas negative outcomes like delinquency and violence are related to minimal adolescent-parent communication, including low honesty with parents as well as low time spent together (Cheung, Pomerantz, & Dong, 2012; Lahey, Van Hulle, D'Onofrio, Rodgers, & Waldman, 2008). Overall, parents' knowledge regarding their adolescent offspring's whereabouts and company tends to result more from youth disclosure than from active parental monitoring (see Lahey et al., 2008).

In terms of discrete underlying processes, ethnographers have delineated several expeditious limit-setting and monitoring strategies used by inner-city families (see Weisner, 2005). These include the avoidance of dangerous areas, temporal use of the neighborhood (e.g., not being outside at night), and restriction of children's relationships with deviant and older peers. Other posited protective mechanisms include those resting on psychological processes: Structure and continuity in the environment can promote the development of effective coping skills among youth, as parental expressions of interest and concern for the child's well-being tend to bolster positive self-esteem.

Related to monitoring—in some ways, the converse of it—is autonomy granting, also important for resilient adaptation. Observational research involving mother-infant

interactions suggests that maternal support of exploration and autonomy (versus maternal restriction and control) is associated with the child's self-regulation, positive affect, mastery motivation, and task-persistence through subsequent years (see Bornstein, Davidson, Keyes, Corey, & Moore, 2003). Among older children, perceptions of their own autonomy are linked with various indices of adaptive development such as interest-focused academic engagement and prosocial behavior (e.g., Roth, Assor, Niemiec, Ryan, & Deci, 2009).

Autonomy has particularly high significance during the teen years, because a major developmental task of adolescence is to negotiate the struggle between developing independence on the one hand, and maintaining close bonds with parents on the other. Research by Allen and his colleagues (see McElhaney & Allen, 2012) has shown that among teens from both low- and high-risk contexts, those with parents who encouraged autonomy and disclosure had higher levels of self-esteem as well as ego development. In addition, maternal behaviors promoting adolescent autonomy and relatedness were associated with coherence/security of attachment during the adult years. In parallel, research has established that low autonomy-granting during adolescence is detrimental. High school students who experienced high levels of parent control associated with authoritarian parenting showed relatively low levels of psychological flexibility (K. E. Williams, Ciarrochi, & Heaven, 2012).

Interestingly, adolescents and parents can have divergent perceptions of the degree to which parents influence their children, and the ramifications for teens' adjustment differ by source of ratings. Adolescents' reports of high parental influence are associated with warm, autonomy-granting parenting as noted by teens' own reports as well as unbiased observers (McElhaney & Allen, 2012). Conversely, when parents believe their own parenting to be highly influential on their children, lower levels of autonomy-granting and low relatedness tend to be reported and observed.

As in the case of parental monitoring, the "optimal" level of autonomy granted to adolescents can vary as a function of socio-demographic context. Among youth in urban poverty, maternal behaviors that undermined adolescents' autonomy (i.e., interrupting them to shut down discussions) were positively linked with mother-adolescent relationship quality, whereas among low-risk comparison youth, associations were inverse in nature (see McElhaney & Allen, 2012). It is plausible that behaviors potentially seen as "overprotective" are seen as expressions of concern and care among youth in high-risk settings, while they tend

to be seen as inappropriately inhibiting and even guilt-evoking by teens in other contexts.

Coexisting Warmth and Appropriate Control

Whereas high levels of warmth and appropriate control each have protective functions, the benefits of each depend to some degree on levels of the other: High warmth with lax discipline can be linked with poor adjustment as can strict discipline without affection. Optimal is the authoritative parenting style, “characterized by high warmth and expectations, with appropriate levels of autonomy granting” (Padilla-Walker, Day, Dyer, & Black, 2012, p. 4).

Among low-income mothers, efforts to facilitate warm and responsive interactions with infants or toddlers enhanced the quality of future discipline techniques, in turn serving as a powerful force against externalizing disorders in childhood and adolescence (Shaw et al., 2012). Conversely, among adoptive families, patterns reflecting overreactive parenting along with low maternal efficacy were associated with increases in the toddlers’ negative emotionality (Lipscomb et al., 2011). A study of academic trajectories among low-income Mexican American adolescents found that maternal warmth moderated the relationship between parental academic socialization (e.g., placing importance on school success) and students’ determination to succeed academically. In the presence of higher maternal warmth, students were more likely to respond positively to parental expectations to succeed at school (Suizzo et al., 2012).

Cavell (2000) has emphasized the importance of an appropriate balance of warmth and discipline within the notion of parental *containment*, that is, “any behavior that fosters in children a sense of restraint while not threatening their relationship security” (Cavell, 2000, p. 131). Other studies have pointed to the protective potential of this construct. Building upon Cavell’s (2000) arguments, Schneider et al. (2003) defined perceived containment as the child’s beliefs concerning the parents’ capacity to enforce firm limits, and the likelihood that the parents will prevail in conflict. Among upper-middle-class teens—who are at much higher risk for alcohol and drug use than national normative samples—teens’ perceived parent containment for substance use was a potent predictor of both females’ and males’ use levels, even after considering other more traditionally examined indices of parent monitoring (see Luthar & Barkin, 2012). Thus, affluent adolescents who believed their parents would enforce rules in response to detected substance use were much less likely to use them, than were their counterparts who believed their parents

would mete out few or no consequences (Luthar et al., 2013).

Intervention studies with at-risk youth further buttress the conclusions from basic research on the importance of firm, consistent discipline in the context of supportive parent–child relationships (see Biglan & Taylor, 2000). In a review of the literature, Kumpfer and Alvarado (2003) note that “Effective parenting is the most powerful way to reduce adolescent problem behaviors” (p. 457) and describe three approaches that are generally found to be successful. The first includes behavior training approaches that are highly structured and involve working only with parents; the second entails an integration of parent behavior training and children’s social skills training, both administered in group format; and the third involves family therapy programs to enhance positive within-family interactions.

Whereas warmth and developmentally appropriate discipline are two “universals” of good parenting, there are other dimensions that can serve important protective functions in particular risk contexts. In families of children with chronic developmental conditions, for example, Crnic and colleagues have pointed to the unique significance of emotional and cognitive scaffolding as well as parent involvement (Crnic & Neece, Chapter 8, this *Handbook*, this volume). In ethnic minority families, much can be gained from parents’ attempts to inculcate in their children a sense of pride in their racial backgrounds (see Spencer, Swanson, & Harpalani, Chapter 18, this *Handbook*, this volume). Among upper-middle-class families in hyper-achieving communities, children fare better when they see their own parents as having balanced value systems, prioritizing the children’s personal decency and integrity every bit as much as their personal accomplishments (Luthar et al., 2013).

Communities

The broader community context affects children and adolescents both directly and through its effects on parents and other adults. Ensuing discussions describe, first, the formidable effects of community violence, followed by various mechanisms through which schools, peers, and neighborhoods can affect trajectories of resilience versus maladjustment.

Effects of Violence

As with chronic maltreatment in the family, chronic exposure to violence in the community can have overwhelming inimical effects, difficult for other positive forces to

override and affecting multiple domains. Exposure to violence significantly exacerbates risks for internalizing problems such as anxiety, depression, and posttraumatic stress disorders, as well as externalizing problems such as delinquent and antisocial behaviors (Fowler, Tompsett, Braciszewski, Jacques-Tiura, & Baltes, 2009). Academic performance has also been found to suffer in the context of exposure to violence, often through mediators, such as aggression or behavior problems, and lowered feelings of safety (Busby, Lambert, & Ialongo, 2013). Repeated exposure to violence, especially early in development, is a form of chronic stressor that also can fundamentally alter neurological system development, and thus may affect children's physiological arousal and ability to process stress (see Gunnar, Doom, & Esposito, Chapter 4, this *Handbook*, this volume).

Several aspects of violence exposure can affect the reactions of a child, including relationship to victims and physical proximity to the events (Fowler et al., 2009). Sharkey's (2010) examination of violence in Chicago neighborhoods showed that children living closest to the location of a homicide were most negatively affected, in terms of lower scores on literacy assessments soon after the event. In a study of urban 16-year-olds, witnessing a close friend or family member being the victim of violence was associated with heightened depressive symptoms among both boys and girls; this was not seen when the victim was a stranger or someone the adolescent did not know well (Lambert, Boyd, Cammack, & Ialongo, 2012).

Disorganization and violence in the community affect children directly as well as indirectly, via effects on their parents. Among low-income single mothers, higher levels of social disorder and maternal exposure to neighborhood violence predicted greater parenting stress (Franco, Pottick, & Huang, 2010), and women who reported moderate to high violence exposure were more likely to demonstrate physically aggressive parenting toward their 3-year-old children (Zhang & Anderson, 2010). Among at-risk preteens and adolescents in large cities, similarly, increased family conflict was a pathway via which violent victimization in the community affected children's adjustment problems (Formoso, Gonzales, & Aiken, 2000; Holtzman & Roberts, 2012).

There is modest evidence that parents' functioning can moderate the effects of community violence on children (e.g., Bailey, Hannigan, Delaney-Black, Covington, & Sokol, 2006), but when people's very survival is constantly threatened, parents are obviously constrained in how much they can confer psychological protection to their children.

This is evident in results of several studies on violence exposure, examining whether positive family functioning might show "protective-stabilizing" influences—helping children to function well even as exposure escalated. Considered together, the findings provided limited support at best for such effects (e.g., Ceballo & McLoyd, 2002; Jain et al., 2012). When study measures were particularly sensitive to level of violence exposure, a common theme was that indices of positive family functioning (e.g., time spent with parent, closeness to them) were beneficial at low levels of exposure. On the other hand, when violence exposure was high, the benefits of these family variables were considerably diminished.

By contrast, poor family functioning clearly does exacerbate the risks of community violence—when children experience significant disturbances in their proximal as well as their distal environments, their risk for psychopathology becomes substantial. To illustrate, low family cohesion predicted delinquency in adolescents who had witnessed violence in their communities, while those with similar violence exposure histories, but high levels of family cohesion, were not affected in the same way (Barr et al., 2012). Similarly, McKelvey and colleagues (2011) found that high family conflict was a moderator of community violence among boys, associated with increases in internalizing symptoms and risky behaviors by the age of 18 years. Among girls, high family conflict was a risk factor for internalizing symptoms regardless of community violence levels. Overall, such results corroborate the view that the lack of a reliable, supportive refuge, or low emotional connectedness to family, tends to exacerbate the risk for maladjustment for children exposed to high levels of community violence.

A specific type of exposure to violence that can be highly disruptive to child and adolescent development is exposure to war and political conflict. Reviewing extant evidence, Werner (2012) indicated that high rates of psychopathology, notably posttraumatic stress disorder, depression, and anxiety, have been documented among children exposed to violent conflict in various countries around the world. Children appear to be especially at-risk when they have been involved in close interpersonal violence, for example, as in the case of child soldiers (Betancourt et al., 2010). Additionally, youth can be differentially affected by wartime experiences according to developmental stage at time of exposure. Adolescents may be at heightened risk of symptoms of trauma due to their greater capacity to understand the implications of the violence they witness, while younger children may feel the effects of forced

separation from parents or caregivers more acutely (Masten & Narayan, 2012).

There is some evidence of resilient functioning among children exposed to the violence of war, though findings on both predictors and outcomes are not consistent (Barber, 2013; Tol et al., 2013; Werner, 2012). Relationship-based factors, including a positive and stable connection to a primary caregiver, parental monitoring, and perceptions of support from extended kin and/or members of the broader community, have in some cases been associated with better postconflict outcomes, such as fewer depressive symptoms (e.g., Betancourt et al., 2010; Durakovic-Belko, Kulenovic, & Dapic, 2003; Tol et al., 2013; Werner, 2012). By the same token, when family functioning is disrupted, risks for child maladjustment are exacerbated. In war-affected populations in Afghanistan, family violence particularly exacerbated the effects on adolescents' mental health (Panter-Brick, Goodman, Tol, & Eggerman, 2011).

Ecological sensitivity is critical in assessing the ways in which war exposure might affect children and adolescents. Commenting on work in this area, Panter-Brick and Leckman (2013) underscored the importance of ensuring that markers of resilience are culturally relevant, with attention to local mores about behaviors that are considered adaptive or maladaptive, as well as ways in which distress is experienced versus manifested. Illustrating the importance of this issue, Tol et al. (2013) cite ethnographic research in northern Uganda where children exposed to conflict did not report high psychological distress. Their ostensible resilience, however, was in fact related to cultural values emphasizing respect for others who suffered in silence, and not wishing to hurt those who did suffer. Thus, individuals' own distress was more freely expressed in somatic symptoms, which were addressed via use of tranquilizers.

Protective Processes in Communities: Early Intervention and the School System

Whereas the ill-effects of chronic exposure to severe violence in the community are rarely overridden by other protective processes, there are exosystemic forces—those in communities and schools—that can attenuate the damages conferred by other types of adversities. Again, the broader community can shape child outcomes by directly affecting youth themselves, and also indirectly, by effects on their parents.

In early childhood, the quality of childcare can serve critical ameliorative functions that endure across extended

periods of children's development. Reports by the NICHD Early Child Care Research Network showed that among families living in or near poverty, mothers whose children were in high-quality childcare showed more positive interactions with their infants. Furthermore, these benefits were evident even through the age of 15 years: High quality of early childcare was linked with lower externalizing behavior during adolescence as well as better cognitive-academic achievement, with the latter association partly mediated by earlier childcare effects on achievement (Vandell et al., 2010).

Among the major features defining "good quality of care," primary are the characteristics of the childcare providers (e.g., education and training levels), the emotional quality of caregiving, the child to adult ratios (e.g., with three or fewer infants per caregiver being optimal), and the stability of childcare providers (Phillips & Lowenstein, 2011). Studies have documented that when caregivers have positive personal characteristics and offer emotionally supportive caregiving, benefits are seen in a range of child outcomes including early academic skills, language development, and social competence (Lamb & Ahnert, 2006).

Unfortunately, accessing high quality care is generally the most difficult for the poorest and most needy families, and key aspects of quality are often in jeopardy, given the poor working conditions of most childcare workers (Hanson & Gottesman, 2012). The average hourly wage of these workers in the United States is \$10.07 (the average hourly wage of school bus drivers is \$14.01 and of animal trainers, \$14.59), and turnover rates are among the highest of any profession that is tracked by the U.S. Department of Labor (U.S. Bureau of Labor Statistics, 2013). Improving the quality of childcare available to all families, but particularly those at high risk, therefore must be treated as a critical social policy priority.

Involvement of families is critical, if not indispensable, in effective early interventions; indeed, some of the benefits of efficacious, multipronged programs derive directly from the support and mentoring that parents receive from childcare providers (Phillips, McCartney, & Sussman, 2006). Research on the relative effects of childcare has shown that despite the benefits that high-quality programs can provide, overall, family characteristics have the greater impact on young children's developmental outcomes, in both the short and long term (NICHD, 2006; Phillips & Lowenstein, 2011).

Exemplifying the effective involvement of parents while using existing resources to provide quality child care is

Zigler's "School of the 21st Century" (Zigler & Finn-Stevenson, 2007). In this program, public school buildings, which remain unoccupied for large portions of the day and the calendar year, are used to house childcare programs for children 3 years and older, and also to host regular support group meetings for parents. Referral and information networks also are developed in schools to help parents make better use of various existing services scattered across their communities, such as those offering counseling, physical health care, or night care for children. A similar approach is indicated in the Promise Neighborhoods initiative, inspired by the Harlem Children's Zone (HCZ) (Komro, Flay, Biglan, & Promise Neighborhoods Research Consortium, 2011). HCZ has included early childhood services in their extensive efforts to transform the educational opportunities for children in their communities, offering a Baby College for expectant and new parents, and pre-kindergarten for children who will be attending HCZ schools (Harlem Children's Zone, 2009).

Attachment-Based Interventions in Schools

Among older children, K–12 schools can bring substantial beneficial effects to youth in at-risk circumstances: Supportive relationships with teachers can be critical in fostering resilience (see Wigfield et al., Chapter 16, this *Handbook*, this volume). Writing from an attachment perspective, Pianta (1999) elucidated, in depth, the benefits that can derive from close child–teacher relationships developed and then sustained for as long a period of time as feasible. Along the same lines, Schneider and colleagues (2003) have suggested that children with low perceived containment—who do not believe in adults' capacities to enforce firm limits and are therefore at-risk for conduct disorder—might actually be better served by interventions focusing on sustained, positive relationships rather than short-term disciplinary techniques designed to counter misbehavior.

While children's past and concurrent attachments to parents remain important factors in their interactions with adults at school, intervention studies increasingly suggest (a) that children's relationships with teachers are modifiable within the school context, and (b) that positive attachments to teachers can serve important protective functions, improving behavioral as well as academic outcomes (J. N. Hughes, 2012; O'Connor, 2010; Sabol & Pianta, 2012; see also Wigfield et al., Chapter 16, this *Handbook*, this volume). Exemplifying such benefits are findings from the My Teaching Partner (MTP) program, a web-based course in which teachers collaborate regularly

with consultants to review and reflect upon videotapes of the teachers' interactions with students in the classroom. MTP was initially developed for preschool classrooms, but trials of an adaptation for middle and high school have shown positive effects on student engagement and academic test results (Pianta, Hamre, & Allen, 2012).

From a developmental standpoint, increasing informal school-based support systems could be particularly critical for the wellness of preadolescent and adolescent students because they face schools that are large and impersonal (as compared to elementary or primary schools), with diminishing supports infused in daily curricula (see Wigfield et al., Chapter 16, this *Handbook*, this volume). Additionally, adolescents can be particularly reluctant to seek professionals for help with even serious adjustment problems (Cigularov, Chen, Thurber, & Stallones, 2008). In engaging supportive adults for preteens and teens, furthermore, it is important to consider not only subject or homeroom teachers but also other individuals to whom students are naturally drawn. Some at-risk students may actually be inhibited about seeking support from their own subject teachers, perceiving them primarily as disciplinarians and evaluators of academic progress; many seek out, as confidants or mentors, other school-based adults ranging from sports coaches and music instructors to administrative or support staff (Luthar, Barkin, & Crossman, 2013; Noam & Hermann, 2002).

Some programs have also used outside facilitators to provide students with supportive relationships outside of the classroom. To illustrate, RALLY (Responsive Advocacy for Life and Learning in Youth) for students in middle school (Noam & Hermann, 2002), and Step-Up, for high (secondary) school students (Alicea, Pardo, Conover, Gopalan, & McKay, 2012) both establish mentoring relationships between students and program staff while also working on teacher, peer, and/or family engagement. Preliminary results for the Step-Up program have shown high engagement and retention within a sample of youth mostly of ethnic minority background, who had high initial rates of mental health symptoms, and were at risk of dropping out of school (Gopalan et al., 2013).

There are some promising school-based interventions that focus on the ecology of the whole school, rather than chiefly on the attachments to teachers. Felner and colleagues' (2001) High Performance Learning Communities Model is one early example of an embedded, whole-school approach. Another is the widely adopted Positive Behavioral Interventions and Supports (PBIS) program for elementary schools, which aims to reduce disruptive,

aggressive behavior while supporting social and emotional development (Bradshaw, Waasdorp, & Leaf, 2012). PBIS employs universal components by implementing school-wide organization and behavioral expectations, as well as more targeted components for students with greater need in these areas.

Another intervention that combines universal and targeted components is the BRIDGE program, which uses a coaching model pairing classroom teachers and school-affiliated mental health professionals. The program addresses classroom relationships and organization to enhance students' behavioral and emotional outcomes (see Cappella et al., 2012). An early randomized trial found positive results for elementary students in several targeted areas, including academic self-concept and perceptions of victimization. In particular, teacher-child closeness was significantly higher in the intervention group, with an impressive effect size of 0.47 (Cappella et al., 2012). Collectively, these findings attest to the promise of school-based interventions targeting teacher-child dyadic relationships within the subsuming contexts of the classroom and school milieu (Pianta et al., 2012; Sabol & Pianta, 2012).

Internationally, there has been growing use of teachers and schools to enhance resilient adaptation in children exposed to traumatic events such as war or political conflict. In such situations, well-functioning schools can be critical in providing children with a sense of routine, predictability, and safety (Masten & Narayan, 2012). Classroom-based intervention programs that have been evaluated in the context of conflict include the Psychosocial Structured Activities program in Uganda (Ager et al., 2011), a cognitive-behavioral/creative-expressive program in Indonesia (Tol et al., 2010), and a preventive intervention based on stress inoculation, for children exposed to rocket attacks in Israel (Wolmer, Hamiel & Laor, 2011). In general, the results of these studies demonstrate that interventions in schools can help to reduce problems such as symptoms of posttraumatic stress disorder and more broadly, to promote effective coping skills for participating children.

Peers and Social Networks

Aside from adults at school, positive relationships with peers can also serve critical protective functions for at-risk children (Elder & Conger, 2000; Furman & Rose, Chapter 22, this *Handbook*, this volume). Among children of divorce, for example, a supportive relationship

with a single friend can help to buffer children from the deleterious effects of marital disruption (Hetherington & Elmore, 2003; see also Bolger & Patterson, 2003). Other longitudinal studies have shown that peer acceptance and friendships attenuated the links between aspects of family adversity and subsequent externalizing behaviors, at the time of enrollment in school, and between the ages of 10 and 12 years (see Lansford, Criss, Pettit, Dodge, & Bates, 2003). Findings such as these are seen as reflecting three potential processes, involving (1) the provision of "remedial" socializing contexts for skills not acquired in dysfunctional homes; (2) modification of children and parents' negative behaviors by the more well-functioning peers and their parents; and (3) enhanced bonds with the social institution of the school (Lansford et al., 2003).

Intervention studies have also suggested that peer-assisted learning can result in improvements in academic achievement as well as nonacademic outcomes such as self-concept, particularly for youth from low-income backgrounds (Ginsburg-Block, Rohrbeck, & Fantuzzo, 2006). The potential in this regard is seen in Fantuzzo and colleagues' resilient peer treatment (RPT) program, a peer-mediated intervention involving pairing of socially withdrawn preschoolers with manifestly resilient peers in the classroom (Fantuzzo, Manz, Atkins, & Myers, 2005). A randomized study revealed that the program led to greater engagement in the salient developmental task of collaborative play based on researcher observation, with a moderate effect size of 0.36 (Fantuzzo et al., 2005).

Further potential for positive socialization is seen in interventions targeting at-risk students in elementary school, such as the PAX Good Behavior Game (PAX GBG; Embry, Staatemeier, Richardson, Lauger, & Mitich, 2003) and the Promoting Alternative Thinking Strategies (PATHS; Greenberg and Kusché, 2006). In the PAX GBG, teams of 6-year-olds received rewards from teachers (e.g., stickers) when the team behaved well. Because individual students' misbehavior lowered the team's chances of winning, students tended to encourage and help each other to conform. Long-term follow-up assessments have shown that by the ages of 19–21 years, participants in this program had been assigned to fewer school-based services such as placement in special classrooms, and they had significantly lower substance abuse problems as well as less involvement in the juvenile and adult criminal justice systems (Poduska et al., 2008).

Just as positive peer relationships can mitigate the effects of adversity, problems in this domain can exacerbate vulnerability. In longitudinal research, both relational

and physical peer victimization were associated with increased internalizing symptoms during adolescence (Yeung Thompson & Leadbeater, 2013). Peer rejection and bullying can lead to poor outcomes in later life across multiple domains, including internalizing problems, school drop-out, and delinquency, with the combination of aggression and peer rejection connoting particularly high risk for long-term adjustment outcomes (see Kupersmidt & Dodge, 2004).

Affiliation with deviant peers is well known to exacerbate vulnerability among at-risk youth, particularly in relation to conduct problems and substance use. Among children and adolescents living in neighborhoods with high poverty and crime, affiliation with deviant peers has been a robust predictor of psychopathology (Barrera et al., 2002; Tiet, Huizinga, & Byrnes, 2010). Data on 9–15 year olds assessed during the first three waves of the Great Smoky Mountains Study showed that association with deviant peers, along with increasing levels of circulating testosterone, contributed to increases in conduct disorders over time. Furthermore, these links were mediated primarily by increases in nonphysically aggressive behaviors (Rowe, Maughan, Worthman, Costello, & Angold, 2004). In some cases, affiliating with deviant peers has been found to be connected to level of monitoring by parents; specifically, such affiliations mediate the relationship between parental monitoring of adolescents' behavior and teens' delinquency and substance use (O'Donnell et al., 2012).

The ill-effects of associations with deviant peers may be particularly strong during adolescence. Dishion's work on this topic has shown that these effects may reflect a combination of both self-selection into deviant peer groups, and deviancy training in adolescent friendships wherein delinquent behaviors and attitudes are socially reinforced (Dishion & Tipsord, 2011). Deviancy training, particularly in close friendships, predicts increases in delinquency, substance use, violence, and adult maladjustment, and tends to weaken connections to positive socializing influences. Longitudinal follow-up data have shown that associating with delinquent peers was predicted by, and in turn exacerbated, poor connections to school and other prosocial ties during adolescence (Tiet et al., 2010).

The potential for iatrogenic effects of peer relationships has often been discussed in relation to the ecology of urban poverty (Dishion & Tipsord, 2011). Within inner-city neighborhoods and schools, the peer culture tends to reflect the larger community such that youth growing up in high-crime neighborhoods can be exposed to more delinquent peers than are others (Murry, Berkel,

Gaylord-Harden, Copeland-Linder, & Nation, 2011). In turn, affiliation with delinquent peers intensifies the risk for adolescent behavior problems. Furthermore, the personal characteristics valued by peers in inner-city settings are often at odds with those endorsed more conventionally. To illustrate, high peer popularity can be associated with disruptive, aggressive behaviors at school as well as low academic effort (Becker & Luthar, 2007), ostensibly reflecting low belief, in poor urban communities, that conformity and application at school will actually result in long-term life successes.

Negative peer socializing influences are not limited to the context of poverty, however; they are found, as well, in upper-middle-class settings. As noted earlier, affluent teens are clearly at elevated risk for the high use of drugs and alcohol, and those youth who report using them frequently are among the most popular in their peer groups (Luthar et al., 2013). This association is particularly strong among boys. Among girls in upper-middle-class settings, negative peer influences are seen most prominently in the inordinate emphasis on their physical attractiveness. Far more so than affluent boys, or inner-city girls or boys, peer acceptance is significantly linked to whether these young women are judged by peers as attractive. The extreme peer emphasis on their physical appearance is likely linked with elevated vulnerability, among these girls, to diverse problems including psychological distress, substance use, and eating disturbances (Luthar et al., 2013).

Adding to the complexities of peer group effects, some studies have shown that teenage peer group influences can be beneficial in some spheres of adjustment even as they are detrimental in others. A study of low-SES urban early adolescents and their affluent, suburban counterparts showed that in both samples, peer admiration was simultaneously associated with high academic effort on the one hand, and with aggressive behaviors on the other (Becker & Luthar, 2007).

There are also probably varying effects of high status in the wider peer group as opposed to support from close friends. Gutman, Sameroff, and Eccles (2002) found that support from peers—as opposed to popularity with the wider peer group in previously discussed studies—was associated with higher math achievement for high-risk adolescents, but not their lower-risk counterparts. The authors argued that peer support for academics may be limited for ethnic minority teens, and that among those exposed to multiple risks, teens who feel that they can depend on peers for help with problems fare better than those with low peer supportiveness.

Unfortunately, negative contagion effects can occur in close dyadic friendships as well as the larger peer group. To illustrate, Rose, Carlson, and Waller (2007) showed that close friendships are a source of support, but they can also involve contagion of internalizing symptoms due to *corumination*, which entails rehashing problems in conversations and focusing on negative affect. Similarly, intervention programs that target adolescents in groups can trigger negative peer socializing influences (Dishion & Tipsord, 2011). Results from controlled studies show that in comparison with control conditions, peer-group interventions for high-risk youth can actually increase problem behaviors in adolescence, and negative life outcomes in adulthood. Developmental processes accounting for the powerful iatrogenic effects included active reinforcement for deviant behavior through laughter and social attention, as well as engaging in conversation about deviance, particularly during unstructured periods.

By the same token, opportunities for deviancy training appear to decrease when intervention sessions are highly structured and well-supervised, though more research examining this moderator is needed (Dishion & Tipsord, 2011). Dodge, Dishion, and Lansford (2006) further asserted that aggregating deviant youth within interventions should be avoided where possible, in favor of more mixed groupings, such as within universal school interventions, or family-centered programs. This recommendation is also relevant to youth in the juvenile justice system (Dodge et al., 2006). In a natural experiment involving first-time adolescent offenders, higher rates of recidivism were seen among those who spent the weeks before their final disposition hearing in a residential facility with other young defendants, as compared to those who spent that time at home (Shapiro, Smith, Malone, & Collaro, 2010).

Among adolescents, an area that warrants further exploration is whether peer leaders can be used as positive socializing influences. While antiestablishment behaviors elicit admiration from peers across socioeconomic settings as previously described, there is always a subset of teens (albeit small) who retain peer admiration by occasional rule-breaking, while at the same time, remaining focused on doing well academically and being prosocial toward others. In future research, we will need to learn from these youth about ways in which they, and others like them, might help sway counterparts who gravitate more strongly toward behaviors destructive to others or themselves. Given the established power of negative contagion effects among adolescent peers, there may well be the potential for parallel “positive contagion” effects that we can

harness in future efforts to promote adaptive adolescent outcomes.

The value of further exploring “positive peer contagion” is evident in the “Names Can Really Hurt Us” anti-bias, anti-bullying program implemented with over 65,600 high school students in Connecticut since 1995, under the sponsorship and supervision of the Anti-Defamation League. Guided by league facilitators, students speak candidly about diverse bullying behaviors and their consequences, addressing topics ranging from gossip and physical harassment, to homophobia and racism, substance abuse, self-mutilation, and suicide. The goals are to empower victimized students to stand up for themselves, to teach bystanders to become allies, and to develop empathy among the bullies themselves. Qualitative data and the students’ willing participation rates conjointly attest to the promise of the “Names” program (see Hirshey, 2007).

Aside from peer group members, relationships with informal mentors can serve important protective functions, as seen in evidence from the Big Brothers Big Sisters of America (BBBSA) movement, a program that typically targets youth aged 6 to 18 years from single-parent homes. Service delivery is by volunteers who interact regularly with a youth on a one-to-one basis, and are supervised on a monthly basis for the first year, and on a quarterly basis subsequently. Benefits of BBBSA have included reductions in substance use and better engagement with school, and improved mentees’ relationships with parents accounted for some of the improvements in adjustment (Rhodes, Grossman, & Resch, 2000).

Continuity of the mentor relationship, however, is critical in ensuring sustained benefits. In a randomized trial of BBBSA (Herrera, Grossman, Kauh, & McMaken, 2011), mentees’ showed improved academic achievement as compared to nonparticipating peers. However, this effect was seen only as long as the mentoring relationship was active, a finding consistent with earlier reports that longer mentoring relationships are associated with better outcomes (Grossman & Rhodes, 2002).

Salutary effects can derive from adolescents’ religious affiliations as well (Elder & Conger, 2000; King, Carr, & Boitor, 2011). Studies by L. Miller and her colleagues have shown that religious teens have attenuated risk for problems such as depression and substance use (see L. Miller & Gur, 2002). Processes posited include indirect effects involving “primary socialization” sources (in that religion shapes major socializing influences including parents, peers, and school), as well as direct ones (aiding in the adolescent search for meaning, purpose, and identity in

life). Research has also suggested that religion and spirituality can have particular benefits for adolescent girls in protecting against depression (Desrosiers & Miller, 2007), possibly reflecting the effects of high social support.

The benefits of community supports for at-risk children are paralleled by those among their parents: Parents with informal social support networks show better psychological well-being and more effective parenting (Ammerman et al., 2005). Kotchick, Dorsey, and Heller (2005) tested the role of social support in the context of neighborhood stress over a 15-month period with a sample of single, African American mothers. For those mothers who felt they received low levels of support from friends and family, neighborhood stress and related psychological symptoms were detrimental to their parenting behaviors over time, while parenting was less negatively affected among mothers who felt well supported.

Intervention trials further establish indirect benefits to children of support received by primary caregivers. For example, immediately following a supportive, relationship-based parenting group intervention with low-income, drug abusing mothers (Luthar, Suchman, & Altomare, 2007), significant improvements were seen in the women's personal adjustment as well as their children's reports of mothers' maltreating behaviors; this, despite the fact that the children were not directly involved in the intervention. Results from the Keeping Families Strong program for families affected by maternal depression have shown multiple positive effects, with improvements in maternal mental health, and in overall family functioning, apparently leading to improved adjustment among the children (Valdez et al., 2011).

Support gleaned from involvement in religious communities can also be beneficial for mothers. In a multi-city study of low-income women, Hill, Burdette, Regnerus, and Angel (2008) found that more frequent attendance at religious services was associated with greater satisfaction and less stress in their parenting role. Similarly, frequent attendance at religious services has been linked with lower parenting stress and also fewer behavior problems in children (Petts, 2012). Associations such as these might reflect, in part, the social supports experienced by those who attend church regularly, as church attendance provides a place for families to gather and socialize. In addition, intrapersonal processes, such as reliance on relatively effective coping strategies, might be implicated.

The connotations of religiousness are not invariably positive, however; in fact, it can sometimes exacerbate vulnerability among youth and adults. King has cautioned that ill

effects can derive from religious contexts that inhibit intellectual or identity exploration, or that encourage exclusion of others (see King & Boyatzis, Chapter 23, this *Handbook*, this volume; King et al., 2011). Similarly, strong beliefs in the supernatural may sometimes take the form of fatalism, and if at-risk youth and parents come to believe that nothing can be done to improve their life situations, this can create formidable barriers to improving the overall quality of their lives (Luthar, 2006).

Neighborhoods: Protective Processes

Moving on from the relatively proximal extrafamilial contexts of school, peers, and interpersonal supports to those more distal: Aspects of the wider community may also play an important role in buffering risk for children (Gorman-Smith & Tolan, 2003; Ungar et al., 2013). Particularly important are social organization processes in the neighborhood, including levels of cohesion, a sense of belonging to the community, supervision of youth by neighborhood adults, and high participation in local organizations. Such social processes can help buffer the impact of structural characteristics of the community (e.g., poverty or violence) either by directly benefiting children themselves, or affecting parents and families (Leventhal, Dupéré, & Brooks-Gunn, 2009).

Direct benefits to children are seen in Gorman-Smith and Tolan's (2003) findings that when inner-city families are lacking in warmth and closeness, children's vulnerability can be reduced somewhat if they feel a sense of belonging and support in the neighborhood. Indirect benefits for youth have been found in longitudinal research, through, and in tandem with, family factors. For example, research in the United Kingdom showed that children in disadvantaged communities benefited significantly from collective efficacy in their neighborhoods, which was operationalized as high trustworthiness and cohesiveness of community members, and the likelihood that local adults would intervene to disrupt altercations or protect local resources (Odgers et al., 2009). Even after controlling for several family factors, collective neighborhood efficacy was associated with fewer antisocial behaviors among children as they started school, though the relationship did not hold when the children were in middle childhood. The authors noted that given the young age of the children at the earlier assessments, the benefits were likely to be transmitted via the impact of positive neighborhood processes on parents.

Further evidence for indirect effects are seen in longitudinal data on adolescents at risk for delinquency: When

parents felt more connected to their neighbors, their children were less likely to report involvement in violent altercations by late adolescence (Kurlychek, Krohn, Dong, Penly Hall, & Lizotte, 2012). Similarly, among participants in the Project on Human Development in Chicago Neighborhoods (PHDCN), high neighborhood collective efficacy strengthened the effect of high family attachment—feeling emotionally and socially supported by family members—which in turn protected against adolescent suicide attempts (Maimon, Browning, & Brooks-Gunn, 2010).

Relocating out of at-risk neighborhoods can also yield some benefits for youth. In the PHDCN study, adolescents who moved from neighborhoods with high violence and low collective efficacy to homes outside the city manifested fewer violent behaviors, lower exposure to violence, and higher self-efficacy, as compared to those teens who remained in such neighborhoods. No such effect was found for youth who made the smaller change of relocating to other neighborhoods within the city (Dupéré, Leventhal, & Vitaro, 2012). These findings appear to reflect another instance of multiple systems at work. As Sharkey and Sampson (2010) point out, youth who move to communities outside of the city engage with a different school system and may leave behind other negative structural factors such as racial segregation, while those who remain in the city stay connected to the same systems. Consistent with these suggestions, Dupéré et al.'s (2012) analyses indicated that attitudes toward school and future educational plans mediated the effect of neighborhood change on self-efficacy, suggesting that youth felt more positive about their educational opportunities in their new communities.

The impact of neighborhood relocation may also differ according to gender. Longitudinal results from the randomized, experimental Moving to Opportunity study—in which families in disadvantaged neighborhoods in several cities were provided with vouchers to enable them to move—indicate benefits for adolescent girls, but not boys. In follow-up studies conducted between 4 and 7 years later, girls who moved to low-poverty neighborhoods had better mental health and educational outcomes, and reported fewer high-risk behaviors, than girls who remained in disadvantaged, high-poverty neighborhoods. No advantage was found for boys who relocated, compared with their counterparts who did not (see Leventhal & Dupéré, 2011). In explaining such findings, researchers have suggested that girls may benefit from reduced exposure to sexual harassment in their new, less-disadvantaged neighborhoods, and that boys who are already teenagers when they move may

bring their patterns of socializing with them (which may be less normative in their new setting), and may also be removed from the positive influence of male kin (Clampet-Lundquist, Edin, Kling, & Duncan, 2011). Adolescent boys in particular who move out of disadvantaged neighborhoods may therefore require greater support to benefit from this transition (Leventhal & Dupéré, 2011).

Within low-income neighborhoods, youth-serving community organizations, such as those providing organized after-school activities, can provide critical protective functions, associated with lower rates of aggression and violent crime as well as positive social and emotional outcomes (Mahoney, Harris, & Eccles, 2006). The protective potential of youth organizations is well illustrated in the 5Cs model of Positive Youth Development, which posits that young people are better able to develop into healthy and constructively engaged citizens when their strengths are aligned with and supported by resources in their families, schools, and communities, promoting development of the 5Cs—character, confidence, connection, competence, and caring (Lerner, Dowling, & Anderson, 2003). Within this model, organizations and programs for youth can be conceptualized as one element making up important ecological assets of the neighborhood, besides resources such as high average education and employment levels, recreation spaces, and neighborhood groups. Analysis of a subset of data from the 4-H study of Positive Youth Development (see Lerner, von Eye, Lerner, & Lewin-Bizan, 2009), based on the 5Cs model, showed that for girls in neighborhoods low on ecological assets in general, participation in youth programs as 10-year-olds was associated with higher scores on a measure of the 5Cs, and lower depressive symptoms and risk-taking behaviors, as 12-year-olds. However, the same was not found for boys. This finding lends further evidence for the iatrogenic effects of exposure to deviant peers to which boys may be particularly vulnerable, and underscores the importance of structured after-school activities for boys in particular.

Finally, the benefits of structured community activities can be amplified if parents are actively engaged with the programs. To illustrate, Mahoney and Magnusson (2001) reported that among at-risk boys in Sweden, fathers' involvement in community activities in late childhood was associated with lower risk for criminal involvement of youth by the age of 13 years. These findings were seen as possibly reflecting the effects of more conventional values of community-involved fathers, their greater personal resources, or their higher levels of involvement in their sons' lives.

Individual Attributes: Malleability Within Contexts

In overviewing the triad of vulnerability and protective processes in resilience, we reiterate that children's own attributes should be considered after aspects of their families and communities, for three critical reasons (see Luthar, 2006). From a basic research perspective, several studies—described in detail below—have shown that many positive child attributes are themselves dependent on influences from the proximal and distal environments. From an applied perspective, it is logical that interventions to foster resilience should focus less on what young children are able to do for themselves, and more on what adults must do to bolster the children's own efforts. From a policy perspective, finally, to place primary emphasis on child attributes could carry the risk that public debate will shift away from the major environmental risks that affect children, leading to decreased allocation of resources to ameliorate these risks (see Luthar & Brown, 2007; Ungar, 2013). These considerations—rather than any devaluing of children's own strengths—lead us to place emphasis on families and communities in transaction with the children, rather than the other way around.

To underscore the perils of overemphasizing children's own attributes, we begin this section by presenting evidence on the malleability of some of the most commonly cited "protective child attributes," starting with intelligence (probably the single most often mentioned asset). Studies on diverse risk groups find that individuals with high IQ tend to fare better than others (Luthar, 2006; Masten & Narayan, 2012). Among 4- to 6-year-old children experiencing homelessness, Masten et al. (2012) showed that superior executive functioning (related to high IQ) was associated with relatively positive social and academic development. At the same time, the potency of environmental influence on intelligence itself is seen in Sameroff and colleagues' (1987) findings that children facing eight or nine environmental risk factors scored more than 30 points lower than children with no risks. Of preschoolers in the high-risk group, 26% had IQs below 85, whereas none in the zero-risk group did.

Powerful testimony on this issue lies in Rutter and colleagues' (2010) data from "natural experiments" involving adoptees from Romanian orphanages. Caregiving conditions in these orphanages ranged from poor to appalling: Infants were usually confined to cots, there was no personalized caregiving and few toys, feeding often occurred via propped up bottles, and washing by hosing the babies down. When these children entered into adoptive families in the

United Kingdom, many showed developmental retardation, with over half functioning in the cognitive/intellectual disability range. Longitudinal evaluations then showed catch-up effects, wherein babies who were adopted by 2 years of age lost their profound early deficits, and by the age of 4, came to show near-average developmental status. Despite these ameliorative effects, however, head circumference for the adopted children remained about 1 standard deviation below the normal population means by Age 11, suggesting the incomplete nature of this catch-up effect by this age (Rutter et al., 2010).

Other researchers have shown that disturbances in parents' functioning can affect child intelligence. Maternal depression, for example, has been linked with relatively low child cognitive functioning both in the postpartum period (Kingston, Tough, & Whitfield, 2012) and in the preschool years (C. Hughes, Roman, Hart, & Esnor, 2013). Among high-risk African American and refugee adolescents, youth exposed to domestic abuse showed a decrease in academic success, as abandonment trauma and direct abuse was linked to a decrease in IQ (Kira, Lewandowski, Somers, Yoon, & Chiodo, 2012).

In terms of underlying processes, environmental deprivation may engender cognitive deficits because of a lack of appropriate stimulation, and even adverse effects on brain development (see Hedges & Woon, 2011). Depressed and psychologically withdrawn caregivers, for example, tend to provide little of the stimulation that fosters the development of cognitive skills and expressive language, and deficits in the mother-child relationships can constrain children's developing sense of self-efficacy and agency, in turn inhibiting their active exploration of the environment (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume). Biologically, we know that stress generates high levels of cortisol and catecholamines, and chronic activation of the stress response can lead to the death of neurons in specific brain regions, with these effects most profound during early childhood when neuroplasticity is high (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume). Results of animal studies clearly establish that early exposure to enriched rather than deprived environments is associated with substantial differences in animals' neurochemical, physiological, and neuroanatomical functioning (Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume).

One might argue that high IQ would remain more consistently beneficial later in development than in early childhood; while probably true, the evidence is not unequivocal even at older ages. Up through middle childhood, it does

seem that bright children tend to show stability in everyday competence despite increasing levels of life stress (e.g., Garnezy et al., 1984). On the other hand, among different samples of low-income adolescents, intelligence was not found to be protective. To the contrary, bright youth seemed to be more sensitive than others to negative environmental forces (Gutman, Sameroff, & Cole, 2003; Luthar, 1991). In other words, intelligent adolescents fared far better than did less intelligent ones when life stress levels were low, but when stress was high, they lost much of this advantage. More strikingly, among adults, Fiedler (1995) found that high-IQ people showed leadership success under conditions of low stress, but that when stress was high, IQ was *inversely* correlated with success. Similar findings have been shown for high ego development, a construct closely linked with high IQ (Luthar, 2006).

Collectively, findings such as these have been viewed as suggesting that the manifest “benefits” of innate intelligence vary depending on aspects of the proximal environment. To illustrate, in areas of concentrated poverty with a dearth of conventional means of achieving self-worth (e.g., good grades, productive employment), intelligent, creative teenagers may use their talents in ways that bring more immediate gains—such as illegal entrepreneurship—rather than through striving for excellence at school (Gutman et al., 2003). Consistent with this suggestion, Loeber and colleagues (2012) found that youth with high IQ and high impulsivity showed greater law-breaking and delinquency over time than did low-IQ individuals (although the effects were attenuated as the adolescents aged).

Rather than IQ as measured by standardized intelligence tests, it is probably several assets that are usually associated with cognitive and overall developmental maturity that confer protection against adversity. These include the ability to come up with different problem-solving strategies; the capacity to generalize learning across situations; the unfolding of high motivation to explore and master new challenges; the capability for long-term planning; and finally, histories of various successful experiences, academic and interpersonal, that tend to derive from the aforementioned skills (Luthar, 2006; Masten, 2011; Rutter, 2012; Shonkoff & Phillips, 2000).

There is accumulating evidence concerning the protective role of such assets derived from research on diverse at-risk groups. In an inner-city sample, for example, Noam and Hermann (2002) noted the protective potential of both insight and the capacity to use problems to motivate positive change. Among children who had experienced the death of a parent, Haine, Ayers, Sandler, and Wolchik

(2008) found that the ability to reframe negative, unhelpful beliefs associated with the parents’ death (into more positive thoughts) was of significant help through the grieving process. Beardslee (2002) found that among children of depressed parents, well-functioning youth had good cognitive awareness of what they were facing—they recognized the parents’ illness, knew that they were not responsible for it, and saw themselves as separate from their parents. In addition, they were able to put this experience in words, and could articulate strategies to offset the effects of the illness on them (e.g., forging close relationships with non-family adults). Hauser and colleagues’ (2006) follow-up of individuals who were psychiatrically hospitalized as adolescents showed that major attributes of those who seemed resilient later in life included self-reflection or high awareness of their feelings and thoughts; self-efficacy or agency in making conscious choices about their lives; self-complexity in recognizing multiple facets to different situations; and persistence and ambition in education and careers.

Vaillant (2012) has established that tendencies to use developmentally mature defenses—such as altruism, suppression, humor, and sublimation—are associated with relatively positive outcomes, over and above the effects of IQ, education, and social class. In a long-term follow-up study of 73 adolescent inner-city boys, and a socioeconomically matched group with an average IQ of 115, Vaillant and Davis (2000) found that at the age of 65, one-half of the low-IQ men were comparable to the high-IQ group in terms of their own incomes and their children’s levels of education. These resilient low-IQ men were far more likely than their low-IQ, poor outcome counterparts to use predominantly adaptive defenses, with the latter group more often using maladaptive defenses such as turning against the self, projection, and fantasy.

Finally, there is accumulating evidence on the benefits of high emotional intelligence—the ability to perceive and express emotions, to reason about and use them, and to manage them to foster personal growth (Mayer, Roberts, & Barsade, 2008; Rivers et al., 2012). This construct is linked to higher social skills and fewer behavior problems in childhood (Mayer et al., 2008; Rivers et al., 2012), and among older youth, is associated with lower substance use and better academic grades (Parker, Summerfeldt, Hogan, & Majeski, 2004; Trinidad & Johnson, 2002).

Based on the accumulated evidence, therefore, there are two major conclusions about the role of intelligence in resilience. First, highly intelligent individuals are likely to reflect what Belsky and Pluess (2009) call “differential

susceptibility," that is, greater sensitivity to good *and* bad environmental influences. Second, rather than high IQ per se, resilient outcomes likely rest on more adaptive "meaning making" (Rutter, 2012)—individuals' phenomenological interpretations of events in their lives—with generally superior problem-solving abilities, better planning for future events, and more effective, developmentally mature coping styles.

Environmental Influences on Diverse Personal Assets

The previously described evidence on intelligence is paralleled by similar evidence on temperament, which has also been shown to confer protection against stress (Chen & Schmidt, Chapter 5, this *Handbook*, this volume; Luthar, 2006; Masten, 2001). Benefits have been found not only in relation to psychological and behavioral indices, but also biological ones. To illustrate, children low on behavioral inhibition may react less to stress than others, as suggested by evidence of resting right frontal EEG activation in inhibited children (Calkins & Fox, 2002), a pattern that is linked with tendencies to respond to stressors with negative affect or depression (Cicchetti, 2013).

Several studies have established the deleterious effects of poor self-regulation from early childhood onward (see Shonkoff & Phillips, 2000). In infants of families facing high adversity, lack of self-regulation at the age of 12 months was linked with increased behavioral problems over time (Halligan et al., 2013). Among low-income children, poor emotion regulation at the age of 3½ was related to low self-control at age 6 (Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002) and among children with low emotional knowledge at 7 years of age, significant increases in internalizing symptoms were seen over the next 4 years (Fine, Izard, Mostow, Trentacosta, & Ackerman, 2003). In a study of adolescents, those with high negative emotionality and low regulation exhibited the most maladaptive responses, including aggression, anger, and distress (Laible, Carlo, Panfile, Eye, & Parker, 2010). Overall, findings suggest that children with poor self-regulation tend to get into a cycle where dysfunctional social exchanges lead to isolation and thus sadness, and these emotions in turn jeopardize future interactions with others.

Whereas temperamental differences can be seen as early as infancy and they do show continuity over early childhood, both the manifestation and ramifications of temperament can be modified by environmental features. As Rutter (2000) noted, scientists have long moved past erroneous assumptions that "constitutional" factors are unalterable. Some children do have a tendency to be more impulsive or

oppositional than others, but their interactions with significant others shape the behavioral conformity they display. In a similar vein, some children are temperamentally more exuberant than others—and some feel negative emotions more intensely than do others—but the external manifestation of these emotions, and whether they lead to problematic social interactions, depends on the degree to which the children can modulate their emotions (Eisenberg et al., 2004). And children's abilities to modulate or inhibit the expression of emotions depend—as will be described in the paragraphs that follow—on the nature of their interpersonal relationships, particularly those early in life.

Emerging self-regulation depends squarely on relationships (see Thompson, Chapter 6, this *Handbook*, this volume). As Sameroff (2010) has underscored, "self-regulatory capacities are heavily influenced by the experience of regulation provided by caregivers.... This regulation by others provides the increasingly complex social, emotional, and cognitive experiences to which the child must self-regulate and the safety net when self-regulation fails" (p. 15). Consistent with these assertions, among young boys in low-income families, secure attachment to mothers and positive maternal control at the age of 1½ years predicted effectiveness of emotion regulation at the age of 3½, and this in turn was related to capacities for self-control at around 6 years of age (Gilliom et al., 2002). Beyond early childhood, Crossley and Buckner (2012) demonstrated that positive parenting practices were related to effective self-regulation skills in older children and adolescents living in poverty.

Other than IQ and self-regulation, there is parallel evidence showing that many other child attributes commonly labeled as protective factors are themselves shaped by the environment. Self-efficacy is strongly influenced by the degree to which adults encourage or hinder the child's attempts at manipulation and control (Bandura, 1997). Positive self-esteem can be protective for at-risk children but is itself affected by parental warmth and communication (McClain et al., 2010). Internal locus of control is often beneficial but chronic ill-treatment by parents or teachers sharply reduces children's capacities to maintain internality of control (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume; Skinner, Zimmer-Gembeck, & Connell, 1998). Finally, spirituality can protect against depression and related problems, as can empathy and altruistic behaviors (Beardslee, 2002; Eisenberg, Spinrad, & Knafo-Noam, Chapter 15, this *Handbook*, this volume; L. Miller & Gur, 2002; L. Miller et al., 2012; Zhou, Valiente, & Eisenberg, 2003); these assets, in turn, rest on a strong sense of ethical

values transmitted to the child, and then reinforced by significant others in the family and community.

The preceding examples not only resonate with cautions in highlighting “protective child attributes” that are continually shaped by the environment (see Hanson & Gottesman, 2012; Luthar et al., 2000; Ungar, 2012), but underscore the importance—indeed, the necessity—of involving significant caregivers in child-focused interventions. In any efforts to bolster children’s own competencies, long-term success can be attained only when programs simultaneously involve adults in the children’s natural settings, including parents or teachers (Luthar & Cicchetti, 2000; Ungar et al., 2013). This is true even among children well past the infancy and preschool years, as seen in the exemplary work of Sandler, Wolchik, and colleagues (see Wolchik, Schenck, & Sandler, 2009). Working with school-age children of divorce, these investigators designed an intervention with separate programs for mothers and for children. Follow-up assessments, conducted several months after the program and then 6 years later, indicated that experimentally induced improvements in the mother-child relationship did lead to a reduction in children’s mental health problems, whereas working with children’s coping skills alone did not. The investigators credit changes in the mother-child relationship for later increases in program effects on adolescent self-esteem and effective coping, via cascading effects (Wolchik et al., 2009).

THE STATE OF THE SCIENCE: ISSUES OF CONSENSUS, CONTROVERSY, AND FUTURE DIRECTIONS

In this final section of our chapter, we review the state of the science of resilience in contemporary times, following almost 70 years of research. In turn, we discuss issues about which there is now broad consensus, and which can now be put to rest. Following this, we review major issues about which there are currently differing perspectives by scientists in the field, which pertain to broad research directions most profitably pursued at this stage. We conclude by reviewing salient directions for future interventions on resilience.

Issues Established or Confirmed

There are several issues that have been amply demonstrated, and are now considered “givens” in the field of resilience. The first is that this is a field of research and scholarship that is fundamentally applied in nature (Luthar

& Brown, 2007; Yates & Masten, 2004). This theme is recurrently emphasized in a special issue of the journal *Development and Psychopathology*, dedicated to Norman Garmezy, major progenitor of research on resilience. Masten and Tellegen (2012) underscored Garmezy’s recognition of the significant “potential for informing prevention, practice, and policy if the pathways that led away from psychopathology could be understood” (p. 346). Cicchetti and Rogosch (2012) noted that Garmezy advocated the study of protective processes toward informing models of primary prevention. Rutter (2012) pointed to Garmezy’s central goal of understanding, through rigorous research, how to best help children who contend with serious stress and adversity. Rutter’s (1987) own highly influential early paper on protective mechanisms was critical in illuminating how science can most effectively inform interventions (Werner & Smith, 1992). Similarly, describing her interest in uncovering protective processes across diverse high risk-contexts, Werner underscored that, “If we encourage and nurture these dispositions and competencies in our children as best we can, we have a basic survival kit for meeting adversities that tax the human spirit” (Werner & Smith, 1992, p. 204).

Aside from the fact that the central goal of resilience research is to benefit humanity, a second issue of consensus is that “resilience does happen”; we do not need more research that simply establishes its occurrence. Across all risk circumstances and age groups, there is inevitably a subset of individuals who show relatively positive adaptation. Some retain well-being right after exposure to the stressor under study; others falter for a while but then bounce back to health.

Third, the core finding derived from accumulated research is that resilience rests fundamentally on relationships (Luthar, 2006). This is true for adults as much as children, as evident in pithy assertions, in research reviews, that “Resilience is social, after all” (Zautra, 2014), and “Other people matter” (Peterson, 2006, p. 249).

Fourth, it is clear that there are multiple transactional systems involved in children’s resilient functioning. Proximal and distal environments affect the child, and the developing child in turn affects each of these, as the behaviors of youth affect their parents and their teachers. Furthermore, different aspects of the environment influence each other, as community cohesion affects parents who, in turn, contribute to cohesiveness as opposed to disorganization in neighborhoods.

Fifth, resilience is not fixed over time. At-risk children who reflect positive adaptation can falter over time if

there are unremitting stressors in their environment, just as those who reflect maladjustment can show dramatic improvements with positive changes in their caregiving environments.

Sixth, overt “successful adaptation” among at-risk children can coexist with nontrivial disturbances in adjustment; the more serious the adversity experienced, the more likely that some problems will coexist (unless there are major corrective experiences). These covert forms of maladjustment can include not just symptoms of depression or anxiety as was established decades ago, but also potentially serious problems of physical health (Brody et al., 2013; Felletti & Anda, 2010).

These last two issues were noted at the very outset of this chapter, but they warrant reiteration in this concluding section as there are major policy implications associated with declarations on “rates” of resilience (Luthar & Cicchetti, 2000). Scientists must be extremely cautious about making summary statements in this regard, because “diagnoses” of resilience obviously depend on the (necessarily limited) criteria that are used to define risk-evasion within a particular study. As Luthar and Cicchetti (2000) emphasized, for those whose science can significantly affect social policy with real implications for decisions to enhance or reduce external resources for highly vulnerable groups, it is imperative to maintain the very highest standards of self-scrutiny in scientific research and conclusions.

Issues Unresolved: Critical Directions for Future Research

Given the current state of the science, there are two major potential directions for future research on resilience. As these involve sharply different priorities in scientific foci—and attendant allocation of resources—we consider in some detail the likely yield of each toward effectively maximizing the well-being of at-risk youth and families.

The first direction involves multilevel studies that include biological indices as well as psychosocial ones. Starting around the turn of the century, there were several calls for the incorporation of biology into models of resilience (e.g., Charney, 2004; Luthar et al., 2000; Masten, 2001), given major advancements in studies of biological processes including technologies to manipulate the genome, examine endocrine functioning, and image the brain. Thus, multilevel models were considered important to illuminate biological processes implicated in psychopathology and well-being, and possibly to get some insights

into constraints within which environmental influences operate.

Over time, the accumulated evidence on biological processes has not only vastly enriched the basic science knowledge-base on developmental processes, but has been invaluable in advocating for the investment of resources in preventive interventions (Luthar & Brown, 2007). For decades, psychologists have noted the long-term negative effects of deleterious caregiving environments on children’s adjustment. Findings based on self-reports or observed behaviors, however, could be dismissed as partly reflecting personal choices or motivations. More persuasive as “objective evidence” are data that significant early adversity has substantial ill-effects on the brain’s architecture, and on the physiological systems implicated in coping. Equally powerful is evidence that sensitive and responsive caregiving can substantially *reduce* these negative effects of toxic stress (National Scientific Council on the Developing Child, 2005).

From the standpoint of advancing future applied work in the field of resilience, however, the yield of studies on biological mediators and moderators remains unclear (Luthar & Brown, 2007). As noted earlier, the central goal of resilience research is to make a difference via a concerted focus on “modifiable modifiers” (Garmezy, 1971), and changing biology is not in the realm of psychologists’ expertise.

To consider this issue more carefully, let us consider the three aspects of biology that have most often, in the decade prior to the time of this writing, been discussed in the context of resilience: brain plasticity, stress-reactivity (HPA axis), and gene by environment ($G \times E$) interactions. Beginning with the first two, studies in both neuroscience and neurobiology have established significant physical changes in reaction to the environment. As described earlier in this chapter, the quality of early environments affects neural networks and brain size, and these changes in the brain, in turn, have major implications for vulnerability to psychopathology (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume). Neurobiological studies similarly show that the HPA axis is negatively affected by early adversity and conversely, that sensitive and supportive caregiving significantly buffers the developing HPA axis (Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume).

In both these instances, it would seem that the biological changes documented are more accurately described as *markers* of vulnerability or resilience, rather than “causes” that might be effectively altered in behavioral interventions. When institutionalized children show improvements in

gray matter of the brain after their adoption (see Sheridan, Fox, Zeanah, McLaughlin, & Nelson, 2012) or demonstrate normal growth trajectories for head circumference (Rutter et al., 2010), for example, they also show improvements in developmental quotient scores, and in various aspects of psychosocial functioning. Thus, changes in the brain's structure are among many markers of improved functioning. Similarly, children who show poor stress regulation via cortisol levels are also those likely to show poor regulation on psychological and behavioral dimensions, for example, via faulty attributions of others' behaviors (Cicchetti & Toth, Chapter 13, this *Handbook*, this volume; Gunnar, Doorn, & Esposito, Chapter 4, this *Handbook*, this volume). Again, dysregulation of the HPA axis may more aptly be characterized as a marker rather than a "modifiable" risk modifier.

As these biological changes inextricably co-occur with, and are manifested in, children's behaviors and affect (Cicchetti, 2013; Rutter, 2012; Sameroff, 2010)—dimensions that are far easier and less expensive to assess—one has to question the utility of measuring them in work that is centrally focused on promoting resilience. Intensive study of such processes is of obvious value to basic developmental science and to researchers who are committed to developing effective psychopharmacological treatments. But for those with expertise in psychological, behavioral interventions, the inclusion of biological mediators and moderators, in hopes that they will substantively and usefully guide future interventions, remains questionable (see Luthar & Brown, 2007; G. A. Miller, 2010).

We next turn to $G \times E$ interactions, the third aspect of biology increasingly mentioned in the context of resilience. Again, there is not yet compelling evidence that this is highly relevant to the field of resilience. Effect sizes are very small in these interaction effects, and even when they are statistically significant, it is not necessarily the risk-exposed child but rather the nonexposed child who is helped (Cicchetti & Rogosch, 2012).

Most important, there is no way that behavioral scientists are going to change the "G" part of this equation; at the same time, there is much that can and should be done to address potent risks in the "E" part. Discussing $G \times E$ research on child maltreatment, Cicchetti and Rogosch (2012) have cautioned that "gene variation is unlikely to be useful to identify maltreated children who may be more in need of intervention" (p. 425), even as they underscore the urgent need for concerted prevention efforts to alter the child's deleterious environment.

In future exhortations for the study of biological processes (and discrete psychosocial processes) toward

promoting resilience, therefore, it will be essential for researchers to explicate clearly (a) the modifiability of each of the vulnerability/protective risk processes posited as well as (b) the likely magnitude of their respective effects. This is particularly crucial at a time when national funding priorities—and concomitantly, developmental research foci—have veered disproportionately to a focus on biologically based research on mental health (see Eisenberg, 2014; Luthar & Brown, 2007; Miller, 2010; Sameroff, 2010). As many as 75%–80% of American children and adolescents who need mental health services today do not receive them. For the thousands of at-risk children and families lacking health insurance compelling evidence is needed to show that there is, in fact, hope for individualized tailoring of mental health interventions for children according to their unique psychobiological or genetic profiles, and that these will yield substantial improvements in their well-being.

We emphasize that our central point here is by no means to be "psychosocial evangelists" (Rutter, 2006, p. 224), but to be aware of the potential costs to prevention science. A large-scale, collective insistence on including biology in research designs (not to mention intervention trials) will inevitably detract substantially from bringing promising behavioral interventions to scale. Our central messages, therefore, are for those whose scholarship and research, based in an understanding of transactional, developmental systems, are committed to illuminating effective programs and policies that foster positive human development—where so very much remains to be done in understanding and changing environmental risks that are known all-too-well to have a profound influence.

Central Priorities: Reducing Child Maltreatment

With this applied conceptualization as a backdrop, we now discuss what we believe are the most pressing needs in future research on resilience. We begin this discussion with the single most important potent "vulnerability factor" that has been identified to date, and one that continues to be an alarming problem for today's youth: maltreatment by parents.

The damage caused by prolonged maltreatment is staggering—this has been repeatedly emphasized (Cicchetti, 2013)—yet, there is a startling lack of understanding about how best it might be reduced. Little is known about protective processes that substantially reduce risks for maltreating behaviors among at-risk children's primary caregivers, usually—and across settings—their mothers (relationships with fathers are obviously also important, and are discussed later).

Because it is well-known that depression and stress vastly impair all aspects of mothers' parenting, a concerted attention to *mothers' well-being as a dependent variable* is needed (see García Coll, Surrey, & Weingarten, 1998; Luthar, 2010). A mother who is psychologically depleted cannot consistently express warmth, enforce appropriate limits, and maintain regular schedules in the home, and without respite, will inevitably be in danger of neglecting or maltreating her children and of failure to shield them against maltreatment by others (Luthar & Brown, 2007). Echoing these assertions, Shonkoff and Fisher (2013, p. 1645) argued that "Promoting resilience in young children who experience high levels of adversity depends upon the availability of adults who can help them develop effective coping skills.... Caregivers who are able to provide that buffering protection have sound mental health and well-developed executive function skills in problem solving, planning, monitoring, and self-regulation."

Future resilience research must focus, therefore, on disentangling what might significantly minimize at-risk mothers' "ego-depletion," and promote their "ego-replenishment." Knowledge of appropriate parenting behaviors is important but this alone is by no means enough; indeed, mothers who fall short (impoverished as well as affluent) often know what are "bad" or "good" parenting behaviors, but do not have the energy or strength to do what is called for (Luthar et al., 2007; Luthar et al., 2013). Thus, developmental scientists must systematically illuminate what most benefits the well-being of "mothers as persons" (Gewirtz, Forgatch, & Wieling, 2008; T. M. Williams et al., 1987), an overarching construct that shapes all parenting behaviors and interactions with children. Moving beyond our long-standing focus on the many critical ways in which mothers affect their children, researchers must examine, with equally rigorous science, the processes that most affect mothers' own states of despair versus equanimity.

One might contend that social support is known to be helpful to mothers (as described earlier in this chapter), but at this time, there is no clear understanding of which specific forms of support are most beneficial. Existing studies have operationalized support in various ways, including instrumental support such as willingness of family members to lend money or help with childcare; emotional support, such as feelings of belonging, emotional security, trust, and nurturance; or combinations of these.

A postulate worth testing in the future is that—as for children—the single biggest predictor of a mother's well-being is whether she feels dependable acceptance and support for herself, as an individual and as a parent.

This was long argued by Knitzer (1982, 2000), a pioneer in children's mental health, who consistently advocated relationship-based interventions for at-risk mothers. It is a postulate consistent with early findings on low-income mothers that more than the actual receipt of social support, it was the expectation that it would be there if needed, that was more powerfully benefited women's parenting (e.g., Hashima & Amato, 1994). Indeed, it is entirely logical that when mothers feel a sense of psychological safety and of being "tended" themselves (Taylor, 2006), they will function well across multiple parenting behaviors (Luthar, 2010; Rotheram-Borus et al., 2011).

Multilevel, Transactional, Relationship-Centered Models

Future research on resilience must, therefore, be grounded in multilevel, transactional models that have, at the core, the quality of relationships between children and their primary caregivers, with these in turn ensconced within the contexts of extra-familial support systems (see Figure 7.1). Reis, Collins, and Berscheid (2000) have provided a useful guiding paradigm in this regard, with the following tenets: (a) From conception onwards, individuals are nested in social relationships; (b) each dyadic relationship is itself nested within a social and physical environmental system; (c) these systems in turn are embedded in larger societal

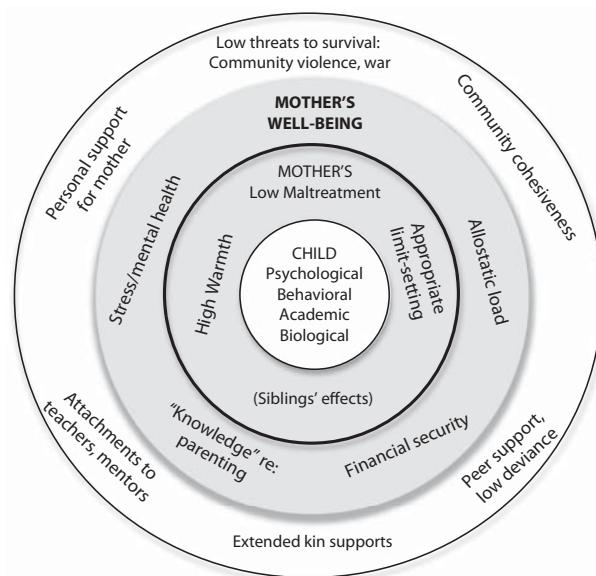

Figure 7.1 Multilevel, transactional systems: Prominent risk modifiers fostering childhood resilience.

Note: As used here, the term "Mother" refers to the child's primary caregiver, but this could be the father in some at-risk families. The emphasis is on ensuring gender-sensitivity in conceptualizing predictors of the primary parent's well-being.

systems; (d) all of these systems continually evolve and influence each other over time. Given all we have learned from developmental research on resilience, the primary focus, in the years ahead, must be to illuminate which aspects of the ecological surround most powerfully bolster the single most powerful dyadic relationship affecting children's development, that with the primary caregiver.

In future efforts to identify exosystemic processes that benefit children's caregivers, developmental scientists will need to collaborate with sociologists and anthropologists with expertise regarding cohesiveness in communities. Researchers will need to draw upon accumulated knowledge—including ethnographic and qualitative evidence (see Weisner, 2005)—about processes that best help to enhance mutual supportiveness among parents in neighborhoods, then derive testable hypotheses, and begin to test these systematically in increasingly sophisticated, multilevel quantitative developmental models.

Research Designs: Within-Group and Within-Gender Analyses

In terms of research design, developmental scientists will have to prioritize in-depth studies of salient processes within particular high-risk contexts (see Spencer, Swanson, & Harpalani, Chapter 18, this *Handbook*, this volume). The inclusion of "low-risk" comparison groups in resilience research is not just unnecessary, but detracts from resources well-spent in disentangling critical protective processes among samples of youth facing major risks (e.g., Hauser et al., 2006; Laub & Sampson, 2003).

The value of within-group studies is well-illustrated in García Coll's work on the "immigrant paradox," wherein first-generation immigrants to the United States often fare better than their children, who are more assimilated into American ways (García Coll & Marks, 2011). A mixed-methods longitudinal study of three groups of immigrant families—Cambodian, Dominican, and Portuguese—revealed several group-specific processes. The Cambodian children reflected the immigrant paradox, with better academic performance among those whose mothers had recently immigrated to the United States. In contrast, for the Dominican youth, higher acculturation to the United States was associated with better grades, whereas cultural attitudes had no effects—negative or positive—among Portuguese youth. These differential sets of predictors were likely related to group differences in the degree of contact retained with families in countries of origin (the lowest for Cambodians and highest for Dominicans) and the degree to which they blended in with mainstream

American culture (the highest for Portuguese, with fair-skinned complexions).

In a related vein, developmental research on at-risk parents must entail rigorous exploration of within-gender processes. Whereas mothers are generally primary caregivers across cultures and socioeconomic settings, there are many instances where it is fathers who maintain primary responsibility in rearing their children, and what affects a mother's personal well-being cannot be assumed to be the same as what affects fathers. In reviews of the literature, Lamb and his colleagues have established that fathers on average spend less time with their children than do mothers, and in some though not all cultures are involved more in play than in caregiving (see Lamb, 2004; Lewis & Lamb, 2003). In traditional families, fathering may also be more impacted by the quality of the marital relationship (satisfaction and level of support) than is mothering. Accordingly, it will be critical, in future research on resilience, to conduct analyses separately by parents' gender, and instead of using gender-neutral terms about at-risk "parents," to describe patterns specific to fathers and to mothers (see Phares, Lopez, Fields, Kamboukos, & Duhig, 2005; Rotheram-Borus, Stein, & Lin, 2001).

Cross-national interventions further attest to the critical importance of attending to gender-specific needs of at-risk parents. Randomized trials with families affected by HIV indicated that across countries (United States, Thailand, and South Africa), men typically responded to stress with flight-or-flight responses, and women with tending and befriending (M. J. Rotheram-Borus, personal communication, September 12, 2013; Rotheram-Borus et al., 2011). Accordingly, interventions were designed to accommodate these gender differences in both delivery formats and activities. Community-based "mentor mothers" were most beneficial for affected women, for example, whereas men were more likely to be engaged via group activities such as those involving sports or vocational training.

Operational Definitions of Core Relationships: Predictors and Outcomes

With all the rich evidence on discrete parenting behaviors that foster resilience, more research is needed to disentangle what exactly it is that forms the central, essential ingredients of children's beliefs that they are truly loved and cherished. All of the manifestly resilient children in Werner's Kauai study had "at least one person in their lives who accepted them unconditionally, regardless of temperamental idiosyncrasies, physical attractiveness, or intelligence" (Werner & Smith, 1992, p. 205). In developmental

science, researchers need to finesse how best to operationalize and capture this broad, overarching dimension from the children's own perspectives.

A critical component is likely to be a steadfast sense of safety; a conviction that the adult will "be there" in times of need. Among youth who experienced considerable disruptions of early foster placement, Dozier, Lindhjem, and Ackerman (2005) identified the importance of children's confidence that their caregiver would stand between them and danger. This sense of security was powerful in predicting long-term indicators of well-being (psychological and biological), more so than the quality of early attachments, or whether the caregiver would comfort the child when distressed. Resonant with these research findings is the description of his mother, by NBA star LeBron James—who grew up in dire poverty, never met his father, and moved 12 times between the ages of 5 and 8.

Whatever my mom could do or could not do, I also knew that nobody was more important in her life than I was. You have no idea how much that means when you grow up without so many of the basic things you should have. You have no idea of the security it gives you, how it makes you think, "Man, I can get through this. I can survive." (Manfred, 2013)

In future research on resilience, it will be important to capture this sense of felt security not just in relation to mothers and fathers but also with other adults, and across different developmental periods. Studies thus far have tended to focus on relationships within particular ecological contexts, but rarely, simultaneously across multiple levels. It would be useful to capture the degree of overall security that the child subjectively experiences, considering not just parents but also teachers, mentors, extended kin, and other adults. Just as cumulative risk scores explain high variance in maladjustment, it is plausible that "cumulative love" scores will account for high variance in resilient adaptation.

Implicit in the aforementioned suggestions is the importance of capturing children's own perspectives on different socializing influences. A widespread tenet of developmental science is that self-report data are biased and thus nonoptimal, but in resilience research, there must in fact be concerted focus on children and adolescents' phenomenological, subjective interpretations of their own realities (Spencer, Swanson, & Harpalani, Chapter 18, this *Handbook*, this volume). The power of contextual factors, arguably, rests largely on the psychological meaning given them by the individual (Rutter, 2012). Emphasizing this point in the context of school climate, Deci and Ryan

(1987) noted that if a given child were to perceive his or her teacher as being highly controlling (regardless of others' ratings), this child could relate to the teacher in ways that lead the teacher to be more controlling with the child, resulting in a mutually exacerbating pattern.

It is important to note, furthermore, that the "problem of shared variance" is easily corrected for in multivariate analyses that include other reliable and valid self-report indicators. To illustrate, with self-reported distress of youth as an outcome, multivariate regressions can simultaneously consider the child's felt closeness to mothers and to fathers, alienation from each parent, monitoring and supervision, as well as perceived criticism. These multiple predictors clearly partial out shared method variance due to self-report of predictors and outcomes, and will illuminate the unique predictive power of each predictor variable (see Luthar & Barkin, 2012).

Obtaining children's own perspectives is critical not just in assessing the quality of their relationships (predictors), but also in capturing intrapsychic aspects of their own adjustment, including positive as well as negative dimensions. In studies of resilience of children and youth thus far, researchers have assessed internalizing and externalizing symptoms, but have neglected indices such as subjective well-being, personal equanimity, optimism, and orientation to intrinsic goals such as personal growth (Luthar, Lyman, & Crossman, 2014).

As the measurement of self-reported adjustment domains is expanded, so too must there be expansion of domains encompassing others' ratings to include—indeed, to prioritize—perceptions of kindness, compassion, and social justice (see Killen & Smetana, Chapter 17, this *Handbook*, this volume). In behavioral measures of "doing well," resilience researchers have relied chiefly on adults' and peers' judgments of whether children adequately meet stage-salient societal expectations, such as getting along with peers, conforming at school, achieving acceptable grades, or holding a job. What is missing are behaviors reflecting proactive generativity, or doing for the greater good—behaviors that are not just positive outcomes in themselves, but also carry the potential to engender cumulative benefits over time. Among the children of Kauai, youth who demonstrated resilient adaptation as adults were those who, "At some point in their young lives, usually in middle childhood and adolescence . . . were required to carry out some socially desirable task to prevent others in their family, neighborhood, or community from experiencing distress or discomfort" (Werner & Smith, 1992, p. 205). Similar findings are evident in Elder's longitudinal

research on youth growing up in the Great Depression, showing that the assumption of new responsibilities in the family was beneficial for adolescents (Elder & Conger, 2000), possibly reflecting “steeling” effects of successfully coping with early family adversities (Rutter, 2012).

Obtaining significant others’ judgments of altruism and social justice must be prioritized in future studies of resilience, among youth and adults alike. Little (2011) has argued that, in adulthood, the most compelling definition of a “life well-lived” is not just self-reported health and happiness, but when the person is judged as committed to doing for others, with positive contributions to society. Similarly, generativity can and should be considered a core positive outcome in operationalizing resilience among children and youth. If the ultimate goal is to promote the well-being of humanity or a “civil society” (Lerner et al., 2003), then humanitarian acts must be a central outcome in how we define children’s positive outcomes in the science of resilience (Luthar et al., 2014).

Intervention Needs: Understanding Mechanisms of Change and Going to Scale

As with directions for basic research on resilience of parents, scientists much disentangle the most powerful underlying active ingredients in parenting interventions that have proved to be effective. Again, it is plausible that over and above learning particular skills, it is improvements in mothers’ overall well-being, within the context of supportive relationships, that is an indispensable “engine” of change. This is suggested by the core components of many existing evidence-based programs. To illustrate, Webster-Stratton’s (2001) the Incredible Years intervention provides training to improve parenting skills and children’s school readiness, while helping parents’ cope with their personal problems; in this program, connections with “buddies” from parent groups allow members to create valuable support networks (Borden, Schultz, Herman, & Brooks, 2010). Ammerman and colleagues’ (2005) Every Child Succeeds program, combines in-home cognitive behavior therapy for depressed mothers with a supportive home visiting component. In other effective interventions described earlier in this chapter (Cicchetti, Rogosch, & Toth, 2006; Dozier et al., 2002; Luthar et al., 2007), a cardinal component is consistent respect, warmth, and support displayed by project staff or therapists to participating mothers.

In attempting to go to scale with relationship-based interventions for mothers, we in science might do well to learn from an effective, widely used intervention that has

been developed by laypeople and involves minimal costs—a critical consideration in these times of limited resources for mental health care—that is, Alcoholics Anonymous (AA). Begun in the 1930s, this is the most commonly sought after source of help for alcohol-related problems with more than 1.3 million Americans meeting each week. The therapeutic benefits of this program can be on par with those of professional interventions, and in some instances, even greater (see Kelly, Hoeppner, Stout, & Pagano, 2012).

Notably, this program is based on processes of change that have a strong basis in science on protective processes in resilience. These include the presence of adaptive, consistent support networks, a realistic, flexible locus of control, and an emphasis on spirituality (see Crape, Latkin, Laris, & Knowlton, 2002; Galanter, 2007; Kelly et al., 2012). Powerful benefits are believed to derive from attendees’ shifts to adaptive social networks (e.g., with reductions in pro-drinking network friends); members speak of unconditional acceptance in “the rooms,” the absence of shame in sharing their most private failings, and their ability to reach out to others at times of stress. With regard to locus of control, a cardinal program goal is striving to accept situations that are outside one’s control, and to actively address those in which outcomes can be personally influenced. The spiritual component, finally, does not necessarily imply practicing religion, but is akin to how it has been defined in science (Greenfield, Vaillant, & Marks, 2009), with an emphasis largely on tapping one’s inner resources, recognizing a power greater than oneself, and feeling a profound sense of caring for others.

Given its effectiveness—and again, the significant fact that it entails minimal costs, shared by members—the AA model might usefully be used for future community-based groups to promote resilience among at-risk mothers (and for at-risk custodial fathers). If in fact the power of AA meetings does lie largely in the authentic connections forged with others sharing similar struggles, with supportive reminders of their own behaviors that can and should be controlled (versus uncontrollable events), this is a model that might usefully be applied for caregivers vulnerable to parenting disturbances (see Luthar et al., 2007; O’Dougherty Wright, Fopma-Loy, & Oberle, 2012).

Increasingly, leaders in prevention and treatment have urged scientists to bolster relationship-based networks that already exist in communities, and to harness these in interventions that can become self-sustaining over time (Knitzer, 2000; Zigler & Finn-Stevenson, 2007). Noting the extensive support that existed among gay men during the early years of the AIDS epidemic, for

example, Rotheram-Borus has exhorted future wellness initiatives that are centrally focused on strengthening social networks within at-risk communities (Rotheram-Borus, Swendeman, & Flannery, 2009). Kazdin and Rabbitt (2013) have described several low-cost, feasible, and effective interventions that use trained laypersons (as opposed to professional psychotherapists), including hairstylists in beauty salons trained to assess depression and anxiety and to provide appropriate referrals, and lay counselors for treating such problems, again, with structured training and appropriate backup for those who need psychotropic medications.

Community and School-Based Systemic Interventions

We close this chapter with directions for interventions beyond the parents and family, beginning with illustrations of established, effective, multilevel interventions that we believe provide models of programs that could, profitably, be taken to scale. The interventions we describe differ somewhat in the core foci—on neighborhoods or schools, for example—but what they have in common is attention to relationships at multiple levels of children’s ecological systems. In other words, all of these interventions reflect explicit cognizance that as long as children remain in settings that are damaging to their adjustment—with failures in systems ranging from communities and schools to law enforcement and social service agencies—any pull-out efforts to promote particular child skills will have limited value; conversely, drawing upon assets across multiple systems is both cost-effective and efficacious over the long term (Pianta & Walsh, 1998; Ungar, 2012; Zigler & Finn-Stevenson, 2007).

Ensuring children’s physical safety in their neighborhoods and communities is the most basic goal in promoting resilience, and there now exist several programs addressing interconnected systems toward combating community violence (Ager, 2013). The Child Development-Community Policing Program (CD-CP) in New Haven (<http://childstudycenter.yale.edu/community/cdcp.aspx>), for example, utilizes a collaborative model involving mental health, law enforcement, education, juvenile justice, and judicial and social services in an effort to reduce the negative effects caused by exposure to violence, while appropriately addressing legal consequences.

There is also much promise in community-based interventions that focus on positive interactions within and across families, such as the “Schools and Families Educating Children” (SAFE Children) intervention (Tolan,

Gorman-Smith, & Henry, 2004). This preventive program is focused on promoting strong family relationships and developing support networks in the neighborhood, with attention also to children’s academic functioning. Similarly, the Promise Neighborhoods initiative (Komro et al., 2011) uses local resources to support the development of children in at-risk communities, with a focus on key malleable factors including influences from the family, peers, schools, and other organizations. Also warranting more exploration are preventive community efforts that involve collaboration directly with groups of youth, such as the Youth Empowerment Solutions for Peaceful Communities (YES) program (Zimmerman, Stewart, Morrel-Samuels, Franzen, & Reischl, 2011).

In efforts to go to scale with such evidence-based neighborhood interventions, attention to local contextual needs and priorities is crucial. Intervention programs that are established with sensitivity to concerns of those in the neighborhood (via needs assessments) have much greater success with recruitment and retention, and in addition, those programs that operate in partnership with local citizens, schools, and agencies are more likely to be sustained over time (Komro et al., 2011; Lapalme, Bisset, & Potvin, 2013).

In the setting of schools, researchers must capitalize more on the potential to use caring adults as allies in fostering resilience, expanding efforts based on existing interventions, and targeting not just elementary school students but also those in middle and high school (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011; J. N. Hughes, 2012; Pianta et al., 2012; Sabol & Pianta, 2012). As with communities, in bringing school-based interventions to scale, it will be vital to build upon “indigenous resources” (Atkins, Hoagwood, Kutash, & Seidman, 2010, p. 42), that is, existing school personnel such as school psychologists, teachers, administrators, and support staff, as opposed to outside professionals. Involvement of local school personnel in planning and implementation stages is critical in ensuring that adopted programs will be sustained as part of a school’s regular programming, rather than a temporary, intrusive or cost-intensive add-on.

From a pragmatic standpoint, Becker, Darney, Domitrovich, Keperling, and Ialongo (2013) have provided specific, useful directions for the large-scale implementation of school-based programs that are known to be effective, addressing the important issue of teachers’ need for ongoing support. Using examples of two evidence-based programs (the Good Behavior Game and the PATHS curriculum; Embry et al., 2003; Greenberg & Kusché, 2006),

the authors outline directions for ongoing professional development in the form of a two-phased “coaching model.” This entails an initial universal coaching phase for all teachers, followed by a tailored coaching phase, varying according to the strengths and needs of each teacher. If childcare workers and teachers are to be the safety net when at-risk parents falter, it is imperative that they, in turn, receive support, validation, and guidance as needed, in their ongoing everyday responsibilities.

CONCLUSIONS

In the years ahead, resilience researchers would do well to adhere firmly to goals underlying the work of pioneers who initiated research in this field—to make a difference; to maximize the well being of children, families, and society. With this in mind, our first priority must be to systematically illuminate how harm to our young can best be minimized. This, in turn, will require careful choices in prioritizing vulnerability and protective influences included in research studies. No scientist can hope to examine all indices that affect children, psychosocial and biological. But for behaviorally trained researchers in the field of resilience, the choices are helpfully narrowed, knowing as we do that our central charge is to illuminate forces that are *broadly deterministic*: with large effect sizes, and set in motion other beneficial effects. Including biological mediators and moderators because the technologies are now available, or because it is the prevailing trend, is not necessarily helpful; this is not our realm of expertise, we cannot change these, and even if we could, effect sizes are small. Most importantly, many of these biological markers are themselves strongly affected by relationships in the environment—which lie squarely within our domain of expertise.

In conclusion, our pressing tasks may be summarized thus. Foremost, we must understand more clearly what minimizes maltreatment by primary caregivers, and promotes positive parenting; illuminating exosystemic, community-based processes that are most critical in affecting these. We need to go to scale with evidence-based interventions—especially those that build upon resources existing in communities—as we work with mothers and fathers, and with teachers and mentors, to provide and sustain the most nurturing possible environments. Concerted attention to bolstering positive relationships within families, schools, and communities is our best hope in fostering resilience of at-risk youth, and of the adults charged with their care.

Shifts Toward Positive Perspectives	300
ENDOGENOUS CONTRIBUTIONS TO SOCIOEMOTIONAL COMPETENCIES: GENETIC CONTRIBUTIONS	300

Developmentalists have long been concerned with the ways in which individual child characteristics serve to affect the nature and course of development across childhood, as well as how ontogenetic processes influence the expression and function of child characteristics. Indeed, the study of such complex relations has a rich history that has in many ways defined developmental science, and can be easily seen across the chapters in this *Handbook*. Nonetheless, the presence of childhood illness or disability, both of which represent immensely influential characteristics that may serve to deflect or alter developmental trajectories, has

We are indebted to our staff and student colleagues at Arizona State University and Loma Linda University. The authors thank Allyson Davis, MA, for her help in reviewing key articles as well as her thoughtful comments on earlier versions of this chapter.

had only a relatively minor reach into basic developmental science.

This historical lack of attention has several probable sources, and these sources may be either shared or differentiated depending on whether it is disability or chronic illness that is at issue. One concern is whether or not children with an atypical status are considered somehow categorically different from typically developing or healthy children, and therefore of less theoretical and empirical interest or relevance to basic developmental theory. Hodapp and Dykens (2004) raised this possibility with respect to mental retardation in particular. But the emergence of developmental psychopathology as an integrated field of inquiry, from its early conceptual roots (Cicchetti, 1984) to its current paradigmatic strengths (Cicchetti & Toth, 2009), suggests that atypicality alone is not a justification for exclusion from mainstream perspectives. In fact, the

presence of atypicality is a call for inclusion in the ways in which it can both inform and be informed by general developmental frameworks (Cicchetti, 1984). An argument for a focus on developmental approaches to understanding child illness can be traced back three decades as well (Maddux, Roberts, Sledden, & Wright, 1986), with notations of the importance of addressing complex developmental models and perspectives (Noll & Bukowski, 2012). Still, developmental interest has not materialized in a way that might have been expected given the salience for children with disabilities or chronic illnesses of particular constructs that dominate more mainstream developmental perspectives on socioemotional functioning, including issues related to emotion regulation and coping, executive function, parent-child relationships, peer relationships, and behavioral competence.

Disability and chronic illness represent a vast array of heterogeneous conditions in childhood that vary widely in severity and effect, and have their own unique characteristics and contexts that invite developmental study. But these differing conditions also represent a constellation of factors that may well be shared by any child whose experience entails some degree of atypicality. A chapter whose goal it is to somehow represent the developmental issues inherent in an understanding of children with developmental disabilities and chronic health conditions is faced with the challenge of determining just where these fields of inquiry cohere, and where they do not, with respect to the developmental processes involved. It is our task to identify the fundamental similarities, and determine how the developmental issues addressed have bridged ontogenetic models of risk and resilience in the prediction of children's socioemotional competencies over time.

Combining a discussion of the socioemotional consequences of both illness and disability within a single chapter suggests that there may be a broad overarching theory of atypicality that can be uniformly applied to such an understanding. Of course, that is something of a naïve or simplistic perspective and the current, much more nuanced and complex developmental models that engage transactions among risk, resilience, context, and systemic influence over time belie any such understanding (Sameroff, 2009). Nevertheless, there is a core group of issues that seem equally applicable across contexts of illness and disability. The chronic nature of the conditions, the additional stresses associated for both children and families, the risk for social relationships, the challenge for regulatory function across domains of emotion and behavior, and the need to negotiate multiple medical and educational contexts are

but a few of those for which some essential features may be shared. Indeed, a handful of studies have emerged that even address the context of coexisting illness and disability (e.g., Blackman & Gurka, 2007; Oeseberg, Dijkstra, Groothoff, Reijneveld, & Jansen, 2011). But although there are a number of features for which similarities can be found, there are also crucial differences that suggest the need for the two conditions to be considered separately with respect to developmental process. Differences may be found on issues that address the level of impairment across domains of functioning, the degree to which basic childhood and family activities must be restricted, and expectation for independent living among others. Additionally, chronic illness in childhood does not often share the same sense of stigma or of developmental "abnormality" that is associated with developmental disabilities, and especially intellectual disabilities (ID). Being typically developing but with a chronic illness that may affect some developmental competencies is perceived differently from having a disorder that is defined specifically by developmental compromise.

These issues are complex, and the integration across the two broad categories of childhood illness and disability challenge existing developmental perspectives to accommodate those differences as well as the similarities. Within the framework of this chapter, we will address both developmental disabilities (DD) and chronic health conditions (CHC) together within each section, separating the two when necessary but drawing both connections and distinctions where appropriate. Within the context of disability, we will focus predominantly on conditions associated with intellectual disability (ID), although where appropriate the broader, more inclusive context of intellectual and developmental disabilities (IDD) will be addressed. Our primary focus on intellectual disability will allow continuity with previous reviews in this series (Hodapp & Dykens, 2004), but also captures the particular depth and richness in developmental modeling that is continuing to emerge in the field (Crnic, Pedersen y Arbona, Baker, & Blacher, 2009). With respect to consideration of illness, we will use the terms illness (CI) and chronic health conditions (CHC) interchangeably as reflected in the relevant literatures reviewed. Given the breadth of the conditions that are subsumed under each of these categories, attention will be focused on those categories of disability and illness that have the greatest breadth with respect to conceptual and empirical approaches to understanding socioemotional functioning, and are grounded in developmental approaches that highlight the critical issues necessary to advance the next generation of study.

Contemporary perspectives on child development are growing more sophisticated at a rapid rate, reflecting the increasing complexity of our measurements, methods, and integrative conceptual models. Development is not only influenced by ongoing everyday interactions within microsystems that contain the child, but also by interactions between systems that operate at mesosystem levels (Kazak, Rourke, & Crump, 2003). Although the complexity and sophistication of emerging developmental science is often now taken for granted in the study of typically developing children and their families, such developmental modeling has not been as easily incorporated into research with children who experience chronic health or disabling conditions. Yet these conditions represent unique child characteristics that influence developmental processes over time, and operate within organizational and transactional frameworks to affect the course of children's well-being and competence (Power, 2006), despite the fact that much of the literature continues to reflect main effect approaches to understanding developmental differences between children with chronic conditions and those who are healthy and typically developing.

The lag in sophisticated developmental modeling for children's socioemotional competencies may reflect the historical expectation that the presence of delay or some other adverse chronic condition was likely to result in uniformly poor developmental outcomes, and those outcomes could be expected across domain. However, this ubiquitous negative or pathological approach has been mostly abandoned for contemporary models that reflect more balanced and nuanced perspectives in which developmental processes are not solely determined by the presence of some specific disabling or chronic condition but instead are influenced by the same complex pathways of influence that represent the interplay of genes, individual child characteristics, parenting, family, peer, school, and innumerable other contexts that emerge and exert their influence across the developmental period.

This chapter will attempt to explore in some depth the complexity of specific developmental processes that address the socioemotional functioning of children with chronic health or disability conditions. Our predominant focus on social and emotional issues reflects an emerging recognition of the importance of these developmental facets not only as outcomes associated with the presence of particular chronic conditions, but also as key process factors or mechanisms that link chronic conditions to related functional and contextual outcomes. We begin by defining the nature of illness and disability, and describing

the scope of the challenge presented by these conditions for children, their families, and society. This background is followed by an exploration of the salient emotional and social correlates and consequences of illness and disability, as well as the risk for psychopathology that has been extensively explored in these populations. Next, we highlight contemporary perspectives on genetic as well as contextual influences involving family, school, and culture as determinants of socioemotional functioning for children, followed by a brief review of intervention research that has addressed socioemotional competencies in these high-risk children and families. Finally, we consider critical directions for research in the next decade.

DEFINITIONS AND EPIDEMIOLOGY

There is substantial heterogeneity and range in developmental disabilities as well as chronic diseases seen in childhood. They both vary in severity of symptoms, time course, treatments or interventions, and their immediate and long-term effects on multiple domains of physical, cognitive, and social functioning (Noll & Bukowski, 2012).

Defining Chronic Illness

In an early attempt to conceptualize the variability in chronic illness, Rolland (1994) suggested that illness could be differentiated along five dimensions: the nature of its onset (acute versus prolonged), its course (consistent versus cyclic), its severity, the level of incapacitation, and its outcome (mild versus severe). Although helpful in framing the basic issues, this approach is limited by the fact that each of the dimensions represents factors that are intrinsic to the disease itself rather than representing any transactional relations among other child characteristics and the multiple contexts in which children develop (Power, 2006).

Multiple conceptualizations and definitions of child chronic illness exist, and this lack of consensus has proven troublesome in identifying the full scope of the issue (van der Lee, Mokkink, Grootenhuis, Heymans, & Offringa, 2007). Nevertheless, several reasonable conceptualizations have emerged. Van Cleave, Gortmaker, and Perrin (2010) suggested that chronic health conditions involve physical, emotional, or mental conditions that prevent regular school attendance and schoolwork, prevent a child from engaging in other typical activities, and require frequent and ongoing medical treatment. Mokkink, van der Lee, Grootenhuis,

Offringa, and Heymans (2008) defined chronic illness as a health problem that lasts at least 3 months, affects a child's normal activities, and requires frequent hospitalizations, home health care, or extensive medical intervention. Compas, Jaser, Dunn, and Rodriguez (2012) suggest that chronic illnesses that affect children and adolescents are often characterized by an acute phase that surrounds the diagnosis, which is followed by ongoing stresses that are linked to processes involving the needs for extended treatment, recovery time, and concerns involving survival. The various phases create ongoing stresses for children and families.

Scope and Prevalence of Chronic Illness in Childhood and Adolescence

Although the absolute numbers vary depending on the methods and definitions employed, the sheer scope of CHC in childhood and adolescence is staggering. It has been suggested that by 2015, worldwide, as many as 1.2 billion children between the ages of 5 and 14 years will have some form of significant chronic condition (Huff, McClanahan, & Omar, 2008). In the United States, the percentage of children and adolescents with chronic health conditions changed dramatically in the past 50 years, increasing from about 2% in the 1960s to more than 25% in 2007 (Van Cleave et al., 2010), although the reasons for such changes may not be entirely clear (Halfon & Newacheck, 2010). Notably, in the United States, more than 50% of the children with chronic health conditions are ethnic minority and/or low SES (Clay, 2009). Not surprisingly, rates of specific CHC range widely both in the United States and globally. For example, more than 10,000 children are diagnosed with cancer each year in the United States; and over 10.5 million children globally have epilepsy. Overweight and obesity are becoming especially more problematic for children's health globally. Estimates from the 2011 World Health Organization (WHO) report suggest that there were 40 million (6%) infants and young children globally with weight-for-height ratios above 2 standard deviations of the growth standards median (WHO, 2011). Prevalence of overweight was greatest for those in upper-middle-income families, although lower-middle-income families showed the fastest rise. Lower socioeconomic status in high-income countries, such as the United Kingdom and the United States, tends to be linked with a higher prevalence of obesity. Indeed, Van Cleave et al. (2010) have suggested that the increasing prevalence of chronic illness in children

overall may in some ways be driven by the epidemic in childhood obesity.

Defining Disability

Developmental disabilities is a broad construct defined by a set of abilities and characteristics that vary from the norm and pose limitations on independent participation and acceptance in society (Odom, Horner, Snell, & Blacher, 2007). These disabilities are "developmental" in nature because the limitations appear in core developmental areas including cognition, language, social, and motor functioning and appear during the "developmental period," typically before young adulthood (18–22 years of age). Subaverage intellectual functioning is a core feature of many developmental disabilities; however, disabilities may also appear in individuals with normal or above average intelligence. Currently, the term "developmental disabilities" captures the formal diagnostic categories of intellectual disability (formerly termed mental retardation), autism, pervasive developmental disabilities, cerebral palsy, and other specific syndromes that exhibit intellectual disability and/or specific behavioral and phenotypic symptoms such as Down, Rett, Fragile X, Prader-Willi, and Williams syndromes.

Theory and research on ID has a long and rich history that is pertinent to present perspectives on the socio-emotional consequences of the condition. As research and social constructions of disabilities have evolved, so has the definition of ID. Currently, ID is characterized by significant deficits in both intellectual functioning and adaptive behavior. The *Diagnostic and Statistical Manual*, Fifth Edition (*DSM-5*; American Psychiatric Association, 2013) criteria for ID include an intelligence quotient (IQ) below 70 and deficits in at least two behaviors related to adaptive functioning that must be present during the developmental period. This definition is consistent with the classification of ID in the international system (i.e., *International Classification of Diseases; ICD-10*; WHO, 1992) as well as the definition used by the American Association of Intellectual and Developmental Disabilities (AAIDD; Schalock, Luckasson, & Shrogren, 2007).

The most recent version of the *DSM* replaced the diagnosis of "Mental Retardation" with "Intellectual Disability" and moved away from the multiaxial approach placing intellectual disability and all other mental disorders on a single axis. Additionally, adaptive functioning is now organized into three domains: conceptual skills, social skills,

and practical, or self-management, skills, and severity levels of ID are now based on adaptive behavior rather than IQ scores because adaptive functioning determines the level of support needed. This shift represents growing movement to focus more on the skills and abilities of the individual with ID as well as the supports needed to function in his or her particular environment (Luckasson et al., 1992). From a broader international perspective, a revised version of the *International Classification of Diseases* diagnostic system is set for publication in 2015 (*ICD-11*) and these revisions may represent another change in the definition of ID.

As definitions of intellectual and other developmental disabilities evolve, so do the people that comprise the category, creating risk by potentially affecting the availability of services and educational interventions to affected children and families. Additionally, as definitions evolve and the composition of these groups changes, challenges are posed for researchers who must evaluate the relevance of previous studies using earlier diagnostic criteria to new research using revised criteria. Although it is imperative to have diagnostic criteria based on the most rigorous scientific research available, the impact of revisions must be assessed quickly so as not to impede emerging research.

Scope and Prevalence of IDD in Childhood and Adolescence

Similar to CHC in childhood, the prevalence of IDD in the United States is increasing, with 1 in 6 children having ID or DD in 2006–2008, representing a 17.1% increase over 10 years (Boyle et al., 2011). Much of this increase is likely accounted for by the exponential increase in the prevalence of autism spectrum disorders (ASD) in recent years (Centers for Disease Control and Prevention, 2012). In contrast to ASD, the prevalence of ID specifically has been relatively stable, accounting for 1%–2% of the general population of children and adolescents (Maulik et al., 2011).

There are four levels of ID—mild, moderate, severe, and profound—which account for 85%, 10%, 4%, and 2% of the overall prevalence, respectively (King, Toth, Hodapp, & Dykens, 2009). Approximately 30% more males are diagnosed with ID than females (APA, 2000), which may be partially explained by their increased risk for X-linked genetic mutations (Kaufman, Ayub, & Vincent, 2010). ID is present in every social class, although there tends to be a higher prevalence, especially of mild ID, in lower-SES populations (Emerson 2007; Maulik et al., 2011). In a meta-analysis of population-based studies examining the global prevalence of ID, Maulik and colleagues (2011)

found that the highest prevalence of ID was seen in low- and middle-income countries, where the rates were nearly double that observed in high-income countries. Social and economic disparities such as un- or underemployment and economic instability, inadequate access to health care, increased incidence of low birth weight, limited access to prenatal care and well-child visits, higher risk of exposure to trauma resulting in injury or illness, increased exposure to environmental toxins, and higher rates of infectious diseases are all likely contributors to such differential prevalence (Maulik et al., 2011). Prevalence rates also appear to change as a function of age, as rates are higher among children and adolescents than among adults.

Autism Spectrum Disorders

Autism spectrum disorders (ASD) are a group of developmental disabilities characterized by impairments in social communication and interaction as well as a restricted range of activities and interests, and often stereotyped repetitive behaviors. Although not a core symptom of ASD, sensory abnormalities are often common features of these disorders. Historically, subcategories of ASD (autistic disorder, Asperger syndrome, Rett syndrome, childhood disintegrative disorder, and pervasive developmental disorder not otherwise specified [PDD-NOS]) differed on the basis of age and onset of symptoms, associated features, and severity of core ASD features, although increasingly, research indicates that ASD represents the extreme end of normal varying traits and may be better classified from a dimensional rather than a categorical perspective (Beglinger & Smith, 2001). From a more dimensional approach, the reliability of subgroups has been questioned (Klin, Lang, Cicchetti, & Volkmar, 2000; Lord, Luyster, Guthrie, & Pickles, 2012), and revisions to the diagnostic system have been made to address these issues (APA, 2013). For *DSM-V*, diagnostic subcategories all fall under a single broad category of ASD and must be present in early childhood. Social and communication symptoms are combined into a single dimension, resulting in two domains of impairment: social/communication deficits, and restricted or repetitive behaviors, interests, or activities (APA, 2013). In contrast to previous versions of the *DSM*, the current revisions were included in international perspectives, and thus similar changes are expected in *ICD-11* (Harris, 2013). As with the evolving definition of ID, preliminary evidence suggests that these criteria may again alter the composition of children meeting criteria for ASD. Specifically, individuals with typical cognitive development and ASDs other than

autistic disorder may be less likely to qualify for the diagnosis of ASD (McPartland, Reichow, & Volkmar, 2012).

At present, ASD is estimated to affect 1 in 88 children in the United States (CDC, 2012), but rates have been rapidly changing. Between 1997 and 2008 the rates of autism quadrupled, representing the largest prevalence increase of any developmental disability (Boyle et al., 2011). Likewise, international rates of ASD have increased exponentially, though prevalence estimates vary greatly between countries. In general, Western countries show the highest rates of ASD, with estimates as high as 116.1 per 10,000, while many Eastern and African countries have lower estimated rates, such as an estimate of 16.1 per 10,000 in China (Elsabbagh et al., 2012). Estimates for the international average rate of ASD range from 27.2 per 10,000 to 62 per 10,000; however, it is generally believed that the prevalence of pervasive developmental disorders (PDD) is not strongly influenced by ethnic, cultural, or socioeconomic factors and that observed differences reflect discrepancies in awareness and service availability, which highlights the crucial need for more research and capacity building in non-Western countries (Elsabbagh et al., 2012). The increase in the prevalence of ASD is partially accounted for by changes in diagnostic criteria, inclusion of less severe cases, earlier identification, and elevated awareness; however, a substantial percentage of the increased rates still remain unexplained (Hertz-Pannier & Delwiche, 2009). Differences in prevalence rates across countries may be related to methodological variations, environmental factors, cultural differences, availability of health care, and differences in awareness (Elsabbagh et al., 2012). The prevalence of ASD is higher among males than females, with current estimates indicating that it affects 1 in 54 boys in the United States and appears to be up to 5 times more likely in boys than girls internationally. Although the rates of ASD are lower among girls, girls with ASD are more likely to have comorbid severe ID (Volkmar, Szatmari, & Sparrow, 1993).

SOCIOEMOTIONAL COMPETENCIES

Historically, research has assumed that the presence of a disability or CHC serves either to heighten risk or determine dysfunction across the range of social and emotional domains for children and adolescents, and leads to increased burden for families (e.g., higher levels of stress and caregiving demand), communities (e.g., accommodations in schools, work environments), and society

at large (e.g., high financial costs). Indeed, most studies have focused on identifying and predicting these negative effects, and this is reasonable from a public health perspective given the importance of identifying those conditions under which risk results in dysfunction. Nonetheless, more contemporary research indicates that, although individuals with CHC or IDD are at risk for problematic trajectories of socioemotional functioning, there is considerable variability observed in these competencies across children and adolescents, as well as in the processes that may operate to mediate and moderate the pathways to related outcomes.

Across conditions of CHC and IDD, the numbers of affected children and families is large and growing. The wide range of conditions, and variability in the degree to which impairments in basic developmental processes are involved, present a challenge for conceptualizations of socioemotional functioning in these children. Nonetheless, issues regarding emerging peer relations and social skills, emotion and emotion regulation, and comorbid behavior problems reflect specific focal concerns in the socioemotional domain that have been of predominant interest, although the depth of exploration of the developmental processes involved with these competencies has been somewhat limited.

Peer and Social Competencies

The study of children's social relationships and competencies has been a rich area of inquiry in developmental science. Peer relations are critical to multiple areas of developmental competence, and serve protective functions with respect to various adverse outcomes (Laird, Pettit, Dodge, & Bates, 2005). Although social competence is a somewhat nebulous construct that has lacked a consensual definition, it has typically incorporated features that include social skills, perceived status by peers, relationship quality, and a variety of functional social outcomes (Rose-Krasnor, 1997). The study of social competence and relationships has been major focus in understanding the consequences of illness and disability.

Social Competence in CHC

In the context of restrictions on physical activity, extended hospital stays, and other illness-related limitations, social competencies have long been considered a specific risk for children with CHC (La Greca, 1990). A wealth of research has approached the study of social competencies in children and adolescents with CHC, and there seems to be some consensus that, despite the reasonable concern for

risk, little convincing evidence exists for social competence deficits in children with CHC (Reiter-Purtill, Waller, & Noll, 2009). Exceptions appear to involve reports of more frequent bullying (Blackman & Gurka, 2007; Curtis & Luby, 2008), and social deficits associated with chronic conditions that involve CNS dysfunction (Pinquart & Teubert, 2012; Yeates et al., 2007).

A meta-analysis addressing social competence in children with a chronic illness compared levels of social competence in children with chronic illness to those of children without chronic illness (Martinez, Carter, & Legato, 2011). The authors identified 57 studies, calculating 90 unique outcomes, and reported a medium overall effect for decreased social competence, in contrast to results reported by Reiter-Purtill et al. (2009). The specific chronic illness, measurement strategy, and reporter-moderated social competence outcomes indicated that the impact of chronic illness varies as a function of child characteristics such as gender or illness type, and may be dependent upon methodological issues such as informant and measurement approach. Noll and Bukowski (2012) challenged this meta-analysis with respect to the studies included as well as lack of attention to critical moderators (e.g., CNS involvement), measurement indices, and validity of source information in the measurements.

Another meta-analysis found that children and adolescents with chronic physical illness had, on average, lower levels of academic, physical, and social functioning than their healthy peers (Pinquart & Teubert, 2012). Impairments were largest for physical functioning and smallest for social functioning. Average levels of impairments of social functioning were very similar to those presented by Martinez et al. (2011), but the larger sample of studies allowed for a broader range of moderator variables to be considered. Levels of social functioning varied by disease, rater, measurement, ethnic minority status, and demographic equivalence of patients and control group. These findings implicate the need to consider the complexity of processes that determine social functioning in children with CHC as was intimated by Noll and Bukowski (2012), rather than simply assuming that the presence of deficits has direct adverse effect.

Not only is there evidence of complexity in moderated relations to social outcomes, but there is also some evidence that connections to social competence deficits may be indirect for children with chronic illnesses. Curtis and Luby (2008) reported that the number of health conditions predicted higher depression scores in children with CI, as well as greater frequency of asocial behaviors

and impairment in cooperative behavior toward others. Preschoolers with at least one CI experienced more peer rejection and bullying than did healthy peers. Furthermore, depressive symptoms served to mediate the relation between illness and asocial behavior, suggesting that pathways to social and peer problems may be more indirect than tied specifically to the presence of the CI. Yeates et al. (2007) also proposed a complex model of indirect pathways to social adjustment, whereby severity of CNS insult, parenting, and information processing skills combined to influence the social interaction and social perceptions of children who experience chronic illness.

In sum, the answers to questions about whether children with CHC have compromised social competence are not straightforward. Evidence from various studies and larger reviews is equivocal, but also dependent on which moderators may be included in the studies, and whether potential mediators are considered in the prediction. The generally competent levels of social functioning for children who experience CHC is encouraging, but there may also be some specific conditions under which risk is manifest in problematic function. Developmental timing of the illness, severity of neurobiological involvement, concomitant effects on executive and cognitive processes, and parenting and family attributes are all likely contributors that transact over time in the determination of social competence in children with CHC.

Social Competence and ID

Social competence of children with ID has long been a focus of research interest, and has consistently shown deficit level performance commensurate with cognitive function in these children. There has been increased interest in skill deficits in social behaviors such as poor eye contact, social interaction difficulties, and lack of social play in children with ID. Historically, research has established reasonably consistent relations between ID and social skills, and those associations have typically suggested that ID leads to difficulties in social adaptation and functioning (Cook & Oliver, 2011).

A wealth of research on sociability in children with ID supports a deficit model, and related findings indicate that deficits or impairments in social skills have been linked to numerous other emotional and disruptive behavior problems (de Boo & Prins, 2007). Given the methodological limitations of much of this cross-sectional and correlational research, cause and effect relations between these associated problems and social skills of children with ID cannot be disambiguated. Nevertheless, available research

suggests a variety of critical correlates for sociability that create additive risk.

In addressing the multiple conceptual and measurement challenges inherent in the study of sociability in children with ID, Cook and Oliver (2011) note that social skill deficits in children with ID are potential indicators for other social problems such as deficits in specific prosocial skills and aggressive behaviors that may lead to an inability to develop relationships in early childhood as well as later social maladjustment. Guralnick's (1999) systematic research on the social play interactions of preschool-age children with mild ID has revealed well-documented problems in peer-related social competence whereby a variety of specific difficulties in social information processing and emotional regulation adversely affect numerous aspects of these children's social competence with peers. These deficits, along with parallel family processes, contribute to the low levels of interactive or group social play typically seen among young children with mild ID (Guralnick, Hammond, Connor, & Neville, 2006; Guralnick, Neville, Hammond, & Connor, 2007a).

Given the apparent deficits in social competencies, difficulties establishing friendships for children with ID are not surprising. Guralnick and his colleagues have found that young children with mild developmental delays rarely form reciprocal friendships (Guralnick & Groom, 1988; Guralnick, Neville, Hammond, & Connor, 2007b). The social deficits typically identified include limited sustained interactive play, difficulties with peer group entry, and generally high levels of solitary play (Guralnick, 1999). Conflict in peer interactions is more frequent, which has been attributed to problematic communication strategies, less responsiveness to peers, and difficulties in attempting to influence peer social play (Guralnick et al., 2007a). Guralnick et al. (2007b) suggest that the social competence deficits of children with ID not only limit their ability to engage in reciprocal friendships in early childhood, but also generally affect interaction with preferred playmates. Although most children with ID develop friendship preferences in early childhood, they do not engage in more socially interactive play with preferred peers than other peers (Guralnick & Groom, 1988). From a developmental perspective, evidence suggests that young children with ID show relatively little growth in peer-related social competence across early to middle childhood, with many showing no growth at all (Guralnick et al., 2006).

It seems apparent that social competence is a complex construct that incorporates a number of specific social and relational behaviors, and the various terms used to describe

similar constructs (e.g., social competence, social skills, sociability, etc.) creates some confusion as to what exactly is being measured or addressed. In contrast to children with CHC, there seems to be little controversy with respect to whether children with ID have compromised social competencies. Research has consistently identified group differences across a number of social domains among children with and without ID. However, the variability across specific social skills warrants closer examination. Although several developmental models and approaches have been promoted with respect to both chronic illness and developmental disabilities, there remains a need to develop and test more comprehensive models of social development that not only differentiate across type, range, and severity of chronic conditions during childhood but also reflect the multifaceted nature of social competence, integrate multiple components (e.g., social skills, peer status, friendship quality), and attend to developmental trajectories using longitudinal approaches that incorporate multiple perspectives and factors that both mediate and moderate the relations that have been established to date.

Emotion and Emotion Regulation

Children's regulatory capacities, especially those addressing emotional regulation, have long been implicated in the emergence of child socioemotional competence (Calkins & Mackler, 2011; Thompson, Chapter 6, this *Handbook*, this volume) as well as children's behavior problems (Cole & Hall, 2008; Suveg, Shaffer, Morelen, & Thomassin, 2011). Although such relations have been extensively explored in populations of children who are typically developing, there has been precious little attention paid to the emergence and function of emotion and emotion regulatory capacities in young children who experience developmental risk in the form of global developmental delay or chronic illnesses. This lack of attention comes as something of a surprise given the salience of executive function in the emergence of emotion regulation (Posner & Rothbart, 2000), the deficit in executive skill that is inherent in children with manifest cognitive delay (Japundža-Milisavljević & Mačešić, 2008), the uncertainties and pain often associated with chronic illness (Dahlquist & Nagel, 2009), and the general importance of the social context for emotion regulatory processes (Thompson, 1994). Emotion regulation involves the ability of an individual to control, modify, change, and direct emotional reactions and expression to achieve one's goals and effectively manage interpersonal relationships (e.g., Cole,

Martin, & Dennis, 2004), a set of abilities likely to be at risk for children with chronic conditions.

Despite their rarity, a handful of studies indicate that children with early developmental risk show specific deficits in regulatory abilities, or dysregulated emotion and behavior, that may be associated with emerging comorbid behavior disorder. Given limited cognitive capacities, for example, young children with ID more often struggle to adapt to the demands of emotionally challenging events, and the risk for behavior problems increases (Morris et al., 2007). In a longitudinal study of regulatory strategy use across the preschool period, Gerstein and colleagues (2011) reported that children with early developmental delays used more maladaptive and less adaptive regulatory strategies over time when observed in a series of mildly frustrating tasks. Jahromi, Gulsrud, and Kasari (2008) reported similarly that children with Down syndrome used more limited regulatory strategies than typically developing children when faced with a frustrating task. Several studies have addressed regulatory capacity in the context of social or peer relations, consistently reporting deficits for children with delays or disabilities (J. K. Baker, Fenning, Crnic, Baker, & Blacher, 2007; Wilson, 1999).

It is not surprising that regulatory capacities were lower or less adaptive in children who show early developmental delays, even though such effects do not appear to be ubiquitous (Gerstein et al., 2011). Such deficits would be expected as a function of the developmental delay itself. Of interest, however, are indications that more dysregulated functioning may serve as one specific process to explain the connections between early developmental status and later behavior and social problems. In the Gerstein et al. (2011) study, children's regulatory abilities were found to mediate the relation between early developmental risk and later behavior problems, suggesting that the relation between developmental risk and behavior problems was indirect and likely dependent on the quality of the regulatory strategies these children could employ. Reporting earlier on the same sample, J. K. Baker et al. (2007) found that, not only did global dysregulation at Age 4 significantly predict children's social skills at Age 6, but partially mediated the association between children's developmental risk and later social skills. These findings suggest that the high rate of behavior problems in populations of children who experienced some degree of early developmental compromise may not simply reflect factors endogenous to the disability itself, but may instead reflect indirect effects that operate through emerging regulatory capacities that are multiply influenced (Cole, Hall, & Radzioch, 2009).

A primary issue to be addressed is the extent to which the regulatory deficits associated with developmental delay are endogenous to the disorder or the result of exogenous family and parenting processes. Normative conceptualizations of emotion regulation have long noted that the development of regulatory ability is socially mediated, from early coregulated states to the eventual emergence of individual self-regulatory skills (Cole & Deater-Deckard, 2009). Integral to the critical contributions of physiological and genetic contributions to the development of emotion regulation (Thompson, Lewis, & Calkins, 2008), various parenting processes have been identified as key determinants of regulatory development in typically developing children (Leve et al., 2010; Morris et al., 2007). Parental affective behavior (Dagne & Snyder, 2011), parenting styles (Betts, Gullone, & Allen, 2009; Eisenberg et al., 2001), marital relationship quality and conflict (Cummings & Keller, 2006), and various aspects of parental well-being (Maughan, Cicchetti, Toth, & Rogosch, 2007) have all been implicated. These same predictive processes have not been studied in families of children with significant developmental delays despite consistent suggestions that such within-family processes may have even greater significance under conditions of risk (Sameroff, 2009). We address family processes below, but they likely only form one critical social base for regulatory challenges observed in children with ID.

In some degree of contrast to research on children with ID, attention to regulatory capacities in children with chronic illnesses is seen more in the study of coping processes, and implied by the presence or absence of internalizing and externalizing behavior problems (Vaalamo, Pulkkinen, Kinnunen, Kaprio, & Rose, 2002) than by traditional developmental conceptualizations of emotion regulation. The conceptual differentiation between coping and regulatory processes has not been especially well articulated to date, although the terms have been used interchangeably by some (Eisenberg, Baker, & Blacher, 1998), and regulation is implied in definitions or conceptualizations of coping (Compas et al., 2012). Regardless, for children with CHC, a substantial number of studies have been published incorporating a control-based model of coping that emphasizes the volitional nature of efforts to manage the stress of the illness (Compas et al., 2012; Rudolph, Dennig, & Weisz, 1995). In general, findings suggest that some types of coping efforts have more consistent effects than others, although type of illness is an important determinant. Secondary control, or coping efforts that address accommodative response to the illness,

is related to better adjustment, whereas disengagement or passive coping seems to more often predict poorer adjustment (Compas et al., 2012; Garnefski, Koopman, Kraaij, & ten Cate, 2009). The success of primary control coping efforts, which involves active behaviors directed at changing the stressor, was less consistent in predicting to better adjustment, likely because there are simply some elements of illness that are simply inaccessible to active efforts at problem solving.

Compas et al.'s (2012) review suggests a number of important themes with respect to effective coping or regulatory functions with chronic illness in childhood and adolescence. The links between secondary control coping, as well as accommodative coping, and greater well-being suggests that secondary control coping is a good match to the typically uncontrollable childhood illnesses. Similar results were reported by Kraaij and Garnefski (2012) in their study of depression in Dutch adolescents coping with CI, indicating that cognitive coping strategies were especially important in reducing depression. As suggested by Rudolph et al. (1995), regulatory strategies involving acceptance, cognitive reappraisal, and distraction often match well the specific demands of particular illnesses, whereas the low levels of actual or perceived control are not well suited to more passive or disengaged approaches. Avoidance, denial, and wishful thinking do not typically result in effective regulation of emotional distress and likely interfere with more effective coping strategies that promote adjustment.

To date, there has been relatively scant attention to emotion or behavioral regulation in children with chronic conditions, be it disability or illness. Perhaps in some ways a call for greater empirical and conceptual attention to this critical developmental skill is premature in that there has been far too little attention to basic processes of emotion development itself, let alone the complexity of regulatory function, in these populations. Issues of emotion recognition, emotion expression, and emotion understanding have generated some limited interest for children with ID (Adams & Oliver, 2011; Zaja & Rojahn, 2008); and emotion processes have typically been conflated with internalizing behavior problems in studies of children with CHC (Vaalamo et al., 2002). Yet, studies suggestive of reciprocity of effect between the experience of pain and children's negative affect (Vervoort, Goubert, Eccleston, Bijttebier, & Crombez, 2006), or those that suggest that both emotion expression and recognition may be compromised in children with significant ID (Adams & Oliver, 2011) give rise to the need to further study these processes

and their influence on developmental competencies. If the basis of emotion regulation is indeed social, as has been often suggested, and concerns about emotion recognition or expression are manifest in children with chronic conditions, then coregulated processes in ID (Crnic et al., 2009; Crnic, Hoffman, Gaze, & Edelbrock, 2004) or dyadic coping in CI (Wiebe et al., 2005) are likely to be affected. The conditions under which emotion processes facilitate regulation or dysregulation are likely to provide an important window on emerging competence as well as adjustment difficulties.

Behavior and Emotion Problems

Perhaps no domain has received more attention relative to socioemotional functioning of children with CHC or ID than has the presence of associated behavior and emotional problems. This is especially true of the past decade in which there has been a significant increase in research examining the mental health of children and adolescents with ID in particular. In general, there are strong and consistent indications that children with ID, and to a lesser extent CHC, show elevated levels of behavior problems compared to children who are typically developing and healthy (Barlow & Ellard, 2006; Blackman & Gurka, 2007; Curtis & Luby, 2008; de Ruiter, Dekker, Verhulst, & Koot, 2007; Emerson & Einfeld, 2010). Behavior problems are particularly concerning given their impact on academic functioning, parenting, family mental health, and later development of comorbid mental health problems (B. L. Baker et al., 2003, 2010; Herring et al., 2006; Neece, Green, & Baker, 2012).

IDD and Psychopathology

An exact estimate of the prevalence of dual diagnosis during childhood is virtually impossible given the considerable variability in assessment methods and measures, classification systems, and referral sources (Borthwick-Duffy, 1994). Epidemiological studies of youth with ID have reported clinically significant emotional and behavior problems and/or diagnosable mental disorders in a third to a half of cases (B. L. Baker et al., 2010; Dekker & Koot, 2003; Emerson & Einfeld, 2010; Neece, Baker, Blacher, & Crnic, 2011; Neece et al., 2012). A large-scale study that used structured clinical interviews to examine the prevalence, comorbidity, and impact of *DSM-IV* disorders among children and adolescents with intellectual disability in the Netherlands found that over 20% of the sample met criteria for an anxiety disorder, almost 5% met criteria for

a mood disorder, and the largest percent of youth (25.1%) met criteria for a disruptive behavior disorder (Dekker & Koot, 2003). Nonetheless, the heightened prevalence of estimates of mental disorders in youth with ID may actually be an underestimate as the diagnosis of ID can sometimes obscure mental health problems that would be diagnosed in a typically developing child. Such "diagnostic overshadowing" occurs when problematic behaviors are attributed to limited cognitive functioning without further assessment, diagnosis, or treatment of the comorbid diagnoses (Jopp & Keys, 2001; Reiss & Szyszko, 1983). Essentially, the salience of cognitive deficit in defining intellectual disability overpowers concerns with or attention to co-occurring problems. Similar overshadowing may occur for children with serious CHC that attract attention to the medical illness itself, although such processes have not been specifically identified.

Most studies examining co-occurring behavior disorders have included only samples of youth with ID rather than including reasonable comparison groups. Thus, less is known about the relative risks compared to same-age youth without ID. When studies included a typically developing comparison group, findings suggest levels of psychopathology that are $2\frac{1}{2}$ to 4 times as great for children with ID (Dekker, Koot, van der Ende, & Verhulst, 2002; de Ruiter et al., 2007; Emerson, Einfeld, & Stancliffe, 2010). Dekker and colleagues (2002), for example, examined a large sample of children aged 7 to 12 years with and without ID and found that 49% of the ID group had parent-reported behavior problem scores in the borderline or clinical range compared to 18% for non-ID children. Teacher-reported scores were comparable, with 46% and 19%, respectively, having elevated scores. Emerson and Hatton (2007), in a sample of over 17,000 children aged 5 to 16 from the United Kingdom, reported clinical range scores for 36% of children in their ID sample versus 8% in non-ID children. In our own research, we found slightly lower relative risk ratios during childhood (1.60:1; B. L. Baker et al., 2010) and adolescence (1.74; Neece, Baker, Crnic, & Blacher, 2013); however, in both cases, this lesser risk may have been accounted for by an elevated prevalence of ODD in the typically developing comparison groups.

The rates of psychopathology in children and adolescents are similar across the range of mild to severe ID, although one study found that the degree of psychopathology decreased over time more for persons with mild ID than for persons with severe ID (Einfeld et al., 2006). Still, however, knowledge is limited with respect to the developmental course of behavior and emotional disorders for

children with ID, as most studies of co-occurring psychiatric diagnosis have used age-mixed samples assessed in cross-sectional designs. In one notable exception, de Ruiter et al. (2007) conducted three assessments over a 5-year period and conducted multilevel growth curve analyses to examine developmental trajectories in a sample that was 6 to 18 years old initially. Children with ID had a higher level of problem behaviors than typically developing children at all ages; however, children with ID also had significantly greater decreases over time in aggressive and attention problems.

With respect to specific symptoms or diagnoses, disruptive behavior disorders appear to be the most prevalent co-occurring disorders among children and adolescents with ID (B. L. Baker et al., 2010; Dekker & Koot, 2003; Neece et al., 2011; Neece et al., 2013). Dekker and Koot (2003) found that 25.1% of their sample of 7- to 20-year-old youth with borderline to moderate intellectual disability met criteria for a disruptive behavior disorder, compared to 21.9% for any anxiety disorder and 4.4% for any mood disorder. Likewise, B. L. Baker et al. (2010) reported that every disorder assessed in a sample of 5-year-old children was more prevalent for children with developmental delays than for those who were typically developing, with ADHD most highly differentiating the two groups (risk ratio 3.21:1). A longitudinal follow-up (Neece et al., 2011) showed that children with ID continued to be at significantly higher risk for meeting ADHD diagnostic criteria at the ages of 6, 7, and 8 (risk ratios ranged from 3.10:1 to 4.07:1) and subsequently into adolescence (risk ratio 3.38:1; Neece et al., 2013).

In some contrast to CHC and ID, comorbidity appears to be the rule rather than the exception for children and adolescents with ASD (Gillberg & Billstedt, 2000). Estimates of prevalence vary dramatically based on subtype of ASD (autistic disorder, Aspergers syndrome, PDD-NOS) and the psychological disorder examined. Some studies have found up to a 15-fold increase in the odds of reporting a comorbid diagnosis among children with ASD (Gurney, McPheeters, & Davis, 2006). The most common co-occurring disorders among youth with ASD appear to be anxiety and ADHD (Gjevik, Eldevik, Fjæræn-Granum, & Sponheim, 2011). Some research suggests that ASD, ADHD, and certain anxiety disorders (e.g., OCD) may have similar genetic underpinnings, leading investigators to question whether these are separate and distinct disorders in these children (Grzadzinski et al., 2011; Ivarsson & Melin, 2008; Polderman et al., 2013; Taurines et al., 2012). Additionally, many children with ASD have been found to

have multiple comorbidities (Leyfer et al., 2006). The significant variability in cognitive functioning and language competence that characterizes children and adolescents with ASD appear to be associated with the extent to which psychopathology may be present. Some studies suggest that cognitive comorbidity may serve as a key mechanism that heightens child risk for developing a comorbid mental illness (Bradley, Summers, Wood, & Bryson, 2004) while others indicate that children and adolescents with high-functioning autism may actually have higher rates of comorbid mental illnesses, particularly anxiety and mood disorders, due to an increased awareness of poor social integration (Hedley & Young, 2006; Joshi et al., 2010). Prevalence estimates among children and adolescents with ASD may also vary as a function of children's language proficiency. One study found that children with lower IQ scores (less than 70) and less language proficiency had fewer psychiatric comorbidities (Witwer & Lecavalier, 2010). It may well be that certain disorders (e.g., generalized anxiety disorder) require some command of language in order for the child to represent internal emotional states. It may also be that symptoms of such disorders are expressed differently by nonverbal individuals (LoVullo & Matson, 2009) and, in order to explicate such possibilities, research must better address the clinical presentation of disorders in this population with more developmentally refined and focused approaches that adopt multimodal, multimethod measurements. Nonetheless, the conditions under which comorbidity of behavioral and emotional problems are present require much further attention as this field of inquiry develops.

Although there is evidence that the prevalence of psychopathology is elevated in children and adolescents with ID, questions remain about the validity of many of these diagnoses for this population. One critical problem in this area of research is that the base rate of most psychiatric symptoms among children and adolescents with ID has not been established and, therefore, the extent to which the symptoms of given disorders are intrinsic to ID is not clear. Thus, it is not known whether certain emotional and behavioral symptoms among youth with ID are solely an expression of impairments in intellectual functioning or if these disorders form a separate construct that accounts for variability in outcomes above and beyond the cognitive abilities of the youth. Limited research has examined the validity of mental health disorders among children with ID, with the exception of ADHD for which these questions have begun to be examined. Two studies from our own lab have examined the clinical presentation, as well as the

validity of ADHD, among adolescents with and without ID (Neece et al., 2011; Neece et al., 2013). In general, the presentation of ADHD was similar among adolescents with and without ID and similar "pre-pathway" influences were associated with ADHD regardless of cognitive functioning. This is a first step in establishing the validity of current diagnostics categories for children with ID.

CHC and Psychopathology

Although empirical evidence indicates that children with CHC have more mental health issues than their healthy peers, controversies and gaps in the literature exist (Huff et al., 2008). Although risks appear to be elevated in general, the nature of the relations between behavior disorders and chronic illness during childhood are complex and vary as a function of the type and severity of CI as well as the developmental period and the contexts in which children are assessed (VanScoyoc & Christopherson, 2009).

In an overview of research regarding the psychosocial well-being of children with chronic disease, Barlow and Ellard (2006) evaluated six reviews of the literature that addressed child and family well-being in the context of CHC. Evidence from this review indicated that children with chronic illnesses were at slightly elevated risk of psychosocial distress, although only a minority actually experienced clinical symptomatology. In a study of 107 Dutch children aged 8 to 12 with a CI, Meijer, Sinnema, Bijsstra, Mellenbergh, and Wolters (2000) found that, compared with healthy child norms, chronically ill children reported less aggressive behavior, a finding that was also consistent with parents' reports. Children with CI also tended to display more submissive behavior than healthy norms, as perceived by their parents. These findings were not, however, differentiated by type of CI with the exception of higher social anxiety for children with skin diseases or cystic fibrosis. Other studies find that the degree to which aggression may be higher in children with CI depends on reporter (teachers versus parents) and whether a variety of salient moderators are included in the predictive models (Gartstein, Noll, & Vannatta, 2000), or age at which the assessment is made (Borge, Wefring, Lie, & Nordhagen, 2004).

A meta-analysis (Pinquart & Shen, 2011) integrated the results of 569 studies to compare the level of behavior problems in children and adolescents with and without CI, and to contrast findings within differing CIs. Findings indicated that children with CI have elevated behavior problems across internalizing and externalizing dimensions in

comparison to healthy peers, and that ratings of internalizing problems were somewhat greater than were ratings of externalizing problems. Internalizing and externalizing problems also varied with respect to the type of CI, as well as gender and age, and parents reported more problems than did the children or adolescents themselves. Although elevations in behavior problems associated with CI were highest for developing countries, no moderating effects of ethnicity emerged.

A population-based study of children with asthma, neurological disorders, and other chronic illnesses compared children with CI to healthy children to assess differences across illness groups (Hysing, Elgen, Gillberg, & Lundervold, 2009). The three illness groups showed an increased rate of emotional and behavioral problems, as well as increased probability of a psychiatric disorder compared with children without chronic illnesses. Effect sizes were large for children with neurological diseases but relatively small for children with asthma or other CI. In children with neurological disorders, emotional problems, inattention/hyperactivity and peer problems were the most frequent concern. The links between severity of neurological or CNS involvement and children's behavior problems have likewise been observed in other studies designed to explore connections between CI and child behavior problems (Howe, Feinstein, Reiss, Molock, & Berger, 1993; Rodenberg, Stams, Meijer, Aldenkamp, & Deković, 2005). These relations closely parallel findings with ID (and to some extent ASD), because inattention/hyperactivity and emotional problems are also the most common concerns among children with ID, as noted above.

Despite some similarities with ID, the connection between CI and psychopathology is much more muddled. Although there are indications that children with CI have elevated behavior and emotional problems, the degree to which those elevations reach clinically meaningful thresholds is not always clear. Similar to indications that neurologically based CI presents the most problems for social relations, these same conditions seem most clearly associated with psychopathology. Nevertheless, the true proportion of children with CI who experience psychopathology or behavioral problems is difficult to disentangle given the variability across and within illnesses, and the interaction of factors such as age, gender, and culture that are likely to be influential (Surís, Parera, & Puig, 1996).

The consequences of comorbid behavior and emotion disorders, whether they are associated with CHC, ID, or ASD, are very concerning. These disorders are linked with

a host of negative correlates for children, their families, and society at large including increased likelihood of academic problems, failure in education or community settings, frequent moves, social isolation and rejection, and reduced employment prospects as they transition into early adulthood (Pearson et al., 2000; Seltzer & Krauss, 2001). These significant individual, family, and societal burdens highlight the need to refine attempts to model those processes that facilitate comorbidities and the consequences that emerge.

VARIABILITY IN SOCIOEMOTIONAL FUNCTION: SHIFTING PARADIGMS

Although there is the possibility that the presence of ID or CHC will result in some adverse consequences for children's social and emotional well-being, such trajectories are not ubiquitous across discrete social and emotion skills, nor are they necessarily present across developmental periods. Various facets of social and emotional functioning may operate differently at different points in time, or be more developmentally salient at some periods than others. With respect to CIs, age at onset may be particularly critical for determining the nature of effect, but again, there is little longitudinal research available from which to draw conclusions, and so much variability across illnesses with respect to the severity and treatment demands that generalization is nearly impossible to reach with respect to chronic pediatric illness.

Available conceptual and empirical efforts regarding chronic conditions of childhood suggest that the variability of effect on socioemotional functioning is indeed great, if poorly understood. Also, variability occurs not only between different diagnoses, but within diagnoses as well. For example, children with ASD appear to be more atypical in their developmental process across domains than are children with ID alone (Blacher, Kraemer, & Howell, 2010; Shattuck et al., 2012). These differences, however, are largely attributed to the behavior problems and social deficits observed in individuals who are identified as having ASD (Blacher et al., 2010). Overall, specific diagnoses may contribute to variability in developmental competence, but the many apparent overlaps in outcomes illustrate the limits to such predictive relations.

Within diagnostic condition, whether focused on health or developmental disability, variability in both proximal and distal effects is not sufficiently explained by the nature of the condition itself (intellectual functioning, type and

stage of cancer, etc.). Developmental effects predicted by individual factors, such as IQ or type of CI, may be limited to specific functional domains (e.g., executive functioning) while other areas (adaptive skill, elements of social and emotional function) align similarly with those of typically developing peers (Seltzer et al., 2005). Conversely, some of the greatest within-disability variability is observed in individuals with ASD, as those with Asperger's and PDD-NOS generally show more typical developmental trajectories than those with autistic disorders (Cederlund, Hagberg, Billstedt, Gillberg, & Gillberg, 2008). However, the specific type of ASD diagnosis still does not explain in total the variance in these domains of interest highlighting the need to identify multiple predictors as well as moderators of these outcomes.

Shifts Toward Positive Perspectives

For the most part, research on children with chronic conditions and their families has focused on the potential detrimental effects associated with the conditions. Positive outcomes have primarily been treated as the absence of negative effects (Shogren, Wehmeyer, Buchanan, & Lopez, 2006). Not surprisingly, when only adverse effects are explored, only adverse effects are found. In the 1980s, research slowly began to adopt strategies that allowed for strengths or positive competencies to be identified, and there have since been numerous calls to explore the entire range of developmental experiences to better capture the full variability of child and family functioning regardless of the presence of a high-risk health or developmental condition (Blacher & Baker, 2002; Kazak, Rourke, & Navsaria, 2009).

Given the historical emphases on more pathological or negative effects for children's socioemotional outcomes at any time point, knowledge of positive developmental competencies for children with chronic developmental and health risks is limited. However, there are a number of competencies that have been identified for individuals with ID. These predominantly include aspects of independent living, such as living completely alone or in an independent living facility, making decisions for oneself, and being able to maintain a job (Gardner & Carran, 2005) as well as social competencies such as establishing meaningful friendships (Gardner & Carran, 2005). The majority of these competencies have been examined in adult samples with ID, whereas "competencies" for children have typically been ascertained by the lack of negative effects rather than a gain in positive effects.

Many of the predictors of long-term positive outcomes for children with ID are externally based, and early support services are one of the strongest predictors of later social and emotional competencies. Claes, Hove, Loon, Vandervelde, and Schalock (2010), using a sample from the Netherlands, found the availability of support strategies, living arrangement, status of employment, and level of intellectual functioning uniquely predicted quality of life. Although external factors cannot be controlled on an individual basis alone, identifying factors that promote more positive outcomes should inform public policy, educational programs, and service delivery in support of high-risk children's development.

In general, information on specific socioemotional developmental strengths in children with chronic conditions is sparse, as is knowledge regarding the predictors of more positive developmental trajectories. Certainly, most children function as well as their healthy peers along many social and emotional dimensions (Barakat, Pulgaron, & Daniel, 2009), and the variability in behavior problem outcomes in children with ID are suggestive of resilient processes in children at risk (see Luthar, Crossman, & Small, Chapter 7, this *Handbook*, this volume). Nevertheless, preliminary research offers promising perspectives across a range of developmental attributes. Additionally, studies examining the developmental cascades triggered by these competencies will be informative (Masten et al., 2005). Just as deficits in one area of functioning affect development in others, it is likely that competencies or achievements in one domain may optimize development in other areas as well, and future efforts should address such reciprocity between domains of functioning.

ENDOGENOUS CONTRIBUTIONS TO SOCIOEMOTIONAL COMPETENCIES: GENETIC CONTRIBUTIONS

The genetic basis of disease and disability has long been of interest and has contributed extensively to current perspectives on causal processes. Genetic and epigenetic processes are gaining further popularity as informative methods for studying the complex interplay of genes, behavior, and context in determining the ways in which disease and disability emerge and influence socioemotional development. Despite their promise, however, genetic approaches are not without controversy, and the specific focus of genetic interest has varied across developmental disability and childhood illness.

The genetic underpinnings of ID are well recognized, at least for a subset of specific syndromes. Trisomy 21 (Down syndrome) was first identified by chromosomal studies in 1959 (Lejeune, Turpin, & Gautier, 1959) and since then, the majority of genetic research in ID has focused on single-gene causes of disorder. Genetic causes are thought to be present in approximately 25%–50% of cases, with the percentage increasing in concert with the severity of the ID (Kaufman et al., 2010). However, the degree to which ID is genetically determined varies from individual to individual. Mild ID is generally thought to represent the lower end of the normal variation in human cognitive functioning and results from interactions between genetic and nongenetic factors (e.g., malnutrition, neglect and deprivation, poor health care). More severe forms of ID have often been linked to specific genetic causes including chromosomal abnormalities or defects of single genes. In the decade prior to the time of this writing, significant progress has been made in elucidating new genetic mutations that result in ID. However, these new genetic defects comprise only a small proportion of cases of ID and the genetic factors involved in the majority of cases of ID are still unknown.

Although social and emotional skills are crucial determinants of longer-term outcomes of individuals with ID, few if any studies have examined the genetic underpinnings of socioemotional competencies in this population. Here we propose a new focus for genetic research in which specific candidate genes involved in ID or CHC continue to be identified, but the developmental cascades that emerge from individual genes and the interdependence between genes and the environment are also considered. These cascades address the wide gap between identification of individual candidate genes and eventual behaviors of interest. Genes code for proteins, which in turn code for cellular systems/signaling pathways, which result in neural systems that comprise the development of social/cognitive systems that ultimately code for behavior. This is the essential basis of the endophenotypic approach, which we detail later.

Different approaches to the study of genetic influences on behavior have emerged in psychiatric genetics (Caspi & Moffitt, 2006). The “direct link approach” assumes a direct linear relationship between genotype and behavior and examines correlations between variations in DNA sequence and behavior. The majority of genetic research in ID has employed this approach to identify specific genetic mutations that result in cognitive and adaptive behavior deficits. Genetic studies have also begun to examine

gene–environment interdependence, seeking to incorporate information about the environment into understanding the role genetics plays in determining the development of disorders. In this approach, genes determine the degree to which an individual is vulnerable to environmental risk factors and, therefore, the gene is not assumed to have a direct link in the absence of environmental risk. Similar approaches have also received attention in the CHC literature with the growing recognition of the interplay between genes, behavior (specifically health behaviors), and the environment in promoting or compromising health (Tercyak, 2009).

Direct Link Approaches

Historically, research has assumed that ID or CHC are the result of genetic defects; therefore, the majority of etiological investigations have focused on uncovering the genes involved in the emergence of disease and disability. Over 1,000 genetic causes of ID have now been identified and these disorders account for about 55% of cases of moderate to severe ID but only 10%–15% of mild ID (Tartaglia, Hansen, & Hagerman, 2007).

The surge of genetic research coinciding with increasingly sophisticated methodologies over the past two decades has led to improved characterization of hundreds of genetic syndromes, which has facilitated attention to behavior phenotypes. Behavioral phenotypes are specific patterns of behavior and cognition that present in syndromes caused by chromosomal or genetic abnormalities. Research on phenotypes characterizes the unique cognitive and behavioral profiles of genetic disorders and links these profiles to the specific genotype in an effort to tailor interventions to the individual profile of each disorder (Dykens & Hodapp, 2007; Hodapp & Dykens, 2004). Pioneering research has connected genetic, neural, and behavioral findings in specific genetic syndromes including Down, Williams, fragile X, Prader-Willi, Angelman, Rett, and velocardiofacial syndromes (Schaer & Eliez, 2007; Venkitaramani & Lombroso, 2007). Nonetheless, this effort has addressed only a small subset of the over 1,000 genetic causes of ID, and although the implications for understanding children’s behavioral and emotional responses to CI are likewise apparent (Tercyak, 2009), attention to illness phenotypes remains mostly promissory.

Improved identification and detection of genetic syndromes for both ID and CHC has increased the use of genetic testing in childhood. Use has been especially

prominent in research examining the social and emotional functioning of children with CHC, with studies identifying both benefits and consequences of genetic testing for at-risk children. Studies generally find that both children with CHC and their parents experience a sharp increase in anxiety upon learning about a positive test, but anxiety subsides over time and these children generally return to their baseline social-emotional functioning (Johnson & Tercyak, 1995). However, the trajectories of social and emotional functioning appear to vary by type of CHC (Simonen et al., 2006) and developmental timing (McConkie-Rosell, Spiridigliozi, Sullivan, Dawson, & Lachiewicz, 2002). Nevertheless, research is needed on the longitudinal impact of genetic testing and influence on the social and emotional development of these children, as well as the ambiguity inherent in trying to predict an individual's future health status.

Gene–Environment Interdependence

Continued advancement of the understanding of social and emotional functioning in children with chronic health or disability conditions hinges on the consideration of polygenic effects as well as environmental interdependence, which will ultimately inform molecular genetic research that seeks to ascertain specific candidate genes involved in the characteristics of identified behavioral phenotypes. Increasingly, research suggests that behavioral phenotypes are neither completely established at birth, nor immutable. Rather, they develop and change over time. Thus, behavioral phenotypes arise from both genetic mutations present at birth as well as ongoing reciprocal interactions across multiple factors at varying levels of development (Fidler, Most, & Philofsky, 2009). Fidler and colleagues (2009) provide a rare example of incorporating a developmental approach when examining the behavioral phenotype of Down syndrome. They argued that understanding the development of behavioral phenotypes is imperative to developing time-sensitive early interventions that may ameliorate the development of poorer functional competencies (see Fidler, 2005, for sample interventions). This approach highlights the need for multiple waves of data collection that examine several domains within a given behavioral phenotype rather than focusing on isolated areas of functioning. Developmental processes are hierarchical and interrelationships across different domains of development are mutually influential. To capture the complex developmental processes that produce specific behavioral phenotypes, the next generation of research must address

multiple domains of development and the way in which they affect each other over time.

A potentially promising avenue for future genetic research in ID or CHC is to employ an endophenotypic approach in which the outcomes of interest are no longer heterogeneous disorders but rather heritable intermediate phenotypes that are closer to the immediate product of the susceptibility genes and genetically simpler than the explicit phenotype of the disorder (Gottesman & Gould, 2003). The assumption underlying this approach is that it will be easier to identify genes associated with endophenotypes of the broad disorder than the disorder itself. In order for this approach to be successful, endophenotypes must be associated with illness in the population, heritable, state-independent (manifest in the individual regardless of whether illness is present or not), co-segregated within families, and present in nonaffected family members at a higher rate than the general population (Doyle et al., 2005). Currently, developmental disability endophenotypes are being identified, specifically within autism spectrum disorders (ASD). Possible endophenotype candidates include weak central coherence as evidenced by a detail-focus bias in visuospatial construction and problem solving (Happé, Briskman, & Frith, 2001), executive function deficits specifically with regard to planning (Nydén, Hagberg, Goussé, & Rastam, 2011), and theory of mind (Scheeren & Stauder, 2008). However, these traits have not consistently met criteria for endophenotypes across multiple studies, requiring further verification of those characteristics that are a part of the broader endophenotype of autism. The extent to which these emerging endophenotypes are linked to socioemotional functioning is not yet clear, either. Nonetheless, clarification of endophenotypes for autism and ultimately other chronic conditions may well enhance the identification of susceptibility genes involved in these complex and heterogeneous disorders.

Although evidence supports strong genetic underpinnings for both ID and CHC, the role of environmental factors in the etiology of these conditions is often equal to or even greater (Faja & Dawson, 2010), highlighting the critical need to distill the ways in which genetic and environmental risk factors interact to influence children's socioemotional competence. From a more transactional perspective, the presence of a child with a disabling health condition creates risk under which the family and other contextual factors may either (a) serve to amplify and realize the risk (e.g., a "risk" genotype) or (b) serve a self-righting or protective function. Thus, gene–environment interactions between child genotype(s) and environmental risk

and protective factors may be particularly relevant for children with these conditions. At a minimum, research must continue to map both genetic and environmental risk factors onto specific observed behaviors in these phenotypes as well as to address individual variations across social and emotional competencies.

BEYOND ENDOGENY: CONTEXTUAL FACTORS THAT INFLUENCE SOCIOEMOTIONAL OUTCOMES

Although genetics and endophenotypic approaches hold some degree of promise for uncovering explanatory processes for the variability in social and emotional functioning of children with chronic conditions, there are a number of key contextual influences that have also produced historically important contributions to risk and resilience processes. Chief among these adaptational influences are family, school, and cultural processes.

Family Processes

Families represent the most proximal environmental influence on children's development and in efforts to optimize the understanding of socioemotional competencies for children with chronic conditions, research on families has increased significantly in the two decades prior to the time of this writing. In fact, there have been paradigm shifts in both theoretical and practice models from an individual-(child)-centered approach to one that focuses more on the entire family unit. This shift has been in response to a growing recognition that family mental health and well-being have both direct and indirect impacts on children's socioemotional development and that any attempt to better understand and intervene to promote child competencies must also understand and address those developmental processes that operate at the systemic level of the family. Still, developmental perspectives addressing family processes in these populations have been predominantly narrow in focus, unidimensional in approach, and more concerned with the effect of the chronic condition on parent or family function than on the interplay of chronic condition and family level attributes over time in the prediction of children's socioemotional competence.

Family Stress and Mental Health

Historically, much of the family-focused research has emphasized the negative mental and physical health

outcomes that parents of children with chronic conditions often report. Stress is a key family variable of interest given its association with numerous undesirable outcomes for both parents and children, regardless of the presence of some risk condition. Parents of children with chronic conditions generally report more parenting stress than parents of typically developing and healthy children (B. L. Baker et al., 2003; Hauser-Cram et al., 2001; Kazak, Rourke, & Navsaria, 2009). Among parents of children with disabilities, those who have children with autism spectrum disorders (ASD) typically report the highest levels of stress (Davis & Carter, 2008; Estes et al., 2009).

However, the degree of stress experienced by these parents may vary by type of stress (e.g., general distress, stress specific to the child's chronic condition, daily parenting hassles), with some studies indicating that parents of young children with developmental delays experience similar levels of parenting daily hassles as parents of typically developing children (Crnic et al., 2009), but greater parenting stress related to the impact of the child on the family (B. L. Baker et al., 2003). Nonetheless, little is known about the sources of heightened stress in families of children with chronic conditions and how various stressors influence the parenting experience. Although parenting stress is a construct in which there appears to be some sense of a shared understanding, there has in fact been far too little differentiation between parenting stress and stressed parenting in the developmental literature. With respect to the stresses associated with children who have specific chronic conditions, illness- or disability-specific stresses may well be operative and can perhaps be further differentiated from more general stress contexts experienced by all families.

Although studies consistently find heightened levels of various stresses among parents of children with chronic conditions, these findings are not ubiquitous within either disability or illness, and there can be marked individual variation in the trajectory of experienced stress over the developmental period (Glidden & Schoolcraft, 2003; Pai et al., 2007). For families of children with ID, parental stress appears to peak around the preschool period and decrease over time as a function of reductions in child behavior problems, although stresses not accounted for by the child may actually increase over time (Crnic et al., 2009; Neece et al., 2012). Parents of children with ID may be more likely to have recurrent and new stressors that maintain and even increase stress levels across time. Similarly, for parents of children with CI, stress may be greatest at the time of diagnosis, and moderate over time as families

adjust (Pai et al., 2007) but also increase coincidentally with increases in children's periods of distress (Robinson, Gerardt, Vannatta, & Noll, 2007). Transitions, including school entry and reintegrations (Canter & Roberts, 2012; DuPaul, Power, & Shapiro, 2009; Madan-Swain, Katz, & LaGory, 2004), may be a particularly difficult time for parents of children with chronic conditions as these are often when parents make peer comparisons and realize how far their children are behind other children, or have to help their children cope with challenging social processes. Parents of children with chronic conditions are faced with multiple challenges across their children's lives, including overcoming the disappointments and fears associated with the original diagnoses, securing appropriate medical interventions and school placements, and learning to navigate the complex health and educational systems (DuPaul et al., 2009; Floyd, Singer, Powers, & Costigan, 1996). Effects may vary depending on the type of parental stress and may be different for fathers and mothers, again highlighting the necessity for multidimensional longitudinal studies addressing the experience of these families.

In addition to elevated levels of stress, and perhaps as a function of them, parents of children with chronic conditions show increased rates of depression (B. L. Baker, Blacher, & Olsson, 2005; Singer, 2006; Tluczek, Koscik, Farrell, & Rock, 2005). With respect to disability, the pattern of parental depression is similar to that of parental stress, with parents of children with ASD showing the highest rates of depression, followed by parents of children with other ID diagnoses, and finally by parents of typically developing children (Olsson & Hwang, 2008). For parents of children with a CI such as cystic fibrosis, patterns appear to be somewhat coincidental with reports of stress, because depression is relatively frequent following identification of the illness but decreases over time (Tluczek et al., 2005). Although the risk for psychological distress in parents of children with chronic conditions is apparent, it is far from always realized (Crnic et al., 2009). Indeed, resilience and protective factors operate similarly for parents as for the children with the conditions themselves, although the processes that account for better or worse outcomes are not as yet well understood.

The marital subsystem is frequently considered at risk in families of children with ID or CHC. However, as with many individual parameters of functioning, adverse effects are not ubiquitous. Some reports from parents of children with ID have indicated high levels of marital conflict (Kersh, Hedvat, Hauser-Cram, & Warfield, 2006; Suárez & Baker, 1997), whereas other reports involving longitudinal

assessments over multiple measurement periods have not (Crnic et al., 2009). Kazak et al. (2009) note similar trends for research exploring marital relationships in families of children with CI. Studies do not support marital conflict differences between families with and without a child with CI, but instead have begun to explore the nuances within marital processes that influence and are influenced by CI, with particular attention to those factors that may serve to moderate relations between CI and marital function (Lewandowski & Drotar, 2007).

Along with challenges to mental health and marital quality, parents of children with chronic conditions also experience challenges to their physical health (Eisenhower, Baker, & Blacher, 2009; Eisenhower, Blacher, & Baker, 2013; Olsson & Hwang, 2008), and higher levels of self-reported health problems appear to persist across the life span (Burton, Lethbridge, & Phipps, 2008; Eisenhower et al., 2013). Consistent with findings on mental health outcomes, it is likely that the compromised physical health in parents of children with ID is related to the elevated behavior problems seen in this population, because parents whose children display high levels of behavior problems are the most likely to rate their physical health as poor (Eisenhower et al., 2009, 2013). The relation between having a child with ID and poorer physical health has important implications for the morbidity of parents and serves as one potentially important target for intervention. Nonetheless, the processes by which ID and behavior problems create health problems for parents have yet to be explicated.

Paralleling the research on parents of children with ID or CHC, most studies on siblings have examined whether these siblings are at risk for negative psychological effects, such as diminished self concept (Singhi, Malhi, & Pershad, 2002), poor psychological adjustment (Sharpe & Rossiter, 2002), and increased psychopathology (Bågenholm & Gillberg, 1991; Del Rosario & Keefe, 2003; Hastings, 2007). However, research has found siblings of children with ID to be well-adjusted and generally indistinguishable from their peers (Levy-Wasser & Katz, 2004; Stoneman, 2005). A meta-analysis by Sharpe and Rossiter (2002) found that the difference between siblings of children with ID and comparison siblings in terms of general psychological adjustment was "small at best" ($M_d = -.03$) and insignificant. To the extent that having a sibling with ID negatively affects typically developing siblings, little is known about the processes that might account for or moderate such impacts. Our own research indicates that the negative impact on siblings is better accounted for

by the children's behavior problems than the disability conditions, and that early child behavior problems may lead to increased sibling negative impact over time (Neece, Blacher, & Baker, 2010). High levels of social support may also moderate adverse effects of chronic illness on sibling well-being (Barrera, Chung, & Fleming, 2004).

Parental Stress and Child Development

With respect to children with ID, relations between child intellectual functioning and parenting stress appear to be mediated by child behavior problems such that once behavior problems are accounted for, significant relations between child cognitive functioning and parenting stress disappear (B. L. Baker, Blacher, Crnic, & Edelbrock, 2002; Hauser-Cram et al., 2001; Herring et al., 2006). The same has been found for parental depression where differences in parental depression among parents of children with ID and parents of typically developing children appear to be tied to the differences in child behavior problems, with parents of children with high levels of behavior problems showing the highest levels of depression (B. L. Baker et al., 2005; Olsson & Hwang, 2008). There is strong support for a bidirectional relation between child behavior problems and parental stress, such that more behavior problems are associated with greater parenting stress over time. Furthermore, high parenting stress has been linked to increases in behavior problems in children (B. L. Baker et al., 2003; Neece et al., 2012). Thus, the association between child behavior and parental stress for children with ID appears to be reciprocal in that greater behavior problems lead to increases in parenting stress over time while high parenting stress is linked to increases in behavior problems, indicating that the two variables may be mutually escalating (B. L. Baker et al., 2003; Neece et al., 2012). Additionally, elevated parenting stress is associated with poorer social skills later in development (Neece & Baker, 2008), ADHD diagnoses among children with ID (B. L. Baker et al., 2010; Neece et al., 2011), and greater distress in children with CIs (Robinson et al., 2007), highlighting parental stress and mental health problems as a concern not only for the individual parents' well-being but also for the negative impact that parental mental health problems may have on the children's socioemotional development over time.

Although it seems apparent that parental stress has an impact on child behavior problems and competencies, the processes through which parental stress influences child behavior are not as clearly understood. Studies in this area have begun to identify mediators and investigate these critical developmental processes, highlighting the complex

development processes involved, and identifying targets for future intervention and prevention efforts. Mainstream developmental models capturing complex transactional interrelationships that characterize family processes are becoming more commonplace; however, with limited exceptions (Crnic et al., 2009; Hauser-Cram et al., 2001; Kazak, 1989), few such models have been proposed to understand these processes in families of children with chronic conditions.

Over the decade prior to the time of this writing, we have examined a model for understanding the emergence of child behavior problems and competencies in which delays in child cognitive functioning lead to elevated behavior problems as a function of ongoing family processes and children's emerging self-regulatory capacities, particularly emotion regulation (B. L. Baker et al., 2003; Crnic et al., 2004; Crnic et al., 2009; Gerstein et al., 2011). We proposed that parental distress influences emotional processes in the family, which ultimately influences child regulatory skills and subsequent behavior problems. Children's emotional development is heavily socialized and parents have a primary influence on the development of emotion regulation, especially among young children (Silk, Shaw, Skuban, Oland, & Kovacs, 2006; Thompson, 1994). High levels of parental stress and depression may disrupt the process of socializing emotion regulation (Silk et al., 2006), placing the children at increased risk for emotional and behavioral problems (Osborne, McHugh, Saunders, & Reed, 2008). Thus, children with disability and health conditions may be more likely to experience emotion regulation difficulties not only because of their cognitive limitations but also as a result of their parents' high levels of stress. However, when parents are less stressed, family emotional processes are enhanced because parents are better able to model adaptive emotion-regulation skills, engage in more sensitive and less harsh or intrusive parenting behavior, and provide stable family environments that facilitate secure attachment, authoritative parenting, healthy emotional expression, and strong marital relationships. In turn, these processes promote optimal development of children's regulatory capacities.

Transactional family processes in the context of chronic health and disability are still relatively early in their conceptual and empirical formation, and the need for theoretically grounded, multifaceted, longitudinal research is critical if developmental science is to capture the complexity of family influences on the socioemotional development of these high-risk children. However, the richness of emerging conceptual models is promising. These models consider

multiple levels of influence (e.g., genetic, school, social, and culture) and the ways in which these factors interact with complex systemic family processes over time. In contrast, simple main effect models are no longer sufficient to uncover the dynamic child–family synergies that create growth in socioemotional process over time for children with chronic conditions.

Furthermore, research must move beyond maternal report as a proxy for the meaning of family, and include perspectives from fathers (partners), siblings, grandparents, and extended families, triangulating measures across sources to obtain comprehensive assessments of these processes. More longitudinal and methodologically rigorous approaches to capturing the individual differences among families will be especially informative, employing more personological and process-oriented approaches that identify mechanisms that underlie putative linkages. Finally, although family process models for children at risk have enjoyed a surge in interest over the past several decades, it is unclear whether this increased focus has yielded any benefits for the families themselves. The increased recognition of family challenges and the potential for positive adaptation have not yet resulted in substantial changes in the approach to intervention with families of children with chronic health or disability conditions.

School as a Salient Context

After the family, schools represent the most powerful developmental context of influence for socioemotional functioning, and at some developmental periods schools may exceed family influence. School settings provide a number of similar and differentiated experiences that influence the course of social and emotional development for both typically developing children and children at risk. However, socioemotional processes associated with school contexts likely vary widely for children depending on whether ID or CHC is at issue. There are significant differences between the educational settings for children with ID versus children with CHC, because self-contained educational classrooms are often necessitated for children with ID either full or part day, whereas children with CHC who return to school typically return to the regular classroom setting. After the preschool years, during which children with ID are often enrolled in early intervention programs, the majority of services that children with ID receive are school-based. The range of services that students are able to access through schools, regardless of the focus of their chronic condition, varies based on the

policies and procedures of the region or country in which they reside. Although many researchers have examined the efficacy of school-based programming, this area is still lacking in that inclusive education methods seem to produce optimal outcomes for children with ID, but knowledge of the predictors of individual outcomes remains somewhat limited for most risk groups.

Inclusion in Mainstream Classrooms

The inclusion of children with ID in general education classrooms has been widely advocated (Blacher, Baker, & Eisenhower, 2009; Chiang, Cheung, Hickson, Xiang, & Tsai, 2012; Cummins & Lau, 2003; Dessemontet, Bless, & Morin, 2012; Waldron & McLeskey, 2010). Mainstreaming has been associated with positive academic outcomes including higher academic achievement (Turner, Alborz, & Gayle, 2008) and postsecondary education (Baer, Daviso, Flexer, McMahan Queen, & Meindl, 2011; Chiang et al., 2012; Flexer, Daviso, Baer, McMahan Queen, & Meindl, 2011), as well as improved social competence and reduced behavior problems (Fisher & Meyer, 2002). Although studies have shown that level of ID is an important moderator of such effects, in that children with more severe ID may make less progress in inclusive settings than children with less severe ID (Flexer et al., 2011), there is little existing knowledge about the processes through which inclusive settings produce favorable outcomes and optimize developmental trajectories for these children.

Inclusive education for children with ID has been promoted as the optimal educational model, but education in an inclusive setting guarantees neither increased progress nor positive outcomes. This may be especially the case in relation to children's social functioning. Although an overall trend toward more favorable academic outcomes is apparent, a percentage of children, particularly those with high levels of behavior problems and low social skills, make little to no progress when integrated with typically developing peers (Cummins & Lau, 2003). Those children who do not benefit may require higher levels of support due to increased levels of behavior problems and social deficits, because these children tend to have poorer transitions to school regardless (McIntyre, Blacher, & Baker, 2006). Additionally, many children with ID or CHC are sometimes less accepted by their peers and may face social isolation, bullying, or experience stigma in an integrated setting (Cooney, Jahoda, Gumley, & Knott, 2006; Curtis & Luby, 2008). Teachers in general education classrooms do not always receive children with ID or those with complex medical needs positively and

may have difficulty managing their increased needs while simultaneously overseeing classrooms full of typically developing children (Blacher et al., 2009; Cummins & Lau, 2003; Eisenhower, Baker, & Blacher, 2007). Finally, despite the belief that children with ID will benefit more from inclusive settings, many children with some disability status obtain positive outcomes equally well in more segregated classrooms (Dessemontet et al., 2012). Thus, some approaches deemed to be "best practice" for children with chronic conditions may actually be creating developmental disadvantages, highlighting a need for more personological approaches that explore critical individual differences across high-risk chronic conditions. It may be that integrated settings produce positive social outcomes as a function of the characteristics of the students who tend to thrive in those settings in some combination with facilitative attributes associated with the school settings themselves.

At the level of the individual child, behavior problems, social skills, and intellectual functioning are likely central to decisions about school integration for children with ID, whereas special health care needs and physical characteristics likely add to considerations for children with chronic health conditions (Power, 2006). Specifically, children with lower levels of behavior problems and more functional social skills gain the greatest benefit from mainstream settings, whereas students with more severe deficits in these areas may actually make more progress in specialized school or classroom settings in which their increased support needs can be appropriately met. At the broader system level, lower resource areas in which class sizes are generally larger and budgets are tighter are less ideal for integrating students with chronic conditions, increasing risk for poorer outcomes. In integrated settings, by contrast, many more predictors of academic and social success exist, such as the characteristics of the typically developing students and their willingness to interact with peers who have chronic health conditions or disabilities.

Social Interaction in Integrated Settings

One of the primary benefits of including children who have ID in classrooms with typically developing peers, or reintegrating children who have been absent because of significant CI, is the opportunity for normative social interaction. Ideally, children with ID will gain valuable social skills from interacting with their peers that they would not otherwise develop. However, peers do not readily interact with children who have these conditions and inclusive programming does not necessarily lead to decreased social

deficits (Carter, Hughes, Guth, & Copeland, 2005; DuPaul et al., 2009). Proximity to peers alone does not guarantee increased social exchanges; rather, these interactions must be facilitated by teachers and staff (Carter et al., 2005; Cummins & Lau, 2003; Prevatt, Heffer, & Lowe, 2000). Interventions can promote socially supportive environments as well as teach social interaction and reentry skills to students with chronic conditions (Carter & Hughes, 2007; Madan-Swain et al., 2004) and school settings may be most beneficial for children if multifaceted programs that encourage interactions such as those in which peers are trained to work with students who have chronic conditions are included in the curriculum (Carter & Hughes, 2007).

Not only is it possible for children with ID or CHC to attend schools with typically developing peers and have little to no interaction with them, many of these children are targeted by their peers and become victims of bullying (Pinquart & Teubert, 2012). There are numerous studies documenting that children with ID experience peer victimization at higher rates than their nondisabled peers (Christensen, Fraynt, Neece, & Baker, 2012; Rose, Monda-Amaya, & Espelage, 2011); however, a small minority of investigations have found comparable rates among students with and without disabilities (Woods & Wolke, 2004). Discrepancies are likely the result of ambiguity about the definition of bullying, variations in reporters, how data are collected, disparities in the settings where bullying occurs, and differences in sample characteristics (e.g., demographics, severity of disability, type of disability). Nevertheless, the majority of studies find a prevalence of bullying among students with chronic conditions that is disturbing, with some studies documenting up to 94% of students with disabilities experiencing some form of victimization (Little, 2002). The most robust risk factors for bullying include social and communication deficits (Cappadocia, Weiss, & Pepler, 2012; Christensen et al., 2012) as well as behavior and mental health problems (Cappadocia et al., 2012; Meijer et al., 2000). Didden and colleagues (2009) examined cyberbullying in a sample of adolescents with ID from the Netherlands and found that 4%–9% of students reported bullying or victimization at least once a week; bullying was related to IQ, computer usage, self-esteem, and depressive symptoms. Sentenac and colleagues (2011) contrasted bullying in Ireland and France for children with disabilities and chronic illnesses, and found high rates across both countries although rates were somewhat higher in France. Rates were higher when children were restricted from certain school activities. Other correlates included family history of mental health

problems, being younger, restriction of social activity, and being in special education programs (Cappadocia et al., 2012; Emerson, 2010; Meijer et al., 2000; Sullivan, 2009). The number of factors that contribute is of concern given the extreme negative consequences of bullying that add to the increased social and emotional risks that these children face. While most research on bullying has focused on victimization, there is some evidence to suggest that children with ID may bully others more frequently than their typically developing peers (Sheard, Clegg, Standen, & Cromby, 2001), too. However, the rare conditions under which such inverse bullying processes may occur are unknown and in general research suggests that children with ID or CHC are much more often victims than perpetrators of bullying (Sullivan, 2009).

Although peer relations have dominated research pursuits, student-teacher relationships are also worthy of greater attention for children with either ID or CHC (DuPaul et al., 2009). Emerging evidence suggests that student-teacher relationships are heavily influenced by both behavior problems and social deficits, but are independent of intellectual functioning (Eisenhower et al., 2007; Hamre & Pianta, 2001). Conversely, positive student-teacher relationships are predictive of decreased behavior problems, increased social competence over time, and increased adherence to medical regimens (Blacher et al., 2009; La Greca & Mackey, 2009; Meehan, Hughes, & Cavell, 2003). Although students generally do not have the same teachers year after year, teacher ratings of relationships with the same children remain relatively stable over time (Blacher et al., 2009). Of some concern, however, teachers in general education classrooms consistently rate relationships with students with ID lower than do teachers in special education classrooms even though the children have similar levels of behavior problems and social skills (Blacher et al., 2009). It seems apparent that stigma remains associated with ID, making general education teachers more likely to make judgments about these children based on the global characteristic of "disability" rather than the student's individual strengths and challenges. Given the well-established influence of teacher perceptions and expectations for child performance, the Blacher et al. (2009) finding highlights the possibility that children with ID are being done a disservice by assuming that inclusive settings are always optimal contexts for development. To optimize outcomes for children with chronic conditions, the characteristics of success must be identified to better tailor inclusive settings to meet student needs.

Cultural Perspectives

Genetics, families, and schools each play a central role in understanding the social and emotional consequences of illness and disability, but each must also be considered within specific cultural frames of reference. Indeed, culture plays a critical role in the development of all children, regardless of the presence of chronic illness or disability. Nonetheless, cultural considerations may have particular salience for children with chronic conditions given the overrepresentation of ethnic minority children and families in such conditions and the putative linkages between factors of race, ethnicity, and culture with health disparities (Adler & Rehkopf, 2008). The majority of "cultural" studies have primarily used race and ethnicity as proxies for culture, focusing on differences between broad racial categories and comparing European American versus African American or European American compared with Latino American. However, race and ethnicity generally are crude or even poor indicators of the broad construct of culture (Clay, 2009). Although multiple definitions exist, culture reflects "explicit and implicit patterns of historically derived and selected ideas and their embodiment in institutions, practices, and artifacts" (Markus & Hamedani, 2007, p. 11). In this respect, culture is not defined as a group of people but rather as psychological processes, thereby suggesting that the focus of research should not be on the groups themselves, but, rather, on the patterns observed in the contexts where people reside (Markus & Hamedani, 2007). The patterns observed in beliefs, practices, and artifacts are variable and not uniform across all people of particular races or ethnicities, highlighting the critical importance of within-group research that considers individual differences.

Most studies of "cultural" considerations have focused on racial and ethnic differences in parental well-being, the impact of children on their families, and treatment choices for the children. Socioemotional processes involving the affected children have rarely been the primary focus of study, but given the salience of family process to children's social competence, exploring the influences on parent and family processes is potentially informative. Across these studies, the well-being of minority parents in the United States tends to be lower whereas the impact of the children on their families appears more positive than with Caucasian parents (Blacher & McIntyre, 2006; Devine, Holbein, Psihogios, Amaro, & Holmbeck, 2012; Magaña, Seltzer, & Krauss, 2004). Treatment selections are affected by culture primarily through etiological attributions; more

specifically, beliefs about the causes of disabilities or illnesses influence the types of therapy parents choose for their children and their adherence to recommended treatments (Al Anbar, Dardennes, Prado-Netto, Kaye, & Contejean, 2010; Mandell & Novak, 2005; Ravindran & Myers, 2011). Al Anbar and colleagues (2010) examined a French sample of parents of children with an autism spectrum disorder and found that treatment choice was associated with perception of disease severity and course as well as the parents' sense of personal control. Many parents of ethnic minority backgrounds do not view illness or disability in the same way as their health care providers and may use alternative medicines for their children (Levy, Mandell, Merhar, Ittenbach, & Pinto-Martin, 2003; Mandell & Novak, 2005; Ravindran & Myers, 2011; Yeh, Hough, McCabe, Lau, & Garland, 2004).

Although few, if any, studies of children with ID have studied culture by investigating behavior in the contexts in which people reside (Markus & Hamedani, 2007), several researchers have begun to examine other aspects of culture, such as socioeconomic status and religious beliefs. In general, lower socioeconomic status is related to increased deficits in developmental domains and the higher prevalence of psychopathology in children with ID and this has been consistent across a number of samples from the United Kingdom (Emerson, Hatton, Llewellyn, Blacher, & Graham, 2006), Finland (Koskenvanta, Ilvanainen, & Almqvist, 2007), and Australia (Leonard et al., 2005). Additionally, religious beliefs affect etiological attributions, which have an effect on treatment selection and adherence (Mandell & Novak, 2005; Ravindran & Myers, 2011). For example, if parental religious beliefs are fatalistic in nature, then parents are less likely to engage in interventions for their children (Mandell & Novak, 2005; Ravindran & Myers, 2011). Unfortunately, these studies are few in number and too often have small sample sizes that limit generalizability.

An important direction for future research using a cultural lens to understand the development of children with ID is to consider specific cultural beliefs (Cohen, 2013). For example, *attitudinal familism*, or a belief in the commitment of family members to their family relationships, has been found to be important in understanding distress among parents, particularly Latino American parents, of children with ID. Familism may be associated with decreased parental burden due to increase family support (Almeida, Molnar, Kawachi, & Subramanian, 2009; Magaña, 1999) or increased distress due to caregivers feeling obligated to care for others rather than feeling

positively supported (Losada et al., 2010). Thus, again, the role of specific cultural beliefs are likely to be moderated by individual and contextual variables and are particularly critical in understanding family processes and parenting behavior. Finally, cultural competencies that reflect an understanding of cultural values are important in planning interventions for children with chronic health or disability conditions (Clay, 2007).

As research in disability and chronic illness proceeds, it is important to recognize that individuals are inseparable from their sociocultural backgrounds and developmental processes must be understood in cultural context (Clay, 2009), a notion that is equally applicable to children with ID or CHC. The processes by which these children and their families are influenced by their cultures and, conversely, affect their culture, are understudied but of immense interest in explicating developmental models of culture and health. The evaluation of developmental compromise from cultural perspectives may suggest critical variabilities in which deficits viewed as problematic in one context may be understood as less debilitating in another (Serpell, Mariga, & Harvey, 1993). Finally, because multiple influences operate on the socioemotional development of children with ID and CHC, culture should not be examined separately from other core developmental domains.

INTERVENTIONS FOR SOCIAL AND EMOTIONAL COMPETENCIES

Given the sheer number of children and families who are affected by chronic conditions, the magnitude of the need for interventions to address the risks for socio-emotional competence stresses educational and health care systems. Nonetheless, there have been impressive attempts to design and implement interventions that either directly or indirectly influence the course of children's social and emotional competencies. The targets of intervention diverge between ID and CHC, and will be addressed separately below. But intervention programs not only serve to build skills and ameliorate child and family stress, but they also inform basic developmental conceptualizations of the nature of disorder and the processes and mechanisms that influence its course.

Interventions Targeting the Disability

Interventions for IDD are generally intensive programs that involve a number of service providers from various

fields and target the core developmental domains, such as academic functioning, cognitive abilities, social skills, adaptive behaviors, and language. These interventions are largely behavioral in nature. Specifically, applied behavior analysis (ABA) and derivatives thereof have the strongest empirical support for children with ID, particularly for children with ASD (Grey & Hastings, 2005; Matson et al., 2012). The effectiveness of early intervention has received international recognition resulting in the development of public policies to ensure that children who need these services are identified early and receive services in a timely manner. Overall, it is apparent that children with ID can make substantial progress in core developmental domains, especially through early interventions that are delivered during the preschool years (Dawson et al., 2010; Grey & Hastings, 2005; Guralnick, 2005; Matson et al., 2012; Reichow, 2012). Researchers have also begun to examine underlying neurobiological indicators of progress in early interventions, and to show that the changes observed in behavior can be reflected in the brain (Dawson et al., 2012).

Although it is clear that early intervention is an effective tool for enhancing the competencies of children with ID, the variability in outcomes indicates the limits to existing knowledge of the developmental trajectories of these children (Heyvaert, Maes, Van den Noortgate, Kuppens, & Onghena, 2012; Howlin, Magiati, & Charman, 2009; Warren et al., 2011). Certain child-specific predictors of early intervention outcome have been indicated, including initial language impairment (Ben Itzchak & Zachor, 2011), child age (Granpeesheh, Dixon, Tarbox, Kaplan, & Wilke, 2009), severity of IDD (Howlin et al., 2009), and child health (Eriksson et al., 2013) but child characteristics do not entirely account for the variance in intervention outcomes. Currently, the variability in developmental outcomes leaves families confused and often seeking other treatments, including those that lack empirical support (Matson, Adams, Williams, & Rieske, 2013). The need to identify meaningful predictors of intervention success remains an important focal goal. Predictors that can map developmental trajectories could inform service providers and allow interventions to be better tailored to the needs of the children and families.

In addition to predictors of intervention outcomes, future research must examine the impact of early intervention on the core developmental domains that are not currently targeted in these programs. The emphasis of early intervention is on addressing the disability itself, primarily deficits in communication, practical skills for daily living, cognition, behavior problems, and social skills. However,

research suggests that more distal outcomes, such as the development of behavioral problems and psychopathology, are predicted by difficulties in emotion regulation processes (Gerstein et al., 2011), and these are rarely targeted in behavioral programming. It is possible that these more distal outcomes could be ameliorated or even prevented if early regulatory skills were more often a focus of intervention programming.

As noted elsewhere in this chapter, children and adolescents with ID (and CHC to some degree) are at increased risk for developing comorbid emotional and behavioral problems, which contribute to their status as an underserved population (McCarthy & Boyd, 2002). Comorbid psychopathology contributes to negative long-term individual and familial outcomes and, thus, serves as an important target for intervention (B. L. Baker et al., 2002; B. L. Baker et al., 2010; Blacher, & McIntyre, 2006; Herring et al., 2006; McIntyre, Blacher, & Baker, 2002; Pearson et al., 2000; Seltzer & Krauss, 2001). However, interventions for children with ID and comorbid psychopathology are limited and primarily represent adaptations from existing interventions for typically developing children. Given the increased needs of this population, these interventions have been largely unsuccessful with a few exceptions (Lang, Mahoney, El Zein, Delaune, & Amidon, 2011; Moree & Davis, 2010). Additionally, most studies have taken an individual child-centered approach to treatment of comorbid emotional and behavioral problems in children with ID, with little consideration of family, school, cultural or contextual factors that contribute to and maintain mental health problems in this population.

Interventions for Families

Our own and other longitudinal research with families of children at risk suggests that the relations between parenting stress and problematic child functioning involve mutually escalating cyclic interactions over time whereby elevations in parental stress predict increases in child problems which in turn predicts exacerbation of parental stress (B. L. Baker et al., 2003; Orsmond, Seltzer, Krauss, & Hong, 2003; Neece et al., 2012). The cyclic relationship between children's emotional, behavioral, and social problems and parenting stress highlights both variables as targets for intervention, although parent stress is rarely a direct focus within established intervention programs. There is, however, considerable evidence that behavior problems in youth with ID can be significantly reduced through effective interventions (Heyvaert, Maes, &

Onghena, 2010; McIntyre, 2008), and parent-training interventions targeting child behavior problems have been found to indirectly reduce parental stress posttreatment, although these studies are almost exclusively with cognitively typical children (Eyberg et al., 2001). In research that has applied these parent-training programs to populations of children with ID, early results suggest that these programs may be effective in reducing negative parent-child interactions, parental stress, and child behavior problems (McIntyre, 2008). However, the long-term effects of the intervention on parenting stress may not be as strong as the long-term effects on child behavior problems (Eyberg et al., 2001).

More contemporary research has begun to examine the efficacy of mindfulness interventions for parents of children with ID. Briefly, mindfulness involves purposeful attention without judgment to one's moment-to-moment experience as it is arising to cultivate an awareness of the here and now without rehearsing the future or rehashing the past (Stahl & Goldstein, 2010). Studies indicate that through mindfulness training, the ever-changing nature of experiences may be recognized and, as a result, individuals become increasingly able to tolerate uncomfortable emotions and sensations (Eifert & Heffner, 2003; Levitt, Brown, Orsillo, & Barlow, 2004), experience improved emotional acceptance (Hayes, Strosahl, & Wilson, 1999; Linehan, 1993), and report decreases in the impact and time needed to recover from negative emotional events (Kabat-Zinn, 2009). Such processes are theoretically linked to better emotion regulation capacities overall, which in turn result in lower perceived stress. In the first study using a mindfulness-based intervention with parents of children with developmental disabilities, Singh and colleagues (2007) found reductions in parenting stress that were associated with decreases in child aggression and increases in social skills. Subsequently, a preliminary study examining the efficacy of Mindfulness-Based Stress Reduction (MBSR) for parents of young children with developmental delays found that parents who participated in MBSR reported significantly less stress and depression as well as greater life satisfaction than a waitlist-control group of parents (Neece, 2013). The children whose parents participated in MBSR were reported to have fewer behavior problems following the intervention, specifically in the areas of attention problems and ADHD symptomology. These early findings utilizing MBSR and other mindfulness interventions suggest that such approaches may prove to be especially effective interventions for specific emotion processes that operate directly at the level of parental well-being and indirectly at the level of children's behavioral and emotional competence.

Whether they prove to help maintain long-term well-being remains to be determined.

Interventions for CHC

The primary intervention foci for children with CHC have both similarities and differences from those of children with ID. Although family stress and well-being are at least indirectly addressed much in the same way as in interventions for ID, primary intervention foci for children with CHC have addressed adherence to medical regimens and/or school reentry and reintegration.

With suggestions that adherence to pediatric treatment may approximate 50% (Rapoff, 1999), the need to develop effective programs for adherence represents a major public health goal (LaGreca & Mackey, 2009). Although adherence presents a number of definitional challenges, and no single approach to its measurement has emerged, it is generally considered to be multifaceted in nature. Further, there is potential reciprocity of effect between socioemotional development processes and adherence to pediatric treatment (LaGreca & Mackey, 2009). More positive psychological adjustment has been linked with better treatment adherence (Jacobson et al., 1990), and conflictual family processes that are associated with poorer socioemotional functioning are tied to poorer adherence (Brosbe, Faust, & Gold, 2013).

An array of interventions with varying foci have produced variable findings across methods that intervene directly with children or indirectly through interventions that seek to strengthen other factors associated with better adherence or disease management. Indeed, two meta-analyses produced relatively similar findings of medium sized treatment effects for reasonably controlled interventions aimed at increasing adherence (Graves, Roberts, Rapoff, & Boyer, 2010; Kahana, Drotar, & Frazier, 2008), although Graves et al. (2010) found that the overall medium effect somewhat masked the difference between group versus individually focused interventions. Group-based interventions produced medium effects ($d = .40$), whereas those interventions that were targeted at individual children and families produced effect sizes that were large ($d = .70$). Regardless, it is apparent that interventions aimed at increasing adherence, especially those that include family members and have multiple components, can be effective (LaGreca & Mackey, 2009).

School-based interventions are frequently designed and implemented to address concerns relevant to children with CHC, including issues that involve adherence to

medication and other treatment regimens as well as issues involving returns to school following hospitalizations. Reintegration into school settings for children with CHC can be challenging at any developmental stage, but appears to be especially difficult during the early school years and at critical school transition periods (DuPaul et al., 2009). Power, DuPaul, Shapiro, and Kazak, (2003) have proposed a multisystemic model for school reentry whereby the family, school, and health care system work together to facilitate smooth reentry processes, although much of the intervention research in this area has not fully incorporated such systemic thinking. Furthermore, research findings across known interventions have not been well integrated overall.

A meta-analysis of intervention studies that attempted to increase illness-specific knowledge among teachers and healthy peers as well as create positive attitude change toward a child with CI (Canter & Roberts, 2012) identified a total of 12 studies that met basic inclusion criteria. Analyses examined any changes in the ill children's global self-worth following the intervention, as a secondary effect of the intervention. Increases in teacher or peer knowledge produced larger effect sizes than enhancing positive attitudinal changes, and effects were larger for teachers than healthy peers. Indirect effects on ill children's self-esteem indicated a medium effect for improvements. In general, much like for adherence interventions, data support a degree of effectiveness for interventions, but the processes that account for these effects and the factors that may moderate treatment effectiveness remain to be identified.

SUMMARIZING THE CURRENT STATE OF THE FIELD

What might be concluded from the incredible array of research that has addressed socioemotional consequences of illness and disability? Perhaps the simplest view is that there is no single overarching theory of atypicality that may be appropriately applied to children who experience chronic physical and or developmental conditions during childhood and adolescence. Childhood illness and developmental disability certainly share some features associated with the presence of chronic challenging conditions that create significant stressors and change the nature of developmental processes as well as the contexts in which they occur. And although our review suggests that any number of similarities exist between illness and disability in the risk for social and emotional functioning, there are

many critical differences that suggest that homogeneity in developmental outcomes or in the processes that determine those outcomes cannot be assumed. Where similarities emerge, it is predominantly for those CHC that are marked by CNS involvement (e.g., Pinquart & Teubert, 2012; Yeates et al., 2007), and impairments are more substantial. Yeates et al. (2007) provide an analysis of social-cognitive neuroscience that underlies key aspects of socioemotional functioning for children with brain disorders, and this CNS involvement typically includes some degree of executive or cognitive deficit, bridging the connection to ID and its associated deficits in social and emotional functioning.

It seems apparent that there is tremendous variability in the social and emotional functioning of these children and their families, and in general, the assumptions of uniformly poorer functioning relative to typically developing and healthy peers are not well supported. That is not to say that the risk for adversities associated with IDD or CHC is not genuine or worthy of concern. Paradigmatic shifts to more positive perspectives have been important and informative, but the pendulum should not swing to the extremes at which only the positives in response to the challenges imposed by these conditions are sought. Balanced perspectives seem to more reasonably reflect the nature of current understanding.

It is not just with respect to between-group comparisons that variability in socioemotional functioning is present. Within groups, there is compelling reason to suggest that children with chronic conditions cannot be treated as homogeneous. The pediatric psychology literature is replete with evidence that different illnesses have vastly different linkages with social and emotional functioning, and severity of the illness is often a key moderator (see Roberts & Steele, 2009). Similarly, behavioral phenotypes associated with specific syndromes involving IDD can differ widely across diagnoses, and differentially predict aspects of social and emotional functioning (Dykens & Hodapp, 2007). This within-group variability extends to differences between children with the same types of illnesses (e.g., leukemia), with the same syndromes (e.g., Down syndrome), or within the same categorical grouping (e.g., mild ID).

The absolute functional levels of, as well as the variability apparent in, social skills, emotion regulation, and behavior problems may be linked in complex ways with a variety of determinants, including specific genetic contributions as well as more exogenous family, school, and cultural factors. In many ways, the function of these determinants is much the same as it is for typically developing and healthy

children; that is, family, school, and cultural contexts exert some degree of influence over children's social and emotional functioning in ways that are often predictable and coherent. Family processes are also somewhat unique in that functional attributes of parents and siblings are often measured as outcomes in attempts to understand the ways in which the stress of chronic conditions in children may affect the well-being of family members.

In all, it seems apparent that children with CHC fare somewhat better across the board in comparison to children with IDD, but the severity of the condition somewhat moderates this conclusion. Children with IDD typically show more social deficits, struggle more with emotion regulation, and have higher rates of psychopathology or behavior problems than do either children with CHC or children who are typically developing. Still, the variability apparent across these domains is notable for both groups, suggesting that resilience processes are operative and critical to understanding the levels at which these children and families function. The success of interventions in affecting social and emotion competencies, whether employing direct or indirect mechanisms of change, is likewise suggestive that these developmental processes are malleable and merit specific attention.

Directions for Future Research

Although research has identified multiple critical processes in understanding the socioemotional consequences of illness and disability, efforts to date have only just begun to address the true complexity of the issues involved. The challenges of research with populations of children with chronic conditions are many, and the efforts of developmentalists and clinical or pediatric researchers alike to tackle these challenges have been instrumental in bringing the field to a point at which it is understood that answers will not come easily, nor will they be straightforward when they are found. But it is this very complexity that holds promise for expanding developmental perspectives on risk and resilience, and uncovering new pathways that connect childhood illness and disability to the full range of developmental possibilities and outcomes.

Throughout this chapter we have identified specific areas of interest for the next generation of research that will address socioemotional processes associated with illness and disability. There was some specificity related to individual topical concerns, but also commonalities shared across developmental domains and chronic conditions. In this final section, we highlight several general

directions for research that may set the stage for more sophisticated modeling of the connections between the risks associated with the presence of chronic conditions during childhood and the important social and emotional adaptations in which these children, and their families, engage.

Perhaps the most obvious need is also the simplest; there must be a much more focused effort to study core processes in social and emotional development for children who experience chronic illness and developmental disabilities. There is a basic need to further explicate the consequences of these conditions, especially given that the consequences may be stronger predictors of related outcomes for these children than are the chronic conditions themselves. Much of the available research has focused on studying threats associated with the central disease or cognitive impairment involved; however, the social and emotional functioning of these children significantly influences long-term competencies and may affect the nature of the outcomes that these children will experience (B. L. Baker et al., 2010). Similarly, intervention research that more frequently targets children's social and emotional competencies may not only change the trajectory of these skills over time for high-risk children, but attention to the processes of change may identify alternative pathways for basic research to explore.

Across chronic conditions, and across the functional social and emotional domains of interest, the next generation of research must engage more theoretically informed perspectives derived from basic developmental theory and research, and include more refined cultural frameworks that influence response. To date, the rich developmental modeling that is applied to the study of typically developing children, and to some risk conditions (e.g., high-risk preterm birth) and contexts (e.g., poverty), has not been as frequently applied to understanding the social and emotional functioning of children with chronic health or developmental conditions. There are, of course, notable exceptions (e.g., Guralnick et al., 2006; Hauser-Cram et al., 2001; Yeates et al., 2012), but the vast majority of the research has been more cross-sectional, focusing on specific single-point-in-time assessments of relatively narrow functional attributes without particular consideration of the processes that might drive the connections found. Even basic consideration of the developmental periods at which processes are studied would be informative, and little systematic attention has been paid to the interplay of specific social and emotional skills and the ages at which they are measured.

Cross-sectional designs are informative, but are fundamentally limited in their ability to address the more sophisticated questions that have emerged in the field. At the core of the next generation of research are longitudinal investigations that engage multiple levels of analysis over extended periods that transcend critical developmental transitions affecting social and emotional functioning. Attention to the biological bases of social and emotional behavior will be especially informative, as evidence begins to accrue with regard to the neurobiological underpinnings of socioemotional functioning and the executive skills that support it. These biological bases are especially important for children with developmental and health compromises, as the deficits that underlie a number of the chronic conditions are neurobiological in nature. Genetic approaches, including the identification of novel illness and disability endophenotypes (South, Wolf, & Herlihy, 2009) and behavioral phenotypes (Dykens & Hodapp, 2007), will be informative.

Nonetheless, the field cannot rely on biological or genetic approaches alone to carry the load of explaining the impressive variety of socioemotional response to illness and disability, nor should it. Throughout this chapter, we have detailed the ways in which various contextual and cultural factors contribute to the adaptive expression of social and emotional competencies in children with chronic conditions. But rarely have studies built and tested explanatory models that integrate multiple biological, personal, and cultural-contextual factors over time that could truly address the complex pathways of influence that likely exist, and identify the processes that connect illness and disability to the variety of social and emotional outcomes.

In a sense, the needs that exist represent a call for big science, or large-scale multisite transdisciplinary studies that combine resources to deconstruct the developmental processes that determine the nature and course of socioemotional competence over time in children with chronic conditions. The most critical resources to be shared are the populations of children and families to be studied. Given the specificity of effect that is often tied to type and severity of the condition, it is challenging to amass adequate sample sizes at any one research site. Multisite research offers the opportunities to develop larger sample sizes of specific illnesses or disability types, and the ability to explore the differentiations that capture the diversity of socioemotional function inherent across and within conditions, and from multiple cultural perspectives. These large-scale longitudinal studies must then engage

multiple levels of analysis that examine not only the differentiation by type and severity of the connection between risk condition and social and emotional functioning, but the mediating and moderating factors that combine to identify the processes by which risk results in problematic outcomes, or is left unrealized.

The developmental model first promoted by Yeates et al. (2007), and subsequently refined (Yeates et al., 2012), offers perhaps the best template for this next generation of study. These researchers proposed an integrative model that combines type and severity of brain insult in addition to parenting and family factors as contributors to a process in which social information processing skills (executive functions, social problem solving, and social-affective behavior) influence subsequent social interactive behavior (affiliative, aggressive, and withdrawn), which in turn determine children's social adjustment status. This multilevel model does not attempt to be overly inclusive in accounting for child social adjustment, but combines multiple levels of analysis that draw on putative neurobiological and developmental processes that operate across time to account for the social adjustment of children with chronic brain disorders. Research models that similarly address intricate developmental processes central to socioemotional functioning will extend developmentalists' understanding of the complex processes that link chronic conditions of childhood and children's social and emotional well-being.

In sum, progress in conceptual and empirical approaches to social and emotional functioning for children with chronic health and developmental conditions has been impressive. It is clear that simple unidirectional predictions cannot account for the richness in the range of function apparent within and between chronic conditions, and across developmental periods. Critical questions now remain about the complex ontogenetic processes that contribute to socioemotional competencies and deficits for children with chronic health and developmental conditions, and the factors that serve to mediate and moderate those connections. The identification of these intricate developmental processes will inform innovative prevention and intervention programs that can facilitate resilient social and emotional adaptations in the face of significant risk.

INTRODUCTION AND THEORETICAL FOUNDATIONS

The human brain and mind are built to categorize. Gordon Allport (1954), a foundational scholar of the science of human prejudice, noted that the earliest developmental tasks of the newborn infant are to differentiate and group sounds, images, contours, and colors. Importantly, these categorization skills also include a social component in which the infant learns to group people through largely implicit processes operating outside conscious control. These basic foundations of social cognition have profound implications for shaping the infant's understanding of the

world around her and how to respond to social cues in her various environments. For example, discriminating friendly faces from unfriendly faces helps infants build a foundation for positive attachments in life-promoting relationships (Bowlby, 1980). Learning to act upon these recognitions socially—to seek out friendly faces, to reject or avoid unfriendly ones—reinforces the basic perceptual and cognitive acts just enacted by the brain and in the mind, and helps promote the survival of the infant.

What happens, though, when children and adults later learn to group and/or separate people by a set of perceived characteristics (e.g., sounds, images, contours, and colors), attribute social meaning and valence to those groupings,

and act upon them in detrimental and maladaptive ways? This chapter in the *Handbook* presents a theoretical and empirically based treatment of the topic of discrimination as it is experienced interpersonally in childhood and adolescence. To do this, we focus our studies in childhood and adolescence on the product of social perception, cognition, and subsequent action, applied interpersonally. Although the human brain and mind are skilled at categorizing objects and sounds, the tendency to do so with people according to learned stereotypes can perpetuate dangerous social inequalities. As children age and encounter new groups of “others” who are similar or dissimilar with respect to physical features, language, culture, economic stature, or some other perceived attribute, discriminatory social practices with highly detrimental consequences can form. We therefore define this interpersonal construct of discrimination as purposeful and harmful actions toward others because of their membership in a social group. Such discrimination can include subtle, ambiguous, or explicit behaviors such as teasing, exclusion, or physical assault (Brown & Bigler, 2005; Fishbein, 1996). It is important to note that *intent* to discriminate is not part of this working definition; individuals may discriminate against others knowingly and/or unwittingly. Research on the impact of discrimination with children and adolescents therefore focuses on the *perception* of discrimination; whether the perpetrator intended to discriminate or not is not the main focus of this line of developmental research. Rather, how a child may recognize discrimination, understand the acts as discriminatory, and how the child psychologically responds to discrimination are of primary importance in contemporary research. Understanding how children’s perceived discrimination influences development is the central goal of this chapter.

Discrimination can be thought of as a conscious act, a series of acts (e.g., microaggressions: brief and commonplace acts of interpersonal discriminatory hostility, including racist jokes), or an overarching societal characteristic or structure that disproportionately places some groups of children at greater risk for poor developmental outcomes than others. The former two types of discrimination (interpersonal acts) have attracted the most attention in the developmental literature, and serve as a basis for our systematic review of the implications of discrimination on a variety of developmental domains and processes including identity formation, academic achievement, peer relationships, and self-esteem. In the latter case, structural discrimination may include inequalities in law (e.g., immigration deportation policies), public services (e.g., access to health care),

opportunities for education or labor, or systematically held beliefs about the capabilities of a group of individuals (e.g., IQ or *g* factor; see Gould, 1996). At the heart of such acts of discrimination are the social and psychological characteristics of individuals as they manifest within everyday social settings (i.e., person–environment interactions). In other words, we contend that these systematic effects of discrimination trickle down from macro-level systems to affect children’s experiences with peers, schools, and their communities at large. Consequently, we attend in this chapter to the characteristics of everyday social settings that may promote or deter interpersonal discrimination among diverse youth, and focus on linkages among settings’ characteristics and children’s perceptions of discrimination wherever possible. Theory and research examining family socialization practices that may help promote healthy responses to perceived discrimination among diverse youth, and interventions designed to ameliorate the detrimental effects of discrimination on child development are also considered.

Inherent in each of these discriminatory acts or structures is the issue of power: a socially more powerful individual or group (perpetrator) who or which overtly or covertly causes harm to a less socially powerful individual or group (victim). Much of the developmental research on racism and discrimination has employed the word “minority” to indicate a social group of low power. This is important to note, as “minority” therefore does not necessarily indicate minority in number (although it may), but rather indicates a child’s position of power in a given social stratification system (e.g., although females are slightly more common in the general U.S. population than males, oftentimes being female means being of relatively lower social, economic, and/or political power than being male). Such power dynamics exist and are perpetuated in many societies around racial, ethnic, religious, gender, and sexual orientation group memberships. The United States, for example, has a long history of systemic social inequalities based on these social constructions, all of which continue to exist today (Dovidio, 1986). Unfortunately, children’s present-day experiences with discrimination are all too common. Each year, thousands of lawsuits are filed in the United States on behalf of children claiming discrimination on the basis of gender, race, and ethnicity (Office of Civil Rights, U.S. Department of Education, 2000), and it is widely recognized that the majority of discriminatory acts go unreported. Furthermore, research has documented that children hold biases about low-status group memberships early in life (e.g., Bigler & Liben, 2006), and act upon them regularly by adolescence (Horn, 2008).

Revealed by our systematic review, the majority of research on discrimination in childhood and adolescence has been conducted in the United States and European countries. Notably, we were limited in our review by the need to examine articles published in English only. Nevertheless, given the deep history of racial inequality in the United States, it is not surprising that racial discrimination has dominated this literature, though a trend examining the effects of gender, sexuality, and religious discrimination in childhood is emerging as well. We therefore attend to both racism as well as the diversity of discrimination experienced by children in the United States and other countries, not only to highlight important topic areas for research and intervention, but also to illuminate the discriminatory processes and effects that underlie all forms of discrimination, regardless of the individual-level social characteristics of perpetrators or victims involved. As we argue in the conclusion, the field needs to move forward with these critical topics not only to document ways to ameliorate the detrimental effects of discrimination on children and adolescents, but also to develop deeper insights into how social discrimination itself is created and perpetuated within communities and across generations. Only by targeting both sides of discrimination—of perpetrator and victim processes alike—will cycles of discrimination and their detrimental effects on development be quelled.

THEORETICAL FRAMEWORKS: PROVIDING A FOUNDATION FOR UNDERSTANDING DISCRIMINATION'S EFFECT ON CHILDREN'S WELL-BEING

Before examining the effects of perceived discrimination on child development, it is important to understand the current-day thinking regarding how children both learn to be biased socially (and potentially act in discriminatory ways; perpetrator), and how they learn to recognize discrimination and respond to it (victim). We begin with the social underpinnings of theory related to the psychology of perpetrators of discrimination. A broad base of research and theory extending back into the mid-1900s and stemming largely from the discipline of social psychology has attempted to understand (a) the social “in-group” and “out-group” dynamics that play a major role in promoting acts of discrimination, (b) how the human mind appears prone to behaving in such groups, adopting biases and prejudicial beliefs, and acting upon them, and (c) how in-group and out-group attitudes, beliefs, and behaviors inform

the individual’s sense of self (e.g., his or her identities). Much as the growing infant’s mind is built to implicitly categorize objects and sounds in his or her environment, there are also implicit (i.e., operating outside conscious control and awareness) social-cognitive processes involved with building the capacity for acts of discrimination. Here, we review theory from the social and developmental literature to better understand how such discriminatory propensities develop, and shed light on the conditions under which they are prone to be enacted.

Social Bases of In-Group and Out-Group Behavior and Attitudes

One of the foundational scholars of the science of stereotype and prejudice, Allport (1954), characterized stereotyping as the tendency for humans to hold overgeneralized beliefs, or form exceptionless generalizations about people based on social group memberships. Although a strong tradition of study regarding intergroup biases and stereotyping has existed within the adult literature (Abrams, Hogg, & Marques, 2005), the systematic study of these important social processes in childhood and adolescence has only just begun. Some of the earliest studies of young children’s racial group attitudes provided alarming evidence of racial prejudice as early as 3 years of age (K. B. Clark & Clark, 1947, 1950; Doyle & Aboud, 1995). The now-historic “doll studies” conducted by Kenneth B. Clark and his wife Mamie Phipps Clark, the Clarks provided the first empirical evidence of early racial play preferences among White and Black children. According to the “Doll” test, the Clarks found that children, when given the option, systematically preferred to play with White dolls instead of Black dolls, regardless of their own skin color. Kenneth Clark (K. B. Clark & Clark, 1950) also used a projective drawing “Coloring” test, asking children to select from a variety of colors including white, tan, brown, and black, to color outlined boys and girls first “the color you are” and then “the color you like little boys (or girls) to be.” Clark also recorded open-ended qualitative spontaneous talking during the children’s drawing sessions. From these studies, he concluded that Black children as young as 5 years showed both identification with dark skin color and “prejudice” for light skin color. He found that children tended to color themselves “noticeably lighter” in color than they “actually were” (based on his own observations), but that the accuracy of coloring a child’s own skin color tended to increase with age. He also concluded that, when asked which color children like other boys or girls to be, they tended, as with the Doll test, to show systematic

preferences for lighter skin colors, regardless of their own skin color. These light-preference skin-color biases, he also noted, appeared to decrease slightly with age. These early and seminal studies combine constructs of both the personal identification with color (what we describe as racial identity below), as well as the social biases for lighter skin color, which continue to be measured and theorized about in today's developmental literature. These findings were and are considered by many to have been shocking revelations in the social sciences, and powerful for enabling social change (e.g., *Brown v. Board of Education*, Warren, 1954; see Keppel, 2002).

It is now well-documented that children learn at an early age to identify and form social groups, including those based on gender, ethnicity, and race (e.g., Aboud, 2003). Research that has used increasingly specific methods for separating the measurement of in-group and out-group attitudes and social preferences has found that in-group social preferences form before out-group judgment begins. In the early childhood years, in-group favoritism is thought to develop alongside early cognitive skills that allow the child to understand his or her own group identification, and recognize others who belong in the group (Bigler, Spears Brown, & Markell, 2001; Nesdale & Flessner, 2001; Yee & Brown, 1992). By about middle childhood, children are cognitively capable of multidimensional methods of categorization, allowing them to come to understand out-group membership (Aboud, 2008; Bigler & Liben, 1993; A. Clark, Hocevar, & Dembo, 1980). These changing developmental processes have been documented using laboratory-based minimal group paradigms (i.e., creation and assignment of children to in-groups and out-groups that are arbitrary; Tajfel, 1978). Importantly, researchers are now documenting that "preferences" for play with children of in-group members does not necessarily translate to "out-group" biases. In research with three ethnically and racially diverse groups of Portuguese, Dominican, and Cambodian children who were 6 to 12 years old, children reported strong preferences to play both with peers of their own ethnic background, as well as other backgrounds, when given the choice to independently rate groups (not make a forced choice between the three; Marks, Szalacha, Lamarre, Boyd, & García Coll, 2007). Although in-group social preference is not a sufficient condition for out-group bias or prejudice, a growing body of research does indicate that in-group favoritism (or bias) can be linked with social exclusion (Killen, Mulvey, & Hitti, 2013), one of the most common forms of childhood discrimination, and may therefore be a necessary condition for prejudice and discrimination.

Social-Cognitive Theory and Prejudice

A novel theoretical addition to the field of child development extends beyond the in-group out-group processes to include the basic social and cognitive processes at play in forming prejudicial attitudes and behaviors. Rutland, Killen, and Abrams (2010) have developed a platform asserting that "prejudice should be investigated in the context of social-cognitive development and the interplay between morality and group identity" (p. 279). These authors argue that most children and adolescents explicitly espouse moral reasoning that dictates that blatant prejudice and discrimination are wrong. However, as situations arise that are complex—akin to more everyday settings than often are created in laboratory manipulations—in which multiple possible reasons may exist for social exclusion, children and adolescents do exhibit prejudicial behaviors (see Figure 9.1). Combining several relevant theoretical perspectives, these authors stress the importance of how children reason about social exclusions when developing prejudice. Children may, for example, rely on "moral" reasoning for social exclusion, noting that exclusion of a child from a group physical activity is simply wrong. Children may also use "conventional" reasoning, which purports to provide a legitimate reason for excluding a child from joining the activity, such as wanting to maintain group cohesion or functioning. According to Figure 9.1, the type of context—whether complex or simple—matters greatly in children's reasoning around socially excluding another child. When children are faced with open-ended and simple conditions for playing with other children, such as joining

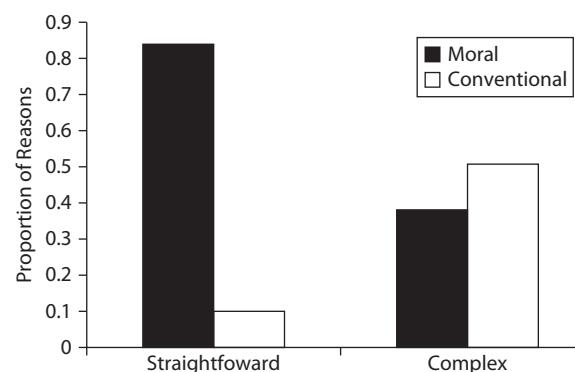

Figure 9.1 Example of context complexity and propensity for prejudice.

Source: From "A New Social-Cognitive Developmental Perspective on Prejudice: The Interplay Between Morality and Group Identity," by A. Rutland, M. Killen, and D. Abrams, 2010, *Perspectives on Psychological Science*, 5, pp. 279–291. Reprinted with permission.

a team, children are less likely to act in prejudicial ways or invoke conventional reasoning. However, when presented with a more complex situation—one in which there are limited spaces to fill on the team—children are more likely to be biased and invoke conventional reasoning justifying their prejudicial choices. These contextualized theoretical viewpoints are a welcome addition to the literature, which has tended to document myriad laboratory-based effects that sometimes appear contradictory: On the one hand, children can espouse egalitarian viewpoints, while on the other they act in prejudicial ways. It follows from the research supporting this theory that *context* characteristics are of central significance in understanding the conditions under which children (and adults) may invoke stereotypes and act in biased or prejudicial ways.

Identity Theory Relevant to Understanding Discrimination

To begin linking an act of discrimination (e.g., social exclusion based on stereotypes) to the well-being of children and adolescents, we focus on the literature regarding identity formation (see also Spencer, Swanson, & Harpalani, Chapter 18, this *Handbook*, this volume). Social Identity Theory (Tajfel & Turner, 1986) has provided a foundation for explaining how claiming membership in a particular social group (e.g., stating “I am a Mexican American”) may inform a person’s sense of self, taking on characteristics of the group’s identity and behaviors (e.g., cultural traditions common among Mexican Americans). Importantly, in situations in which children identify highly with their in-group, stereotype threat (i.e., being at risk of confirming a negative stereotype for one’s self; Steele & Aronson, 1995) is greatest. It is therefore through the processes of threat to a child’s identity as a member of a social group or groups (e.g., girl, Dominican, American, Black, gay) that the child may suffer psychologically when perceiving discrimination based on his or her social group membership. As stated previously, gender, race, and ethnicity are the predominant social groups under which children perceive discrimination. We present the theoretical foundations of ethnic and racial identities here as background for understanding how perceived discrimination may influence a child’s well-being. It should be noted that many (although not all) of the processes examined here can be extended in principle to other role, class, sexual orientation, and other stigmatized group identity threats as well.

Ethnic identity—the personal attitudes toward and feelings of belonging to an ethnic group—plays an integral

part in many aspects of development, including dealing with perceived discrimination among ethnic/racial minority children and adolescents. Ethnic identity reflects not only membership in an ethnic group, but also a complex of changing attitudes and feelings including ethnic pride, the centrality and importance of one’s ethnicity relative to other parts of the self (i.e., centrality), and involvement in one’s ethnic heritage (Nesdale & Mak, 2003; Phinney, 1990; Yip, Seaton, & Sellers, 2006). Past research has established the importance of positive ethnic identity and pride for optimal educational and social development (Phinney, Cantu, & Kurtz, 1997). Among Mexican and Chinese immigrant adolescents, for example, ethnic identity may support the extra motivation needed to attain levels of academic success comparable to those of European American students (Fuligni, Witkow, & Garcia, 2005). Among African American adolescents, a strong sense of ethnic pride may help to diminish the effects of school-based racial discrimination (Wong, Eccles, & Sameroff, 2003). There is also evidence suggesting that ethnic identity exploration (i.e., active and abstract consideration of what it means to be a member of an ethnic group) may promote deeper interethnic group social understanding among adolescents (Karcher & Fischer, 2004), though the association between ethnic identity exploration and interethnic group social processes in childhood is currently being explored less.

Despite a sound foundation of research documenting the importance of a strong ethnic identity for adolescent and adult well-being, strikingly little is known of the development of ethnic identity prior to adolescence. As school-aged children form in-group and out-group social preferences and biases, including those based on ethnicity and race (e.g., Doyle & Aboud, 1995; Katz & Kofkin, 1997), it may be that the strength of pride and salience a child feels about his or her ethnicity plays an important role in developing preadolescent interethnic group social preferences. In the tradition of social identity theory (Tajfel & Turner, 1986), research with children has shown that national identification (i.e., a strong sense of belonging to a national group) is associated with less social distance to in-group members and greater social distance from out-group members (Verkuyten, 2001a). Children also tend to assign more favorable characteristics to members of their own nationality group than to others, whether or not they identify with being members of their nationality group (Bennett, Lyons, Sani, & Barrett, 1998). Among adolescents, the salience and importance one feels toward one’s ethnic group also relates to in-group social preferences (Verkuyten, 1991, 2001b).

Following the seminal work of Erikson (Erikson, 1968), who brought attention to the importance of identity formation in adolescence, ethnic identity development is today considered an essential developmental task among ethnic/racial minority adolescents (Marcia, Waterman, Matteson, Archer, & Orlofsky, 1993; Phinney, 1990). Several models have been developed to provide a framework for understanding the development of ethnic identity prior to adulthood. In Phinney's developmental model, individuals move from childhood, when ethnic identity is largely unexamined by the child, through an identity exploration that culminates in a fully achieved ethnic identity in late adolescence (Phinney, 1989, 1993).

Sociocognitive theories of ethnic identity development have also been proposed; they present the only theoretical models for incorporating preadolescent developmental perspectives into ethnic identity formation (Aboud & Doyle, 1993; Bernal & Knight, 1997). In these models, children acquire the capacity to form ethnic identities during middle childhood when their cognitive abilities become more sophisticated and abstract. There are conflicting findings, however, with regard to the type of cognitive abilities that may support early ethnic identity awareness. Nevertheless, Aboud and Doyle (1993) have demonstrated that "ethnic constancy" (i.e., the knowledge that one cannot change one's race or ethnicity) begins to appear during middle childhood around Age 10, and is important to the formation of in-group and out-group social biases. Further, Bernal and colleagues (Bernal, Knight, Garza, Ocampo, & Cota, 1990), studying preschool and school-aged children using a cognitive developmental framework, showed that, as children become capable of more complex and abstract reasoning skills with age, their understanding of their ethnicity becomes more sophisticated. In this cross-sectional study, 86% of the Mexican American children (6–10 years old) were able to correctly identify themselves ethnically with labels, though only about 10% of the children were able to provide abstract reasons to describe why they selected the labels they did. The use of correct identity labels was correlated with Spanish language use, and children's preferences for in-group ethnic experiences increased with age. In subsequent studies, however, these authors directly measured general cognitive ability and found no association between cognitive stage development and ethnic identity development (Ocampo, Knight, & Bernal, 1997). Despite these inconclusive findings regarding the relation between cognitive development and ethnic identity among Mexican American children, their parents' ethnic socialization practices were a consistent correlate of ethnic identity development.

Racial identity development theory also has contributed an important foundation for ethnic identity research and in-group/out-group research in adolescence (e.g., Sellers, Caldwell, Schmeelk-Cone, & Zimmerman, 2003). Cross (1971, 1991) initially proposed a framework in which individuals explore their racial identities from ignorance to self acceptance. In this framework, individuals remain largely unaware of their racial identities until they encounter racism, which triggers active identity exploration. As with ethnic identity theory, children are not expected to actively explore their racial identities, as they usually have yet to encounter racism and name it as such. Nevertheless, children of color are often socialized at a young age to recognize and understand overt and subtle acts of racism as it pertains to others (Hughes et al., 2006) and they often feel a sense of ethnic and/or racial group pride (Aboud, 2003; Bernal et al., 1990; Cameron, Alvarez, Ruble, & Fuligni, 2001). In spite of this, according to both the prevalent ethnic and racial identity theoretical frameworks, children themselves are most frequently depicted as unaware of their own racial and ethnic identities and therefore are not expected to actively explore them until adolescence or adulthood. This is an area in need of research moving forward: the full integration of childhood social, cognitive, and identity theory and processes as they emerge prior to adolescence.

A mounting body of empirical evidence exists to support these ethnic identity developmental frameworks. A paper by French, Seidman, LaRue, and Aber (2006) reported one of the few longitudinal studies of U.S. ethnic identity during the early and middle adolescent period, including children of African American, European American, and Latino American ethnicities. These authors documented the rise in ethnic group esteem across the course of early and middle adolescence, and found evidence that the exploration of identity can be particularly salient during middle adolescence. Importantly, ethnic group similarities and differences were observed. Exploring the longitudinal data within the Latino American group (i.e., between Caribbeans, Puerto Ricans, Dominicans), ethnic subgroups appeared to have similar levels of identity and pride. However, differences between the larger ethnic groups were observed, with African American and Latino American adolescents starting with lower levels of ethnic group esteem that rose sharply across adolescence, while the European Americans maintained high, stable ethnic group esteem throughout adolescence.

Taken together, the above theory and supporting literature suggest that ethnic/racial identities play important

roles in developing ethnic/racial minority children's overall awareness, exploration, and understanding of interethnic group social experiences. In adolescence, research suggests that Asian American adolescents with predominantly same-ethnic and mixed-ethnic friendships have higher levels of ethnic identity exploration than adolescents with predominantly other-ethnic friendships (Kiang, Peterson, & Thompson, 2011). Importantly, immigrant adolescents with greater levels of ethnic identity were also more likely to report higher perceived discrimination than adolescents with lower levels of ethnic identity. It follows, then, that these relations between self-esteem building ethnic identification processes and awareness of interethnic group biases may be adaptive for immigrant or ethnic/racial minority children who will need to navigate community stereotypes and prejudice as they age.

Integrative and Person-Context Perspectives

We take our next step in the theoretical literature toward understanding how discrimination may influence child and adolescent well-being by deepening attention to contexts and unpacking how the capacity to perceive discrimination is formed. In doing so, we now turn our attention to theory

focused squarely on victims of childhood discrimination. Guiding the field are two seminal theoretical frameworks highlighting the saliency of discrimination and racism for influencing minority youth development in particular. These two theories—the Integrative Model (García Coll et al., 1996) and Perceptions of Discrimination Model (Brown & Bigler, 2005)—together comprise the main foundation of theoretical frameworks specifically developed with and for understanding discrimination's impacts on child and adolescent development.

The first framework presented an integrative and ecological model for the development of minority youth (see Figure 9.2; García Coll et al., 1996). In this model, García Coll and colleagues (1996) placed the treatment and understanding of discrimination in childhood as a central consideration for explaining or predicting minority youth development. Social position variables including race, ethnicity, social class, and gender represent socially constructed groupings to which children may be ascribed by others or identify with themselves. Membership (either ascribed by someone else or personally identified as in the case of ethnic identity) in such groups often places children who fall into the “minority” groups (e.g., by virtue of social power) at risk for developmental problems. This risk

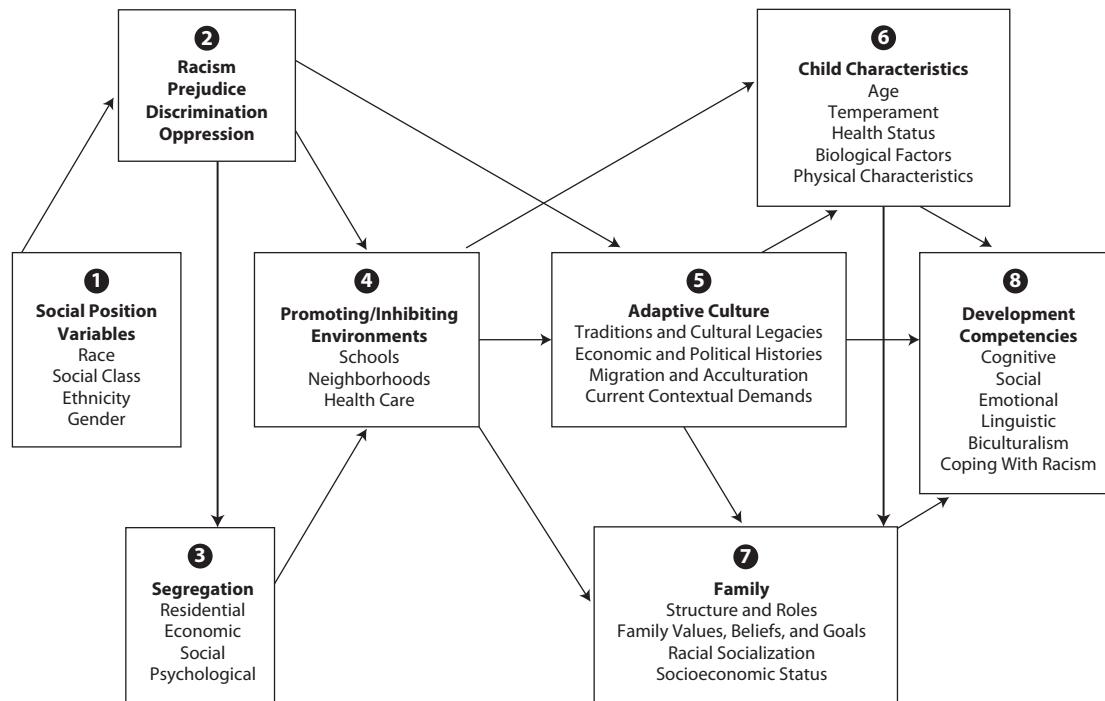

Figure 9.2 Integrative model for the study of minority child development.

Source: From “An Integrative Model for the Study of Developmental Competencies in Minority Children,” by C. García Coll et al., 1996, *Child Development*, 67, pp. 1891–1914.

is attributable to racism, prejudice, discrimination, and oppression which lead to segregation both physically (i.e., neighborhood) and socially (i.e., peer exclusion).

Importantly, these social position and risk processes are filtered through promoting or inhibiting social settings such as schools, family socialization practices, and adaptive culture (e.g., historical traditions and cultural legacies) to explain how individual minority youth build a variety of developmental competencies. According to this framework, then, if child development is to be measured and understood among ethnic, racial, gender, or social class minority youth, understanding children's exposure to, perceptions of, and management of discrimination is of central importance. A discussion of health outcomes, cross-ethnic group academic disparities, or any other developmental phenomena without considering discrimination and the promoting/inhibiting environments in which children live is invalid. In other words, to say that African American children underscore on standardized academic achievement tests when compared to European American children thereby indicating lower academic abilities without measuring, understanding, and/or considering the psychological and social constructs relevant to systematic racial oppression in the United States is invalid and perpetuates misconceptions and biases about the innate academic abilities of African American children.

Of import in this model is the focus on developmental competencies instead of deficits, a focus that has been historically absent in the literature regarding racial and ethnic minority youth (García Coll, 1990; García Coll et al., 1996; McLoyd, 1991). Reflecting the larger society in which developmental scholars operate, numerous scholars have noted that the field of child development research has been slow to recognize the promise, competencies, and resiliency of minority youths, focusing instead on deficit models of development (e.g., the academic achievement gap example above). Researchers continue today to compare ethnic and racial groups of individuals against one another (often to a majority reference group) across a myriad of developmental and health outcomes without attention to the underlying social and psychological processes that may explain documented socially constructed group differences that perpetually favor the majority group (Helms, Jernigan, & Mascher, 2005). Furthermore, considering the substantial social, historical, and economic barriers many racial, religious, and ethnic minority youth continue to face in the United States, it has been argued that there are unique developmental competencies—above and beyond the basic academic, social, and self-care skills

shared by all U.S. children—that minority youth must master in order to thrive. These competencies include developing healthy ethnic/racial identities, as well as bilingual and bicultural competencies (Marks, Godoy, & García Coll, 2014). Such skills are necessary to thrive socially in increasingly diverse societies, and to understand and recognize social discrimination and navigate its detrimental effects.

Related to the idea that ethnic, racial, religious, and language minority youth must actively cultivate developmental competencies (e.g., identities, language skills, bicultural social skills) to thrive, another important theoretical framework has detailed the precise skills and situational factors necessary for children to learn to perceive discrimination. Brown and Bigler (2005; see Figure 9.3) provided a developmental model incorporating the cognitive, individual, and situational factors necessary for children to acquire and hone the essential skill of discrimination perception. Although, as the authors argued, discrimination exerts detrimental effects on children and families regardless of whether or not the discrimination is directly perceived by the children, the ability to perceive discrimination—to recognize an act of discrimination and name it as such—is essential for children to then be able to interpret the social conflict or act accurately and to recover from it. Without accurate perceptions of discrimination, children may suffer in self-image (e.g., dislike their bodies or skin color) or self-esteem (e.g., believe they are less capable in school than they are) and be left without a way to explain or overcome these detrimental psychological experiences. Furthermore, there is a growing body of empirical literature documenting children's and adolescents' abilities to perceive discrimination. Among preschool-aged children, exclusion of others based on social group membership seems to be the most recognizable form of discrimination (Theimer, Killen, & Stangor, 2001), while elementary school children recognize that other forms of discrimination exist. Verkuyten, Kinket, and van der Weilen (1997) reported that 92% of 10-year-olds identified behaviors such as name-calling, an unequal sharing of goods, and social exclusion as forms of discrimination. By adolescence, there is an understanding of both explicit as well as more subtle forms of discrimination (Wong et al., 2003).

In the Brown and Bigler (2005) model, to perceive discrimination, children must first be capable of understanding socially constructed groupings such as race and gender, be able to attribute and understand others' intentions and actions, and be able to make social comparisons and categorizations. Such skills are present among

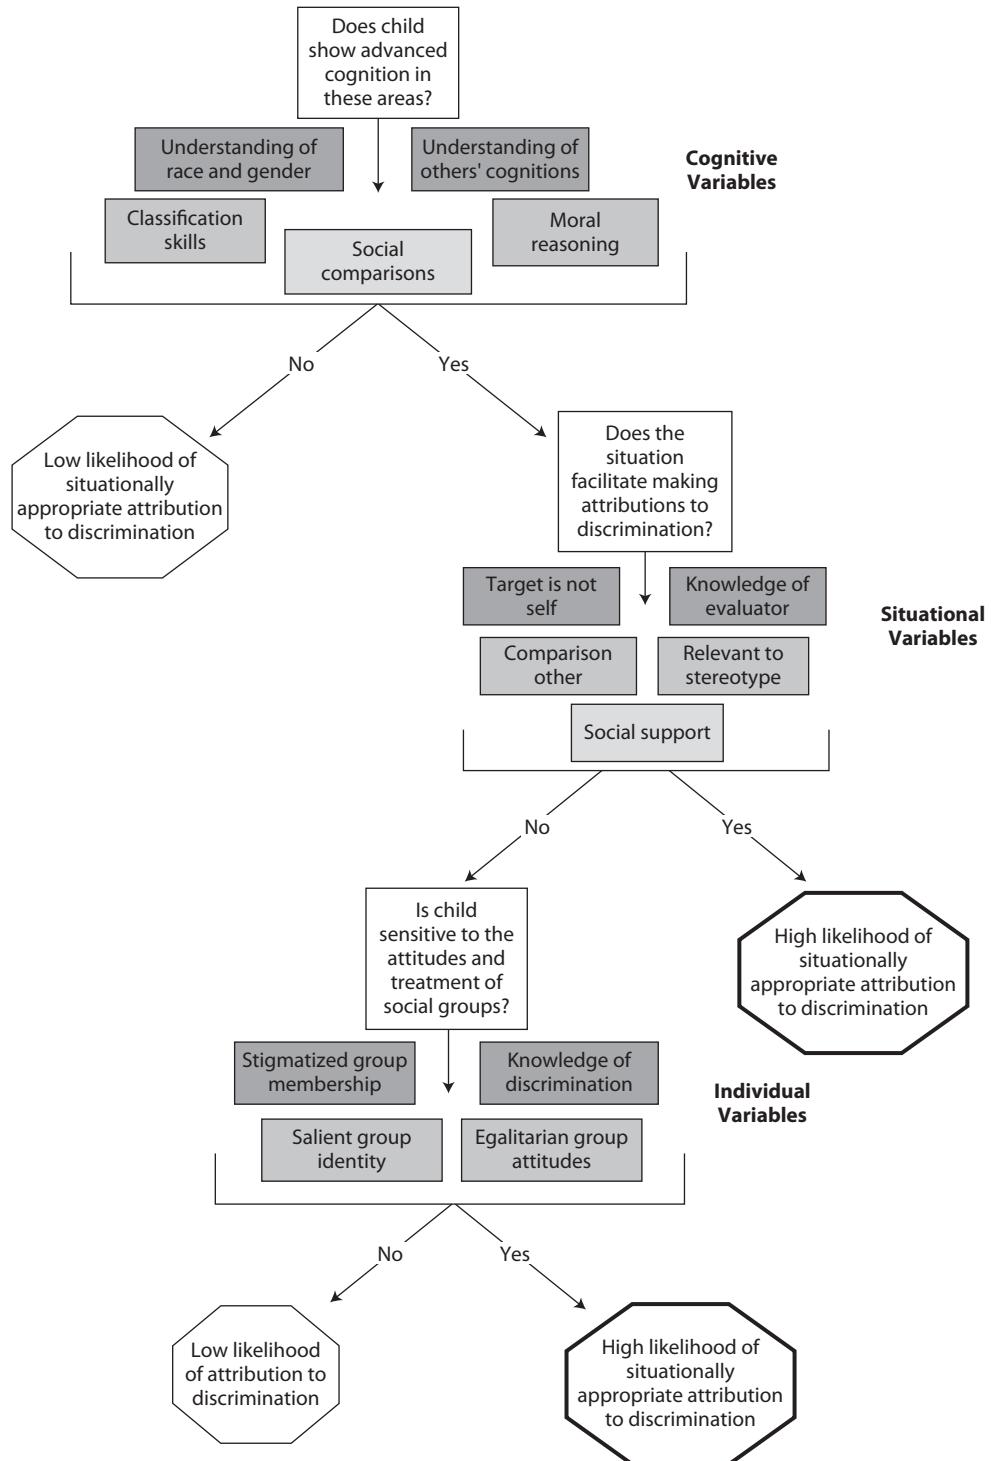

Figure 9.3 Social cognitive model of perceptions of discrimination.

Source: From "Children's Perceptions of Discrimination: A Developmental Model," by C. S. Brown and R. S. Bigler, 2005, *Child Development*, 76(3), pp. 533–553.

children as early as 5 years of age, although the age at which children reliably use such skills is typically later (7–8 years) and is influenced greatly by factors including other cognitive abilities and characteristics of the social environments the child is accustomed to. Next, as with the García Coll et al. (1996) model, these authors also emphasized the importance of context for developing discrimination perception—*situational* factors, including characteristics of the setting, that may make the act likely to be interpreted as discriminatory. These situational variables include characteristics of the perpetrator (e.g., whether the individual is well-intended or biased), and whether the context typically has produced discriminatory acts in the past (e.g., other group members have been victimized, and the context is relevant to stereotypes). A point of divergence, however, between the García Coll and Brown and Bigler models, is that the proximal context (the immediate surroundings at the moment of the discriminatory act) is the focus of the perception of discrimination model. This makes sense given the focus on explaining a child's ability to perceive a specific act as discriminatory; however, it is likely that more distal contexts including race relations in the community at large may also play an important role in the likelihood that children correctly perceive discriminatory acts at another given moment (see "Discrimination in Context," further on).

The third and final level of the model by Brown and Bigler (2005) focused on *individual* factors including identity processes such as in-group affiliation, knowledge of discrimination, and egalitarian beliefs (i.e., children with more egalitarian beliefs more readily perceived discrimination). These psychological factors increase children's abilities to perceive discrimination, and a growing body of empirical literature supports the assertions that, by adolescence, all of the necessary cognitive and individual-level skills in this model are in place to allow youth to perceive discrimination. Simons et al. (2002) showed that African American 10- to 12-year-olds reported experiencing at least one instance of racial discrimination, with verbal insults and racial slurs reported as the most commonly experienced discriminatory behaviors. Wong and colleagues (2003) reported that adolescents perceive discrimination to occur relatively frequently in public as well as educational settings. For example, many African American (32%), Latino (38%), and Caucasian students (13%) reported that they had been discouraged from joining advanced level classes, disciplined wrongly by teachers, or graded unfairly because of their race (Fisher, Wallace, & Fenton, 2000). From a theoretical point of

view, such discrimination perceptual skills are paramount to understanding not only a momentary act of discrimination, but for understanding the larger societal propensities and histories of more systematic discrimination, and their implications for child and adolescent well-being. Clearly, the individual-level factors related to children's abilities to perceive discrimination will be shaped by and responsive to the larger societal messages extant in media, day-to-day interpersonal interactions, and depicted in written, video, and oral histories.

PERCEIVED DISCRIMINATION AND ITS INFLUENCE ON CHILDHOOD AND ADOLESCENCE

As stated in the introduction to this chapter, our primary goal is to examine the full array of implications that discrimination can have on child and adolescent development.

Introduction to the Systematic Review

We undertook a systematic review of the empirical, peer-reviewed social science literature. We did this because, to our knowledge, no such systematic review has focused specifically on the linkages among discrimination and developmental outcomes. To make our review as standardized and rigorous as possible, we followed the guidelines published by Moher, Liberati, Tetzlaff, and Altman (2009) and the Meta-Analysis of Observational Studies in the Epidemiology Group (Stroup et al., 2000) in the design and reporting of our review. We also followed the editorial on literature reviews published in *Psychological Bulletin* (R. J. Cooper, Wears, & Schriger, 2003) detailing guidelines for taxonomy and reporting of results. The methods and coding for this review are as follows.

Search Strategy

Studies were considered for inclusion if they provided quantitative or qualitative data on the association between racism and/or discrimination and mental and physical health of children. All observational studies, cohort, and case-control studies were considered for inclusion. Participants in the included studies were youth ranging in age from 2 to 18 years. Note that we made no date or publication year restrictions on our search. Research studies published in English, but based in any society or country, were included.

In March 2013, we searched the databases ACADEMIC SEARCH COMPLETE, MEDLINE, PsycINFO, and SocINDEX using the Boolean phrase “adolescent or child or youth” and “discrimination or racism” and “development or health or achievement or socioemotional.” The results yielded 18,333 articles. To narrow our search, we excluded dissertations, review articles, and books. We also excluded duplicates from multiple database searching; 7,007 articles remained. In brief, we next looked for articles whose main focus was interpersonal discrimination (or other synonyms, as opposed to sensation/perception stimulus discrimination research) but also mentioned child health (mental or physical health) or whose main focus was child health (mental or physical health) but also mentioned interpersonal discrimination.

Inclusion/Exclusion Coding

Two rounds of coding were conducted to identify relevant articles. Two doctoral-level graduate students reviewed the 7,007 article abstracts using the following inclusion/exclusion criteria: Exclusion criteria: (a) Non-peer-reviewed studies; (b) studies not written in English; (c) studies with only adult subjects (Ages 18+). Inclusion criteria: (a) articles that provided quantitative or qualitative data on the association between racism or discrimination and child/adolescent development, mental health, physical health, well-being, socioemotional functioning, and/or academic achievement, or on children’s perceptions of discrimination and racism; (b) youth 17 years and younger; (c) peer-reviewed articles. In the first round of coding, the

two graduate students reviewed 500 of the 7,007 article abstracts for interrater reliability. Agreement was excellent, with only two discrepancies (Cohen’s kappa = .996). The lead author then resolved the discrepancies with the graduate reviewers. Each graduate student then independently reviewed 3,253 article abstracts each. Using the inclusion/exclusion criteria, 481 out of 7,007 articles (6.8%) were included after this step. In the second round of coding, the same two graduate students acquired PDFs of the 481 full-text articles identified as meeting inclusion criteria, in order to conduct full-text reviews. Both students reviewed 100 of the 481 articles using the same inclusion/exclusion criteria so that interrater reliability could be assessed. Agreement was still excellent, with eight discrepancies (Cohen’s kappa = .84). The lead author again resolved the discrepancies along with the graduate reviewers. Using the inclusion/exclusion criteria above, 179 of 481 articles (37%) remained for final inclusion in this review.

Coding for Outcomes

In order to systematically examine methodology and outcomes in the remaining 179 articles, an Excel spreadsheet was created to code each of the 179 articles using the following categories: APA citation, inclusion criteria, procedure, type of data collected, measures (focusing on the measures used for perceived discrimination/racism), sample size (including age, gender, ethnicity/race), household income, analyses used, and outcome measured (racial socialization, mental health, physical health, well-being, socioemotional functioning, academic achievement, and

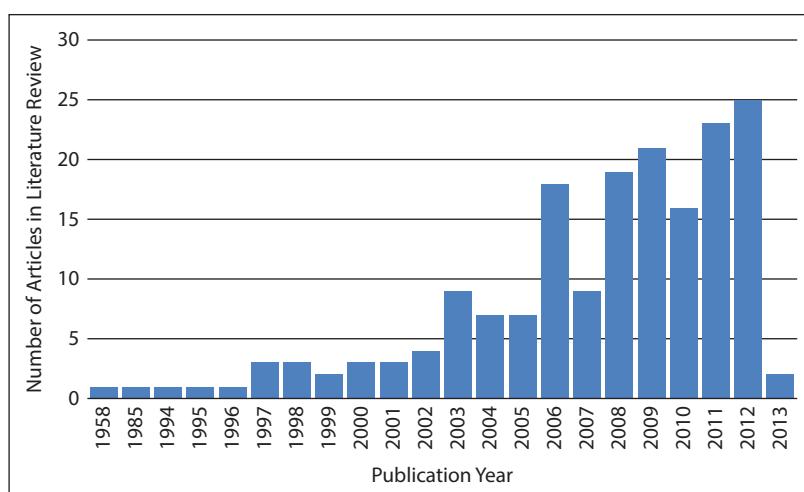

Figure 9.4 Number of empirical, peer-reviewed journal articles published on discrimination and its effects on child or adolescent development, by year of publication.

children's perceptions of discrimination/racism). Data from this final spreadsheet constituted the basis for this chapter's review.

We were struck as we began examining this final subset of empirical, peer-reviewed literature, at how newly emerging this body of knowledge was (see Figure 9.4). Plotting the number of articles that fitted our search criteria, we found 179 articles directly linking discrimination to child or adolescent developmental outcomes, with approximately 93% of the articles on children aged 17 and younger published after the year 2000. The next section of the chapter represents a comprehensive review of this literature, organized first by developmental process areas that are important correlates of perceived discrimination in development, and next by developmental outcome domain. In each section, we pay close attention to the diversity of findings, whenever possible, with respect to type of discrimination (e.g., gender versus racial versus religious), country/society in which the research was conducted, and important potential mediators or moderators (i.e., explanatory processes or important contexts such as gender) that may change the way discrimination influences development.

LINKING DISCRIMINATION WITH CHILD AND ADOLESCENT DEVELOPMENT: RESULTS OF A SYSTEMATIC REVIEW

The deleterious effects of perceived discrimination on child and adolescent development are currently being established, and a close look at the literature reveals that a developmental perspective on discrimination's impacts is comparatively new. Children's perceptions and understanding of discrimination, as well as the development of racial discrimination abilities (i.e., being able to effectively and efficiently categorize individuals of different racial/ethnic backgrounds) have been some of the most prominent areas of interest in the early developmental ethnic/racial discrimination literature. Within the 20 years prior to the time of this writing, there has been a distinct shift in this research base. Researchers have been progressively moving away from discovering the "why" and "how" discriminatory acts occur and are now moving toward understanding the multitude of developmental outcomes and consequences that can arise from perceived discrimination. As an example, in their study of perceived discrimination and early substance abuse among Native American children and adolescents, Whitbeck, Hoyt, McMorris, Chen, and Stubben (2001)

reported that almost half of the adolescents had been insulted because they were Native Americans. One-fourth had felt disrespected at a place of business due to ethnicity, 49% had heard a racial slur directed at them, and 14% had been threatened physically. Notably, more than half of the children reported that their teachers seemed surprised when they did well in school, while 25% felt their teachers did not expect them to do well on their schoolwork. Finally, 20% felt other children excluded them due to their ethnicity, and 31% felt that other children treated them unfairly because of their ethnicity. Clearly, these children and adolescents did not just perceive discriminatory acts—they were able to detail the many ways these acts influenced their lives. From disadvantage in stores and in the school context to strained peer relations, perceived discrimination has far-reaching consequences for minority youth development.

This review on the widespread influence of discrimination focuses on physical health, well-being, socio-emotional functioning, academic achievement, and mental health domains. Each of these areas can be drastically influenced by perceptions of discrimination on their own, although it is highly likely that, if one area of development is considerably affected, one or more of the other domains will also be affected. For example, if perceptions of discrimination are creating significant mental health issues for a child, such as problems with depression and anxiety, chances are high that the child will also be struggling in areas of socioemotional functioning, well-being, or perhaps academic achievement as well. For ease of presentation, we organize our review by developmental domain areas, while at the same time noting the considerable amount of overlap among developmental outcomes in studies that offer evidence across domains. As these outcome domains are described with respect to discrimination, we also offer insights into the potential processes linking discrimination to developmental outcomes across a variety of emerging mediators and/or moderators of the discrimination-outcome linkages.

Physical Health

Although physical health outcomes of perceived discrimination are not as widely discussed or researched as the psychological and social developmental domains we cover, we begin our review by highlighting this compelling area of emergent research. Physical consequences can and do arise from racism and discrimination, and these consequences can be severe. In looking at the correlates of physical outcomes of discrimination, it can often be

difficult to pinpoint perceived racism or discrimination as the direct cause of physical harm, health disadvantage, or discomfort. Unlike measures of depression, self-esteem, or well-being, there are no physical health surveys currently in use designed specifically to assess the physical effects of perceived discrimination. Instead, researchers must often use retrospective reports of physical symptoms or health behaviors that appear to co-occur with perceptions of discrimination. Despite these current methodological limitations, several areas of physical health appear to be affected by discrimination in childhood.

Smoking and Substance Use Behaviors

Early smoking initiation and other negative substance use behaviors have frequently been linked to discrimination—a troublesome finding considering the long-term consequences of substance use and abuse in adolescence and adulthood. In a study of U.S. adolescents, Wiehe, Aalsma, Liu, and Fortenberry (2010) demonstrated that participants who had dropped out of high school were more likely to report histories of discrimination and cigarette smoking. Unsurprisingly, gender differences were also uncovered in this research. Males who reported discrimination were 2 times more likely to smoke than males who did not report discrimination in any settings, while the odds of smoking among females due to perceived discrimination was consistently lower than that among males. Additionally, males who reported experiencing discrimination in stores and in interactions with police were more likely to smoke—an association not observed among females. These findings offer a glimpse into just one of the numerous areas where seemingly unassociated physical consequences can be associated with acts of discrimination. In addition, they allow for the observation of just one of the many occurrences in which gender plays a role in moderating the influence of discrimination.

The connection between discrimination and its associated physical correlates is by no means country-bound. Similar relationships between smoking and discrimination have been documented in several countries outside of the United States. In their assessment of middle-school-aged children in Jujuy, Argentina, Alderete and colleagues (2012) identified perceived discrimination as one of the precursors of early smoking. The authors found that having experienced racial insults was associated with current smoking, and that this relationship was moderated by participant ethnicity (Amazonian or indigenous). Amazonian participants who were 13–14 years old and had experienced a racial insult in the 9th grade were almost

4 times more likely to be smoking at 15 years of age in the 10th grade, when compared to Amazonian participants who had never experienced any racial insults. In contrast, indigenous participants who were exposed to a racial insult at 13–14 years old were only 80% more likely to be smoking at 15 in the 10th grade, as compared to indigenous members of the same group who did not report being exposed to racial insult(s).

Perceived discrimination has been shown to be directly associated with smoking behaviors in early and late adolescents, but there are also indirect ways in which racism and discrimination have been shown to influence early smoking initiation and later smoking behaviors. Increases in perceived discrimination are not only associated with increased risk for smoking, but are also associated with increased risk for association with friends who smoke (Fagan, Brook, Rubenstein, Zhang, & Brook, 2009). When considering the well-established body of literature that has documented that children can learn to both identify and form social groups at a very young age (e.g., Aboud, 2003), these findings offer insight into the development of social groups later in life by those who are influenced by discrimination and discriminatory acts. In the face of discrimination (both shared and unshared), certain friendship groups and associations are being formed based on mutual substance use behaviors, which not only serve to reinforce engaging in these behaviors that can be extremely damaging to overall physical health, but also limit the other shared “factors” that typically affect the formation of social groups (e.g., gender, age, race). In measuring perceptions of discrimination and substance use in African American parents and their children, Gibbons, Gerrard, Cleveland, Wills, and Brody (2004) demonstrated that children’s perceptions of discrimination were correlated with the children’s own and their friends’ substance use. In other words, children who perceived more discrimination not only tended to have higher substance use themselves, but were also more likely to have friends with the risky behavior as well. These results suggested that the effects of discrimination can be far-reaching—extending beyond immediate health risk behaviors into peer and friendship contexts as well. Discrimination can be directly related to the individuals’ substance use and smoking behaviors, but as shown, perceived discrimination can also be indirectly related to friends’ substance use and smoking behaviors, as well as the number of associations individuals make with friends who engage in these unhealthy behaviors.

As noted earlier, boys and older youth appear to be at the greatest risk for negative substance use outcomes

(Alderete et al., 2012), perhaps because males tend to perceive more discrimination than females (Oxman-Martinez et al., 2012; Umaña-Taylor & Updegraff, 2006). This gender difference in discrimination perception persists across countries and cultures; Oxman-Martinez et al. (2012) established that, in a sample of children who had newly immigrated to Canada, boys were more likely to report discrimination than were girls. Nevertheless, although the risks of perceiving discrimination may not be as high for females, those who do perceive discrimination face some of the same health challenges as males, which is important to consider in light of the substantial literature showing that many, if not most, substance use behaviors are typically more common in males than females (e.g., Greenfield, Manwani, & Nargiso, 2003). With regard to early smoking behaviors, females who reported higher levels of perceived discrimination were more likely to also report having ever smoked in their lives (Guthrie, Young, Williams, Boyd, & Kintner, 2002). Further, for every 1-point increase in perceived discrimination, there was a 37% increased likelihood of smoking—a very large effect. Lorenzo-Blanco, Unger, Ritt-Olson, Soto, and Baezconde-Garbanati (2011) found similar results: The odds of past-30-day smoking increased as girls reported higher levels of discrimination.

Physical Health Correlates

The indirect discrimination-to-physical outcomes “routes” demonstrate that the consequences of discrimination are not just far-reaching, but that they can take any number of paths to a final physical result. In a study looking at the physical health correlates of discrimination, Chambers, Tuli, Fraser, and Mutunhu (2004) aimed to uncover the relationship between internalized racism and both body fat distribution and insulin resistance in adolescent youths of African descent. Participants in this study were recruited via their mothers at a well-known hospital in Barbados. Correlational results indicated that internalized racism was positively associated with waist circumference for girls, but not for boys, although the correlation was weak-to-moderate. For the sample as a whole, internalized racism was positively correlated with hostility such that children who internalized racism more also tended to be more hostile. The relationships between internalized racism and physical outcomes remained significant for girls, even when controlling for age and birth weight. Girls who reported a high level of internalized racism also had significantly higher body mass indexes (BMIs), waist circumferences, and insulin resistance as compared to girls

who reported a low level of internalized racism. Further, even when controlling for hostility and lifestyle behaviors (in addition to birth weight and age), girls who reported high levels of internalized racism were over 3 times more likely to show early insulin resistance than girls who reported low levels of internalized racism. Again, these relationships were not found to be statistically significant for boys. The attempt by Chambers et al. (2004) to link two seemingly unrelated variables such as internalized racism, BMI, and insulin resistance is both unique and impactful. While causation can by no means be inferred from these findings, they can be used to attempt to further the case that the effects of discrimination are more far-reaching, more pervasive, and more omnipresent than most perpetrators or even victims may realize.

In addition to affecting BMI and levels of insulin resistance, perceived racism has been shown to relate to resting blood pressure rates for Black adolescents (R. Clark & Gochett, 2006), when other personality factors, like trait anger, are taken into account. High levels of trait anger tend to dispose individuals to find a wide variety of situations bothersome or frustrating, and increase the tendency to respond to emotionally charged situations with a higher level of state anger (Spielberger et al., 1985). Perceptions of racism have been shown to be moderately and positively related to trait anger—the more adolescents perceive racism, the more likely they are to report elevated trait anger (R. Clark & Gochett, 2006). A critical question, the answer to which cannot necessarily be inferred from these findings, surrounds the directionality of these associations. Does an increased level of trait anger predispose certain individuals to perceive more discriminatory acts than would be perceived by individuals with lower levels of trait anger? Or does the experience of perceiving racism encourage individuals to react with more anger in certain discriminatory situations? Either way, it is important to consider that discrimination and racism can relate to the way children and adolescents react to prejudice in both the present and the future. These reactions do not necessarily have to be in the realm of emotional reactivity—they can be body-focused and well out of the range of conscious control. R. Clark and Gochett (2006) demonstrated significant interactions between perceived racism and trait anger in predicting both systolic and diastolic blood pressures. Follow-up analyses indicated that perceived racism was marginally (nonsignificant at a $p < .10$) negatively associated with systolic blood pressure for individuals who were low in trait anger, such that for these individuals, increases in perceived racism were associated with decreases in

systolic blood pressure. The interaction was the same for diastolic blood pressure; for individuals low in trait anger, there was a negative, marginally significant (nonsignificant at a $p < .10$), correlation between perceived discrimination and diastolic blood pressure. Neither of these interactions were significant for individuals who were high in trait anger. These findings may suggest that adolescents who tend to be less angry show a physiological arousal pattern in response to discrimination. For adolescents with greater trait anger, however, such physiological arousal patterns were not documented. These findings are in keeping with a body of literature that suggests that some amount of dynamic physiological reactivity to salient stressors may be adaptive for individuals under duress. It may be that low trait anger therefore provides the adolescent more physiological room to adapt to the pressures of discrimination, though more research in this area is needed to truly unpack these emergent findings.

Fuller-Rowell, Evans, and Ong (2012) also looked at the associations between perceptions of discrimination and changes in blood pressure, this time among rural-poor U.S. adolescents. Among these youth, greater perceived discrimination was associated with higher levels of allostatic load, a combined variable created by the authors that included measurements of systolic and diastolic blood pressure, BMI, and overnight cortisol, epinephrine, and norepinephrine levels. Unlike the previous study, these findings pointed to a more long-term accrual of detrimental health effects of perceived discrimination itself. Additionally, the significant, positive correlation between poverty and allostatic load (higher levels of poverty were related to higher levels of allostatic load) was mediated by perceptions of discrimination; 13% of the effect of poverty on allostatic load was explained by perceived discrimination. Given the myriad findings linking poverty to poor health among children, these findings call on us to question how much of poverty's influence on physical health disadvantage among poor children may be attributed to perceived discrimination. Clearly, new research is warranted in this critical area.

Well-Being

We next turn our attention to the influence of discrimination and racism on children's well-being. Conceptualized differently from physical health, a child or adolescent's well-being can be understood as a range of different psychological factors including, but not limited to, self-esteem, feelings of self-worth, overall life satisfaction, stress levels,

and feelings of trust and confidence. Well-being factors such as these provide a foundation for leading healthy, happy lives, supporting children's longevity and promoting achievement in school and work domains. Unfortunately, perceived discrimination or racism can affect an individual's well-being by directly influencing any or all of these areas. Additionally, as other domains of development are influenced by perceived discrimination, overall well-being also tends to suffer.

Self-Esteem

Global self-esteem takes a drastic hit in the face of perceived discrimination—studies have shown that, when attempting to create an explanatory model conceptualizing the components of self-esteem, as much as 15% of the variance in personal self-esteem can be explained by both personal and group discrimination (Armenta & Hunt, 2009). The crippling blow that can be dealt to a child or adolescent's self-esteem via discrimination is crucial to consider in light of both general identity and ethnic identity development theories. It has been demonstrated repeatedly that the development of strong ethnic identity is essential for both adolescent and adult well-being; however, solid ethnic identity cannot be built on a shaky foundation of weakened self-esteem. Furthermore, while males tend to be at greater risk for many of the negative developmental consequences of racism and discrimination, females' self-esteem appears to be at the greatest risk in the face of perceived discrimination (Behnke, Plunkett, Sands, & Bámaca-Colbert, 2011; Umaña-Taylor & Updegraff, 2006). As perceptions of societal discrimination increase, global self-esteem tends to decrease (Behnke et al., 2011). Notably, for females this decrease is much more pronounced—it is steep, and occurs more rapidly than it does for males (Umaña-Taylor & Updegraff, 2006). However, while girls' self-esteem generally faces the most significant consequences in light of perceived discrimination, there are other factors that can exacerbate an otherwise negligible role of perceived discrimination on male self-esteem. Umaña-Taylor and Updegraff (2006) also discovered a significant three-way interaction between sex, acculturation, and discrimination in predicting self-esteem, such that, when boys reported low enculturation, there was a significant negative association between discrimination and self-esteem. For girls, the negative association existed for those who reported both high and low enculturation. Enculturation—or engagement with the culture-of-origin—can also be understood as strong cultural socialization at home. It appears that,

for both girls and boys who are more deeply socialized with their family's culture-of-origin at home, awareness of discrimination takes its toll on self-esteem. These findings point to an important role of ethnic identity in moderating the influence of discrimination on child and adolescent development, which we discuss in more depth below.

This negative relationship between self-esteem and perceived discrimination has also been shown to persist in countries outside the United States. In a study of Dutch and Surinamese adolescents in the Netherlands, Verkuyten and Thijs (2006) determined that, for both groups of individuals, "ethnic victimization" (e.g., ethnicity-based discrimination) was negatively related to ethnic self-esteem and also negatively related to global self-worth. In other words, increases in ethnic victimization were associated with decreases in both ethnic self-esteem and global self-worth. It is interesting to note, however, that ethnic self-esteem mediated the relationship between ethnic discrimination and feeling of global self-worth. Adolescents, both Dutch native and Surinamese, who reported higher levels of ethnic self-esteem tended to report less severe drops in global self-worth in the face of higher levels of ethnic discrimination. These findings suggest a buffering role of ethnic pride in the wake of perceived discrimination, which is crucial when considering the best routes to use to both support and protect the self-worth and self-esteem of children and adolescents worldwide. It has been well-established that these subjective senses of self diminish in the face of chronic discrimination regardless of immigration status or country of origin (Finland—Jasinskaja-Lahti & Liebkind, 2001; Greece—Motti-Stefanidi & Asendorpf, 2012; Netherlands—Verkuyten & Brug, 2002); however, if researchers are able to identify processes, such as ethnic self-esteem, that help protect these areas so often targeted by discriminatory events, this decline can potentially be slowed or prevented completely. Clearly, across numerous countries and ethnic regions, perceived discrimination is associated with lower levels of self-esteem or self-worth. Future studies using longitudinal designs will help document the extent to which perceived discrimination may detrimentally affect the self in childhood and adolescence, another area of cross-cultural research that is sorely needed.

Stress

Stress affects development in myriad ways. Through physiological mechanisms such as interrupted sleep and high cortisol, it can negatively influence physical health. Through interpersonal processes, it can exacerbate mental health problems. In the discrimination and racism literature,

"stress" itself can be directly attributed to discrimination—yielding its own form of daily stress that children and adolescents must learn to navigate. In using perceived discrimination stress to predict self-esteem levels over time, Edwards and Romero (2008) found that, in a sample of U.S. adolescents of Mexican descent, discrimination stress was moderately negatively associated with self-esteem. As youth reported more discrimination stress, their self-reported self-esteem levels also tended to decrease. Previously mentioned studies have linked the actual acts of discrimination with sharp decreases in self-esteem, particularly for female adolescents. Nevertheless, Edwards and Romero (2008) have established that it is not only the acts themselves that can be detrimental to the well-being and development of youth. The stress surrounding the expectation for discrimination, or in navigating the emotional path left in its wake, can play an equally damaging role. Stress is neither bound nor stagnant; it can freely move to influence other areas of emotional, mental, and physical well-being. Furthermore, while the stress of discrimination can elicit negative changes in child and adolescent well-being, others have shown that the perception of discrimination can lead to increases in other forms of stress (physical, behavioral, emotional; Szalacha, Erkut, García Coll, Alarcón, et al., 2003; Szalacha, Erkut, García Coll, Fields, et al., 2003). The study of perceived discrimination as a source of stress itself adds some robustness to the literature.

It is of paramount importance that we attempt to understand measurable, stress-related physical changes that can occur in the face of discrimination when considering that the effects of stress can have such a wide variety of negative influences on the developing mind and body. Stress can easily be measured via self-report, however. Zeiders, Doane, and Roosa (2012) were interested in determining the underlying physiological correlates of stress. In measuring salivary cortisol levels (a hormone that is often released in times of heightened stress) in Mexican American adolescents in response to perceived discrimination in their daily lives, the authors were able to ascertain that discrimination was significantly correlated with cortisol wakening response, such that increased perceptions of discrimination were associated with increased cortisol wakening responses (i.e., cortisol levels upon wakening). Zeiders et al. (2012) also determined that discrimination was associated with increased daily life stress, which was self-reported by participants. In these studies, children and adolescents were not simply reporting perceptions of discrimination, but also reporting on (or having directly measured) their stress reactions to perceived discrimination.

When aiming to determine the stress impact of discrimination, it is imperative to consider both the context in which the discriminatory acts have taken place (i.e., in school, at home, in the neighborhood) and the status of the perpetrator (i.e., peer, friend, teacher). Aroian (2012) was interested in revealing the themes underlying discrimination's influence on Muslim American adolescents in the United States. Several focus groups were conducted with adolescent males and females who self-identified as Muslim or Muslim American. Contrary to expectations, the most potent perpetrators of discriminatory acts were not always class peers. These students reported that teachers were salient perpetrators of discrimination; coming from an adult in a position of power in these adolescents' lives, it is understandable why adolescents would find such discrimination to be particularly disturbing. Albertini (2004) also examined correlates of racial mistrust among immigrant minority 10- to 12-year-old children and found that between 35% and 50% reported perceptions of racial mistrust toward both their White teachers and Whites in general. These perceptions measured at moderate-to-high levels, with clear implications for negatively influencing early adolescents' well-being.

Ethnic and Racial Identification

In light of the aforementioned findings suggesting that individuals who face discrimination tend to seek support and refuge in stronger ethnic or racial identifications (Brittian et al., 2013), Galliher, Jones, and Dahl (2011) found moderation effects of ethnic identification on the association between perceived discrimination and self-esteem. Aligning with many of the previous studies showing that perceived discrimination is negatively associated with self-esteem, Galliher et al. (2011) found yet more evidence of this persistent relationship—males who reported higher discrimination also tended to report lower self-esteem. However, an interesting interaction was also found between perceived discrimination and the Native Americans' scores on the Orthogonal Cultural Identification scale, which was used to measure participant identification with multiple cultures, with respect to effects on self-esteem. When males reported a low Native American identification, there was a weak relationship between perceived discrimination and self-esteem; however, for males with a high identification, this relationship was not significant. A similar relationship was seen for Navajo girls; those who reported more affirmation and belonging to their Navajo identity tended to display a weaker association between perceptions of discrimination and self-esteem than girls who

reported less affirmation and belonging to their Navajo identity. For males at the lowest levels of Native American identification, a negative relationship was observed between perceived discrimination and social functioning over time: Higher perceived discrimination co-occurred with poorer social functioning. Yet, at the highest levels of Native American identification, a positive relationship was seen between perceptions of discrimination and social functioning over time, indicating a protective role of ethnic identity for buffering the negative social ramifications of discrimination. Additionally, a strong, positive relationship was seen between perceptions of discrimination and substance use frequency among participants who had a high White American identification, but the relationship was not significant among individuals who had a low White American identification. Perhaps most interestingly, for girls, identification moderated the relationship between perceived discrimination and self-esteem differently. A high level of White American identification was associated with a positive relationship between discrimination experiences and self-esteem, but for individuals with a low level of White American identification, the relationship was inverted. This study thus highlights the important role ethnic identity plays not only in buffering detrimental effects of discrimination on social functioning, but also highlights the importance of context and gender identities in these relationships.

Socioemotional Outcomes

At present, there is a strong literature supporting the assertion that perceptions of discrimination can greatly influence socioemotional functioning. Like most other developmental outcomes influenced by discrimination, socioemotional functioning can be immediately influenced by discriminatory events, or it can be affected over time. Gibbons and colleagues (2012) discovered that increased perceptions of discrimination were significantly, negatively associated with decreases in the socioemotional area of self-control, and positively associated with increases in substance use over time. The results of a directional model indicated that early discrimination was associated with low self-control by the ages of 10 or 11, and that changes in discrimination were thereafter associated with corresponding changes in self-control. Further analyses also indicated that discrimination had significant paths promoting higher levels of anger and substance use, and a direct negative path to self-control. There was also an indirect effect of discrimination on substance use through both self-control

and anger during a single time point in the study. Similar longitudinal effects have been observed in other cultural samples as well. For example, in looking at the effects of perceived discrimination on self-esteem among Turkish and Moroccan minority adolescents living in the Netherlands, Verkuyten (1998) found that, as levels of reported personal discrimination increased, there were subsequent decreases in social competence and personal self-esteem reported. Such longitudinal studies add fascinating and compelling evidence about the potency of discrimination's many causal, negative effects on socioemotional development.

Prosocial Behavior

With respect to socioemotional development, there are two particular subthemes of note in discrimination research. The first of these themes centers on findings related to prosocial behavior, or the propensity for children and adolescents to act in socially beneficial, collaborative, or altruistic ways. This area of development is one that suffers greatly under the effects of discrimination. For example, Brittan and colleagues (2013) found that in the face of discrimination, individuals' prosocial behaviors declined greatly. Compliance ("When people ask me to help, I don't hesitate"), Emotional ("Emotional situations make me want to help others who are in need"), and Altruistic ("I feel that if I help someone, they should help me in the future") prosocial behaviors decreased over time in association with increases in perceived discrimination. Interestingly, there was also a positive correlation between perceived discrimination and public prosocial behavior ("I can help others best when people are watching me"), indicating that more perceived discrimination was associated with higher endorsement of this prosocial attribute. Individuals who reported more perceived discrimination tended, over time, to find these prosocial behaviors less like them, but also tended to increase public displays of prosocial behavior (Brittan et al., 2013). One way to interpret these results is to suggest that, as children and adolescents face sustained or increased levels of discrimination over time, they tend to (consciously or unconsciously) engage less in these prosocial behaviors in reaction to the chronic negativity that they consistently perceive. However, increases in overt, public displays of prosocial behaviors along with increased levels of discrimination over time could suggest a need for positive recognition in the face of such negativity. Grossman and Liang (2008) found similar results in a study demonstrating that discrimination distress was significantly and negatively associated with cooperation,

while Romero and Roberts (1998) found that perceived discrimination was significantly associated with attitudes toward others, such that increases in perceived discrimination were associated with decreases in overall positive attitudes toward others. Taken together, this collection of studies points to the detrimental effects of discrimination on children and adolescents' willingness to cooperate with, attend to, and engage in prosocial behaviors in their communities. The full implications of this pattern of findings has yet to be established. Whether such loss of prosocial behavior translates into further marginalized identity or hostility toward others is largely left to be documented in future studies.

Coping Strategies

Another theme in the socioemotional literature centers on the types of coping strategies individuals use in response to perceived discrimination. Coping strategies can often determine the qualities and successes of the socioemotional outcomes of the challenging event that the child or adolescent needs to cope with (Scott, 2003a). While there is no single best coping strategy, it is important to recognize that two individuals may respond to the same discriminatory event in vastly different ways—and therefore "cope" with the event differently. Scott (2003a) showed that some African American adolescents are more likely to report seeking social support as a coping strategy in the wake of discrimination, whereas others are more likely to use self-reliance and/or problem-solving strategies when faced with perceptions of discrimination. Scott (2003b) also uncovered a moderate correlation between perceptions of discrimination and externalizing coping strategies, indicating that, as perceived discrimination increased, so did externalizing coping strategies. In general, research supports the notion that coping strategies that involve social support-seeking and problem-solving promote healthier recoveries from psychological threat than more avoidant or emotion-focused strategies (Levesque, 2011). Further analyses by Scott (2003b) showed that participants who experienced high levels of racial socialization reported marginally higher support-seeking coping strategies and significantly greater use of self-reliance or problem-solving coping strategies to deal with the effects of perceived discrimination as compared to participants who reported lower levels of racial socialization. These findings seem to indicate that the process of racial socialization can help individuals learn to cope in more effective ways (and learn self-reliance and problem-solving skills) when faced with discriminatory events.

Academic Achievement Outcomes

Numerous studies have demonstrated the significant negative associations among perceived discrimination and academic outcomes including GPA, academic motivation, academic goals, and perceived academic efficacy (Alfaro, Umaña-Taylor, Gonzales-Backen, Bámaca, & Zeiders, 2009; Smalls, White, Chavous, & Sellers, 2007; Tabbah, Miranda, & Wheaton, 2012; Wong et al., 2003). These effects hold true both for males and females, but as previously mentioned, males are generally at greater risk for more negative outcomes in most developmental domains. Smalls et al. (2007) found that racial discrimination was a predictor of lower academic persistence, and more frequent negative school behaviors. The academic achievement domain seems to be particularly sensitive to the effects of discrimination—not necessarily because the effects of discrimination are more detrimental in this developmental domain (although the school has been cited as the most common site for experiencing any form of discrimination; Yeh et al., 2003) as compared to any other. Rather, the spread, reach, and sheer pervasiveness of, for example, decreased academic persistence is tremendous. For instance, racial discrimination has been found to be only marginally predictive of lower levels of academic curiosity (Smalls et al., 2007). While this particular variable only reached marginal significance (nonsignificant at a $p < .06$), it is important to consider the rather serious implications of this association. Conceptualized as a precursor of academic persistence, academic curiosity is often the spark that encourages children and adolescents to be passionate about school and learning, and the fuel that drives their desire to seek out higher education later on in life.

The results of school-based peer discrimination can make themselves immediately apparent in the classroom; however, it is crucial to recognize that peers are not the only perpetrators of school-based discrimination, and that the results of discrimination often extend far beyond the walls of the classroom. In studying the self-concept of Arab American adolescents, Tabbah et al. (2012) revealed that 50.8% of the students reported either experiencing or knowing of some form of discrimination. Discrimination was associated with decreases in scholastic competence and decreases in classmate support. Discrimination also predicted scholastic competence (Tabbah et al., 2012), which further supports the case that school-based discrimination can play a drastic role in the academic achievement outcomes of children and youth in its wake.

Teacher Discrimination

Teachers and other students can both play equally contributory roles in perpetuating and perpetrating discrimination in the classroom, although some students report feeling more helpless in the face of teacher discrimination as compared to peer discrimination (Aroian, 2012; Thomas, Caldwell, Faison, & Jackson, 2009). Teacher discrimination can also influence the subjective sense of how well students feel that they are doing in school, regardless of their actual calculated grades. Some students, in the face of discrimination from their teachers, have reported that they are doing more poorly in school (whether or not that is actually the case) than those students who do not report teacher discrimination (Thomas et al., 2009). Aroian (2012) found that Muslim youth often cope with the discrimination they face from both teachers and peers by doing nothing, both out of fear of retribution and thoughts of futility. The youth felt that they had “no options” regarding responses to the discriminatory acts against them. These themes are particularly salient when considering that it is likely much more difficult to respond to teacher-perpetrated discrimination than to peer-perpetrated discrimination. In a similar qualitative analysis, Baker, Varma, and Tanaka (2009) uncovered analogous themes in reports by Canadian youths of frequent racism perpetrated by individuals in positions of power, with name-calling and threats/actual physical violence being the most common forms of racism experienced.

Berkel and colleagues (2009) reported that African American adolescent males in particular felt it was more difficult for them to succeed academically because of the negative, discriminatory messages received from and attitudes held by many of their teachers in school. They felt they were treated as both less capable and less intelligent than their White peers. The youth felt that they were quickly written off and rarely called on in class because their teachers assumed that they would not be able to answer their questions. Further discussion revealed that mothers played a significant role in socializing their children against discriminatory events both within and outside of school, particularly regarding African American adolescent males’ school achievement, which is essential information when considering ways in which the effects of discrimination within the school context can be attenuated. In their study of perceived discrimination against children of Mexican immigrants at school, Stone and Han (2005) highlighted the influence that teacher discrimination can

have on students' future educational attainment and academic drive. They also uncovered a significant difference between males and females in their expectations of discrimination. Females were 35% less likely to report that they expected discrimination in the future, despite educational attainments comparable to those of males, suggesting that females felt more confident that succeeding educationally would help mitigate future discrimination. Considering the earlier-discussed relations between students' perceptions of discrimination and academic curiosity, subjective feelings of success, and academic drive, these findings paint a rather stark picture for the future educational attainments of male students, in particular. If some male students are more likely to report that they expect discrimination in the future, despite their educational attainment, there is then less incentive to strive for higher education—the same prejudice will have to be faced no matter how successful or unsuccessful they are in the academic realm. Female students, however, may perceive that discrimination toward them is dependent upon the level of education they achieve, so striving for higher education could potentially lessen perceptions of discrimination in the future.

School quality and school interracial harmony can both play roles in the perception of discrimination (Stone & Han, 2005). As reported by Stone and Han (2005), individuals who perceived poor school quality are more likely to report experiencing discrimination by teachers than individuals who perceived better school quality—alluding to the possibility that the physical school context can play a role in both the act of and perception of discrimination. As further reported by Stone and Han (2005), individuals who perceived school interracial harmony were less likely to expect future discrimination, despite educational attainment, than individuals who perceived no school interracial harmony. In each of these cases, the physical and metaphysical school environment(s) played a direct role in both the immediate perception and future expectation of discrimination.

Finally, Stone and Han (2005) were able to demonstrate that both students' length of stay in the United States and self-esteem levels played a role in their expectations and perceptions of discrimination by teachers. Participants who had been in the United States for between 5 and 9 years were 54% less likely to experience discrimination by teachers than individuals who had been in the United States for less time. Individuals who reported higher self-esteem during the onset of the study were 66% more likely to report experiencing discrimination by teachers in the second wave

of the study as compared to individuals who reported lower levels of self-esteem. Interestingly, Stone and Han (2005) also showed that students who reported that they did not prefer "the American way" of life (i.e., the American way of living) were 39% more likely to report that they expected discrimination in the future, despite educational attainment similar to that of individuals who reported preferring "the American way."

In addition to determining the perpetrator of the discrimination, ascertaining the context in which the discriminatory act has taken place is crucial to understanding the actual consequences of the event. Brown and Chu (2012) found that, for children at predominantly White and moderately diverse schools, increased perceptions of teacher discrimination explained more negative academic attitudes. It was further shown that ethnic identity moderated this relationship, such that the negative relationship between perceptions of teacher discrimination and academic attitudes at predominantly White and moderately diverse schools was only significant for children who had less positive ethnic identities. The type of school (public, religious, or private institution) can also influence students' perceptions of school-based discrimination. In one study of African American adolescents in public schools, perceptions of discrimination were significantly associated with school importance, such that increases in perceived discrimination were associated with decreases in school importance. For African American adolescents in Catholic schools, perceptions of discrimination were associated with self-concept of ability, grades, and school engagement, such that increases in perceptions of discrimination were associated with decreases in self-concept of ability and a significant increase in school engagement. Finally, for White adolescents in Catholic schools, perceptions of discrimination were associated with school engagement, such that increases in perceptions of discrimination were associated with decreases in school engagement (Taylor, Casten, Flickinger, Roberts, & Fulmore, 1994).

Peer Discrimination

The negative relationship between perceptions of peer discrimination and academic attitudes can be moderated by both school composition and ethnic identity (Brown & Chu, 2012). For children who attended moderately diverse schools and had a less positive ethnic identity, peer discrimination was significantly and negatively associated with poorer academic attitudes. It is important to note that perceptions of peer discrimination were associated

with less school belonging for everyone at every type of school, except that children at predominantly Latino schools reported very positive ethnic identities.

Finally, the findings by Brown and Chu (2012) indicated that children who reported less perception of community discrimination also tended to report greater feelings of school belonging than children who reported more community discrimination. There was, however, a negative association between teacher discrimination and school belonging that was also moderated by both ethnic identity and school belonging. For children who attended predominantly White and moderately diverse schools, perceptions of teacher discrimination were significantly and negatively associated with school belonging, but only for children who reported less positive ethnic identities.

Classroom Discrimination

In their study of the influences of school racial discrimination and racial identity on academic engagement outcomes among African American adolescents, Chavous, Rivas-Drake, Smalls, Griffin, and Cogburn (2008) showed that peer and classroom discrimination could have very different outcomes, even for the same individuals. Among girls, classroom discrimination and peer discrimination at Age 13 were both negatively related to academic importance, such that increases in classroom and peer discrimination were associated with decreases in academic importance. Classroom discrimination at Age 17 was related to decreases in GPA, academic importance, and academic self-concept while peer discrimination was significantly related to decreases in academic importance and academic self-concept at Age 17. For boys, however, classroom discrimination at Age 13 was negatively correlated with all academic outcomes: GPA, academic importance, and academic self-concept. More peer discrimination at 13 was also associated with lower academic importance attitudes for boys at Age 17. Additionally, 17-year-old boys' classroom discrimination was negatively related to both academic importance and self-concept, and peer discrimination at Age 17 was strongly and negatively related to school importance.

The Role of Cultural Values

Berkel et al. (2010) uncovered several more academic correlates of perceived discrimination. There was a relation between perceived discrimination and academic self-efficacy and grades, such that increased perceptions of discrimination were related to decreased feelings of academic self-efficacy, as well as lower grades. Contrary

to the authors' hypothesis that Mexican American values would serve as a protective factor (i.e., moderating the relation between discrimination and negative mental health and academic outcomes), Mexican American values were not found to moderate the relation. However, support was found for the authors' second hypothesis that Mexican American values would serve as a risk reducer (i.e., mediating the relation between discrimination and negative mental health and/or academic outcomes). Mexican American values mediated the relation between discrimination and adolescent outcomes. Discrimination, mental health, and academic outcomes were all also associated with increases in Mexican American values. Mexican American values in turn were predictive of improvements in internalizing and externalizing symptoms and academic self-efficacy.

Indirect Effects of Perceived Discrimination

Perceived discrimination can have both direct and indirect consequences on academic achievement. Indeed, often when researchers ascertain that there are no direct effects of discrimination on academic achievement, they look for secondary, or indirect effects, and this leads to significant findings. Benner and Graham (2011) found that, although there were no direct effects of discrimination on academic outcomes in their study, there were indirect effects of discrimination on academic outcome through both school climate, and the number of total absences reported by participants. Results also indicated that change in discrimination over time was associated with students' perceptions of their own school climate—higher levels of perceived discrimination were associated with lower perceptions of school climate. In turn, school climate was predictive of students' GPA and total absences. This is just one example of the complex web that can be woven both by and through discrimination: Even when there appears to be no direct influence of discrimination on academic outcomes (or any other realm of development) there can be several less apparent, or less readily measurable outcomes that are secondary and even tertiary effects of increased levels of perceived discrimination.

Engagement, Alienation, and Goals

Higher levels of perceived discrimination can also be predictive of greater feelings of alienation, lower levels of classroom engagement, and poor grades over time (Benner & Kim, 2009). Kiang, Supple, Stein, and Gonzales (2011) found similar associations between discrimination and academic outcomes; discrimination was significantly

negatively associated with education goals, educational expectations, school centrality, and school connectedness, such that increases in discrimination were associated with decreases in educational goals and expectations, school centrality, and school connectedness.

“Defense” Mechanisms

Although few would argue that perceiving discrimination is a positive experience for the victims of these actions, several researchers have found correlations between perceived discrimination and purported protective factors. Seaton (2009) demonstrated that, in a sample of African American adolescents, although individual and cultural racism were both associated with a host of negative outcomes (see Seaton, 2009), each was also significantly associated with race centrality. Increases in individual and cultural racism were both associated with increases in race centrality. This relation was also observed by Stevenson and Arrington (2009), who found that the racism experience was associated with increases not only in race centrality, but in private regard, nationalism, cultural pride, legacy, and racial/ethnic socialization. It is important to note that most of these correlations were moderate-to-strong in strength. These connections may suggest that, as youth perceive more discrimination, they tend to assimilate the source of this discrimination (i.e., their racial/ethnic identity) as part of their own self-concept as a sort of defense mechanism (Seaton, 2009; Stevenson & Arrington, 2009; Stevenson, McNeil, Herrero-Taylor, & Davis, 2005). As suggested by the literature stressing the important impact of a healthy, positive ethnic identity on both educational and social development (e.g., Phinney et al., 1997), increased perceptions of discrimination may serve to accelerate the development of a positive ethnic identity because, when this self is challenged, it may then become a more centralized part of one's ethnicity relative to other parts of one's identity (Phinney, 1990; Yip et al., 2006).

In addition to the aforementioned relations between perceived discrimination and protective factors, Stevenson et al. (2005) demonstrated that individuals who were more alert to racism and aware of its presence in their everyday lives also tended to have stronger coping skills and strategies, stronger ethnic/racial pride, and a more salient cultural legacy.
