and identify the most efficient way to locate them (e.g., school, pediatrician's office). At times, parents may have the belief that an uninformed, fresh start is better for the evaluation process, as they may fear that the records are going to bias the clinician's point of view (Baron, 2003). Rather than an obstacle, this common situation offers an opportunity to address the issue of individualization of the assessment process, and the importance of obtaining as much information as possible about the child's developmental background. After all, an assessment is conducted cross-sectionally rather than longitudinally; thus, the clinician's perception of the child's situation is biased by the most current presentation of the behaviors in question, and a more diverse range

of information facilitates a better understanding of the child's behavior. Taking the time to have this discussion will most certainly assist the subsequent steps in the evaluation process.

## Review of Records and Background Information

The review of any obtainable record is oftentimes a continuous process rather than a step in isolation, as the data may not be readily available to the clinician. Access to these records varies significantly between settings. For instance, a school psychologist may have an easy time locating a child's educational history, while finding it difficult to obtain medical records. In contrast, a psychologist in an inpatient medical unit may have easier access to such records but lacks access to school information. On occasion, the referral source sends valuable records to the psychologists in order to facilitate the intake process (e.g., copies of their own reports or notes). More often, parents provide clinicians with copies

of previous reports, hospital and school records, and other supplementary information that aids the clinician's understanding of the case. In most instances, records are obtained upon guardian's authorization and via direct request to the original sources (e.g., school, pediatrician's office) as deemed necessary during intake and clinical interviews. In any psychological assessment, records play a crucial role in providing clinicians with information about the history, environment, and behaviors, not only about the child but also about his or her family and their dynamics. Records provide clinicians with a documented, multi-setting, and hopefully, multidimensional registry of variables that must be taken into account during the assessment process. Some of these variables include socio-economic conditions, familial mental health history, educational background and academic achievements, developmental milestones, child's strengths and weaknesses, physical health, relevant medical preconditions, interventions, and cultural background. Table 18.1

**Table 18.1 List of Relevant Background Documents and Information to Review**

Medical records	Birth history and developmental charts. Relevant pediatrician records. Recent or relevant hospitalization records. Medical treatment records.
School records	Academic achievement (e.g., marks and progress notes, awards, areas of strength and weaknesses). Teacher notes (special attention to records of early adjustment, changes in achievement, classroom conduct). Special education records (e.g., special education classification, services and placements, records of accommodations). School evaluations (history of behavioral problems in school, school activity/service participation).
Psychiatric records	Psychiatric evaluations (emphasis on consultation, onset and progression of symptoms, diagnosis and clinical recommendations). Medication intake records.
Psychological records	Reports from previous evaluations (diagnosis, areas assessed, instruments used, findings, observations, and any information that would allow identification of clinical change, symptom progression, relapse or remission). School psychologist or counselor records (as presented above, with special emphasis in history of learning and/or behavioral problems in school). Previous neuropsychological evaluations (as above, plus emphasis on history of head trauma, neurodevelopmental, inherited or congenital disorders, exposure to neurotoxins, neurosurgical evaluations, and notes on neuroimaging records and findings). Reports from psychological interventions (individual or group psychotherapy or neurorehabilitation).
Legal reports (if applicable)	Documented family legal issues involving the case (e.g., child custody, child abuse, social worker reports, foster care). Criminal records or charges (e.g., adolescent cases).

includes examples of relevant records to collect. This information can serve as a guideline during the clinical interview process and for the design of the assessment itself.

Obtaining these records is only the initial part of the process. A skillful review of them requires training and practice. Having clarity about the relevant information one is looking for facilitates the process. At times, clinicians find themselves flooded with amassed pieces of information that may not be meaningful or pertinent to the assessment at hand; thus, there is skill in sorting them. When available, the records of any previous psychological or psychiatric assessments are highly desirable. Depending on the age of the child, educational records may be abundant, and some isolated pieces of information on them may be highly relevant to the case (e.g., marks, a teacher's note); or, in contrast, distracting to the assessment goals as they may lead to faulty interpretations. For example, a grade teacher may use descriptors, adjectives, or make rich comments about a child's performance and behavior based on isolated situations; or perhaps some of those notes tend to be similar to those made about most peers in the same class. Due to the multitude of possibilities, looking for patterns of behavior, consistent observations across raters and settings, and placing some emphasis on objective variables (e.g., composite scores or averages), becomes crucial during the review of records. At the same time, looking for salient and unique observations that may contribute to our understanding of the child's current behavior or situation is equally relevant. Thus, reviewing records is a very dynamic and ongoing process; a clinician may have to revisit them at different stages during the assessment process.

When reviewing these historical records, two approaches could be used: an exploratory or a guided approach. An *exploratory approach* includes a thorough review of all the materials collected, allowing the data to "speak" about possible patterns of behaviors, forgotten or potentially withheld information, and consistent observations. In this approach, there is no preconceived idea about the kind of information the clinician may find; it is simply an exploration. In contrast, a *guided approach* includes a search for a specific behavioral pattern, pieces of information or answers to *a priori* questions, and it is mostly confirmatory. Both approaches are complementary rather than exclusive, and some assessment protocols may require both or only one of them. An exploratory approach may facilitate an unbiased comprehension of a case in which there

is not a clear consulting question (e.g., inconsistent concerns about the child's performance at school). A guided approach may be useful when the case is presented with a specific referral question: for instance, does this child classify for a diagnosis of learning disability? In synthesis, understanding the referral question at intake facilitates the subsequent review process.

## History Taking and the Clinical Interview

One of the most important milestones in the assessment process is the completion of the clinical interview (McConaughy, 2005; Strauss, Sherman, & Spreen, 2006). Groth-Marnat (2009) stated that the interview is perhaps "the single most important means of data collection during psychological evaluation" (p. 65). Sattler (2008) includes clinical interviews as one of the core pillars of any psychological assessment, stating that "results of an assessment may be meaningless or inconclusive if you examine the child without interviewing those who play an important role in his or her life" (p. 6). Designed to complement our information about the case, the clinical interview is perhaps the most relevant scenario to establish rapport and obtain detailed information about the developmental history of the child and his or her family. As presented by Merrell (2008), "[i]n contrast to other methods of assessment that may be used for the same purposes, clinical interviewing is unique in its emphasis on direct face-to-face contact and interpersonal communication between the clinician and the client" (p. 133). During clinical interviews, there is a shared amount of verbal and nonverbal communication that becomes crucial in understanding the child's situation and for the child and his or her family to understand the clinician's evaluation methods and goals. The clinician usually controls this flow of communication as he or she plays the role of the interviewer. Therefore, interviewing is a highly demanding clinical skill, requiring training and experience, and further, it can potentially facilitate or impede the ease of the assessment process. The quality of the interviewer has an impact on the reliability of the background information recalled during the history taking process. A clinician's verbal and nonverbal communication during the interview process can signal personal biases, judgements, cultural differences, and other variables that may lead the clients to somewhat distort their valuable information.

Merrell (2008) pointed out several advantages of clinical interviewing as an assessment method: (a) it

provides a great deal of flexibility that is lacking in other assessment methods; (b) it provides a structured context for behavioral observations during a social interaction; and (c) as it serves a medium for the establishment of rapport and trust, clinical interviews facilitate the bridge between assessment and intervention. One of the limitations of clinical assessment interviews, and perhaps the most worrisome of all, is its own vulnerability to an unreliable and inconsistent collection of data. Ironically, this particular disadvantage of this assessment method is derived from its flexible nature (McConaughy, 2005; Merrell, 2008). To compensate for this significant pitfall, obtaining data from several sources in addition to the interview becomes a crucial step in any assessment process; it is, in fact, the defining characteristic of the multi-method assessment approach. This method includes direct behavioral observations; rating scales from parents, teachers, and other relevant caregivers; self-reports; psychological tests; and other strategies deemed appropriate to the specifics of the evaluation. Examples of commercialized multi-method assessment approaches for child psychological assessment include the Behavioral Assessment System for Children–Second Edition (BASC-2; Reynolds & Kamphaus, 2004) and the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach, 1986, 2001; Achenbach & Rescorla, 2000, 2001; McConaughy & Achenbach, 2001). Chapter 26 in this handbook provides more information on the combined utility of behavioral observations and rating scales. Furthermore, if the appropriate written consent forms have been received from the parents or guardians, interviewing teachers and consulting with other professionals involved in the case can serve as a valuable source of additional information.

Due to the relevance and sensitivity of clinical interviews, it does not come as a surprise that psychologists have classified them as the most used assessment method. A survey conducted on 412 active clinical psychologists demonstrated that 83 percent of them classified clinical interviewing as the assessment procedure they “always” used in their clinical practice. In the same study, “clinical interview” was ranked from 1 to 4 (out of 37 options) as the most frequently assessment method used across settings (e.g., private, university, medical; Watkins, Campbell, Nieberding, & Hallmark, 1995). Another study surveyed 162 child and adolescent psychologists across the United States, and in a range of settings, including private practice, hospitals and outpatient clinics, and schools,

clinical interviewing was ranked as the number-one social-emotional assessment procedure, used by 71 percent of the sample, followed by behavioral observations (ranked number two) used by 51.9 percent of their sample (Cashel, 2002). An earlier survey among the clinical psychology internships demonstrated that 53 percent of the training facilities with a pediatric emphasis have included child assessment interviews as a regular topic in their didactic seminars (Elbert & Holden, 1987).

### ***Clinical Assessment Interview Methods***

While there are shared commonalities among clinical interviewing methods in several contexts, clinical interviews in a multi-method assessment process significantly differ from those conducted under an intervention process (e.g., psychotherapy, counseling), and from those performed in some research and survey studies. As pointed out by McConaughy (2005), “[a] major goal of clinical assessment interviews is to obtain information” (p. 4), which explains why clinical interviews are often discussed in the context of history taking. For this reason, when conducting clinical assessment interviews, clinicians oftentimes resort to structured or semi-structured interviewing protocols to elicit the discussion of relevant pieces of information, to facilitate the cohesion and progression of the interview, and to make the process more efficient and effective. In some assessment situations, a skilled clinician may feel more comfortable using an unstructured, open-ended type of interview; however, their level of experience is not the main variable to consider when making the choice between interviewing formats. Several variables play an important role in this decision, such as the context of the interview (e.g., as part of a behavioral assessment versus neuropsychological assessment), intended aim (e.g., as a diagnostic tool versus historical background), and clinician’s theoretical orientation (e.g., psychodynamic versus cognitive; Merrell, 2008). A discussion of unstructured, semi-structured, and structured methods follows.

#### **UNSTRUCTURED INTERVIEWS**

*Flexibility* is perhaps the most descriptive characteristic of this type of clinical interview. As the name implies, “unstructured” interviews are defined in terms of their open-ended, conversational format in which there is more demand put on the role of the interviewer as the director of the communicative flow, due to the lack of a preconceived structure. Analogous to a dance performed by a

skillful ballerina, the art of the unstructured clinical interviewing arises in how effortlessly the clinician facilitates the communication between the parties involved. Moreover, this effortlessness also reflects how well the child and his or her caregivers' make use of the opportunity to express their thoughts, feelings, fears, and needs concerning the issues that brought them to the assessment, while divulging the relevant historical background and other diagnostic information.

There is no gold standard for the administration of an unstructured interview, and the format varies across different theoretical orientations. Some clinicians use the unstructured format to frame the interview while nevertheless maintaining full control over the questions that will be asked of the client. This control is exerted by moderating shifts in the direction of the interview, signaling and changing the flow at times, and deciding what could be considered a satisfying response or not. Others may consider this format too invasive, and furthermore, that it could leave the client unguided in expressing themselves without cues. A skillful clinician may be able to engage the child in either play (e.g., in the case of younger children) or conversation (e.g., in the case of teens and adolescents), allowing them to express themselves without an intrusive layout of questions. Because of the nature of this type of interview, the clinician must feel comfortable with letting the patient take charge, while making careful notes of a range of observations regarding symptoms (e.g., anxiety, inattention, speech problems, slowness of movement), emotions, and behaviors, in addition to recording the appropriate background information provided in their discourse (Greenspan & Greenspan, 2003).

It is worth noting that "unstructured" does not equal "aimless." An experienced clinician uses this conversation-like environment to facilitate gathering of the most valuable assessment information. Although it is recognized that one of the main benefits from this method is, ultimately, the facilitation of rapport with the client, there has been a growing concern among clinicians about the degree of reliability of the information gathered during this kind of interview (Kamphaus & Frick, 2002). This reliability issue can be aggravated by the clinician's personal biases and values, the client's perception of the clinician's assessment goals, the nature of the assessment situation, and the potential associated outcomes. Furthermore, the clinician's orientation has been identified as an important source of bias, having an impact on the clinician's perception of the case

and their clinical judgement, particularly in the case of junior clinicians (Houts, 1984). Research-based interviewing can be especially susceptible to these reliability limitations. Dougherty, Ebert, and Callender (1986) found that when interviewers are trained in specific strategies, intra-rater consistency rates decrease, but inter-rater reliability scores rise. Increasingly, research has demonstrated that adding structure to an interview format increases its validity and reliability indexes (Groth-Marnat, 2009). These consistent findings originated the development of a series of structured and semi-structured interview protocols, to aid not only clinical assessment in the context of research but also as a component of any multi-method assessment in the general psychology practice. Chapter 3 in this handbook offers a complete review of the measurement issues frequently observed in child assessment.

### SEMI-STRUCTURED CLINICAL INTERVIEWS

As a general practice, established clinicians often times create or adapt their own assessment interviewing protocols following a semi-structured format. As the name entitles, a "*semi-structured*" clinical interview is somewhat flexible, yet it is also fairly contained within a set of questions that prompt dialogue and face-to-face interactions between the clinician and the child. Semi-structured interviews are often used to gather general information about the child and to obtain an overall appraisal of his or her current psychological and adaptive functioning. Due to their flexibility, they are easily adapted to different assessment needs, theoretical orientations, clinicians' styles, and settings. For these reasons, they are often referred to as "traditional" interview methods.

Different referral questions may prompt the clinician to make changes in a semi-structured interview protocol, making it relevant to emphasize some areas over others. For instance, a child who is brought to an assessment due to school adjustment issues may require extensive collection of information about his or her peer relationships, educational experiences, areas of academic strength and weakness, quality of relationship and interactions with teachers and school personnel, separation anxiety symptoms, and history of abuse. In contrast, a child who has been brought in to a consultation due to cognitive deficits following a traumatic brain injury would require a fairly different set of questions. Merrell (2008) recommends targeting at least five areas during an interview with children: (1) intrapersonal functioning, (2) family relationships, (3)

peer relationships, (4) school adjustment, and (5) community involvement. Table 18.2 illustrates a few examples of the types of questions that can be used to gather information around those five areas.

There are relatively few valid and reliable semi-structured interviews available for pediatric

clinical assessment. In this regard, the Semi-structured Clinical Interview for Children and Adolescents (SCICA; McConaughy & Achenbach, 1994) was made available earlier in the literature (e.g., Verhulst, 1995), and recently, it was formally introduced as a component of the ASEBA system. Examples of

**Table 18.2 Typical Areas of Questioning Included in a Nonstandardized Semi-Structured Clinical Interview with a Child**

Area of Questioning	Specific Issues to Address
Intrapersonal functioning	<p><i>Feelings and emotions</i></p> <p>How does the child feel about him/herself? What kind of emotions are he/she expressing? How does the child feel about the issues that brought him/her to the consultation? Have there been any significant change/trauma/loss in this child's life?</p> <p><i>Activities and well-being</i></p> <p>How is a regular day for this child? Does he/she have any particular hobbies, interests, or activities? How independent and well-adjusted is the child? Is there any concern about his/her sleep hygiene/habits?</p> <p><i>Development and mental health functioning</i></p> <p>Is there any concern about this child's development? Is there report of any unusual experience?—including hearing or seeing things. Does the child seem oriented?</p>
Family Relationships	<p>Who are the members of this child's family? How are the relationships among them? Does the child get along with brothers and sisters? What is the child's role in this family? Does he/she have chores and responsibilities? Who lives in the house with the child? Is this child's family supportive of his/her needs? How is discipline implemented? Is there any concern about abuse or danger to the child?</p>
Peer Relationships	<p>How many close friends does the child have? Can he/she name them? In what kind of activities are they usually engaged? How easy does he/she make new friends? How easily does he/she cope with losing a friendship? Does the child feel like an outcast, an outsider? Is he/she a member of a social clique, club, band, team, or gang? Is he/she being victimized or bullied by peers?</p>
School Adjustment	<p>Does the child like school? Learning and studying? What are this child's academic strengths and weaknesses? Does the child go to school regularly? Is he/she home-schooled? How are his/her relationships with teachers? Is there a favorite? One he/she dislikes? Is he/she enrolled in extracurricular activities or school clubs? Has he/she been in trouble at school?</p>
Community Involvement	<p>Is the child part of a community group or activity (e.g., church, youth clubs, and sport teams)? Is he/she working part-time? Does he/she volunteer in any community services? Does he/she have friends not associated with his/her school? Are there concerns or complaints about this child's behavior in the neighborhood?</p>

items included in the SCICA and some applied case examples are further described by McConaughy (2005). This instrument was designed for use with children and adolescents aged six to 18, and comprises two sections. During the first section, the clinician conducts a semi-structured interview using open-ended questions from a list of six areas: activities and interests, school and homework, friendship and relations, home situation and family relations, self-awareness and feelings, and adolescent issues. The second section includes the scoring of two forms, a child's self-report form (125 items) and an interviewer observations form (120 items) to rate the child's behavior during the interview using a four-point Likert scale. The ratings are further scored into a standardized system that yields profile information on five syndrome or behavioral scales: Anxious, Withdrawn/Depressed, Language/Motor Problems, Attention Problems, and Self-Control Problems; three more scales are derived from the child's self-report: Anxious/Depressed, Aggressive/Rule-Breaking, and Somatic Complaints (McConaughy, 2005). Merrell (2008) states that, although information on its psychometrical properties is still limited, "the SCICA is recommended as an innovative semi-structured interview tool for use with children and adolescents" (p. 166).

Semi-structured interviews are often used to aid a functional assessment of behavior, aiming at collecting information about the problem behaviors, factors that may elicit and maintain them, and potential reinforcers and mediators of the associations between behaviors and their consequences. Furthermore, there are semi-structured clinical interviews designed to serve the purpose of identification of specific symptomatology, ultimately aiming for diagnostic classification of childhood psychopathology (e.g., ADHD, conduct disorder, pervasive developmental disorder). For example, Angold & Costello (2000), used a construct-validation approach to develop the Child and Adolescent Psychiatric Assessment (CAPA), a semi-structured and flexible interview system that includes forms for children (aged 8–17) and their parents. For the scoring of the CAPA, a coding system is applied after the clinical interview, and, once entered into the software database, its algorithm generates diagnoses for DSM-III, DSM-IV and ICD-10. Test-retest reliability coefficients for the CAPA, available for child report forms only, range from 0.55 for conduct disorder to 1.0 for substance abuse/dependence (see Angold, Costello, & Egger, 2007), while the construct validity of the CAPA

has been strongly attested to by its creators (Angold & Costello, 2000). A preschool version of the CAPA has also been developed: the Preschool Age Psychiatric Assessment (PAPA; Egger & Angold, 2004), with test-retest reliability coefficients ranging from 0.36 for specific phobias to 0.74 for attention deficit/hyperactivity disorder (ADHD; see also Angold, Costello, & Egger, 2007).

Another example comes from Sherrill and Kovacs (2000), who reviewed a series of versions of the Interview Schedule for Children (ISC; Kovacs, 1985) and developed the Interview Schedule for Children and Adolescents (ISCA). This semi-structured, symptom-oriented psychiatric interview has been standardized for use in children aged eight to 17, and includes forms for children and their parents. It is composed of five sections: symptoms and signs, mental status, behavioral observations, clinician's impressions, and developmental milestones. It uses an open-ended questioning format, and responses and impressions are rated using a Likert scale, according to severity of symptoms. In contrast to the CAPA, the examiner inputs the ratings of the ISCA *during* the interview (Sherrill & Kovacs, 2000). These authors suggest that the inter-rater reliability of the ISCA is quite good, whereas more evidence is needed for the test-retest reliability. Moreover, research on the predictive validity of specific disorders diagnosed using the ISCA suggest it has high predictive utility (Phillips & Gross, 2010).

Although criticized for lacking sufficient reliability and validity data (Kamphaus & Frick, 2002), an interesting semi-structured *pictorial* interview system was introduced by Ernst, Cookus, and Moravec (2000), the Pictorial Instrument for Children and Adolescents (PICA-III-R). This interview system includes 137 simple, schematic, and neutral pictures (Ernst et al., 2000) representing DSM-III-R criteria for five diagnostic categories: anxiety disorders, mood disorders, psychotic disorders, disruptive behavior disorders, and substance abuse. The child is asked to rate on a five-point Likert scale how much he or she likes the person in the picture. Along with ranking, open-ended questions are provided to the interviewer to enhance the interactions with the child. However, some limitations of this interview are that the standardization data included only severely disturbed children and diagnostic classification is outdated.

Other commonly used semi-structured interviews include the Anxiety Diagnostic Interview for DSM-IV-Child and Parent versions (ADIS-C/P; Silverman & Albano, 1996) and the Schedule

for Affective Disorders and Schizophrenia for School-Aged Children (K-SADS; Ambrosini, 2000). As reported by Rapport, Kofler, Bolden, and Sarver (2008), “the inter-rater reliability estimates for the K-SADS are among the highest of any semi-structured clinical interviews” (p. 394). However, even though both are used in the context of a clinical interview, the focus of these two schedules is too narrow for the present discussion. The following chapter (see Chapter 22) further reviews formal methods in assessing mood and affect in children and adolescents.

### STRUCTURED CLINICAL INTERVIEWS

Structured interviews became popular among researchers interested in using reliable tools to collect their data. Due to its psychometric strength, this form of interview gained a relevant place in most clinician’s assessment protocols (Kamphaus & Frick, 2002). Although structure yields reliability, these instruments are fallible to the periodic updates on the diagnostic criteria they are based on, the *Diagnostic and Statistical Manual* (DSM; Verhulst, 1995). Two of the best-known instruments in this category are the Diagnostic Interview for Children and Adolescents–Fourth Edition (DICA-IV; Herjanic & Reich, 1997; Reich, 2000) and the Diagnostic Interview Schedule for Children (DISC; Piacentini et al., 1993; Schwab-Stone et al., 1993; Shaffer et al., 1993).

The DICA (Herjanic & Reich, 1982; Reich, Herjanic, Welner, & Gandhy, 1982) was first introduced to “improve the extent and quality of information obtainable from children, particularly younger children,” with later versions including separate forms for children and adolescents (Reich, 2000, p. 59). The current version, DICA-IV, can be administered to children aged 6–12 or adolescents aged 13–17, as well as their parents. As it closely follows diagnostic classifications such as the DSM-IV and ICD-10, this schedule is very extensive; it includes over 1,600 possible questions, yet, it is structured following an algorithm that allows systematic selection of questions within dimensions and diagnostic categories, minimizing the length. Completion of the DICA-IV can take about one to two hours, depending on the number of categories to be covered. A computerized version of this instrument facilitates data entry. Although it is still often classified as a highly structured interview schedule (e.g., Kamphaus & Frick, 2002; Merrell, 2008), authors’ revisions enhanced the wording flexibility to the extent that they actually described it as

a semi-structured, polydiagnostic, glossary-based, and highly criteria-based tool (Reich, 2000). These characteristics have made the DICA a preferred instrument for research purposes; and subsequently, several studies have demonstrated moderate to high indices of inter-rater agreement (e.g., Ezpeleta et al., 1997), test-retest reliability (e.g., Boyle et al., 1993), parent–child agreement (e.g., Reich et al., 1982), and sensitivity to differentiate clinical from nonclinical samples (Merrell, 2008). Although efforts have been made to evaluate the clinical validity of this instrument (e.g., Welner, Reich, Herjanic, Jung, & Amado, 1987), caution about the minimal level of validity evidence available for the DICA has been also raised (e.g., Hodges, 1993; Kamphaus & Frick, 2002; Merrell, 2008).

The most recent version of the DISC, the DISC-IV (Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000), was produced by the National Institute of Mental Health (NIMH) and was based on both the DSM-IV and ICD-10 diagnostic classifications. It is described by its authors as “a highly structured diagnostic instrument designed for use by nonclinicians” (Shaffer et al., 2000, p. 28). It is this last characteristic (i.e., minimal training) that has made the DISC an appealing instrument for epidemiological and screening research studies. The DISC is composed of two forms: the DISC-P (parent of children 6–17) and the DISC-Y (children aged 9–17). It includes almost 3,000 possible questions, but only 358 are considered “stem” and are therefore included in every interview. About 1,300 questions are asked according to the positive or negative response to one of the stem questions; in this way, they are contingent to the initial responses collected. Similar to the DICA, the interviewer can use computerized software to facilitate the administration of the DISC. The time to complete the interview ranges from 70 minutes (in community samples) to 90 to 120 minutes for clinical cases. Authors acknowledged that this highly structured instrument can be limited in that it does not allow for documentation of atypical presentations, and it is vulnerable to undetectable mistakes in data entry (Shaffer et al., 2000). Furthermore, Verhulst (1995) pointed out that this level of structure and symptom dichotomous approach (presence/absence) dismisses the “extent of psychopathology that is just below or above the cutoff for diagnosis” (p. 205). Among its strengths, it is noted that the DISC is available in Spanish and English, only requires trained lay interviewers, and its psychometric properties (i.e., reliability and validity) are

fairly strong (Kamphaus & Frick, 2002; Merrell, 2008; Shaffer et al., 2000).

### ***Conducting Developmentally Appropriate Interviews***

It is important to consider the developmental stage of the child when conducting a clinical interview. Knowledge of typical and atypical child development is crucial, including a thorough understanding of the range of cognitive, social, and emotional characteristics that underlie each stage. Equally relevant is the clinician's sensitivity toward the needs of the children at different developmental levels which facilitates the establishment of rapport (Morrison & Anders, 1999). A skilled clinician makes an effort to adapt the assessment protocol to these explicit or implicit needs, from the beginning to the end of the process. For instance, when selecting an interview format or method, a clinician may be inclined to use an unstructured and nondirective format for preschoolers; one that is full of flexibility, avoids questions when possible and uses declarative statements instead, such as, "It seems that you are angry" instead of "Are you angry with me?" (Greenspan & Greenspan, 2003, p. 179). Use of toys and props to elicit pretend play and communication is highly recommended. In contrast, a school-aged child or teenager may be able to communicate more concretely, answering direct and specific open-ended questions, expressing their opinions about familiar concrete situations (McConaughy, 2005), and demonstrating a better understanding of their social circles (Merrell, 2008). They respond well to the introduction of humor to ease the conversation (Cepeda, 2010). The clinical interview with younger children may take place with the parents present; at least initially, as this will ease trust and rapport.

Adolescents may be able to handle a more structured interaction with the clinician, in which open-ended questions are presented and answered in an organized manner; yet, their sensitivity about feeling judged for their developing lifestyles, choices, and relationships, in combination with a growing sense of self-consciousness, make interviewing them equally challenging. Adolescents can provide a rich range of information during an interview, but they can easily feel intimidated or challenged by the clinician's interest in their developing identities, and rapidly disengage from the assessment. It is important to show respect for their opinions and feelings, as well as avoid signs of judgement and a condescending attitude. Developing trust is the

most important feature of an interview with young adolescents, weighing heavily the acquisition of trustworthy data. Morrison and Anders (1999) recommend using statements such as: "Don't tell me what you don't want to, but don't lie. If you can't tell me the truth about something, just ask me to move on to another topic" (p. 71).

To facilitate the establishment of rapport and trust with a teenager or young adolescent, a clinician may have a two-section interview. During the first section, both the adolescent and the parents are welcomed to the office, where the parents are invited to present their concerns openly and transparently to the clinician. The clinician will then ask them to leave and will follow up during a second part in which the adolescent is left alone to further discuss his or her own insights into the issues (Cepeda, 2010). Some clinicians recommend the reverse order—the adolescent enters the interview first, and then both parents and adolescent together (Morrison & Anders, 1999). Independently of the method used, significant differences in their points of view may direct the examiner to talk about their relationships. It is recommended to carefully evaluate suicidal risk, which may not be included in the parents' concerns but may become apparent during the individual interview with the child. Table 18.3 includes a range of recommended strategies for the clinical assessment interview with children at different developmental stages.

### ***Conducting Culturally Appropriate Interviews***

In order to fully benefit from any clinical interviewing technique, the clinician must feel comfortable with managing cultural matters, language and communication, as well as any interpersonal issues that may interfere with the assessment's ultimate goal: obtaining reliable information about the child. Common barriers to effective communication during an interview are the cultural differences between the clinician and the child and his or her family. In a growingly pluralistic North American community, census data demonstrate increasing changes in the demographic distribution of countries such as the United States and Canada. These demographic shifts are characterized by an increasing representation of a diverse range of ethничal groups, and a reduction of the size of the mainstream Caucasian group. The American and Canadian Psychological Associations have all made efforts to increase our awareness of the professional and ethical importance of considering cultural differences when conducting psychological assessments, including child assessment. Despite these efforts, a

**Table 18.3 Conducting a Developmentally Appropriate Interview**

Developmental Group	Clinical Interview Strategies
Preschoolers (aged 3–5)	<p>Make sure the space for the interview is adequate for a young child. Appropriate low-level table and chairs are recommended; be prepared to conduct the interview on the floor; a comfortable mat would make a difference.</p> <p>Involve the child in the interview as early as possible; for instance, initiating questions and interactions during the family interview. Early engagement and cooperation ease the clinical interview.</p> <p>Pretend play may facilitate interactions and child conversation. Allow the child to take control over the interview/play and use toys and props accordingly.</p> <p>If questions are asked, limit them to short, simple, and open-ended questions. Start with questions you know the child can answer. Avoid questions that can be answered with “yes/no.” At times, using declarative statements may be more efficacious, “I think you are upset right now.”</p> <p>Sentence completion may facilitate indirect expression of emotions and feelings.</p> <p>Use reassurance when appropriate, demonstrating interest. Positively phrased comments are also recommended; e.g., “it may be scary to feel out of control,” instead of “I think you are scared.”</p> <p>Take your time.</p>
School-aged children (6–11)	<p>Be as flexible as possible. You may want to go for a walk around the clinical setting, play a short video game on a computer, or draw together.</p> <p>Take your time establishing rapport and trust.</p> <p>Straightforward and simple communication with the child is recommended.</p> <p>Let the child initiate conversation and redirect if necessary.</p> <p>Avoid constant eye-contact; it can be intimidating for a child.</p> <p>Use concrete examples; refer to situations, contexts, or events that are very familiar to the child.</p> <p>Demonstrate deference to the child’s feelings and expressions by avoiding any kind of judgement.</p> <p>An intellectually adept child may disengage when being asked questions with obvious answers. Be creative without being too abstract. Examples or choices may help.</p> <p>Sparse use of sensitive humor is always welcome.</p> <p>Direct questions may elicit too-concrete answers; e.g., “tell me about your family.” Instead, a question such as, “How is a typical day at home?” or “What does your family do for fun?” may generate more information.</p> <p>Allow the child to express negative feelings. You may express assumptions that lead to it: “All children fight with their brothers and sisters at times” or “Many children would feel angry in a situation like that.”</p> <p>Talk about peer relationships: it can be an excellent way to gather information about the child’s emotional and social development.</p>
Adolescents (12–18)	<p>Make an effort in establishing trust and rapport.</p> <p>Treat the adolescent with deference, but avoid being too distant.</p> <p>Offer a comfortable, private, and safe place to talk.</p> <p>Avoid physical contact.</p> <p>It is important not to pretend to be “cool” or too “hip.” Adolescents would easily see through it.</p> <p>Establish the limits of confidentiality early on.</p> <p>Elicit conversation about their opinions on peer activities, social distress, and risk behaviors.</p> <p>Make sure to follow up on any indication of suicidal risk or harm to others.</p> <p>Avoid judgemental comments.</p>

disproportionate representation of students from ethnic minorities in special education placement continues to be an issue (Rhodes, Ochoa, & Ortiz, 2005).

When language differences are evident, significant obstacles arise in communication and information gathering. At times, it may be recommended to refer the patient to a clinician that is proficient in the child's and his or her family's native language. Not being familiar with their first language would interfere not only with reliable data collection about the child but also with the establishment of rapport and trust. On occasion an interpreter may be needed; for instance, when relevant information from a caregiver is needed, but he or she does not speak fluent English. It is becoming increasingly common that the child is fluent in English (e.g., due to schooling) but his or her parents (and extended-family members) may not be fluent in the language, especially in the case of recently immigrated families or when elders are involved. In these instances, the clinician must be sensitive to their communication needs and make the appropriate accommodations. Under other necessary circumstances, the interview pace and format may be modified, keeping in mind that deference and courtesy would facilitate rapport. To enhance verbal communication in all contexts, it is recommended to avoid using slang, colloquial expressions with double meanings, or jargon. Clear communication is encouraged, while being mindful that there is a sensitive line between trying to communicate more clearly and being disrespectful to the client. Adolescents who have recently immigrated may be particularly sensitive and self-conscious about language barriers.

Furthermore, beyond language differences, and even in the absence of significant verbal barriers, there are several behavioral and nonverbal communication styles across cultures to take into account (McConaughy, 2005; Merrell, 2008; Rhodes et al., 2005; Sattler, 2008). Efforts to accommodate for cultural differences between the client and the examiner should start with active research into the child's cultural background, typical parenting and education styles accredited to their culture, health and healing practices, level of acculturation to the new dominant culture, and language proficiency. The clinician should also evaluate personal beliefs and expectations about the child's culture, as those may interfere with the quality and reliability of observations and, ultimately, interpretation of the data. Although any attempt to generalize patterns across cultures is cautioned against, an awareness of some typical characteristics of their nonverbal communication styles is relevant. In this regard, Sattler (2008) noted that significant

differences arise in terms of quality of physical interactions (i.e., kinesics and proxemics) and paralanguage. *Kinesics* refers to the use of facial expressions, manual movements, and use of gestures during a communicative interaction. Hispanics and African Americans, for instance, tend to present a very expressive range of gestures and facial and hand movements; in contrast, Asians and Native Americans tend to exert more control over their expressions. There are also different values associated with these different expressions. What, in one culture, may mean character and confidence (e.g., smiling and gesturing for Hispanic cultures), in others may be a sign of immaturity and insecurity (e.g., Asian Americans). An inexpressive face creates mistrust among Latinos, while it may be an admirable sign for members of other cultures. *Proxemics* refers to the personal distance or space between the persons involved in the communication. In the case of an interview, the clinician should make an effort to arrange the seating in a manner that accommodates the child's and his or her family's needs (Sattler, 2008). For instance, some Asian cultures (e.g., Chinese) may prefer a side-by-side seating (avoiding direct eye contact) while a Caucasian "mainstream" American may feel uncomfortable with this seating arrangement during an interview. Distance and personal proximity may also vary according to status, age differences, or types of relationships. An African American child may distance him- or herself during the first stages of an evaluation and eventually allow some proximity later in the process; while a Hispanic child may maintain some proximity throughout the entire assessment process. In contrast, a Native American child may maintain some distance consistently throughout the assessment (McConaughy, 2005). Eye contact is an important behavior to monitor. Whites/Caucasians may feel comfortable with direct eye contact, while other cultures may avoid it as a sign of respect. Hispanics may lower eye contact if feeling punished or judged, whereas African Americans may prolong eye contact when speaking and lower it while listening (McConaughy, 2005; Merrell, 2008; Sattler, 2008). *Paralanguage* refers to the use of nonverbal communication cues such as tone of voice, pitch, and volume. Different cultures value pace, silent pauses, and voice volume differently. Asians and Native American children may use a soft voice to show respect. Hispanic children may be louder and more vivacious at times, with variations of this pattern being associated with their status and acculturation level.

To conclude, it is worth noting once again that there is no rule of thumb or specific behavioral characteristics

that can be generalized to everyone within a group. Clinician's discretion is advised. Chapter 7 is recommended for a review of assessment of diverse populations. Furthermore, Rhodes, Ochoa, and Ortiz's (2005) book is highly recommended for a review of assessment practices with bilingual children.

### **Background Questionnaires**

The clinical interview should be an opportunity to establish rapport, to get to know the child and his or her family, to interact with all members involved, and to gather as much information as possible about the child's current situation. A review of the child's records complements the information about the antecedents and relevant historic background of that child. An additional common source of information is the background questionnaire. Child questionnaires are often used to collect specific information regarding the development, medical/academic history, and current functioning (at home and at school) of the child being brought to the assessment (Baron, 2003; Strauss et al., 2006). As the main purpose of background questionnaires is to complement information gathered through the clinical interview and the records collected, most background questionnaires are highly structured and could be administered prior to, during, or after the clinical interview. Some clinicians may attach a developmental questionnaire to the consent and intake forms, getting as much information as possible in anticipation of the assessment and to aid in the planning of it. Other clinicians may prefer having the parents or guardians complete the form while they interview the child. Similarly, some clinicians prefer to develop their own structured or semi-structured questionnaires according to the needs of their typical clientele, their theoretical orientation, or assessment method preferences. Some research, academic, and institutional settings (e.g., schools and hospitals) have established a protocol that is systematically followed. Regardless of how questionnaires are used or administered, it is recommended that they not replace the clinical interview (Strauss et al., 2006).

There are several published examples of detailed background questionnaires (e.g., Baron, 2003, pp. 61–65; Strauss et al., 2006, pp. 68–74). For example, among some commercialized forms like the BASC-2 (Reynolds & Kamphaus, 2004), a structured developmental history (SDH) is included that provides a comprehensive and detailed review of medical, developmental, academic, social, psychological, and familial history of the child. Items that survey information about family configuration and

health and socioeconomic status are included in the SDH. Items of the developmental history include questions associated with prenatal, perinatal, and postnatal history, milestones in development, and level of maturation. In addition to the level of comprehensiveness of the SDH, one of its main strengths is its current availability in English and Spanish. Table 18.4 summarizes some of the typical areas covered in standard background questionnaires.

### **Child Mental Status Examination**

The Mental Status Examination (MSE) is a common tool used to obtain an overall perspective about a person's general level of functioning, including his or her emotional state, perceptual functioning, flow and content of thought processes, overall intellectual functioning (language, memory, attention, concentration, and orientation), psychomotor speech, and general appearance (Aiken & Groth-Marnat, 2006; Lezak et al., 2004). The MSE was originally designed for neurological and psychiatric evaluations; accordingly, they were brief (about 20–30 minutes), semi-structured, and usually combined questioning with direct observations. This approach has been defined as a "method of organizing and evaluating clinical observations pertaining to mental status or mental condition" (Sommers-Flanagan & Sommers-Flanagan, 2003, p. 214). In 1902, Adolf Meyer introduced the MSE into American psychiatry (Groth-Marnat, 2009), and ever since, there have been many prototypes of the MSE, ranging from brief to comprehensive, and from fully structured to semi-structured. Despite its popularity among pediatricians, child psychiatrists, and clinical neurologists, the MSE is not typically used in child psychological evaluations; perhaps because the information provided by the MSE can be collected from pieces of the full assessment process. In most cases, the MSE is not used in isolation but rather as a component of a multi-stage assessment. Oftentimes it will be administered during the early clinical assessment interview to provide the clinician with some guidelines about the client's broad strengths and weaknesses, facilitating subsequent design of the full assessment protocol. This is frequently the case in neuropsychological assessments in which a more comprehensive and detailed evaluation of core cognitive areas will follow the initial interview (for a review, see chapters 14 and 20).

Though the MSE has its advantages, it should be used with caution. Similar to screening measures, the MSE could provide the clinician with a biased view, as well as potentially generate

**Table 18.4 Sample of Areas Covered in a Child Background Questionnaire**

<b>Demographics</b>	<b>Name</b> <b>Date and country of birth</b> <b>Race /gender /primary language</b> <b>Grade at school</b> <b>Information about the person completing the form</b>
Referral Information	Motive of consult Referral source Strengths and weaknesses Type of assessment requested
Family Information	Available information on biological parents Parents/guardians/caregivers Family and household configuration Who is the primary caretaker of the child? Family income/members' occupations Current family stressors
Pregnancy and Birth	Maternal pregnancy history/health problems/substance use or abuse/medications Type of delivery/labor conditions Neonatal conditions: Term, weight, size, APGAR scores, neonatal intensive care, hypoxia/anoxia, medical problems at discharge Perinatal problems
Developmental History	Developmental motor milestones Language development Toileting and adaptive/independent functioning Social behavior Cognitive development
Medical History	Sensory and perception (hearing, vision) Head injuries/accidents/loss of consciousness History of seizures History of surgery History of medical illnesses or chronic conditions Previous assessments
Educational History	Learning problems Areas of strengths and weaknesses Current educational placement Problems in any academic area Behavior at school Social adjustment
Family Health History	Learning disabilities Attention deficit hyperactivity disorder Mental health/psychiatric history Substance abuse Physical abuse Chronic illnesses (e.g., cancer, epilepsy, diabetes) Familial disease (e.g., Alzheimer's, Parkinson's)
Child's Current Functioning	Adaptive behavior Leisure activities/hobbies/sports Social interactions History of physical/sexual abuse Alcohol/drugs use/abuse Trouble with the law Distressing situations (e.g., illness, deaths, separations, accidents, significant changes, financial problems) and ability to cope Mental health concerns/features

initial false positive or negative classifications of the child's behavioral pattern. A common vulnerability of the brief MSE is cultural insensitivity (Sommers-Flanagan & Sommers-Flanagan, 2003). Cultural styles and beliefs could be easily misinterpreted in the context of a brief examination of thought processing; socioeconomic variables, parental neglect, or other environmental variables may be associated with disorganized or inappropriate physical appearance in the absence of psychopathology. Eye-contact-avoidance may be associated with cultural values of respect and hierarchy in the absence of developmental disorders. The most common MSE structure includes nine areas, which are discussed below in the context of child assessment. Table 18.5 contains a list of helpful indicators for each area, which are presented in the form of questions to the clinician.

### ***Appearance and Attitude***

There is a wealth of information in a client's appearance, which by itself may be less relevant than when placed in the context of a psychological assessment. Although a client's appearance is often a sign of his or her mental health (Wiger & Huntley, 2002), in the case of a pediatric evaluation, it may also indicate the parents' mental health, parenting quality and style, caregivers' attention to the child's needs, or the guardian's level of concern for the child's well-being.

The examiner should document his or her first impressions that the child evokes, while answering questions such as: "Is the child likeable?" or "Is there anything odd about this child?" (Cepeda, 2000). Furthermore, the examiner should note the physical characteristics of the child, including height and weight in relation to age, facial characteristics and expressions, eyewear, pupils' dilation and contraction, eye contact, unique body odors, hair and skin quality that may indicate nutritional status, and skin markings that may be signs of injuries or self-abusive behaviors. Several developmental genetic disorders include specific facial features as part of their phenotypic expression; thus, it is relevant to make note of the relevant features on the child's face and head, such as head size in relation to age, weight, and height; different irises' coloration; eyes' separation; and the shape of the forehead. The examiner should observe the child's grooming and general hygiene, the appropriateness of his or her attire for the assessment and the current weather conditions, footwear, presence of body piercings or tattoos, and make-up. All these observations should be placed in the context of the child's sex, age, race, and socioeconomic and ethnic background.

Moreover, the examiner takes notes about the child's manner in relating to the examiner, and the child's overall attitude toward the assessment and the clinician, including ease in separation from parents or guardian and the overall posture of

**Table 18.5 Components of the Child Mental Status Examination**

<b>Mental Status Examination Components</b>	<b>Indicators</b>
Physical Appearance and Attitude	<p>Is this child likeable?</p> <p>What first impression do I have of his/her family?</p> <p>How easily did the child separate from his/her parents?</p> <p>Does this child look his/her age? His or her gender?</p> <p>Is the child too slim? Overweight? Is there presence of marked obesity?</p> <p>Does the child look tired and sleepy, or animated and energetic?</p> <p>What is the child wearing? Is this attire age-appropriate? Weather-appropriate? Clean?</p> <p>Is the child well groomed? Is there any marked body odor?</p> <p>Are there observable tattoos, piercings, body ornaments? (If not visible, ask the child).</p> <p>Are there signs of injuries or self-abusive behaviors? Are there noticeable scars?</p> <p>Is there any sign of any physical compulsive traits such as nail biting, licking, or hair pulling?</p> <p>Is there a physical disability?</p> <p>How are this child's facial features? Skin complexion? Do the skin and hair look healthy?</p> <p>How is the shape of the head?</p> <p>How would you qualify the child's attitude towards you and towards the assessment situation? Is the child aggressive? Impatient? Indifferent? Defiant? Cooperative?</p> <p>Is there any memorable aspect about this child?</p>

*(continued)*

**Table 18.5 (Continued)**

Mental Status Examination Components	Indicators
Activity Level and Psychomotor Functioning	<p>How is this child's gait?</p> <p>Is the child constantly changing postures, moving, or fidgeting?</p> <p>Is there any observable tic, mannerism, or eye-contact avoidance?</p> <p>Does the child smile?</p> <p>Is the child alert, awake?</p> <p>Is this child impulsive, agitated, or slow to respond?</p> <p>What kind of games does the child like?</p> <p>Does he/she help at home with chores? Which ones?</p>
Emotional State	<p><i>Range:</i> Does the child express a full range of affect? Is affect restricted, expansive, or flat?</p> <p><i>Intensity:</i> Is the intensity of the child's emotional expression normal?</p> <p><i>Stability:</i> Is the affect stable or labile?</p> <p><i>Appropriateness:</i> What is the predominant affect during the interview? Is it appropriate? Does the child become angry, frustrated, or impatient during the assessment? Does the child manifest anxiety? Does he/she fidget or is calm during the interview?</p>
Speech	<p><i>Form:</i> Is the child's speech articulated? Is the volume of his/her speech loud? Soft? Normal? Is the pace of the speech fast, slow, or normal? Is the child talkative or reserved? Is there a delay in the response to questions or instructions? Are the child's speech tone and melody (prosody) monotonous or normal?</p> <p><i>Content:</i> Is the child's speech full of details? Is it excessive? How is the child's vocabulary level? Appropriate for age, limited, or advanced? Is the content organized? Is it grammatically correct? Are words used appropriately? Does the child make sense?</p> <p><i>Receptive language:</i> Does the child follow the instructions correctly? Does he/she require multiple repetitions and clarifications? Does the child seem to understand questions? Does he/she react to comments and feedback?</p> <p><i>Expressive language:</i> Is the child verbally fluent? Can the child read aloud correctly? Can the child adequately describe a picture?</p>
Thought Process	<p><i>Flow and form:</i> Is it logical and coherent? Spontaneous? Conversational? Pertinent? Is the language purposeful and goal-directed?</p> <p><i>Content:</i> Is it selective? Obsessive? Distorted? Delusional? Is it inappropriate or bizarre for age level? Is the content indicative of harm risk for him/her or others? Is there any evidence of visual, auditory, or other kinds of hallucinations?</p>

*(continued)*

**Table 18.5 (Continued)**

Mental Status Examination Components	Indicators
Orientation	<p>Is the child oriented in person, time, place, and situation?            Examples of typical questions about orientation include:</p> <p><i>Person</i>            “What is your name?”            “What school do you go to?”</p> <p><i>Time</i>            “How old are you?” “When is your birthday?”            “What time is it?” “What date is it?” “Is it morning or afternoon?”</p> <p><i>Place</i>            “Where do you live?” “Where are you now?”</p> <p><i>Situation</i>            “Why are you here?”</p>
Attention and Concentration	<p>Does the child sustain attention during the interview?            Is the child able to shift the focus of his or her attention from one task to another?            Is the child distractible during the examination?</p>
Memory	<p>Is the child able to repeat an instruction?            Can the child repeat a series of letters or digits?            Can the child recall names of people or places from his or her recent past?            Can the child recall some recent past events?—e.g., the last weekend activities, last movie seen.            Can the child recall events from his or her life history?—e.g., early school years, last year’s Halloween, or vacations.</p>
Overall Cognitive Functioning and Development	<p>After interacting with the child and throughout the interview, does the child seem to behave and think at an appropriate age level?            How is the child’s general vocabulary level?—Advanced for his age, adequate, below expectations?            What is your impression of this child’s level of responsiveness?            Can the child comprehend most of your instructions? (Have in mind cultural and language barriers.)            What is your impression of this child’s abstract thinking? (e.g., establishing similarities and differences between two objects).            Can he or she point at a few body parts?            In young children, how is this child’s drawing of a person?—Advanced, mature, age-appropriate, immature?            How is this child’s academic performance in the school?</p>
Insight and Judgement	<p>Is the child aware of the situation or problems that brought him/her to the consultation?            How easy or difficult is it for him/her to make decisions?            What words does the child use to describe him/herself?            Does the child recognize hazardous situations and risk-taking behaviors?            Is the child aware of the consequences of his/her behaviors?            Does the child have plans for the short and long-term future?            How does the child relate past situations or events to his/her current difficulties?</p>

the child. Carlat (2005) stated that “[d]escriptors of attitude are similar to descriptors of affect, but the emphasis is on words that describe a relationship toward someone” (p. 126). Sommers-Flanagan and Sommers-Flanagan (2003) defined some useful descriptors to characterize the overall attitude of a client towards the interviewer. Some examples include *aggressive* (e.g., attacking the examiner verbally or

physically), *cooperative* (e.g., teamwork gathering information during the interview), *hostile* (e.g., the client uses sarcasm, irony, or other such gestures), *impatient* (e.g., Type A personality style), *indifferent* (e.g., lack of concern), *intense* (e.g., loud, inquisitive eye contact), *manipulative* (e.g., efforts to solicit agreement from the interviewer), *negative* (e.g., opposes examiner comments), *open* (e.g., actively

engaged), *passive* (e.g., disconnected from interview), *seductive* (e.g., flirtatious or suggestive comments), and *suspicious* (e.g., remarks on examiner's notes; Sommers-Flanagan & Sommers-Flanagan, 2003, p. 219). Once again, it is important to evaluate these perceived attitudes in the context of the child's cultural background.

### ***Activity Level and Psychomotor Functioning***

When possible, it is recommended that the examiner walk the child into the interviewing room while observing his or her gait and coordination (Cepeda, 2000). Throughout the interview, the examiner pays close attention to the child's psychomotor activity and should register any sign of excessive or reduced motor activity, tics, muscle twitching, fidgeting, odd and repetitive movements, slowness of movement, clumsiness, and both gross and fine motor coordination. Any observable, atypical activity-level of a child should lead to further examination of his or her medical records, medications, mood, and affect (Wiger & Huntley, 2002). In the case of an adolescent, inquiries about substance abuse may be relevant. Psychomotor retardation and psychomotor agitation can be indicators of neurodevelopmental disorders, mood disorders, or medication side effects (e.g., akathisia produced by neuroleptics or serotonin reuptake inhibitors). The examiner should make an effort to identify if the motor activity exhibited by the child is goal-directed or if it should be characterized as aimless behavior. If suspecting mania, the examiner should pay attention to other manifestations (e.g., pressured speech, grandiosity; Cepeda, 2000).

In the context of a MSE, and in combination with the behavioral observations, a quick examination of psychomotor coordination can also include a few questions directed to the child and his or her parents (when appropriate) about the child's everyday activities, independence, playfulness, home management participation, adaptive skills, and self-care. It is worth noting that these observations are only meaningful if the developmental and cultural contexts of the child are taken into consideration.

### ***Emotional State***

This concerns the child's reported mood (emotional tone) and overall observable affect. There are some noteworthy differences in the evaluation of mood and affect. For instance, *mood* refers to a persistent emotional state over time; therefore, information about mood is often obtained by direct endorsement of the child (if developmentally

appropriate) or via the parents' reports. When assessing *affect* in the context of the MSE, the examiner should pay close attention to the range, frequency, intensity, stability, and appropriateness of emotional expressions. Depending on their developmental stage, children may present some emotional characteristics more overtly (e.g., joyful or irritated), while anxiety and depressive symptoms may be covertly camouflaged by an adolescent. A tearful preschooler may not be considered "sad"; the stress associated with the assessment may create fear, and the novelty of the situation could have triggered their underdeveloped ability to cope with this stress (Goodman & Sours, 1967). In these cases, a skilled clinician pays attention to nonverbal clues about the child's feelings, and the consistency between their emotional display and verbal statements.

### ***Speech***

The child's speech is a crucial indicator of his or her thought processes; consequently, it should be observed throughout the assessment. Speech examination can include both *delivery* (rate, volume, tone quality, articulation, and amount) and *content* (age-inappropriate confusion of words, grammatical and syntactical errors, organization, and spontaneity). It is important to rule out the possibility of a developmental hearing impairment before drawing any definite conclusions about the child's language.

Receptive language abilities can be informally examined during the early stages of the clinical assessment interview. A child who is able to follow instructions and responds accordingly arouses no major concerns at this point. Children with receptive language difficulties may look very confused during the interview. A short formal assessment can include a series of questions and verbal commands. Zuckerman (2005) offered examples for the assessment of language comprehension in the context of conducting the MSE, such as, "The lion killed the tiger, which one is dead?" and commands such as, "Close your eyes. Open them. Raise an arm" (p. 29). Expressive language can be observed in the child's verbal fluency rate (spontaneous or if prompted), or by asking the child to describe an object or a picture. With a school-aged or older case, reading some sentences or a short paragraph, and describing a situation, should allow the clinician to build an overall appreciation of the individual's fluency and language expression.

The child's ability to communicate can be affected by neurodevelopmental disorders such as autism. To distinguish autism from other communication

disorders, Cepeda (2000) recommended considering the following questions: “Is the patient attempting to communicate at all? Is the patient gesturing or attempting to use other nonverbal behavior? Is the patient capable of developing rapport? Is the patient attempting to connect with the examiner?” (p. 102). Carlat (2005) recommended using descriptors such as “normal, thoughtful, articulate, intelligent, continuous, rapid, rambling, pressured, loud, soft, slow, and halting” (p. 127) when noting the characteristics of the client’s speech.

### ***Thought Process***

Wiger and Huntley (2002) stated that “[a] person’s stream of consciousness is a measurement or indication of how one’s speech reflects thought processes” (p. 172). Thus, the examiner should observe the flow and form of the child’s thought process, as well as the content. Evaluation of thought content in children is challenging, and caution in making conclusive statements is advisable; delusions are rare in children, and while auditory and visual hallucinations could be identified during the clinical interview, they can also be easily confused with imaginary, fantasy, or play situations. Furthermore, severe language disorders can make it difficult to determine thought content.

In addition to form and content, during the brief screening of thought processing in the context of the MSE, it is recommended that the examiner pay attention to speech content involving risk of harm toward the child or others, including suicidal and homicidal ideation, involvement in violent actions, gangs, delinquent or antisocial risk behaviors, or obsessive thinking, among others.

### ***Orientation***

The examiner identifies if the child is oriented in person, place, time, and situation. Age-appropriate expectation of child’s orientation is important; a younger child may only have a vague reference of the date (month, year) and may be confused about place or type of setting. Common questions to a child include, “What is your name? What school do you go to? Where do you live? How old are you? When is your birthday? What time is it? What date is it? Is it morning or afternoon? Where are you?” and “Why are you here?”

### ***Attention, Concentration, and Memory***

Attention and memory are fundamental functions for information processing and cognitive functioning. A distractible child who cannot

concentrate during the interview and MSE may perform poorly during testing as well. Therefore, assessment of attention, concentration, and basic memory skills at this early stage of the assessment process is recommended. Morrison and Anders (1999) suggested a brief evaluation of these three areas using age-appropriate simple math such as counting backwards by ones, and other indicators of immediate (e.g., digits or visual objects), recent (e.g., “What did you have for breakfast this morning?”), and remote memory processing (e.g., information about people, things, or events). Observations collected during the brief assessment of attention and memory in the context of an MSE will help the clinician to further design and personalize the full cognitive assessment protocol. In some cases, referral to neuropsychological assessment may be appropriate.

### ***Overall Cognitive Functioning and Development***

One of the primary goals of the brief MSE is to provide the clinician with an overall initial appreciation of the child’s cognitive capacity. The underlying question would be, “Does this child seem to behave and think at an appropriate age level?” With this in mind, the examiner can estimate the level of general mental ability of the child by observing his or her general vocabulary, responsiveness, comprehension of instructions, abstract thinking (e.g., establishing similarities and differences between two objects), identification of body parts, drawing a person, writing, and demonstration of age-appropriate ability to read or recognize graphemes, letters, or words. Information about the academic performance of the child can also facilitate the estimation of his or her overall intellectual functioning.

### ***Insight and Judgement***

Examination of this area varies greatly according to the age and developmental stage of the child. The clinician should aim to develop some appreciation of the child’s awareness about his or her problems (e.g., “Why are you here today?”); make-believe situations can be posed to an older child in order to observe his or her position about them (e.g., “What would you do if...?”). Furthermore, an informal, yet skilled conversation with the child during the interview can provide the clinician with information about his or her abilities to think about their present and future plans, to make decisions; his or her awareness of consequences of one’s behavior, self-image, insights into social situations,

moral judgements, hobbies and favorite activities, risk-taking behaviors, and hazard recognition.

Groth-Marnat (2009) states that, "Adequate insight and judgement involves developing and testing hypotheses regarding their own behavior and the behavior of others" (p. 83). The examiner may propose questions that allow for an evaluation of the child's insights into his or her current situation, and how these insights may be related to past events, decisions made by the child or others, and any potential explanations the child may have for his or her problems.

# Psychological Testing by Models of Cognitive Ability

A. Lynne Beal, John O. Willis, and Ron Dumont

## Abstract

Intelligence has been conceptualized as both a general ability (*g*) and as multiple abilities. These two views have been the basis for several theories of cognitive abilities. Derived from those theories, models of cognitive functioning have formed the basis of recent tests of intelligence and component abilities. This chapter maps the CHC theory, Luria theory and Cross-Battery approaches and models of cognitive abilities onto the most recent tests of cognitive ability. By understanding the abilities measured by cognitive tests, practitioners can better appraise the strengths and needs of the clients they assess. Reviews of recent tests guide practitioners in choosing the most appropriate tests and subtests to measure their client's abilities as they relate to learning disabilities, giftedness, and intellectual disability.

**Key Words:** cognitive, ability, assessment, models, theory, learning disabilities, intelligence, gifted, mental retardation, review

## Introduction

Knowledge about human cognitive abilities has evolved over the years based upon a variety of theories of cognitive functioning. With this knowledge have come the desire and then the need to actually assess those abilities thoroughly and accurately. This evolution from theory to practice is described from an historical perspective in the Greenberg, Lichtenberger, and Kaufman chapter (Chapter 2) in this book (2012). Willis, Dumont, and Kaufman (2011) traced the factor-analytic models of intelligence from their theoretical roots to the specific models upon which modern-day intelligence tests have been built. These two chapters provide excellent theoretical underpinnings to understanding how models of cognitive ability link to cognitive ability tests.

A large body of research literature shows that IQ scores predict many important variables, including academic achievement test scores, grades, job performance, occupation and social status, and income

(Brody, 1997; Jensen, 1998; Schmidt, 2002). Because results from a cognitive assessment are often required for the identification of individuals with intellectual disability (mental retardation), learning disabilities, or intellectual giftedness (American Psychiatric Association [APA], 2000; Individuals with Disabilities Education Act, 2004; National Research Council, 2002; Rosa's Law, 2010), intelligence test batteries are considered essential tools in the fields of psychology and education, and in particular in special education. They are among the most frequently used assessment instruments in clinics, schools, and forensic settings (Camara, Nathan & Puente, 2000; Rabin, Barr, & Burton, 2005; Ryba, Cooper, & Zapf, 2003). According to Belter and Piotrowski (2001), intelligence test batteries were considered by psychology training directors to be essential for practice.

The purpose of this chapter is to link various models of cognitive ability, described elsewhere in

this volume, to several of the intelligence test batteries that are currently in use in psychological practice. Given the plethora of tests available, it is possible to include in this short chapter only a very few of actual tests available. As Floyd, Clark, and Shadish (2008) discovered when they searched the Buros Institute of Mental Measurements' *Test Reviews Online* website (<http://www.unl.edu/buros>) looking for tests that assessed "intelligence and general aptitude," there were no fewer than 250 published instruments to choose from.

The tests discussed in this chapter are those that seem most relevant and useful in the diagnosis of broad cognitive abilities and are commonly used by psychologists, school psychologists, and educational specialists. Some of the tests incorporate in their structure the major models described in this chapter. The chapter ends with short reviews of several individual tests of cognitive ability that are often used today. The historical roots and the derivations of the models underlying these tests will not be reiterated here. Our assumption is that, by understanding the various broad theories of cognitive functioning across the lifespan and the functional models—the actual tests—that are derived from those theories, practitioners and researchers can better understand the abilities and human functions that current cognitive ability tests measure. Indeed, as Flanagan, Ortiz, Alfonso, and Mascolo (2006) have suggested, application of theory to the assessment of learning disabilities (LD) is perhaps one of the most significant advances necessary if LD assessment is to improve and become more reliable and valid. This understanding enables practitioners and researchers to rely on the results of cognitive ability tests, to integrate the results of different tests, to combine those test results with other sources of information, and to draw conclusions about cognitive strengths and deficits, and their implications for education, careers and other daily activities of the people they assess.

The second purpose of this chapter is to link the current tests of cognitive abilities based on the various models to the practice of diagnosis and the determination of eligibility for special services. We will focus on the diagnosis and identification of learning disabilities using the definition of "learning disability" in the United States from the Individuals with Disabilities Education Act (IDEA; 2004), and in Canada using the Learning Disabilities Association of Canada definition (2003). We will focus on the diagnosis of developmental delay using the definition of "mental retardation" from the *Diagnostic*

*and Statistical Manual IV-TR* (American Psychiatric Association, 2000). We will focus on the identification of gifted students based on overall intellectual level. The significance of assessment as a means to identify and to develop interventions for children with disabilities is evident in the United States in the passage of multiple legislative acts safeguarding children's rights. One of the most important of those laws is the Individuals with Disabilities Education Act (IDEA, 2004), under which children with identified disabilities must be provided free appropriate public education (FAPE), often through direct services provided as special education. IDEA defines "special education" as specially designed instruction to meet the unique needs of children with disabilities at no cost to parents. To be eligible, children must demonstrate impairments in areas (e.g., academic, cognitive, physical, behavioral) that interfere with their ability to learn from the general education curriculum. IDEA thus mandates that states evaluate all children suspected of having a disability, including young children not yet enrolled in schools, to determine whether they are eligible to receive early intervention or special education services. According to the IDEA, "evaluation" means procedures used to determine eligibility for special education services. States are required to conduct multidisciplinary comprehensive assessments when determining eligibility for special education services under IDEA. There is, of course, a difference between the constraints and special considerations imposed by IDEA (2004) on *identification* of a disability when one is evaluating school-aged children and the guidelines for a *diagnosis* by, for example, the criteria of the *Diagnostic and Statistical Manual* (DSM-IV-TR) (American Psychiatric Association, 2000). While federal regulations provide general guidelines in regard to identification and classification, states have considerable flexibility in how they interpret and institute policies and practices in definitions, classification criteria, assessment processes, and other considerations (Bergeron, Floyd, & Shands, 2008; Reschly & Hosp, 2004).

In Canada, the definition of "learning disabilities" can vary greatly, depending upon whose definition one is working under. The definition offered by the Learning Disabilities Association of Canada (2003) has not been universally adopted by ministries of education within the various provinces. Ministries and advocacy groups promote their own consensus-based definitions within each province (Kozey & Siegel, 2008). Definitions within Canadian educational settings are often related

more to the need for special education, rather than the specific diagnostic criteria for any disorder or disability. Nonetheless, the Ontario Ministry of Education, for example, has adopted the opinion of the Expert Panel on Literacy and Numeracy Instruction for Students with Special Education Needs that notes, “knowledge about a student’s strengths and weaknesses in cognitive processing helps teachers provide appropriate instruction and accommodations for children in their classrooms” (Ministry of Education, 2005, retrieved from <http://www.edu.gov.on.ca/eng/document/reports/speced/panel/speced.pdf>).

A diagnosis of a specific learning disability or of intellectual disability is not always necessary to access special education services in schools because there are, at least in the United States, 13 categories of disability under which a child might be eligible, and under IDEA, a child does not have to be labeled with any particular disability, although most states require a specific identification. Nonetheless, cognitive ability tests are frequently used in assessments of students seeking services. We focus in this chapter on current tests of cognitive ability for children and adults, including promising developments in group tests of cognitive ability related to specific models.

## Models of Intelligence and Component Abilities

Since scores on various intelligence tests are correlated with each other, people who do better than average on one test tend to do better than average on another. The same is true of school grades and many other measures of human performance. The idea that these correlations are due to a single “general factor of intelligence,” which has come to be called *g*, was originally proposed by Charles Spearman at the turn of the twentieth century (Spearman, 1904, 1927). Researchers interested in human cognitive abilities responded to the difficulties of the one-general-factor theory (such as obviously disparate strengths and weaknesses in an individual) by developing models with *multiple* unobserved factors. In the multiple-factor models, the bulk of the correlations between tests are attributed to a leading common factor, still called *g*. However, the smaller but non-negligible correlations left after accounting for *g* are attributed to other, lesser factors. The reality and importance of *g* are retained because *g* accounts for so much of the correlations among the tests.

In contrast to the focus on *g*, L. L. Thurstone (viz., 1926, 1931), developed and applied techniques of factor analysis to emphasize several separate mental

abilities established by clusters of subtests that correlated with each other in addition to correlating with the total, and more than they correlated with other subtests in other clusters. Thurstone’s (1938) theory of *primary mental abilities* offered an alternative to Spearman’s *g*.

Borrowing McKusick’s (1969) terms, we can differentiate between these approaches by describing advocates of theories and models based on the concept of one overall level of “intelligence” or *g* as “lumpers”; and proponents of theories based on a set of several separate abilities as “splitters.” Reference to *g* and correlations of the split-off, or component abilities, to the lump or general ability factor have been studied extensively, largely through factor-analytical studies. We will find in the models of cognitive ability and the more recent tests based on these models that splitting has become a more important feature, while retaining the importance of the lump, or measure of overall cognitive ability.

As for the separate abilities, Carroll (1993, p. 8) provides a thoughtful definition that is first dependent on the definition of *cognitive task* as “any task in which correct or appropriate processing of mental information is critical to successful performance.” A *cognitive ability* is “any ability that concerns some class of cognitive tasks, so defined.” Finally, he defines a *cognitive process* as “one in which mental contents are operated on in order to produce some response.”

The history of intelligence testing can be characterized as a quest for two outcomes: (1) to provide reliable measures of *g*, or general intellectual ability; and (2) to catalogue and measure the critical cognitive abilities embodied within *g*. Greenberg et al. trace that history in Chapter 2 in this volume through the role of theory in psychological assessment. Willis et al. (2011) trace the history through factor-analytic models of intelligence. Over the years the varying theories and models have resulted in different numbers of cognitive abilities being identified and validated. John Carroll’s (1993) landmark meta-analysis of factor-analytic studies is the best existing compilation and analysis of the cognitive abilities. He reanalyzed 461 data sets from a collection of about 1,500 studies using exploratory factor analysis to present extensive data in the domains of language, reasoning, memory and learning, visual perception, auditory reception, idea production, cognitive speed, knowledge and achievement, psychomotor abilities, miscellaneous domains of ability and personal characteristics, and higher-order factors of cognitive ability (1993, p. v). Raymond Cattell

(e.g., 1941, 1963, 1987; Cattell & Horn, 1978) and his student and colleague, John Horn (e.g., 1988, 1991, 1994; Horn & Blankson, 2005), developed a theory of fluid ( $Gf$ ) and crystallized ( $Gc$ ) abilities, to which other abilities were later added. Carroll's work was remarkably congruent with that of Cattell and Horn, which provided the foundation for the development of the Cattell-Horn-Carroll (CHC) Theory of Cognitive Ability (Flanagan, McGrew, & Ortiz, 2000; McGrew, 2005; McGrew & Woodcock, 2001; Woodcock, 1990, 1993, 1997).

Constructs of cognitive abilities, cognitive processes, cognitive tasks, and  $g$  from psychological science have found their way into the nomenclature for the diagnosis of cognitive disorders and disabilities. The definition of *mental retardation* (American Psychiatric Association, 2000) refers to "significantly sub-average intellectual functioning." There must also be deficits in adaptive behavior and onset before adulthood. A wide range of sub-test scores with some in the average range, despite a significantly sub-average total, is problematic, especially for splitters. The definition of *learning disability* in Canada (2002) refers to "average abilities essential for thinking and/or reasoning," and "global intellectual deficiency." It goes on to include "impairments in one or more processes related to perceiving, thinking, remembering or learning. These include, but are not limited to: language processing, phonological processing; visual spatial processing, processing speed; memory and attention; and executive functions (e.g. planning and decision-making)." In the United States, the definition of a *specific* learning disability in the 2004 Individuals with Disabilities Education Act (IDEA) statute, 20 USC 1401, Section 603 (3) is as follows:

- (A) IN GENERAL.—The term "specific learning disability" means a disorder in 1 or more of the basic psychological processes involved in understanding or in using language, spoken or written, which disorder may manifest itself in the imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations. (B) DISORDERS INCLUDED.—Such term includes such conditions as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. (C) DISORDERS NOT INCLUDED.—Such term does not include a learning problem that is primarily the result of visual, hearing, or motor disabilities, of mental retardation, of emotional disturbance, or of environmental, cultural, or economic disadvantage.

Nowhere in the IDEA definitions and descriptions does it specifically name the "basic psychological processes" that might be impaired. Indeed a 1990 letter from the Office of Special Education Programs, quoted in McBride, Dumont & Willis, 2011 ( pp. 89–90) indicates that the U.S. federal law and regulations do not require documentation of a processing disorder. Still, there is nothing in the final 2006 Regulations for the IDEA that would prohibit an evaluation team from requesting assessments of psychological processing,

Despite the lack of any clear definition, and no requirement to actually assess for the "disorder," states are allowed to impose their own understanding of these terms based on the congressional definition and to require adherence to those guidelines as an additional burden on eligibility groups. Models of intellectual abilities that include separate cognitive abilities seem to offer some candidates for processes to evaluate.

Flanagan and Mascolo (2005) present an operational definition of *learning disability* that includes "analysis of cognitive ability." Their rationale for the model includes the concept that a significant ability-achievement discrepancy need not be present to establish a learning disability (Siegel, 1999; Stanovich, 1999), primarily because different ability measures will result in different discrepancies (either significant or non-significant) for different reasons (p. 22).

Effective diagnosis of these disabilities as defined through cognitive abilities relies on tests that provide effective measures of these cognitive abilities and processes. Cognitive ability tests that have evolved along with theories and models of cognitive ability are integral to the diagnoses of these disorders. This chapter will focus on those models and their utility for understanding people's abilities and impairments, and diagnosing learning disabilities, and developmental delay. Current individual tests of cognitive ability will be evaluated within the models.

### ***Intelligence as Overall Ability or $g$***

According to Hale and Fiorello (2004) (who believe "that IQ overemphasis is one of the major problems in psychology practice" [p. 18]), researchers such as Jensen (1998), Gottfredson (1997), and Herrnstein and Murray (1994) have asserted that general intelligence ( $g$ ) is the single most important predictor of important life outcomes such as academic success, job attainment, income level, and the likelihood of incarceration. Despite its importance, there is still a lack of an accepted definition for the construct of *intelligence*. Sattler (2008, p. 223) provides a list of

**Table 19.1 Cognitive Ability Tests and the Name Given to the Global Score**

Test	Name of Global Score
Cognitive Assessment System	Full Scale
Differential Ability Scales-II	General Conceptual Ability
Insight	Insight Ability Index
Kaufman Assessment Battery for Children-II	Fluid Crystallized or Mental Processing Index
Kaufman Brief Intelligence Test-II	IQ Composite
Leiter International Performance Scale-R	Full Scale Quotient
Reynolds Intelligence Assessment Scales	Composite Intelligence Index
Stanford Binet-5	Full Scale IQ
Wechsler Scales	Full Scale IQ
Woodcock-Johnson III	General Intellectual Ability

19 different definitions that have been suggested over the years by several of the major experts in the field of psychology. The lack of a single, accepted definition of intelligence has further contributed to many disagreements about how to actually assess intelligence (or intelligences, as the case may be). Without agreement on the definition of intelligence—and even on whether IQ exists—it is no wonder that there is little agreement on how to measure intelligence. For information about the major theories of intelligence that have influenced testing, see Anastasi and Urbina (1997); Carroll (1993); Eysenck vs. Kamin (1981); Flanagan, Genshaft, and Harrison, (1997); Gould (1981); Kaufman (2009), McGrew & Flanagan (1998, Chap. 1), Sattler (2008, Chap. 7); and Woodcock (1990), among many others.

As shown in Table 19.1, because there has not been a single, agreed-upon definition of intelligence, cognitive ability measures have themselves utilized many different names for the global constructs or abilities they purport to measure. The choice of a measure of intellectual functioning in a particular setting, such as school or clinic, and for a particular child, adolescent, or adult may have much to do with the individual evaluator's definition and understanding of intelligence or intellectual functioning. Consequently, it is important for the evaluator to adopt or develop an explicit theory of intellectual functioning and reflect on the possible consequences of that theory in evaluating and reaching conclusions about the client.

Many of the current cognitive ability tests have their roots primarily as measures of *g*. Examples include the

Stanford-Binet Intelligence Scale (e.g., Form L and M, Terman, 1960); and the early Wechsler scales (WISC, Wechsler, 1949), and the Wechsler-Bellevue Intelligence Scale (Wechsler, 1939).

Several intellectual ability tests, such as the Reynolds Intellectual Assessment Scales (RIAS; Reynolds & Kamphaus, 2003, 2005), are explicitly designed to assess *g*; for example, "general intelligence and its two primary components, fluid and crystallized intelligence" (Reynolds & Kamphaus, 2003, p. iv). The RIAS would be ideal for the evaluator who believes that intellectual functioning is a matter of *g*, including only or primarily fluid (*Gf*) and crystallized (*Gc*) abilities (see, for example, Cattell & Horn, 1978). [The RIAS also includes a separate verbal and visual memory scale.]

### ***Components of g as Multiple Abilities***

Many current cognitive ability tests are structured on different conceptualizations of intellectual functioning, placing less emphasis on *g* and more emphasis on the multiple indexes tapping various levels of processing. For example, the Differential Ability Scales (DAS-II, Elliott, 2007a) includes only verbal ability, nonverbal (fluid) reasoning, and spatial ability in its total, general conceptual ability (GCA) score. Although other important abilities are assessed with the "diagnostic" subtests and clusters, these do not influence GCA score (Elliott, 2007b; Dumont, Willis, & Elliott, 2008). The fifth edition of the Stanford-Binet (SB5; Roid, 2003a,b) divides intellectual functioning into verbal and nonverbal domains, within which it assesses fluid reasoning,

knowledge, quantitative reasoning, visual/spatial ability, and working memory (including nonverbal knowledge and verbal visual/spatial ability).

The Wechsler scales (WISC-IV; Wechsler, 2003; WPPSI-III; Wechsler, 2002; WAIS-IV; Wechsler, 2008) are based on Wechsler's famous definition of intelligence: "the capacity of the individual to act purposefully, to think rationally, and to deal effectively with his environment" (1944, p. 3). However, over the years, through various editions, these scales have gradually given greater emphasis to separate index scores, expanding from the original verbal and performance IQ scales to current verbal comprehension, perceptual reasoning, working memory, and processing speed index scores. Although the Wechsler scales are not explicitly based on CHC theory, these indices more or less correspond to the CHC broad abilities of crystallized ability, fluid reasoning and visual/spatial thinking, short-term memory, and processing speed, respectively.

Further cognitive ability tests have been developed based on cognitive theories that have multiple abilities in the model. They are discussed within the context of their models later in this chapter.

Table 19.2 provides a summary of the design characteristics of several cognitive assessment batteries. The table shows that an evaluator has many options for how to assess the concept of intelligence. The test batteries in Table 19.2 assess cognition using various numbers of measures (tests or subtests) that range from a single test like the TONI-4 to tests incorporating up to 31 tests or subtests like the WJ III, including the Diagnostic Supplement. The overall global scores (called different things by different tests, e.g., FSIQ, GIA, GAI, GCA, FCI, MPI), can include as few as one subtest or as many as 14 subtests.

## Models of Intelligence as Multiple Abilities

The developments of many of the older cognitive ability tests and the more recently developed tests have largely moved toward models that describe intelligence as multiple abilities. For example, Wechsler (2008) describes the evolution of the Wechsler Adult Intelligence Scale-IV from its early roots considering intelligence to be a *global* entity characterizing behavior as a whole, as well as *specific* because it is composed of elements or abilities that are at least partly distinct from each other. More recent versions of the Wechsler intelligence scales have enhanced the measurement of more discrete domains of cognitive function. The author's evidence for support of a theoretical basis in the Wechsler scales is the

appearance of the same or similar subtests in other measure of intelligence, as well as the high correlation of Wechsler Intelligence Scales with other measures of cognitive ability (Wechsler, 2008, pp. 2-4). Other tests, such as the Woodcock-Johnson Tests of Cognitive Ability, the Kaufman Assessment Battery for Children, and the Cognitive Assessment System have been developed through models of cognitive ability based on cognitive theory.

The next section presents the major theoretical models of cognitive ability and the tests developed within the models, including CHC theory and the Luria model. Cross-battery assessment (XBA) provides a framework for making optimal use of components of tests to assess the range of cognitive abilities subsumed by CHC theory. For each of the tests we describe the component abilities and revisit the overall *g* score as the composite or weighted average of the component abilities.

### CHC Theory

"CHC" stands for "Cattell-Horn-Carroll," a synthesis of the research and theoretical model of Cattell and Horn with those of Carroll. CHC theory is one of the most widely recognized current theories of intellectual abilities (e.g., Alfonso, Flanagan, and Radwan, 2005; McGrew, 2005; Sternberg & Kaufman, 1998), although its application to test construction and interpretation is also subject to criticism (e.g., Frazier & Youngstrom, 2007). For a history of the development of CHC theory as it relates to theories and models of intelligence, see the Greenberg, Lichtenberger and Kaufman Chapter 2 in this volume; Flanagan, Ortiz, and Alfonso (2007); McGrew (2005); and Willis, Dumont, and Kaufman (2011).

CHC theory focuses on the measures of broad (stratum II) abilities as well as the narrow (stratum I) abilities within each broad ability. Carroll (1993, 1997/2005) strongly emphasized the importance of a third stratum (*g*) at the top of the hierarchy. Horn (1994; Horn & Blankson, 2005) emphatically did not. Assessments that utilize the CHC theory focus primarily on the broad abilities since they have been linked to the kinds of processing deficits that are integral to definitions of learning disabilities. The narrow abilities, while important in CHC theory, are described as individual subsets of the broad abilities, and thus less emphasis is placed upon them. Several books have been written that are useful in understanding how the individual subtests of many intelligence and achievement tests can be classified by the broad ability and even by narrow abilities they

**Table 19.2 CHC Broad and Narrow Abilities and Cognitive Tests That Assess Them**

The information in this table is provided only as a guide to the publications cited above and *cannot stand alone*. You *must* use the essential references listed below to understand CHC theory and apply it to the McGrew, Flanagan, & Ortiz's Integrated Cattell-Horn-Carroll Cross-Battery Approach. Most of the examples of tests for various narrow abilities below are taken from those sources and from Mather & Woodcock (2001a; 2001b) and McGrew & Woodcock (2001). They are only a few examples of the many given in Alfonso's, Flanagan's, Mascolo's, Mather's, McGrew's, and Ortiz's cited texts. Tests in (parentheses) are secondary measures of the narrow ability and a primary measure of some other narrow ability. Tests or procedures marked with "?" are our guesses. The information on significant relationships between other CHC abilities and reading and math achievement are taken from Flanagan and Ortiz (2001, pp. 50–51); Flanagan, McGrew, and Ortiz (2000, p. 286), Flanagan, Ortiz, and Alfonso (2007), Flanagan, Ortiz, Alfonso, and Mascolo (2006), and McGrew and Flanagan (1998, p. 422), where there are also in-depth discussions of this issue, including the basis in research.

Broad Abilities	Narrow Abilities
<b>Fluid Intelligence Gf</b>	<i>General Sequential Reasoning (RG)</i> (a.k.a. deductive reasoning) WJ III Analysis-Synthesis; (WJ III Planning); KAIT Logical Steps; LIPS-R Picture Context, Visual Coding; SB5 Nonverbal Fluid Reasoning & Verbal Fluid Reasoning.
Fluid reasoning. Problem-solving tasks that are not automatic. Often considered the essence of g. Gf and Gsm (MW) are probably essential components. I and RG "play a moderate role in reading comprehension.... [and] are consistently very important at all ages" in math achievement (Flanagan & Ortiz, 2000, p. 50). We suspect that first encounters with new, generally non-Gf tasks have a Gf component that wears off quickly.	<i>Induction (I)</i> WJ III Concept Formation; LIPS-R, Classification, Design Analogies, Repeated Patterns, Sequential Order; Raven's & other matrix tests (DAS II Matrices, Wechsler Matrix Reasoning); WISC-IV & WPPSI-IV Picture Concepts; KABC-II Pattern Reasoning & Story Completion.

<b>Crystallized Intelligence Gc</b>	<i>Speed of Reasoning (RE)</i> LIPS-R Attention Divided?
Largely verbal intelligence; not only one's knowledge of one's culture, but also one's ability to apply that knowledge effectively. This is a <i>cognitive</i> ability. Most LD tests also measure VL and vice versa. Although most oral, verbal tests are classified under Gc, some clearly involve more reasoning (Gf?) than others. LD, VL, and LS are important [for reading and math achievement] at all ages. These abilities become increasingly ... important with age" (Flanagan & Ortiz, 2001, p. 50). Obviously, Gc abilities are also very important for writing and for achievement in content-area subjects. Many Gc abilities are covered better by the tests used in speech and language evaluations than by those used in psychoeducational evaluations.	<i>Language Development (LD)</i> WJ III COG Verbal Comprehension; Wechsler Comprehension., Similarities;  <i>Lexical Knowledge (VL) (vocabulary)</i> WJ III Verbal Comprehension; WJ III DS Bilingual Verbal Comp.; DAS-II Word Definitions, Naming Vocabulary; most vocabulary tests; KABC-II Expressive Vocabulary, Riddles, & Verbal Knowledge; SB5 Verbal Knowledge; Wechsler Similarities, Vocabulary, & Word Reasoning, WPPSI-IV Picture Naming & Receptive Vocabulary;  <i>Listening Ability (LS)</i> General (verbal) Information (K0) WJ III COG General Information; Wechsler Information  <i>Information about Culture (K2)</i> KAIT Famous Faces; K-ABC Faces & Places

Broad Abilities	Narrow Abilities
<b>Visual Processing Gv</b>	<i>Spatial Relations (SR)</i>
<p>Our favorite definition of Gv is Richard Woodcock's "fluent thinking with images that are visual in the mind's eye." Gv does include simple, perceptual, visual processing tasks, but it also includes higher-level cognitive reasoning and problem-solving. There might be some real merit to separating the two. Gv "may be important primarily for higher-level or advanced mathematics (e.g., geometry, calculus)" (Flanagan &amp; Ortiz, p. 50). My experience is that students with much stronger Gv than Gc abilities use the Gv abilities in unexpected ways, sometimes maladaptively. Weaknesses in Gv can impair mental visualization (sometimes interfering with reading comprehension) and nonverbal communication. Visual Memory (MV) is a Gv narrow ability, not Gsm.</p>	<p>WJ III COG Spatial Relations; Wechsler Block Design; DAS-II Pattern Construction; LIPS Figure Rotation; (WPPSI-IV Object Assembly); KABC-II Triangles; SB5 NV Visual-Spatial Processing; KM/R/NU Geometry</p>

	<i>Spatial Scanning (SS)</i>
	<p>WJ III COG Planning; KABC-II Rover; WISC-IV Integrated Elithorn Mazes</p>
<b>Auditory Processing Ga</b>	<i>Phonetic Coding: Analysis (PC:A)</i>
<p>"Phonetic coding (PC) or 'phonological awareness/ processing' is very important [to reading development] during the elementary school years" (Flanagan &amp; Ortiz, 2001, p. 50). Phonological abilities and Rapid Automatized Naming [Glr (NA)] are, of course, the hot topics in reading assessment. Even more fundamental sound discrimination and perception issues are important for neuropsychological assessment. The ability to hear clearly under less-than-ideal circumstances is very important for school functioning. See your friendly, local audiologist.</p>	<p>WJ III COG Incomplete Words; DAS-II Phonological Processing</p>
	<i>Phonetic Coding: Synthesis (PC:S)</i>
	<p>WJ III COG Sound Blending; DAS-II Phonological Processing</p>

Broad Abilities	Narrow Abilities
<p>important [for reading and math] especially when evaluated within the context of working memory" (Flanagan &amp; Ortiz, 2001, p. 50). Weaknesses in working memory seem to be very significant for writing. It is an irony that those who need to memorize "math facts" or spelling rules because they cannot afford to be distracted while working are learning them.</p>	<p><i>Working Memory (MW)</i> DAS-II Recall of Digit Backward, Recall of Sequential Order; Wechsler Digit Span backward; WJ III Numbers Reversed &amp; Auditory Working Memory; Wechsler Letter-Number Sequencing; WISC-IV Arithmetic</p>
	<p><i>Learning Abilities (L1)</i> (also in Glr)</p>
	<p>"A number of factors...specific to particular kinds of learning situations and memory ....Not clearly defined by existing research" (McGrew &amp; Flanagan, 1998, p. 35). For example, speed of relearning material after other tasks, e.g., WJ III COG Visual-Auditory Learning-Delayed?</p>
<p><b>Long-Term Storage and Retrieval Glr</b></p>	<p><i>Associative Memory (MA)</i></p>
<p>The issue here is the storage <i>and</i> retrieval. Glr is how information gets into Gc. Glr seems to be very important for Gf. "Naming Facility (NA) or 'rapid automatic naming' is very important [for reading] during the elementary school years. Associative Memory (MA) may be somewhat important at select ages (e.g., age 6)" (Flanagan &amp; Ortiz, 2001, p. 51). Weaknesses in both Ga (PC) and Glr (NA) constitute the "double- deficit" pattern of dyslexia that is receiving much current attention. The definition of NA seems to have shifted usefully from category naming to item naming. Lack of fluency in recalling "math facts" can be a serious hindrance to math achievement.</p>	<p>WJ III COG Visual-Auditory Learning &amp; Visual-Auditory Learning-Delayed; WJ III DS Memory for Names &amp; Memory for Names-Delayed; LIPS-R Delayed Recognition, Associated Pairs, Delayed Pairs; KABC-II Atlantis, Atlantis Delayed, Rebus &amp; Rebus Delayed; KAIT Rebus and Rebus Delayed; various paired-associates learning tasks</p>

*Notes:*

See Flanagan, Ortiz, and Alfonso (2007) for the most up-to-date advice on how to apply this information. When you simply average subtests, you get a different result than the total score for the same subtests from the norms of a test. There are two reasons for this: First, normative total scores are more extreme than the average of their parts, just as it is more unusual to excel (or do very poorly) at all ten events in the decathlon than at only one event. Second, when tests are combined, the one(s) with the largest standard deviation(s) carry more weight than the one(s) with the smaller standard deviation(s). People notice this effect most often on the WJ III because it uses standard scores for both (sub)tests and totals. However, you will see these effects on any test with subtests and total scores, not just the WJ III. If you are using only one test, you should, of course, use the total scores provided. If you are mixing tests, it might be best to be consistent and create your factor scores by averaging in every case, even when normative total scores are available from some groupings.

Flanagan, McGrew, and Ortiz (2000), Flanagan, Ortiz, and Alfonso (2007), and McGrew and Flanagan (1998) recommend translating all scores into standard scores with a mean of 100 and standard deviation of 15 [they, Sattler (2008), Willis & Dumont (2002), and others provide tables for this conversion, and there is a handy downloadable score-conversion program at <http://alpha.fdu.edu/psychology/>]. They recommend using a confidence band of  $\pm 7$  points for subtests and  $\pm 5$  points for totals. If the bands overlap, the total can probably be accepted as a reasonable summary of that ability for that examinee. If they do not overlap, the total is questionable. If the gap between confidence bands is wider than the narrowest band, the narrow abilities very probably cannot be summarized by the total [Flanagan, McGrew, & Ortiz (2000); Flanagan, Ortiz, & Alfonso (2007), and McGrew & Flanagan (1998)]. See also Elliott (2007b). However, scores may fluctuate for reasons other than genuine strengths and weaknesses and normal measurement error. Pay attention to reality! Consider test conditions, your observations, and the student's background when you make your interpretations (O'Neill, 1995).

This information is derived from detailed explanations in Appendix A in D. P. Flanagan, S. O. Ortiz, and V. C. Alfonso, (2007) *Essentials of cross-battery assessment* (2nd ed.) (New York: Wiley); from Table 2.1, pp. 32–41, in D. P. Flanagan, K. S. McGrew, and S. O. Ortiz (2000), *The Wechsler Intelligence Scales and Gf-Gc theory: A contemporary approach to interpretation* (Boston: Allyn & Bacon); and from Figure 1.1, p. 7, in D. P. Flanagan and S. O. Ortiz (2001) *Essentials of cross-battery assessment* (New York: Wiley) which were slightly changed from Table 1–1, pp. 15–19, in K. S. McGrew, and D. P. Flanagan (1998), *The Intelligence Test Desk Reference (ITDR): Gf-Gc cross-battery assessment* (Boston: Allyn & Bacon). “Most all definitions were derived from Carroll [J. B. Carroll (1993) *Human cognitive abilities: A survey of factor-analytic studies* (Cambridge, Eng.: Cambridge University Press)]. Two-letter factor codes (e.g., RG) are from Carroll (1993a). Information in this table was adapted from McGrew [K. S. McGrew (1997), Analysis of the major intelligence batteries according to a proposed comprehensive Gf-Gc framework. In D. P. Flanagan, J. L. Genshaft, & P. L. Harrison (1997), *Contemporary intellectual assessment: Theories, tests, and issues* (New York: The Guilford Press) with permission from Guilford Press” (Flanagan, McGrew, & Ortiz, 2000, p. 41). See also Flanagan, Ortiz, Alfonso, and Mascolo, (2002) *Achievement Test Desk Reference (ATDR): Comprehensive assessment and learning disability* (Boston: Allyn & Bacon) and D. P. Flanagan, S. O. Ortiz, V. C. Alfonso, and J. T. Mascolo (2006) *Achievement Test Desk Reference (ATDR-II): A guide to learning disability identification* (2nd ed.) (Hoboken, NJ: Wiley).

tap (Flanagan and Harrison, 2005; Flanagan, Ortiz and Alfonso, 2007; Flanagan, Ortiz, Alfonso, and Mascolo, 2006; and McGrew and Flanagan, 1998). Some classifications were made by factor-analytic research, while others are made on the basis of surveys of expert opinion. The following definitions are brief summaries of syntheses compiled by Willis, Dumont, and Kaufman (2011) drawing very heavily on presentations in Carroll (1993); Flanagan and McGrew (1997); Flanagan, McGrew, and Ortiz (2000); Flanagan, Ortiz, and Alfonso, 2007; Flanagan, Ortiz, Alfonso, and Mascolo (2006); McGrew, 1997; and McGrew and Flanagan (1998).

*Gf: fluid intelligence*, refers to inductive, deductive, and quantitative reasoning with

materials and processes that are new to the person doing the reasoning.

*Gc: crystallized intelligence*, refers to the application of acquired knowledge and learned skills to answering questions and solving problems presenting at least broadly familiar materials and processes.

*Gv: or visual-spatial thinking*, involves a range from fairly simple visual perceptual tasks to higher level, visual, cognitive processes.

*Ga: auditory processing*, involves tasks such as recognizing similarities and differences between sounds; recognizing degraded spoken words, such as words with sounds omitted or separated; and mentally manipulating sounds in spoken words.

*Gs: processing speed or attentional speediness*, refers to measures of clerical speed and accuracy, especially when there is pressure to maintain focused attention and concentration.

*Gt: decision/reaction time or speed*, reflects the immediacy (quickness) with which an individual can react to and make a decision about (decision speed) typically simple stimuli.

*Gsm: short-term or immediate memory*, refers to the ability to take in and hold information in immediate memory and then to use it within a few seconds. Gsm is divided in current CHC formulations into memory span (MS) and working memory (MW) with a distinction between simple recall (MS) and mental manipulation of material held in short-term memory (MW).

*Glr: long-term storage and retrieval*, involves the efficiency of memory storage and retrieval over longer periods of time than Gsm.

*Grw: includes reading and writing.*

*Gq: quantitative knowledge*, is distinct from the quantitative reasoning that is a narrow ability within Gf.

For complete definitions and explanations, please see the above references, especially the most recent Flanagan, Ortiz, and Alfonso (2007) and Flanagan, Ortiz, Alfonso, and Mascolo (2006) and the Cross-Battery Assessment website (<http://www.crossbattery.com/>).

Those last two broad abilities (*Grw* and *Gq*) in CHC theory challenge the traditional distinction between “academic achievement” and “intellectual ability,” which is implicitly or explicitly a central component to many definitions of specific learning disability. Carroll (1993, p. 510) recommends that we “conceptualize a continuum that extends from the most general abilities to the most specialized types of knowledges.” Flanagan, Ortiz, Alfonso, and Mascolo (2002, p. 21) quote both Carroll (“It is hard to draw the line between factors of cognitive abilities and factors of achievement. Some will argue that *all* cognitive abilities are in reality learned achievements of one kind or another” [emphasis in the original; 1993, p. 510]) and Horn (“Cognitive abilities are measures of achievements, and measures of achievements are just as surely measures of cognitive ability” [1988, p. 655]). Flanagan, Ortiz, Alfonso, and Mascolo similarly conclude, “Thus, rather than conceiving of cognitive abilities and academic achievements as mutually exclusive, they may be better thought of as lying on an ability continuum that has the most general types of abilities

at one end and the most specialized types of knowledge at the other (Carroll, 1993).”

Given the various definitions of specific learning disabilities, and within those definitions specific language about “processing,” researchers have attempted to show some logical link between a child’s area of processing deficit and the deficits in areas of academic achievement. Tables summarizing the recent literature on the relationship between CHC cognitive abilities and specific academic abilities are provided in Flanagan and Mascolo (2005, p. 353) and are updated in Flanagan, Alfonso, Mascolo and Sotelo-Dynega (2012, pp. 656–662).

CHC theory is the basis for many instruments, or is at least acknowledged in the test manuals, Adherents to the Cattell-Horn-Carroll model of intelligence (Carroll, 1997, 2005; Flanagan, Ortiz, & Alfonso, 2007; Horn & Blankson, 2005; McGrew & Flanagan, 1998; Woodcock, 1990) would probably include in an assessment of intellectual functioning all stratum II broad abilities: fluid reasoning, crystallized ability, spatial thinking, long-term storage and retrieval, short-term memory, auditory processing, and processing speed. A single instrument designed to assess this wide array of abilities, such as the Woodcock-Johnson III (Woodcock, Schrank, McGrew, & Mather, 2007a) might be used, or the evaluator might choose to assemble a battery of tests and subtests to measure all of the desired abilities, performing the Cross-Battery Assessment developed by Kevin McGrew and Dawn Flanagan and still being expanded and refined by Dawn Flanagan, Samuel Ortiz, and Vincent Alfonso. The most recent formulations of the cross-battery approach may be found in Flanagan, Ortiz, and Alfonso (2007) and at the “official website of the CHC Cross-Battery approach” (<http://www.crossbattery.com/>). The cross-battery approach is a subject of lively debate: see, e.g., Floyd (2002); Ortiz and Flanagan (2002a, 2002b); Watkins, Glutting, and Youngstrom (2002); and Watkins, Youngstrom, and Glutting (2002).

Table 19.3 shows the CHC broad abilities measured in recent editions of the Wechsler Scales, the Woodcock-Johnson III Tests of Cognitive Ability and Diagnostic Supplement, the Stanford-Binet-V, the Differential Ability Scales-II, and the Kaufman Assessment Battery for Children-II. These charts show that not all of these tests measure all of the CHC abilities, and not all of the processing abilities within the definition of “learning disability” of the Learning Disabilities Association of Canada. In addition to these tests, CHC theory has been applied in the development of Insight (Beal, 2011),

**Table 19.3 CHC Abilities as Measured by Frequently Used Individual Tests of Cognitive Ability**

WJ III: Woodcock Johnson-III Tests of Cognitive Abilities classifications are from McGrew, R. W., Schrank, F. A., & Woodcock, R. W. (2007), *Technical manual. Woodcock-Johnson III normative update*. Rolling Meadows, IL: Riverside Publishing.

DAS II classifications are from Dumont, Willis, & Elliott (2008).

Wechsler classifications are from Alfonso, Flanagan, & Radwan (2005), Flanagan & Kaufman (2004), Lichtenberger & Kaufman (2009).

KABC-III classifications are from Kaufman, A. S., & Kaufman, N. L. (2004), *KABC-II manual*. Circle Pines, MN: AGS Publishing.

SB-V classifications are from Nelson Education catalogue, available at <http://www.assess.nelson.com/test-ind/stan-b5.html>.

a group-administered cognitive abilities test for school-aged children, normed in Canada.

CHC theory works well within a diagnostic context. The general ability (stratum III) measure of *g* provides an overall level for establishing developmental delay. The CHC broad abilities map well

onto the processing deficits linked to the diagnosis of “learning disability” as defined by the Learning Disability Association of Canada (2003). From their definition, phonological processing is measured by *Ga*, auditory processing; memory and attention are measured by *Glr*, long-term storage

and retrieval, and by *Gsm*, short-term memory; processing speed is measured by *Gs*, processing speed; language processing is measured by *Gc*, crystallized ability; and visual-spatial processing is measured by *Gv*, visual processing. Note that *Gf*, fluid reasoning, is not considered to be a process, but stands alone as integral to establishing a learning disability, distinct from a more global developmental delay.

Further practical uses for the CHC model include linking cognitive strengths and weaknesses to skills integral to vocations and careers. While not exhaustive, the range of abilities measured provides a broad scope and a common language for discussing abilities.

### **Luria Theory**

Alexander Luria presented his theory of brain organization and function in 1970. He described the basic building blocks of intelligence as *functional units*, which he believed were the basic cognitive processes that provide the “ability” to perform certain acts, each of which is distinctive in character. He postulated that the human brain can be considered to be made up of three main blocks incorporating basic functions. The first block regulates the energy level and tone of the cortex for organization of its various processes. Located particularly in the reticular formation, which controls wakefulness, it is responsible for selectivity of cortical actions and of normal discrimination of stimuli. These functions are referred to as arousal and attention. Block 2 plays a decisive role in the analysis, coding and storage of information. Located in the rear of the cortex, these areas include the occipital, parietal, and temporal lobes. Block 3 is involved in the formation of intentions and programs for behavior, referred to as executive functions of planning and programming behavior. Located in the frontal lobes, the functions serve primarily to activate the brain and regulate attention and concentration. Luria stressed that brain functions in the three blocks are integrated, and must work together for normal cognitive functioning. Yet, disruptions in each of the blocks will disrupt behavior in different ways. With this specificity, the Luria model is well suited as the basis for the development of cognitive ability tests for diagnostic purposes (Kaufman, Lichtenberger, Fletzer-Jantzen, & Kaufman, 2005; Kaufman & Kaufman, 2004; Luria, 1970).

The Kaufman Assessment Battery for Children (KABC) (1983) and the Kaufman Assessment

Battery for Children, Second Edition (KABC-II, 2004) operationalized the Luria model in tests of cognitive ability for children. Under the Luria model, the KABC-II examines four broad areas of cognitive ability: learning ability; sequential processing; simultaneous processing; and planning ability (Kaufman & Kaufman, 2004; Kaufman et al., 2005). When combined, these scales yield a total score called the Mental Processing Index. Note that crystallized knowledge is not a component of the Luria model.

Naglieri and Das developed the Planning, Attention, Simultaneous and Sequential theory of intelligence (PASS; e.g. Das, Kirby, & Jarman, 1979; Naglieri & Das, 2002; 2005). The theory proposes that planning, attention, simultaneous, and successive cognitive processes are the basic building blocks of human intellectual functioning. Within the Luria model, attention occurs within Block 1; simultaneous and successive processing occur within Block 2; and planning occurs within the executive functions of Block 3. The theory proposes that these four basic processes are interrelated and interact with person’s knowledge base (Naglieri, 1999). While all PASS processes are involved in all human activities, sometimes one or more processes will dominate an activity. Naglieri and Das’s (1997) Cognitive Assessment System (CAS) “is built strictly on the Planning, Attention, Simultaneous, and Successive (PASS) theory” (Naglieri, 2005, p. 441). Table 19.4 shows how the Luria model is operationalized in the KABC-II and the CAS for assessing children’s cognitive abilities.

The KABC-II was also developed to fit within CHC theory (Kaufman & Kaufman, 2004). Under this model, the scales are called Short-Term Memory (*Gsm*), Visual Processing (*Gv*), Long-Term Storage and Retrieval (*Glr*), and Fluid Reasoning (*Gf*), and a fifth scale (Knowledge or Crystallized Ability (*Gc*) is added to complete the Fluid-Crystallized Index (Kaufman & Kaufman, 2004a, p. 2).

Since the KABC-II was developed to fit within both the Luria model and CHC theory (Kaufman & Kaufman, 2004), each subtest is classified by the block within the Luria model, and also by the broad ability within CHC theory. Subtests of other tests of cognitive ability might be mapped onto the Luria model, showing the block that each one measures through the linkage provided between the Luria model and CHC theory by Kaufman and Kaufman (2004). Subtests that are confirmed to measure *Glr* would measure Block 1, arousal and attention. Subtests that are confirmed to measure *Gsm* would

**Table 19.4 Processes of Luria Neuropsychological Model in the Kaufman Assessment Battery for Children-II and Cognitive Assessment System, Shown with CHC Classification.**

			KABC-II	CAS
<b>Block 1</b>				
<b>Arousal and Attention</b>	<b>Learning Ability</b>	<b>Glr</b>	Atlantis	Expressive Attention
	<b>Attention</b>	<b>Long-Term Retrieval</b>	Rebus	Number Detection
		<b>and Storage</b>	Atlantis Delayed	Receptive Attention
			Rebus Delayed	
<b>Block 2</b>				
<b>Use of Senses to Analyze, Code, and Store Information</b>	<b>Sequential</b>	<b>Gsm</b>		
		<b>Short-Term Memory</b>	Number Recall	Word Series
			Word Order	Sentence Repetition
			Hand Movements	Speech Rate
				Sentence Questions
	<b>Simultaneous</b>	<b>Gv</b>	Block Counting	Nonverbal Matrices
		<b>Visual Processing</b>	Conceptual Thinking	Verbal-Spatial Relations
			Face Recognition	Figure Memory
			Rover	
			Triangles	
			Gestalt Closure	
<b>Block 3</b>				
<b>Executive and Planning Functions</b>	<b>Planning</b>	<b>Gf</b>	Pattern Reasoning	Matching Numbers
		<b>Fluid Reasoning</b>	Story Completion	Planned Codes
				Planned Connections
		<b>Gc*</b>	Expressive Vocabulary	
		<b>Crystallized Knowledge</b>	Riddles	
			Verbal Knowledge	

\* The KABC-2 includes tests of crystallized knowledge that are not included in the Mental Processing Index for the Luria Model

measure sequential processing, and subtests that are confirmed to measure  $Gv$  would measure simultaneous processing in Block 2, analyzing, coding and storing information. Subtests that are confirmed to measure  $Gf$  would measure planning in Block 3, executive and planning functions.

Tests such as the KABC-II and the CAS, based on the Luria model, work well within a broader assessment battery for diagnostic purposes. The KABC-II was designed to be a clinical and psychological instrument, and to identify process integrities and deficits for assessment of individuals with specific learning disabilities (Kaufman, Kaufman, Kaufman-Singer, & Kaufman, 2005). The KABC-II's Mental Processing Index and the CAS's Full Scale each provide an overall measure of  $g$  that does not include  $Gc$  crystallized knowledge. As such, they present less of a cultural demand than do  $g$  measures from cognitive ability tests that include  $Gc$  and language abilities in their composite scores. Differences between scores of African-American and Euro-American students are notably smaller on the CAS (3.5 points' difference for Full Scale), and KABC-II (5 points' difference on the MPI and 6.5 points' difference on the FCI, even with the  $Gc$  measure included) than on other comprehensive cognitive ability tests in current use (Kaufman & Kaufman, 2004; Kaufman et al, 2005; Naglieri & Das, 1997; Naglieri, 2005). This could be an important consideration for choosing the KABC-II MPI to assess an African American child in situations where the overall  $g$  level is important for determining eligibility for services. The KABC-II MPI or CAS Full Scale could also be a better measure of  $g$  for students with hearing impairments, who showed the lowest scores on the Knowledge/ $Gc$  scale in a validation study (Kaufman et al., 2005). The same rationale would hold for the assessment of students with language impairment. This would have the effect of eliminating from the overall score an area of cognitive function that is reduced by the cultural difference or by the sensory disorder. Specific uses might be in qualification for gifted education or eligibility for programs for students with developmental disability.

For the diagnosis of learning disabilities, the Luria model measures processing deficits that are integral to the definitions of LD. For example, tests like math calculations may be heavily weighted toward planning functions, while reading decoding tasks may be heavily weighted toward successive processing (Naglieri, 1999). Children with reading disabilities generally evidenced average Planning, Attention and Simultaneous scores, but

low Successive scores (Naglieri, 2005). Research has revealed correlations between PASS measures and various aspects of educational achievement and has provided evidence that profiles of PASS abilities can be used for planning instruction (e.g., Naglieri & Johnson, 2000).

While LD definitions do not refer explicitly to Block 1, 2, and 3 processes, or specifically to sequential, simultaneous, and planning processes, these processes are easily linked through CHC theory to the processes in the definitions of LD. Processes that are not measured by the Luria model, such as  $Gc$  crystallized knowledge and auditory phonemic awareness and processing speed, can be measured using other cognitive ability tests, under a cross-battery approach.

Further information on the applications of the Luria model for diagnostic purposes is provided in books and articles on interpreting the KABC-II and the CAS. Notably, *The Essentials of KABC-II Assessment* (Kaufman et al, 2005) has a chapter on clinical applications that addresses assessment of children with various characteristics and disabilities. *The Essentials of CAS Assessment* (Naglieri, 1999) also has a chapter on clinical applications.

### ***Cross-Battery Assessment***

In 1997, Flanagan and McGrew developed the CHC (Cattell-Horn-Carroll) Cross-Battery approach to intellectual testing. They stated that an intelligence battery ought to be able to measure the full range of broad cognitive abilities that define the structure of intelligence (McGrew & Flanagan, 1998, p. 356). While crossing or mixing tests in a neuropsychological or cognitive assessment was not a new concept, the cross-battery approach arose primarily out of the finding that none of the major intelligence batteries adequately measured the full range of important  $Gf/Gc$  abilities according to contemporary theory and research. The Woodcock-Johnson III (Woodcock, McGrew, & Mather, 2001a, 2007) was explicitly designed to assess all of the CHC abilities.

There are three "pillars" to this approach (Flanagan, & Ortiz, 2001; Flanagan, Ortiz & Alfonso, 2007, pp. 22-29; McGrew & Flanagan, 1998). Pillar 1 is the Cattell-Horn-Carroll Theory of Cognitive Ability, providing a relatively complete taxonomic framework for describing the structure and nature of cognitive abilities. Horn (1998) and others have likened this to a Periodic Table of the Elements for cognitive psychology. Pillar 2 is the CHC broad (stratum II) classifications of cognitive

and achievement tests. Pillar 3 is the CHC narrow (stratum II) classifications of cognitive and achievement tests.

The classifications of current cognitive ability tests according to CHC theory have been published in various volumes (including Flanagan & Ortiz, 2001; Flanagan, Ortiz & Alfonso, 2007, and Flanagan, Ortiz, Alfonso & Mascolo, 2002; Flanagan, Ortiz, Alfonso & Mascolo, 2006; McGrew & Flanagan, 1998). Our updated summary, drawn from these sources, is in Table 19.3. Whether or not a practitioner or theorist agrees with CHC theory and the classifications, this approach represents a major step in linking cognitive ability subtests to a theory and model for more uniform interpretation.

The Cross-Battery Assessment model is implemented through a series of planned and sequential steps (Flanagan & Ortiz, 2001; Flanagan, Ortiz & Alfonso, 2007). Essentially, an examiner selects the primary intelligence battery for the assessment, notes the adequately represented CHC abilities and processes that are included; and then selects additional tests to measure the CHC abilities processes not measured by the primary battery. Guidelines are provided in the sources listed above and at the Cross-Battery Assessment website (<http://www.crossbattery.com/>) to assist the examiner in determining the adequacy of specific test's representation of the CHC abilities, and suggested testing procedures to utilize when measures of a broad ability are not consistent.

A similar template for crossing test batteries using Luria theory or any other theory of cognitive ability could be developed by classification of subtests according to that theory.

The cross-battery approach works well for the diagnosis of learning disabilities, particularly in Canada, where academic achievement deficits must be logically linked to deficits in underlying cognitive processes. This approach has also been linked to instructional, environmental, and assessment accommodations for students when underlying processing deficits are known to exist (Elementary Teachers' Federation of Ontario, 2007; Weiss, Beal, Saklofske, Packiam Alloway, & Prifitera, 2008).

The remainder of this chapter presents an updated review of several of the tests that assess the broad and narrow abilities within CHC theory.

### **Choosing the Model and Test to Best Assess the Client**

Choosing the tests for a battery to assess a client should begin with the referral question. As discussed in this chapter, the model upon which the

test is built, and the psychometric characteristics of the test for similar populations, will help guide the evaluator to an appropriate choice. The following test descriptions are meant to be a source of general information regarding each test to assist the evaluator in making a good choice for each client.

### ***Cognitive Assessment System***

The Cognitive Assessment System (CAS; Naglieri & Das, 1997a; see also Naglieri, 1999; Naglieri & Das, 1997b, 2005) is an individually administered test of cognitive ability for children ages 5 years through 17 years and 11 months. The test includes 12 subtests, and can be administered in two forms. The Standard battery consists of all 12 subtests, while the Basic battery is made up of 8 subtests. Standard scores are provided for all subtests, with a mean of 10 and a standard deviation of 3. The four scales, along with the Full Scale score, are reported as standard scores with a mean of 100 and a standard deviation of 15.

The CAS is based on the PASS model (Das, Kirby, & Jarman, 1975; Naglieri & Das, 2005), which is derived in part from Luria's theories (e.g., 1966, 1973, 1980). The model is represented by four scales representing Planning, Attention, Simultaneous, and Successive cognitive processes (PASS). *Planning* is the ability to conceptualize and then apply the proper strategies to successfully complete a novel task. The individual must be able to determine, select, and then use a strategy to efficiently solve a problem. *Attention* is a cognitive process by which an individual focuses on one cognitive process while excluding extraneous competing stimuli. *Simultaneous* processing is the integration of stimuli into a coherent whole. *Successive* processing involves organizing various things into a specific sequential order. A Full Scale score can also be obtained from the data.

Examiners who find Luria's theories especially helpful and examiners seeking a test structure and content different from Wechsler, Binet, and Cattell-Horn-Carroll formulations may find the CAS useful, especially when the PASS theory is most likely to answer the specific referral questions for a particular student.

### ***Comprehensive Test of Nonverbal Intelligence***

The Comprehensive Test of Nonverbal Intelligence (CTONI; Hamill, Pearson & Wiederholt, 1997) now in its second edition as CTONI-2 (Hamill, Pearson, & Wiederholt, 2009) measures nonverbal

reasoning abilities of individuals aged 6 through 89. The CTONI-2 contains no oral responses, reading, writing, or object manipulation. There are six subtests in total. Three subtests use pictured objects and three use geometric designs. Examinees indicate their answers by pointing to alternative choices. The CTONI-2 provides three composite IQ scores: Nonverbal Intelligence Quotient, Pictorial Nonverbal Intelligence Quotient, and Geometric Nonverbal Intelligence Quotient.

The CTONI-2 offers the advantage of completely non-oral administration. The lack of verbal subtests is obviously helpful for testing children with limited oral language or English language abilities, but this omission also limits the scope of the assessment. The consistent multiple-choice format can be an asset for children who have difficulty learning or shifting between tasks; but this format again limits the scope of the assessment. See also the Test of Nonverbal Intelligence, 4th edition (TONI-4; Brown, Sherbenou, & Johnsen, 2010), which is a recently normed, non-oral multiple-choice test that offers two parallel forms.

### ***Differential Ability Scales—Second Edition***

The DAS-II (Elliott, 2007a, 2007b; see also Dumont, Willis, & Elliott, 2008; Elliott, 2005; Sattler, 2008) is an individually administered measure of cognitive ability designed to measure specific abilities and assist in determining strengths and weaknesses for children and adolescents aged 2 years, 6 months, through 17 years, 11 months.

At the Upper Early Years and School-Age levels, the DAS-II is composed of 10 “core” cognitive subtests and 10 “diagnostic” subtests. Four core subtests plus most of the diagnostic subtests are used at the Lower Early Years level. The core subtests are used to calculate a high-level composite score called the General Conceptual Ability (GCA) score, and three lower-level composite scores: Verbal Ability, Nonverbal (fluid) Reasoning Ability, and Spatial Ability cluster scores. The diagnostic subtests, which yield three cluster scores: Processing Speed, Working Memory, and School Readiness, are used predominantly to assess strengths and weaknesses and do not contribute to the composite scores.

The DAS-II uses standard scores ( $M = 100$ ,  $SD = 15$ ) for the composite scores and T scores ( $M = 50$ ,  $SD = 10$ ) for the 20 individual subtests. Overlapping age ranges for the Lower Early Years (with fewer subtests and clusters), Upper Early Years, and School-Age batteries and out-of-level norms allow considerable flexibility in standardized

testing of low- and high-scoring children. Examiners who agree with Elliott that verbal, fluid reasoning, and spatial abilities are core intellectual abilities and that other important cognitive functions with lower  $g$  loadings should be measured but not included in the total score will find the DAS-II especially appealing.

### ***Kaufman Adolescent and Adult Intelligence Test***

The Kaufman Adolescent and Adult Intelligence Test (KAIT, 1993; see also Lichtenberger, Broadbooks, & Kaufman, 2000) is an individually administered measure of general intellectual ability for use with persons between the ages of 11 and 85+ years. The KAIT consists of Crystallized and Fluid Scales that yield a Composite IQ score. The Crystallized Scale, a measure of knowledge acquired through education and sociocultural experience, includes Definitions, Auditory Comprehension, Double Meanings, and an alternate subtest—Famous Faces. The Fluid Scale, primarily a measure of problem-solving ability in novel situations, comprises Rebus Learning, Logical Steps, Mystery Codes and an alternate Memory for Block Designs subtest. In addition to the Core Battery subtests, the KAIT includes memory measures that allow for interpretation of immediate and delayed recall (Rebus Delayed Recall and Auditory Delayed Recall).

Subtests use scaled scores that have a mean of 10 and a standard deviation of 3. The Fluid, Crystallized, and Composite IQ scales yield scores with a mean of 100 and a standard deviation of 15.

While the Cattell-Horn concept of fluid ( $G_f$ ) and crystallized ( $G_c$ ) intelligence (1966, 1967) is the predominant theory on which the KAIT is founded, the test also draws upon neuropsychological and cognitive developmental models, specifically Golden's (1981) concept of planning ability as related to pre-frontal lobe development and Piaget's (1972) highest stage of cognitive development—formal operations.

Although old, the KAIT is a very useful measure of intelligence that can be used with a variety of populations. The use of fluid and crystallized scales is consistent with the multiple factor theory of intelligence and allows for administration to people with diverse backgrounds.

### ***Kaufman Assessment Battery for Children—Second Edition***

The KABC-II (Kaufman & Kaufman, 2004a; see also see also Kaufman, Lichtenberger,

Fletcher-Janzen, & Kaufman, 2005) contains a total of 18 subtests grouped into core or supplementary tests. Subtests not only combine to produce the Global Index scores (FCI or MPI) but also yield up to four (Luria model) or five (CHC model) Indexes. These Index scores represent sequential processing/short term memory ( $Gsm$ ), simultaneous processing/visual processing ( $Gv$ ), learning ability/long term storage and retrieval ( $Glr$ ), planning ability/fluid reasoning ( $Gf$ ), and crystallized ability ( $Gc$ ). This last (crystallized ability) is represented only in the CHC model. The KABC-II uses standard scores ( $M = 100$ ,  $SD = 15$ ) for the five scales, and the three global indexes and scaled scores ( $M = 10$ ,  $SD = 3$ ) for the 18 individual subtests.

There are two interpretative models: the CHC (Carroll, 1997/2005; Flanagan, Ortiz, & Alfonso, 2007; Horn & Blankson, 2005) and the Luria (1966, 1973, 1980). The core subtests have individual scaled scores and are used to compute either the CHC Fluid-Crystallized Index (FCI) or Luria Mental Processing Index (MPI), while the supplementary subtests provide expanded coverage of the abilities measured by the core KABC-II subtests and allow for the computation of a Nonverbal Index (NVI). Some examiners will welcome the option of choosing either the Luria or the CHC interpretation and the availability of a nonverbal index.

### ***Kaufman Brief Intelligence Test, Second Edition***

The KBIT-2 (Kaufman & Kaufman, 2004b; see also Homack & Reynolds, 2007) is an individually administered test of verbal and nonverbal ability for persons aged 4 through 90. The KBIT-2 consists of two scales, verbal (crystallized or  $Gc$ ) and nonverbal (fluid or  $Gf$  abilities). The verbal scale is composed of two parts: Verbal Knowledge and Riddles, and the nonverbal scale contains the subtest Matrices. For Verbal Knowledge, the individual is asked to point to one of six pictures to match a vocabulary word spoken by the examiner or to answer a question of general knowledge. Riddles requires the examinee to answer oral questions that require both knowledge and logical reasoning. Matrices is a nonverbal test in which the individual looks at a sequence or pattern and then selects the one of five or six alternative pictures or abstract designs that best completes the logical pattern. The KBIT-2 provides standard scores ( $M = 100$ ,  $SD = 15$ ) for both the subtests and the resulting IQ Composite.

The KBIT-2 is, as stated, a brief intelligence test. Brief tests are especially valuable when an assessment

is directed at broader purposes and the examiner wants to check intellectual ability as one part of the assessment.

### ***Leiter International Performance Scale-Revised***

The Leiter International Performance Scale-Revised (Leiter-R; Roid & Miller, 1997; see also Braden & Athanasiou, 2005; McCallum, Bracken, & Wasserman, 2001) is an individually administered nonverbal test designed to assess intellectual ability, memory, and attention functions in children and adolescents ages 2 years to 20 years, 11 months. The Leiter-R requires no spoken language by either the examiner or the examinee. Instructions are given by pantomime, demonstration, and facial expression.

The Leiter-R consists of two groupings of subtests: the Visualization and Reasoning (VR) Battery, consisting of 10 subtests (4 reasoning and 6 visualization-spatial), and the Attention and Memory (AM) Battery, also consisting of 10 subtests (8 memory and 2 attention).

The subtests use scaled scores (mean 10, standard deviation 3) while Brief and Full Scale IQ scores are calculated using IQ standard scores (mean 100, standard deviation 15). Composite scores can also be obtained for fluid reasoning, fundamental visualization, spatial visualization, attention, and memory. The Leiter-R is obviously especially useful for assessment of children who have difficulty understanding or using spoken English. It taps a much wider variety of CHC abilities than do most non-oral, non-reading tests.

### ***Reynolds Intellectual Assessment Scales***

The RIAS (Reynolds & Kamphaus, 2003; see also Reynolds & Kamphaus, 2005) is an individually administered test of intelligence assessing two primary components of intelligence, verbal (crystallized or  $Gc$ ) and nonverbal (fluid or  $Gf$ ). Verbal intelligence is assessed with two tasks (Guess What and Verbal Reasoning). Nonverbal intelligence is assessed by visual fluid reasoning and spatial ability tasks (Odd-Item Out and What's Missing). The Verbal and Nonverbal scales combine to produce a Composite Intelligence Index (CIX). A Composite Memory Index (CMX) can be derived from two supplementary subtests: Verbal Memory and Nonverbal Memory. The subtests are reported as T scores and the Indexes as standard scores ( $M = 100$ ,  $SD = 15$ ).

In contrast to many existing measures of intelligence, the RIAS eliminates dependence on motor

coordination, visual-motor speed, and reading skills. Examiners who wish to efficiently assess intelligence through only crystallized verbal and nonverbal (fluid reasoning and visual) measures and examiners who want an accurate assessment of intelligence for an examinee with motor coordination, motor speed, or reading challenges would find the RIAS valuable for this purpose.

### ***Slosson Intelligence Test Revised–Third Edition***

The Slosson Intelligence Test Revised–Third Edition for Children and Adults (SIT-R3, 2002 with 1998 calibrated norms) provides a quick and reliable individual screening test of crystallized verbal intelligence. The SIT-R3 has minimal performance items and features embossed materials, making it one of the few effective measures of intelligence not requiring special accommodations for the visually challenged population of both children and adults. The SIT-R3 is composed of the following subtests: Vocabulary, General Information, Similarities and Differences, Comprehension, Quantitative, and Auditory Memory.

### ***Stanford-Binet Intelligence Scale, Fifth Edition***

The SB5 (Roid, 2003; see also Roid & Barram, 2004; Roid & Pomplum, 2005) is an individually administered test of cognitive abilities for ages 2 to 85. The Full Scale IQ (FSIQ) is derived from the administration of ten subtests (five verbal and five nonverbal). Subtests are designed to measure five factors: fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing, and working memory. The SB5 FSIQ and five factor scores have a mean of 100 and a standard deviation of 15. Individual subtests use scaled scores with a mean of 10 and a standard deviation of 3. Results are easily interpreted within CHC theory. On the basis of his factor analysis, Canivez (2008), recommends that “interpretation of the SB-5 should focus primarily, if not exclusively, on the general, Full Scale IQ” (p. 533).

The nonverbal subtests do involve some oral language; they are not purely non-oral like the Leiter-R, UNIT, CTONI-2, or TONI-4, for example. Examiners who wish to include crystallized ability, working memory, visual-spatial ability, and separate measures of fluid reasoning and quantitative reasoning (rather than subsuming quantitative reasoning under fluid reasoning) would find the SB5 appropriately structured for their needs.

### ***Universal Nonverbal Intelligence Test***

The UNIT (McCallum & Bracken, 1998; see also McCallum & Bracken, 2005; McCallum, Bracken, & Wasserman, 2001) is an individually administered instrument designed for use with children and adolescents from age 5 years 0 months through 17 years 11 months. The UNIT measures intelligence through six culture-reduced subtests that combine to form two primary scales (Reasoning and Memory), two secondary scales (Symbolic and Nonsymbolic), and a Full Scale (FSIQ). Each of the six subtests (Symbolic Memory, Cube Design, Spatial Memory, Analogic Reasoning, Object Memory, and Mazes) is administered using eight standardized hand and body gestures, demonstrations, sample items, corrective responses, and transitional checkpoint items to explain the tasks to the examinee. The entire process is nonverbal, but it does require motor skills for manipulatives, paper and pencil, and pointing. Half of the six subtests involve memory.

Three administrations are available for use depending on the reason for referral. These are an Abbreviated Battery, containing two subtests; the Standard Battery, containing four subtests; and the Extended Battery, containing six subtests.

### ***Wechsler Abbreviated Scale of Intelligence–Second Edition***

The Wechsler Abbreviated Scale of Intelligence–Second Edition (WASI-II; Wechsler, 2011; see also Homack & Reynolds, 2007) is an individually administered test designed for individuals between 6 and 90 years of age. The WASI-II consists of four subtests: Vocabulary, Similarities, Block Design, and Matrix Reasoning, which yield a Full Scale IQ score (FSIQ-4). An estimate of general intellectual ability can also be obtained from just a two-subtest administration that includes Vocabulary and Matrix Reasoning and provides only a FSIQ-2 score. Scores can also be split into the Verbal Comprehension Index (VCI) and the Perceptual Reasoning Index (PRI). The VCI is based on Vocabulary and Similarities, while the PRI is based on Matrix Reasoning, which measures nonverbal fluid ability, and Block Design, which measures visual-spatial thinking.

### ***Wechsler Adult Intelligence Scale***

The Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV, 2008) is an individually administered measure of intellectual ability for ages 16 to 90. The WAIS-IV contains fifteen subtests, which provide four indexes: Verbal Comprehension (VCI), Perceptual Organization (POI), Working

Memory (WMI), and Processing Speed (PSI), and a global Full Scale IQ (FSIQ). Each of these scores is a standard score with a mean of 100 and a standard deviation of 15. Each of the 15 subtests is a scaled score with a mean of 10 and a standard deviation of 3.

The Verbal Comprehension Index is composed of three subtests (Similarities, Vocabulary, and Information), with Comprehension acting as a supplemental subtest. The Perceptual Organization Index is composed of three subtests (Block Design, Matrix Reasoning, and Visual Puzzles), with Figure Weights and Picture Completion provided as supplemental subtests. The Working Memory Index is composed of Digit Span and Arithmetic, with Letter-Number Sequencing serving as a supplementary subtest. Finally, the Processing Speed Index is composed of Symbol Search and Coding, with Cancellation being the single supplementary subtest.

The *WAIS-IV Technical and Interpretive Manual* provides evidence, based upon several confirmatory factor analyses, to support the four-factor structure. However, Lichtenberger and Kaufman (2009) report on CFA analyses done by Keith in which he compared several models, including the four-factor model of the WAIS-IV and a five-factor model in line with Cattell-Horn-Carroll (CHC) model. These analyses suggest that a CHC model, with separate *Gf* and *Gv* constructs, fits the data well.

### ***Wechsler Intelligence Scale for Children—Fourth Edition***

The WISC-IV (Wechsler, 2003; see also Flanagan & Kaufman, 2009; Prifitera, Saklofske, & Weiss, 2005, 2008; Weiss, Saklofske, Prifitera, & Holdnack, 2006) is an individually administered clinical instrument for assessing the cognitive ability of children of ages 6 years 0 months through 16 years 11 months. It includes 15 subtests (10 core and 5 supplemental). The test provides a composite score (Full Scale IQ) that represents general intellectual ability, as well as four factor index scores (verbal comprehension, perceptual reasoning, working memory, and processing speed). Each of the IQs and factor indexes is reported as a standard score with a mean of 100 and a standard deviation of 15. The subtests on the WISC-IV provide scaled scores with a mean of 10 and a standard deviation of 3.

Three subtests compose the Verbal Comprehension Index: Similarities, Vocabulary, and Comprehension. Two supplemental verbal subtests, Information and Word Reasoning, are also available.

These subtests assess verbal reasoning, comprehension, and conceptualization.

Three subtests compose the Perceptual Reasoning Index: Block Design, Picture, Concepts, and Matrix Reasoning. Picture Completion is a supplementary subtest. These subtests measure perceptual reasoning and organization.

There are two subtests in the Working Memory Index: Digit Span and Letter-Number Sequencing. Arithmetic is a supplementary subtest. These subtests measure attention, concentration, and working memory.

There are also two subtests in the Processing Speed Index: Coding and Symbol Search. Cancellation is a supplementary subtest. These subtests measure the speed of mental and graphomotor processing.

The WISC-IV is part of the long tradition of Wechsler scales, which allow examiners to draw on a wealth of research and interpretive opinions, including their own experience with various Wechsler scales. The theoretical model underlying the current development of this version is complex, and, while there is considerable overlap with CHC theory, which is discussed in the manual, CHC theory is not the basis for the WISC-IV.

### ***Wechsler Preschool and Primary Scales of Intelligence—Fourth Edition***

The Wechsler Preschool and Primary Scales of Intelligence—Fourth Edition (WPPSI-IV; Wechsler, 2012) is an individually administered instrument that assesses cognitive functioning and global intelligence for early childhood (ages 2:6 to 7:11). The instrument can provide information pertaining to a child's cognitive strengths and weaknesses related to language, visual-perceptual skills, visual-motor integration, reasoning, and memory. The test consists of fifteen subtests (not all used at all age) that combine into three or five Primary Index Scales and three to four Ancillary Index Scales. The primary indexes include Verbal Comprehension (VCI), Visual Spatial (VSI), Fluid Reasoning (FRI), Working memory (WMI), and Processing Speed (PSI). Ancillary indexes include Vocabulary Acquisition (VAI), Nonverbal (NVI), General Ability (GAI), and Cognitive Proficiency (CPI).

The FSIQ is a general measure of global intelligence reflecting performance across various subtests within several cognitive domains. In general, the VCI contains subtests that measure the general fund of information, verbal comprehension, and degree of abstract thinking. The VSI comprises subtests that collectively assess visual-motor integration

and perceptual-organizational skills. The FRI measures the child's concept formation, while the WMI assesses working memory and attention span. PSI is a measure of speed of mental processing, nonverbal problem solving, and graphomotor ability. The composite standard scores have a mean of 100 and a standard deviation of 15. Subtest scaled scores have a mean of 10 and a standard deviation of 3.

The WPPSI-IV provides continuity of format and organization with the WISC-IV and WAIS-IV.

### ***Wechsler Nonverbal Scale of Ability***

The WNV (Wechsler & Naglieri, 2006; see also Brunnert, Naglieri, & Hardy-Braz, 2008) is a cognitive ability test with non-oral administration for ages 4 years 0 months through 21 years 11 months. There are six subtests, with four (Matrices, Coding, Object Assembly, and Recognition) used for the Full Scale at ages 4 years 0 months through 7 years 11 months; and Matrices, Coding, Spatial Span, and Picture Arrangement at ages 8 years 0 months through 21 years 11 months. There are also norms for a two-subtest battery at each age range. Subtests use T scores ( $M = 50$ ,  $SD = 10$ ) and the IQs are standard scores ( $M = 100$ ,  $SD = 15$ ). Administration is normally accomplished with pictorial instructions and standardized gestures. Examiners are also permitted to use standardized verbal instructions provided in six languages, and they may use a qualified interpreter to translate the instructions into other languages in advance.

The WNV is an efficient nonverbal test. The four-subtest format, using mostly subtests similar to those on other Wechsler scales, is quicker than the Leiter-R, but provides fewer subtests and abilities to analyze. The flexibility of standardized pictorial, pantomime, and verbal instructions, with a provision for additional help as dictated by the examiner's judgement, makes the WNV especially useful. The lack of overlapping norms for low-scoring older students and high-scoring younger ones can be a limitation in rare cases.

### ***Woodcock-Johnson III Tests of Cognitive Abilities and Diagnostic Supplement***

The Woodcock-Johnson III Tests of Cognitive Abilities (WJ III COG; Woodcock, McGrew, and Mather, 2001a; Woodcock, Schrank, McGrew, & Mather, 2007; see also Mather & Jaffe, 2002; Schrank & Flanagan, 2003; Schrank, Miller, Wendling, & Woodcock, 2010) is an individually administered test of abilities appropriate for ages 2 to 90. The Diagnostic Supplement (Schrank,

Mather, McGrew, & Woodcock, 2003) provides supplementary subtests. The WJ III COG Tests are explicitly designed to assess a person's abilities on many specific Cattell-Horn-Carroll *Gf-Gc* (CHC) "cognitive factors," not just a total score or a few factors. The General Intellectual Ability (GIA) score of the WJ III is based on a weighted combination of tests that best represents a common ability underlying all intellectual performance. Examiners can obtain a GIA (Standard) score (7 tests) or a GIA (Extended) score (14 tests). Additional tests from both the Tests of Cognitive Ability and Diagnostic Supplement (Woodcock, McGrew, & Mather, 2001) can be used to further explore CHC abilities and other factors. Each of the cognitive tests represents a different broad CHC factor.

Examiners are permitted to select the tests they need to assess abilities in which they are interested for a particular person. The WJ III Tests of Cognitive Abilities provide interpretive information from 20 tests, while the Diagnostic Supplement adds 11 more.

The WJ III provides raw scores that are converted, using age- or grade-based norms, to standard scores, percentile ranks, age and grade equivalents, Relative Proficiency Index (RPI) scores and W scores (Jaffe, 2009), instructional ranges, and Cognitive-Academic Language Proficiency (CALP) levels. All score transformation is performed through the use of the computer program (WJ III Compuscore).

### **The Current State and Possible Future Directions of the Science and Practice of Cognitive Assessment**

In 1997 Mark Daniel surveyed the current status and trends in intelligence testing. He predicted that "tests based on the psychometric-ability model probably will continue to be prominent," partly because of its basis in "decades of empirical findings.... The model is well suited to the multiple-abilities perspective that is currently popular." Daniel stressed the need to "demonstrate the practical applications and benefits of abilities in educational, occupational, and clinical settings." Without such demonstrations, Daniel predicted that users of tests would "look for tests based on alternative models" (p. 1043). (See, for example, Braden & Niebling, 2005.)

Alan Kaufman, in the chapter, "The Future of IQ Tests" (2009, pp. 287-300), anticipates that current practices will continue with updates and improvements, but that computerized IQ testing will become common and will improve. Kaufman

also contemplates research and development of the “test-teach-test paradigm” (p. 298) (see, for example, Feuerstein, Feuerstein, & Gross, 1997) and increased use of improved “neuroimaging techniques...in the psychologist’s office, the classroom, or the local shopping mall” (Kaufman, 2009, p. 299).

In 1998, McGrew and Flanagan described Gf/Gc theory as “the most comprehensive and empirically supported psychometric theory of intelligence, and the theory around which intelligence tests should be interpreted” (1998, pp. 30–31.) They also predicted that the use of cross-battery assessment would foster a common language or nomenclature for what specific tests and subtests measure, thus dramatically increasing the likelihood of consistent interpretation by examiners of cognitive abilities (McGrew & Flanagan, 1998). Indeed, 14 years later, the authors of many new tests have incorporated CHC theory and the cross-battery classifications of abilities into the design and development for their tests, while others have adhered more loosely to the theory (Alfonso, Flanagan & Radwan, 2005). A good example is the Stanford-Binet 5, which was designed specifically to measure five of the ten CHC broad (stratum II) factors, within the verbal-nonverbal format of the Wechsler scales (Roid, 2003), a dramatic change in a test that was designed a century ago (Binet & Simon, 1916/1980) simply to measure *g* with only a single, total score, until its fourth edition (Thorndike, Hagen, & Sattler, 1986).

Many modern cognitive ability tests have embraced the CHC theory, if not in their design, then in their interpretations. Continuing to establish empirical links between the specific CHC cognitive abilities and academic and vocational functioning seems critical for those using cognitive ability tests as part of the evaluation of specific learning problems. The work of CHC researchers (e.g., Evans, Floyd, McGrew, & Leforgee, 2002; Flanagan, Ortiz, Alfonso, & Mascolo, 2006; Floyd, Bergeron, & Alfonso, 2006; Floyd, Evans, & McGrew, 2003; Proctor, Floyd, & Shaver, 2005) provides models for the work that needs to be done, and their preliminary endeavors offer some important understanding of links between cognition and specific learning successes or failures. Further refinements of CHC theory will need to strike a balance between the validation of broad abilities and their component narrow abilities. We predict that these developments will continue to lead practitioners to consistent interpretation of cognitive ability tests.

There are several important, current models of intelligence that we did not address in this chapter.

Two such models are Sternberg’s Triarchic Theory (e.g., Sternberg, 1997, 1995, 1999, 2005) and Gardner’s Multiple Intelligences (e.g., Gardner, 1983, 2006). To date, these theories have not been operationalized as practical, formal, standardized, normed tests in common use (see Chen & Gardner, 2005). However, continued research and validation of these theories may lead to their incorporation into a much broader model for the development of cognitive ability tests, a model acknowledging more facets of human cognitive abilities than do the theories discussed here.

One cautionary question about the incorporation of multiple models into one broad theory is, “How much is too much?” Alan Kaufman, in his *IQ Testing 101* (2009), described *size*, either too small or too big, as one of the problems associated with Guilford’s Structure of the Intellect (SOI) model (Guilford, 1967, 1988; Meeker, 1969, 1975). Kaufman noted that SOI would not be the theory that would turn IQ testing into a theory-based profession. “On the most basic level, it suffered from a similar problem to the one that afflicted Spearman’s *g* theory. If one ability was too few to build a theory on, then 120 was just as clearly too many. And Guilford did not stop at 120. He kept refining the theory, adding to its complexity” (p. 52). Guilford (1988) eventually described 180 separate mental ability factors. Acknowledging the merit of these theories and incorporating them into some broader model of cognition would move cognitive theorists more into the camp of “splitters,” and maybe even into “micro-splitters,” raising the question of how each of these abilities might contribute to the “lump,” or overall intelligence, *g*.

Differential weightings of abilities as they contribute to *g* will probably become essential building blocks for cognitive measures. Most current tests convert subtest scores to standard scores, which are then summed and converted to standard scores for the total battery. This procedure assigns the same weight to each subtest. The KABC-II (Kaufman & Kaufman, 2004), however, permits use and interpretation of two different models, a four-factor Luria model or a five-factor CHC model, so each of the four Luria factors represents 25 percent of the total Mental Processing Index or 20 percent of the total Fluid-Crystallized Index, including a knowledge/Gc factor that is not part of the Luria model.

The WJ III General Intellectual Ability score (Woodcock, McGrew, & Mather, 2001) uses computer scoring to calculate a general intellectual ability score in which each of the seven CHC factors

is weighted according to its loading on the overall *g* factor (McGrew, Schrank, & Woodcock, 2007). Similar complex procedures for differential weighting may become commonplace.

As the theories grow in size, there will still be the need to link the multitude of identified abilities to educational attainment and the selection and success of vocational pursuits (Daniel, 1997). Well-validated empirical links that provide an evidence-based foundation would be required in the development of any cognitive ability tests based on such theories. As Daniel warned, the failure to demonstrate such links would send practitioners in search of other models that offered more proven practical utility for educational and vocational planning.

Although we are predicting increased emphasis on measurement of discrete cognitive abilities, not just a total score, many authorities continue to discourage the interpretation of intelligence tests much beyond evaluation of overall *g*. Abilities other than *g* should, it is argued, be measured by specific, direct assessments, not by components of intelligence tests. See, for a few examples, Canivez (2008), Livingston, Jennings, Reynolds, and Gray (2003), McDermott, Fantuzzo, and Glutting (1990), and Watkins, Glutting, and Lei (2007).

The use of cognitive ability tests in the diagnosis of learning disabilities and developmental and intellectual disabilities and the identification of gifted functioning appears to be enshrined in current diagnostic definitions and legislation on disability entitlement in the United States and in Canada. It must be noted, however, that in the United States, with the increasing push toward Response to Intervention strategies and the IDEA guidelines allowing for the identification of learning disabilities to be done based on a lack of response to empirically based interventions as part of a comprehensive assessment, the use of, or reliance on cognitive ability testing is diminishing. This change may or may not be a good thing. The dramatic shift in the practice of school psychology has required school psychologists, ready or not, to master new skills, new approaches, and new roles for the parts of their jobs involving learning disabilities assessments. Willis and Dumont (2006) argued against a system of identification that was either/or (cognitive testing OR response to intervention) and for the integration of both approaches (cognitive testing AND response to intervention). Regardless of the reasons that a cognitive assessment is chosen, when it is, the ability to reliably interpret both a

general ability factor, such as *g*, and specific abilities will continue to be an essential element expected for the use of cognitive ability tests. As the range of tests available for our use increases, it will be even more important to use a classification system that easily translates test and subtest scores into meaningful statements about the person's cognitive abilities. Theories of ability as they apply to models and design of tests will continue to make the linkage from score to understanding functioning.

It is likely that cognitive ability tests will continue to be influenced strongly by CHC theory and cross-battery classification. The benefit will be ease of comparing test scores across different tests, especially when a person is tested several times across their lifespan. Several major developments for future consideration are computerized assessments and group ability tests. In the future we do expect to see computerized cognitive ability tests that are developed, standardized, and normed specifically for that administrative procedure. One such attempt at this procedure is the Computer-Optimized Multimedia Intelligence Test (COMIT; Phelps & Martin, 2000; TechMicro, 1999). This interactive computer-administered measure of general intelligence has been standardized for ages of 6 through 18 and is composed of 12 subtests that assess associative reasoning, word knowledge, visual-spatial competencies, auditory and visual memory, hypothetical-deductive reasoning, general knowledge, processing speed, and social awareness. According to the manual (TechMicro, 1999), the design of the COMIT is explicitly based on the *Gf-Gc* and CHC models. The COMIT seems like a valuable and certainly interesting approach to computerized cognitive assessment.

With regard to group-administered ability tests, CHC theory is the basis for a new test of cognitive ability called "Insight" (Beal, 2011), developed in Canada. Insight is the first group test of cognitive ability to be based specifically on a theory of cognitive ability. Subtests were classified by CHC ability through an expert consensus study early in its development. The test administration is through a DVD to ensure accuracy of administration. This format also frees up the examiner to observe the behavior of the students who are taking the test in a group format. Validation studies have been completed with WISC-IV Canadian norms and WJ III. This group test, which provides an overall ability score as well as cluster scores and individual subtest scores, can provide practitioners with a good starting point for forming hypotheses about possible processing

deficits that would warrant further assessment for the purpose of diagnosing any disability. Insight provides clearer linkages between the abilities measured by this group test and by individual tests of cognitive ability since it is based on a current theory of cognitive ability. Further developments in group tests are likely to follow specific theories and models of cognitive ability.

Future cognitive ability tests will need to keep a focus on abilities that are logically linked to specific academic functions (for the purpose of diagnosing learning disabilities), and to specific vocational functions (for the purpose of career planning). Recently, Flanagan, Alfonso, Mascolo and Sotelo-Dynega (2012, pp. 653–662) have provided an updated summary of the logical and empirical links between CHC abilities and academic achievement. Continuing validation and research on these links will inform test developers on the importance of component abilities for the different areas of the academic curriculum. Clear linkages to intervention strategies have been developed, based on this research (Elementary Teachers' Federation of Ontario, 2007; Weiss, Beal, Saklofske, Packiam-Alloway & Prifitera, 2008). Research on the most important abilities in different vocational pursuits would be useful when using cognitive ability tests for career planning. These approaches all continue to take cognitive assessment more into the splitting approach than the lumping approach.

As Daniel (1997) cautioned, the usefulness of cognitive ability tests will continue to hinge on their predictive validity. The more we know about the abilities we are trying to predict and their relationship to specific cognitive abilities, the better the science will become in areas like compensation and remediation for deficit areas.

# Methods of Neuropsychological Assessment

Susan Homack

## Abstract

While the field of pediatric neuropsychology is young, neuropsychological assessment of children has much to offer toward understanding the functional systems of the brain and the mechanisms involved in learning. Child neuropsychology provides a theoretical framework for understanding patterns of strengths and weaknesses, and the extent to which patterns may remain stable over time. Once the clinician identifies the assessment needs of the individual child, he or she must make decisions regarding the appropriate assessment measures for exploring the dimensions of behavior. When an evaluation is complete, understanding the strengths and weaknesses of a child provides the neuropsychologist with needed information to recommend appropriate interventions. When communicating results, the clinician must remember that the audience includes caregivers who need straight-forward, easily understood information. Of paramount importance, clinicians must recognize that providing useful, scientifically supported conclusions that contribute to the treatment of the child is the ultimate purpose of assessment.

**Key Words:** neuropsychology, child assessment, test selection

## Introduction

Neuropsychology is the study of brain-behavior relationships that uses the theories and methods of both neurology and psychology. The underlying premise of neuropsychological assessment is that different behaviors and abilities involve differing neurological structures or functional systems (Luria, 1980). Unlike CT or MRI scans, which show abnormalities in the structure of the brain, or EEG, which shows electrical abnormalities of the brain, neuropsychological assessment is used to show the ways in which a person can or cannot perform certain functions or tasks that are dependent upon brain activity. A neuropsychological evaluation typically involves assessment with a group of standardized tests that are sensitive to the effects of brain damage or differences in brain functioning. The standardized tests used in a neuropsychological evaluation typically

assess functioning in the following areas: cognitive functioning, attention, memory, problem-solving, visual spatial functioning, language, and motor skills. Assessment of academic skills and emotional functioning are often assessed as well.

While neuropsychology has origins dating at least as far back as the 19th century, it is during the past 25 to 30 years that neuropsychology has been widely recognized and accepted as a formal professional specialty area (Hartlage & Long, 2009). The field of neuropsychology has rapidly matured since the early empirical work of Ralph M. Reitan (1955) and other important contributors (please see Fitzhugh-Bell, 1997, for a review of the early history of clinical neuropsychology). Historically, neuropsychology has been used for the assessment and diagnosis of adults with brain injury or other forms of central nervous system (CNS) dysfunction. Due

to recent advances in neuroimaging techniques, the use of neuropsychological tests for the primary diagnosis of the presence or absence of CNS damage has declined (Mayfield, Reynolds, & Fletcher-Janzen, 2009). However, a rise in the use of neuropsychological testing has occurred for determining functional deficits. An assessment of strengths and weaknesses using a neuropsychological assessment is necessary because neuroimaging techniques cannot specify the true functional implications of any visualized abnormality or damage. As more became known about brain-behavior relationships, theories and findings also were applied to the understanding of learning and behavior problems in adults where brain injury was not evident.

With the increasing recognition that learning and other neuropsychological functions could be evaluated in adults, researchers and clinicians became interested in determining whether research gleaned from adults could be applied to children. The increased interest and emphasis in the application of neuropsychology to children may be due to a variety of factors, including: the development of neuropsychology as a specialty area, knowledge obtained from localized brain damage in childhood and adolescence, advances in technology (e.g., functional imaging) that are providing exciting new information regarding brain development and function, and continued research using neuropsychological assessment data to gain more information regarding specific problems encountered by children (Riccio & Reynolds, 1998).

Child neuropsychology provides a framework for understanding patterns of strengths and weaknesses and the extent to which these patterns remain stable or change over the course of development (Temple, 1997). Children in general have always posed special problems in clinical assessment due to their rapid and often uneven development in the areas of language and motor acquisition, attention, memory, and problem-solving. As the extent of disability increases, accurate assessment becomes more challenging (Reynolds & Mayfield, 1999). A minor variant of normal development need not be a cause for alarm; however, a significant problem should not be ignored.

An increased understanding of a child's strengths and weaknesses is useful for many reasons. Neuropsychological testing can help establish the presence of a cognitive disorder. In having a better understanding of the ways in which neurological conditions impact learning and behavior, clinicians are able to recommend compensatory strategies that

may be provided by the school, at home, or within the community. Children can be reevaluated over time to assess progress and determine whether there may be changing symptomatology. The effectiveness of interventions can be evaluated and altered as necessary based on the child's functioning.

As a result of the growing interest in child neuropsychology, the knowledge available regarding the developing brain has increased dramatically since the 1980s (Riccio & Reynolds, 1998). A great deal of information has been obtained regarding child development and neuropsychological functions (e.g., Miller & Vernon, 1996; Molfese, 1995). Furthermore, advances in educational areas have been made that facilitate the understanding of learning disabilities (Riccio, Gonzalez, and Hynd, 1994; Riccio & Hynd, 1996), traumatic brain injury (Dennis, Wilkinson, Koski, & Humphreys, 1995; Yeates & Taylor, 1997), the impact of cancer treatment on CNS function (Kerr, Smith, DaSilva, Hoffman, & Humphries, 1991; Seidel et al., 1994), and the sequelae in children with prenatal or perinatal difficulties (Aylward, 2002; Daniel, Lim, & Clark, 2003).

This chapter will provide an overview of the neuropsychological assessment process for children, both historically and in the context of current practices and future trends. Areas covered in this chapter include neurodevelopmental considerations and approaches to test selection in the assessment of children. An overview of the domains for assessment including examples of frequently used tests is provided. Finally, a description of the general organization of the neuropsychological assessment of children and adolescents is described.

## **Neurodevelopmental Considerations in the Assessment of Children**

Due to the demand for neuropsychological testing of children and adolescents, traditional adult neuropsychological batteries such as the Halstead-Reitan Neuropsychological Battery (Reitan, 1955; Reitan & Davison, 1974) and the Luria-Nebraska Neuropsychological Battery (Golden, 1981; Plaisted, Gustavson, Wilkening, & Golden, 1983) were modified for use with children (Hartlage & Long, 1997). This involved altering or adding some tasks to the batteries that were more suitable for children. Another option involved collecting normative data on children for existing tests. Both of these attempts were based on the assumption that tasks for adults could measure the same constructs when used with children.

A pitfall of using adult tests with children results when neurodevelopmental differences that exist as a result of the age of the child are not taken into consideration. If one directly applies norms from adult tests to children, then one completely ignores what is known about changes in the functional organization of the brain of growing children. Rapid growth takes place during childhood and adolescence and occurs at different rates for individual children. Infancy and childhood are the times of the greatest breadth and depth of change throughout one's lifetime.

According to Luria (1980), neurodevelopment follows an ontogenetic course, with primary cortical zones generally maturing by birth, and secondary and tertiary areas continuing to develop after birth. Secondary and tertiary areas include systems involved in learning, memory, attention, emotion, cognition, language, and association. The association areas are the last of these areas to develop and myelinate (Goldman & Lewis, 1978). According to Spreen, Risser, and Edgell (1995), the developmental sequence for the formation of neural pathways and myelination of specific locations corresponding to specific behaviors have been identified; however, these sequences do not correspond directly to models of cognitive development.

Research suggests that traumatic brain injury (TBI) as well as other brain insults can disrupt the neurodevelopmental process of children, especially in young children (Kriel, Krach, & Panser, 1989). The impact of an injury is influenced by the child's age as well as by its location in the brain, and the nature of the injury. The theory of neural plasticity (Harris, 1957) has been used to explain the potential for recovery of function seen in children that is not observed in adults. It has been suggested that the young brain undergoes "reorganization" of brain function. For example, brain damage occurring in infants and toddlers may produce very different behavioral effects than in adults because early injury has also altered fundamental brain organization. The insult does not affect the function of only the brain areas that are damaged directly but also disrupts other neuroanatomical sites and circuitry that are dependent on intact structures (Kolb & Fantie, 2009).

Interestingly, researchers (Brink, Garrett, Hale, Woo-Sam, & Nickel, 1970; Kriel et al., 1989) found that children over 10 years of age at the time of brain insult were likely to have a better prognosis than those under age six, regardless of the injury's severity. According to Riccio & Reynolds (1999),

this may be due to the difference in neurodevelopmental status of children in these age groups. Alternatively, it may be because older children have spent more time in school, and many of the functions assessed by standard measures correlate highly with the number of years spent in school (Ryan, LaMarche, Barth, & Boll, 1996).

Evaluation of children and adolescents with acquired injury or neurodevelopmental disorders is complex because of the neurodevelopmental nature of abilities. When assessing these children, the evaluation not only evaluates skills that should already be acquired, but also requires follow-up evaluations to assess how well later-developing skills do indeed develop.

## Approaches to Test Selection with Children

### **Nomothetic Approach**

The fixed battery, or nomothetic approach, uses the same assessment battery for all children being assessed, regardless of their referral questions (Sweet, Moberg, & Westergaard, 1996). This approach may be either empirically or theoretically based. Using an empirical approach, the test battery is selected according to its ability to separate groups, while theoretically based batteries are founded on a theory of development as it relates to broad or narrow dimensions of behavior (Fennell & Bauer, 2009). Clinicians utilizing a fixed battery approach often use a published neuropsychological battery in conjunction with an IQ and achievement test. The published neuropsychological batteries most frequently used with school-aged children are the Luria Nebraska Neuropsychological Battery—Children's Revision (Golden, 1986) and the Halstead-Reitan Neuropsychological Test Batteries for Children (Reitan & Wolfson, 1985). The batteries contain numerous subtests that are considered crucial for understanding brain-behavior relationships in children and adolescents. Research has indicated that both batteries are effective in detecting the presence, lateralization, and localization of brain dysfunction (Bauer, 1994).

There are several advantages to using a fixed battery approach to assessment. A large number of functions are assessed using standardized procedures and objective measures and clinicians rely on cutoff scores for the determination of the presence of brain damage. In order to prevent the referral question from dictating the measures used, a "blind" assessment may be preferred (Goldstein, 1997). Additionally, by adhering to a fixed-battery approach, it is possible for clinicians to develop

impressive research databases that provide interpretation of large numbers of clinical groups (Hartlage & Telzrow, 1986).

While there are advantages to using a fixed-battery approach, there are also disadvantages. A standardized battery may not take into account variables such as age, education, and other important idiopathic considerations. The standardized battery may not answer the referral question. Finally, while a certain number of functions need to be evaluated with any child, rarely do clinicians have the time to evaluate areas that do not appear compromised. The use of a fixed-battery approach to neuropsychological assessment appears to be declining (Sweet et al., 1996).

### ***Idiopathic Approach***

In contrast to the nomothetic or fixed-battery approach, the idiographic approach tailors the assessment battery to the referral question and the child's test performance on initial measures administered (Christensen, 1975, Luria, 1973). Rather than providing a comprehensive evaluation in all areas of functioning, this approach is intended to isolate the neurobehavioral mechanisms that underlie the difficulties of the individual being assessed. With the idiopathic approach, the primary goal is to answer the referral question, rather than provide a comprehensive assessment. With no uniformity across evaluations, this approach requires that the clinician have substantial clinical knowledge regarding brain-behavior functioning in order to determine the appropriate assessment tools necessary to meet this goal.

While this approach appears to be the most cost-effective of the methods described due to the small number of domains assessed (Goldstein, 1997), the major drawback of the idiopathic approach relies on the limited research base generated and the inability to study the efficacy of this method compared to the other approaches (Riccio & Reynolds, 1998). Furthermore, information regarding the neuropsychological functions and organization of behaviors in children and adolescents with various disorders is limited at this time (Baron, Fennell, & Voeller, 1995). As a result, the individualized approach is less frequently used than the other approaches (Fennell, 1994).

### ***Flexible Approaches***

The flexible battery involves choosing specific instruments based on the presenting issues or neurobehavioral mechanisms that underlie the

difficulties of a child, rather than administering a predetermined neuropsychological battery. In order to meet this goal, the clinician administers a core set of standardized tests to all children in order to provide a comprehensive assessment. The clinician then supplements the battery with a selected set of additional tests designed to answer specific referral questions (Rourke et al., 1986) or to further examine potential areas of weakness that are detected while using the core battery (Bauer, 1994). Consistent with the fixed battery approach, the flexible battery approach may be either empirically or theoretically based. While the core set of tests may be empirically based, the components of the flexible battery often reflect the theoretical position of the clinician with regard to which behavioral performance reflects brain pathology (Bauer, 1994).

The major advantage of the flexible battery is that both a nomothetic and an ideographic approach to neuropsychological assessment are applied. This method allows for the assessment of a broad range of functions as well as specific areas related to the referral question. Clinicians generally agree that this approach more accurately identifies specific deficits. As such, the flexible approach is the method preferred by most neuropsychologists working with adult and child populations (Sweet & Moberg, 1990, Sweet et al., 1996).

The Boston Process Approach (Kaplan, 1988) is a good example of the use of the flexible battery. A core set of tests with low specificity is initially used to assess various neuropsychological constructs. In addition to core tests, several "satellite tests" are used to clarify particular problem areas and to confirm the hypotheses developed from observations of the individual. According to Milberg, Hebben, and Kaplan (1986), the only limits to the procedures that are employed are the examiner's knowledge of available tests of cognitive function and his or her ingenuity in creating new measures for particular deficit areas. With the Process Approach, there is less focus on the results of standardized testing and more focus on the presentation of symptoms, strategy used in task completion, and error analysis. The Process Approach uses standardized measures, experimental measures, and "testing the limits" that often involve procedural modifications in order to gain insight into brain-behavior relationships (Kaplan, 1988; Milberg, Hebben, & Kaplan, 1986). While the Boston Process Approach shows great promise, there is concern regarding the questionable reliability of scores obtained on measures where the standardized procedures have been compromised.

(Rourke et al., 1986). In response to these concerns, the Wechsler Intelligence Scale for Children-Fourth Edition-Integrated (WISC-IV-Integrated; Wechsler et al., 2004) and Delis-Kaplan Executive Function System (D-KEFS; Delis, Kaplan, & Kramer, 2001) were designed so that changes to input modality were normed.

## Domains for Assessment

### *Cognitive Functioning*

A neuropsychological evaluation should include measures of the child's cognitive skills. To accomplish this task, a comprehensive IQ test is used to measure general intellectual ability (*g*). Using an intellectual test with a strong measure of *g* provides a solid baseline for the interpretation of other domains. However, interpretation of a child's performance on cognitive measures is complicated by the fact that no two tests conceive of intelligence in the same way. In fact, cognitive instruments that attest to measure the construct of intelligence can differ substantially from one another (Kamphaus, 2005).

The Wechsler Intelligence Scale for Children, Fourth Edition (WISC-IV; Wechsler, 2003) and the Kaufman Assessment Battery for Children, Second Edition (KABC-II; Kaufman & Kaufman, 2004) are two measures frequently used with children. The WISC measures are a downward extension of the Wechsler's adult measure, the Wechsler Adult Intelligence Scale. The most recent version, the WISC-IV was designed for use with children and adolescents six to 16 years old. According to Wechsler (2003), the neurocognitive models of information processing provide the basis for the structure of the WISC-IV. While the WISC-III adhered to the traditional verbal IQ/performance IQ dichotomy, the WISC-IV provides four index scores: Verbal Comprehension (VCI), Perceptual Reasoning (PRI), Working Memory (WMI), and Processing Speed (PSI). The full-scale IQ score is derived from the 10 subtests included in the four indices. Unlike previous versions of the WISC, the WISC-IV includes the working memory and processing speed subtests in calculating the full-scale IQ.

The Wechsler Intelligence Scale for Children, Fourth Edition-Integrated (WISC-IV-Integrated; Wechsler et al., 2004). is based on the Boston Process Approach and assists clinicians in better understanding the cognitive processes involved in the performance of core or supplemental WISC-IV subtests. While the WISC-IV-Integrated provides the same four indices and overall full-scale IQ score

as the WISC-IV, an extended array of 16 subtests is available to complete the core components of the WISC-IV. Based on the Boston Process Approach, the WISC-IV Integrated subtests use standardized approaches to modifying the input modality or item content in order to better understand the underlying cognitive processes that are involved in the performance of core or supplemental WISC-IV subtests.

The KABC-II was normed for children three to 18 years old and is composed of four required scales and one optional scale. The Simultaneous, Sequential, Planning, Learning, and Knowledge (optional) scales make up the Mental Processing Index, Fluid-Crystallized Index, and Nonverbal Index. The KABC-II was influenced by both the Lurian model and Cattell-Horn-Carroll (CHC) model. The Kaufmans define *simultaneous processing* as referring to the child's mental ability to integrate input simultaneously in order to solve a problem correctly. *Sequential processing*, on the other hand, emphasizes the arrangement of stimuli in sequential or serial order for successful problem-solving (Kaufman & Kaufman, 1983). Sequential skills are tied to left-hemisphere, step-by-step logical analysis, while simultaneous skills were believed to assess right-hemisphere abilities. With an emphasis on processing rather than content, the KABC-II is far less dependent on prior learning and exposure to cultural experiences than many of the other mainstream intelligence measures.

### *Academic Achievement*

Assessment of basic academic skills, including reading, mathematics, and written language, is important in determining the need for classroom modifications or special education support. A standardized battery such as the Woodcock-Johnson Psychoeducational Battery-Third Edition-Tests of Achievement (WJ-III; Woodcock, McGrew, & Mather, 2001) or the Wechsler Individual Achievement Test-Third Edition (WIAT-III; Wechsler, 2009) can provide information on the child's current functioning in major academic areas. According to Goldstein and Schwebach (2009), the WJ-III is the most comprehensive, well-developed assessment of academic skills. Subtest analysis of the WJ-III often reveals patterns of verbal, visual, rote, or conceptual weaknesses. Because one of the most common complaints of parents of children who have sustained a TBI is slowed processing speed, the WJ-III is the academic assessment tool of choice when evaluating children with TBI. The

WJ-III provides timed reading, math, and writing fluency subtests that evaluates a child's ability to work quickly and accurately.

In the absence of a comprehensive battery such as the WJ-III or the WIAT-III, a neuropsychologist may use other basic achievement data. In the area of reading, a measure should be used to assess phonetic skills, sight word reading, and comprehension. The Comprehensive Test of Phonological Processing (CTOPP; Wagner, Torgesen, & Rashotte, 1999) provides assessment of phonetic awareness, phonological memory, and rapid naming. The Gray Oral Reading Test–Fifth Edition (GORT-5; Wiederholt & Bryant, 2012) can provide clinicians with information regarding reading rate, accuracy, fluency, and comprehension. In the area of spelling, the Wide Range Achievement Test–Fourth Edition (WRAT-4; Wilkinson & Robertson, 2006) provides estimates of phonetic ability and sight word memory. The WRAT-4 measures an individual's ability to count, identify numbers, solve simple arithmetic problems, and calculate written math problems. In the area of written language, the Story Writing subtest of the Test of Written Language–Fourth Edition (TOWL-4; Hammill & Larsen, 2009) provides information regarding vocabulary, grammar, punctuation, sentence composition, and thematic organization.

### **Attention**

Problems with attention are inherent in a multitude of disorders in children, including TBI, stroke, cancer, and developmental disorder, but they are most frequently noted in conjunction with attention-deficit/hyperactivity disorder (ADHD). Problems arising from symptoms of ADHD constitute the largest single source of referrals to mental health centers (Barkley, 1981); more recently, it has been suggested that children with ADHD may account for as many as 40 percent of referrals to child guidance clinics (Barkley, 1998). By definition, children with ADHD display difficulties with attention relative to normal children of the same age and sex. However, *attention* is a multidimensional construct that can refer to alertness, arousal, selective or focused attention, distractibility, and sustained attention, among others (Barkley, 1998; Mirsky, 1996). According to Douglas (1983), children with ADHD most likely have their greatest difficulties with sustaining attention to tasks, persistence to effort, and vigilance.

While a large number of children are referred to clinics, the development of a norm-referenced,

psychometric assessment battery specifically designed to assess attention has been an elusive goal for clinicians (Goldstein, 1999). Computerized assessment of behaviors associated with attention problems represents an effort to incorporate reliable and objective assessment into evaluations. These techniques were born from concern about the degree to which diagnostic decisions were founded upon subjective measures and clinical judgment. Currently, the determination of attention problems is made primarily from anecdotal information from parents and teachers report. One problem with using scores from parents and teachers reports is the lack of congruence often found between these measures. As noted by Sattler (1990), a lack of reliability between these measures is primarily related to varying expectations and tolerance on the part of parents and teachers.

Computer-based measures allow the clinician to incorporate data into the assessment that is derived from a child's actual behavior. Unlike other clinical techniques, computer-based measures generate objective data about a child's ability to perform in situations tailored to assess the characteristic weaknesses of a child with attention problems (Gordon, 1986a). One venture for a computerized measure included the development of continuous performance tests (CPTs). The CPT is one group of paradigms used for the evaluation of attention and the response inhibition component of executive control. The CPTs are frequently used to obtain quantitative information regarding an individual's ability to sustain attention over time; the duration of the task varies, but is intended to be sufficient to measure sustained attention. The CPT involves selective attention or vigilance for an infrequently occurring target or relevant stimulus. The CPT paradigm is generally characterized by rapid presentation of continuously changing stimuli with a designated target stimulus or target pattern (Riccio, Reynolds, & Lowe, 2001).

The Gordon Diagnostic System (Gordon, 1983) was the first commercially available CPT and has probably been the most frequently used CPT in research studies (Riccio, Reynolds, & Lowe, 2001). The GDS is a microprocessor unit, as opposed to a computer software program, that generates 11 tasks. There are three basic paradigms: the delay task, the distractibility task, and the vigilance task. Of the three paradigms, the distractibility and vigilance tasks are CPTs. More than one version of the distractibility and vigilance tasks are available (Gordon, 1986a, 1986b; Gordon & Mettelman,

1988; Gordon Systems, Inc., 1991). The Gordon uses numbers as stimuli. The children's standard version of the vigilance task, for ages six to 16 years, lasts nine minutes and requires the child to press a button every time a two-number target combination (a 1 followed by a 9) is presented. The numerals for the children's version are displayed for 200 milliseconds, with a 1000-millisecond interstimulus interval (ISI). The distractibility task incorporates the two-number target presentation, but simultaneously includes the display of digits on either side of the target stimulus to assess whether the individual can selectively attend to the target stimuli (Gordon Systems, Inc., 1991). In addition to the vigilance and distractibility tasks, the GDS includes a delay task (lasting nine minutes) that is designed to measure impulse control. On this task, the child earns points for inhibiting a response.

Information provided in the technical manual (Gordon Systems, Inc., 1987) indicated that the GDS children's standard version provides moderate to high test-retest reliability for a clinical and non-clinical population. Test-retest reliability estimates for non-clinical population ranged from 0.67 to 0.85, while estimates for the clinical sample ranged from 0.68 to 0.94. Validity studies included in the 1987 manual supported the use of the GDS in the diagnosis of attention problems with approximately 70 percent agreement with parent and teacher ratings of children with ADHD depending on the age, the rater, and the scale.

The Conners' Continuous Performance Test (2nd ed.; CPT-II; Conners, 2000) is a visual paradigm used for the evaluation of attention as well as the response inhibition component of executive control. The standard version of the CPT-II can be administered to children six years of age and older and takes approximately 14 minutes to complete. Unlike traditional CPTs that require the individual to press a computer key after an X is presented, the CPT-II requires individuals to press the computer key immediately after every letter *except* the X. Conners (2000) asserted that this format ensured a greater number of responses and therefore decreased chance error. For four- and five-year-olds, the Conners' Kiddie CPT (K-CPT) may be used; this version is shorter in duration and uses pictures instead of letters as the stimuli. The updated version of the CPT-II (Conners, 2000) differs from previous versions of the CPT-II (Conners, 1992, 1995) in that it provides a validity test to identify invalid administrations, a confidence index (CI) score to assess the likelihood that the examinee's responses

fit those given by individuals with ADHD, new theory and methods for computing signal detection theory statistics, and new and expanded norms.

The CPT-II standard paradigm consists of six blocks, with each block divided into three sub-blocks. The targeted and non-targeted stimuli (letters) are randomly shown for 250 milliseconds, with the interstimulus interval (ISI) varying within each block. For the three subblocks within a block, the ISI may be 1, 2, or 4 seconds; the order of the three difference ISIs subblocks varies from block to block (Conners, 2000). Examination of results by block allows for the assessment of vigilance. By varying the ISI, it is possible to assess the examinee's ability to adjust to changing tempo and task demands.

Conners (2000) provided reliability information obtained from the original standardization sample (Conners, 1994). Split-half reliabilities across variables appeared adequate and ranged from 0.66 and 0.95. Test-retest reliability estimates ranged from 0.05 to 0.92, indicating that some of the variables do not produce good consistency across administrations. In one validity study using the original standardization sample (Conners, 1994) the ADHD group responded more slowly, had greater variability of reaction times, made more omission and commission errors, and was more affected by changes in the ISI than the group with a variety of other clinical diagnoses. In a similar analysis using updated CPT-II data (Conners, 2000), no significant differences were observed between the ADHD and nonclinical groups on the commissions variable; for all other variables, a significant difference between the groups was evident, with the ADHD group performing more poorly on all variables.

The Test of Variables of Attention is an X-CPT available in separate visual (TOVA; Greenberg, 1988–1999) and auditory (TOVA-A; Greenberg, 1996–1999) versions. The TOVA is composed of both a clinical version and a preschool version. The TOVA and TOVA-A require an individual to press a microswitch every time the target stimulus is presented. The target stimulus consists of a colored square with a smaller square contained within and adjacent to the top edge of the larger square. In contrast, the non-target stimulus has a smaller inscribed square adjacent to the bottom edge of the larger square. For the TOVA-A, two audible tones are used as stimuli, one as the target and one as the non-target. Supporters of the TOVA and TOVA-A argue that by virtue of being non-language-based tests, these measures serve as "purer" measures of inattentiveness and executive control, compared

to other CPT measures (Riccio, Reynolds, & Lowe, 2001). The clinical version of the TOVA and TOVA-A are approximately 22 minutes in duration.

For both the TOVA and TOVA-A, the target and non-target stimuli are presented randomly for 100 ms with an ISI of 2000 ms. The clinical versions are composed of four intervals. During the first half of the test (intervals 1 and 2), the target stimulus is randomly displayed on 22.5 percent of the trials. This condition is called the "stimulus-infrequent condition," and it is believed to create a situation in which an individual who is inattentive is less likely to respond and therefore will make omission errors. As such, the stimulus-infrequent state is used to assess the individual's attention. During the second half of the test (intervals 3 and 4), the target stimulus is shown on 77.5 percent of the trials. This stimulus-frequent condition creates a strong response set in which an individual who has an impulse control problem is more likely to respond and make commission errors. This stimulus-frequent condition is used to assess the individual's impulsivity (Greenberg & Crosby, 1992; Lark, Dupuy, Greenberg, Corman, & Kindschi, 1996).

Test-retest reliability studies indicated that the stability of performance across time (4 months) ranged from 0.51 to 0.82 (Llorente et al., 2000). Llorente and colleagues concluded that omission and commission error variables were the least stable, and reaction time and reaction time variability were the most stable. No test-retest study of the TOVA-A was found. Results of a factor analysis indicated a three-factor solution for the TOVA consistent with the premise that the task is measuring attention, disinhibition, and processing speed. For the TOVA-A, five factors emerged including the processing speed of the TOVA and separate attention and disinhibition factors for both the target-frequent and target-infrequent conditions. Results of a clinical validity study of children with ADHD and normal controls indicated that false positive rates of 80 and 90 percent were obtained, depending on the cutoff scores used (Lark, et al., 1996).

The Integrated (or Intermediate) Visual and Auditory Continuous Performance Test (IVA; Sandford & Turner, 1994–1999) is a 13-minute CPT that uses both auditory and visual stimuli within the same task. Of the CPTs discussed here, this is the only one that requires an individual to shift modalities within the same task. On the IVA, the individual is to press a mouse button in response to a visual or auditory target stimulus (the number

1) and to refrain from pressing the mouse button when the non-target stimulus (the number 2) is presented either visually or verbally. The target and non-target stimuli are presented in a random pattern with a 1500 ms ISI for 500 trials (Sandford & Turner, 1995). The IVA varies the frequency of the target. During the test, the IVA's target to non-target ratio is altered by blocks to elicit omission and commission errors. Under the frequent-target condition, a response set is created such that the dominant response is to press the mouse button. As such, an individual who is impulsive is more likely to make commission errors. During the infrequent-target condition, vigilance and response inhibition are assessed.

Test-retest reliability correlations across auditory and visual variables of the IVA ranged from a low of 0.18 to 0.88 (Sandford & Turner, 1995). These findings show that the temporal stability of some variables is adequate, whereas the stability of other variables is low. Results of a validity study using the IVA indicated that the IVA results were in agreement with group membership (ADHD or normal controls) in 92 percent of the cases.

In reviewing the above CPTs, it is important to point out that CPTs are not identical assessment tools. Different CPTs may measure different facets of attention and executive functioning. According to Conners (1992, 1995), CPTs are not a unitary measure, but rather a family of measures with differing parameters and scoring indices. Little is known about how the differences in measures affect diagnostic considerations.

### ***Executive Functioning***

Executive functions are a set of cognitive processes that guide goal-directed behaviors. They do not refer to an individual's knowledge or skills, but to the mental processes that direct whether and how these are applied to accomplish a goal. While a child may demonstrate an IQ and achievement abilities within the average range, he or she may struggle with executive functioning. Executive processes include control of attention, inhibition of impulses, cognitive flexibility, working memory, planning, organization, self-monitoring, and emotional regulation. From a brain-behavior relationship perspective, executive processes are related to the frontal and prefrontal areas. Because the frontal lobes constitute a complex neurological and functional system (Luria, 1966; Welsh & Pennington, 1988), both discreet and diffuse damage resulting from TBI can cause children to have difficulty with

self regulation and problem-solving. Children with neurodevelopmental disorders (e.g., ADHD, autism spectrum disorder) also tend to have problems with executive functioning.

While the umbrella of executive functioning may include a variety of constructs, including attention, self-regulation, and working memory, the “executive” processes focus on strategic planning, effortful and flexible organization, and proactive reasoning (Denckla, 1994). Because the frontal and prefrontal areas continue to develop and mature throughout adolescence, it is difficult to assess executive functioning in children. Most executive function measures used with children are downward extensions of adult measures (Riccio & Reynolds, 1999), and many lack adequate normative data. Below is a review of measures used to assess executive functioning.

The Trail Making Test (TMT), parts A and B, is one of the most widely used screening instruments in current neuropsychological practice (Moses, 2004). It was originally developed by Partington in 1938 to serve as a model of “divided attention” (Partington & Leiter, 1949). While this test is an excellent global screening measure sensitive to the integrity of cognitive performance, it was not well normed, and there is not a set of current norms that matched the United States population.

In order to provide a revision and extension of the TMT, Reynolds (2002) developed the Comprehensive Trail Making Test (CTMT) that consists of five timed trials that are designed to highlight and isolate specific components of performance. On the first “trail,” the examinee connects numbers in order. This task assesses sustained attention, as well as basic sequencing and visual-spatial scanning skills. On CTMT Trails 2 and 3, the examinee is again required to sequence numbers; however, simple empty circles (Trails 2) and complex, busy circles (Trails 3) are added to the visual array. The subject must sustain and focus attention despite the distractors. On the CTMT Trail 4, both numerical and lexical numbers are presented in a random alternating sequence. On the CTMT Trail 5, the examinee must connect numbers and letters in an alternating sequence, while also being presented with empty distracter circles.

The CTMT is appropriate for administration to individuals from age 11 years 0 months to age 74 years 11 months. More recently, Reynolds provided norms that extend to those aged 8 years 0 months to 11 years 0 months so that the test can be administered to younger children. In the areas of reliability

and validity, the CTMT meets rigorous standards. All internal consistency values for the five CTMT trials meet or exceed a value of 0.70, and the reliability value of the Composite Index score is 0.92. Test-retest reliability values for the five trials of the CTMT range from 0.70 to 0.78, which are quite high for a speeded measure. Preliminary studies are provided in the manual that establish the test’s construct, concurrent, and content validity. Results of a more recent study (Armstrong, Allen, Donohue, & Mayfield, 2008) indicated that the CTMT did a good job of correctly classifying adolescents with traumatic brain injury and controls; however, some variability in classification accuracy was present among various trials.

The Delis-Kaplan Executive Function System (D-KEFS; Delis, Kaplan, & Kramer, 2001) represents the first set of executive tests co-normed on a large and representative national sample and designed exclusively for the assessment of executive functions, including flexibility of thinking, inhibition, problem solving, planning, impulse control, concept formation, abstract thinking, and creativity. The D-KEFS is composed of nine tests that provide a standardized assessment of executive functions in children and adults between the ages of 8 and 89. Utilizing a “cognitive-process approach,” the D-KEFS tests allow examiners to systematically generate and evaluate relevant clinical hypotheses on executive functioning of a given examinee by comparing and contrasting performance on multiple testing conditions and using contrast measure scores and error analyses. The D-KEFS is composed of the following nine stand-alone tests that can be individually or group administered: Trail Making Test; Verbal Fluency Test; Design Fluency Test; Color-Word Interference Test; Sorting Test; Twenty Questions Test; Word Context Test; Tower Test; and Proverb Test.

One of the important objectives of designing the D-KEFS was to provide psychologists with a large, comprehensive collection of executive-function tests for the assessment of complex and multifactorial domains of frontal lobe functioning. The authors noted that most of the existing executive-function tests were developed in the 1940s. As such, the authors indicated that the designs of these extant tests have not benefited from the knowledge that has accrued over the past 60 years of research and clinical practice. The authors sought to incorporate the principles and procedures from this extensive body of knowledge into a new set of executive-function tests by employing several unique approaches. By

embracing a “cognitive-process approach,” the component functions of higher-level cognitive tasks can be assessed. The authors indicate that most existing clinical instruments of higher-level cognitive functions yield a single score for each task, which is problematic because such tests typically tap a host of fundamental and higher-level cognitive skills. Several D-KEFS tests allow the examiner to assess the relative contributions of multiple fundamental and higher-level cognitive functions to overall performance on each executive-function test by using multiple testing conditions and providing “contrast measures.” In using modifications of the traditional tests, it was possible to add features and testing conditions that would increase the sensitivity of the tests to mild brain damage.

Each D-KEFS test includes primary and optional measures and provides between six and 34 scores. In addition, five D-KEFS tests provide several primary or optional “contrast” measures. Some tasks measure similar cognitive functions but under somewhat different conditions. Separate normative scores are derived for each of the testing conditions. In addition, a total achievement score that reflects the examinee’s ability at the task across the testing conditions is computed. The clinician can be flexible in terms of administering only some of the D-KEFS tests or conditions within a test. The selection of conditions or tests to be administered depends on the assessment needs of the specific examinee or the time constraints of the examiner.

Test developers presented correlations between the D-KEFS tests and other measures to provide evidence for adequate convergent and discriminant validity. Exploratory factor-analytic results were not provided, because factor scores derived from normative or mixed-clinical populations often mask critical cognitive distinctions, especially on process-oriented tests (Delis et al., 2003). Evidence of validity is provided in studies indicating that tests from the D-KEFS have reasonable sensitivity in distinguishing many different types of clinical groups (e.g., fetal alcohol exposure, focal frontal lesions, etc.) from controls. Many overall achievement scores of the tests have adequate to good reliability coefficients; however, some of the optional process measures have low reliability coefficients. A review of its administration, scoring and interpretation, test construction, standardization, and technical adequacy indicate that the D-KEFS holds much promise, not only as a clinical instrument, but also as a research tool for increasing knowledge of the frontal-lobe functions.

The NEPSY-II: A Developmental Neuropsychological Assessment (NEPSY-II: Korkman, Kirk, and Kemp, 2007) is the revision of the original NEPSY (Korkman, Kirk, and Kemp, 1998) and can be used with children three to 16 years of age. The NEPSY-II assesses six domains of functioning. In addition to the executive functioning/attention domain, the NEPSY-II also measures language, memory and learning, sensorimotor functioning, visuospatial processing, and social perception, the last of which is a new domain specific to the NEPSY-II. While the original NEPSY required a fixed administration of subtests to obtain domain scores, the NEPSY-II does not require a set administration of subtests and does not provide domain scores. Rather, the clinician is allowed to create a tailored assessment of subtests across the six domains and interpret individual subtest scores. The NEPSY-II also provides a greater array of subtests from which the examiner can select. The computerized scoring program provides an electronic “decision tree” that assists the clinician in selecting subtests based on the child’s presenting history.

One of the greatest strengths of the NEPSY-II is the comprehensive standardization of the measure using 1200 children and adolescents, which closely approximates the demographics of the United States population based on 2003 census data. The NEPSY-II manual provided evidence that the NEPSY-II has good internal reliability; however, construct validity appears questionable in some areas. Although most subtests appear to have adequate reliability and validity, some of the subtests may not provide consistent and accurate scores. The Design Fluency, Oromotor Sequence, Manual Motor Series, and Route Finding subtests appear to have lower reliability. Animal Sorting, Narrative Memory, and Visuomotor Precision subtests should be interpreted with care since they do not appear to measure the same construct as other subtests in these domains.

According to D’Amato and Hartlage (2008), there is general support for the clinical usefulness of the NEPSY-II in distinguishing between various neuropsychological disorders. Specific group studies by Korkman et al. (2007) reported lower functioning on subtests across all domains in groups of 23 autistic children. Severe deficits were evident in the areas of executive functioning, language, and memory. Children with Attention-Deficit/ Hyperactivity Disorder generally exhibit lower scores than control groups on Phonological Processing, Speeded Naming, Visuomotor Precision, Arrows, and

Geometric Puzzles subtests (Korkman, Kirk, & Kemp, 2007). Select subtests are particularly useful in diagnosing ADHD, autism spectrum disorder, and learning disabilities.

### **Learning and Memory**

We rely on memory to carry out most daily activities (Reynolds & Bigler, 1997). Unfortunately, nearly every CNS disorder associated with disturbances of higher cognitive functions presents with some form of memory problems (Fletcher-Janzen & Reynolds, 2003; Lezak, Howieson, Loring, Hannay, & Fischer, 2004). Memory difficulties are the most common complaint in individuals with traumatic brain injury (D'Amato, Fletcher-Janzen, & Reynolds, 2005). According to Reynolds and Voress (2009), TBI produces the least predictable forms of memory loss, with the exception of increased forgetting curves. Furthermore, recovery of memory after a TBI is less predictable than improvement in general cognitive functioning and may be due to concurrent difficulties with attention. Some of the more frequently occurring disorders in which memory and learning are likely to be compromised in children include: attention deficit-hyperactivity disorder (ADHD), learning disabilities, mental retardation, autism and other developmental disorders, cancer and iatrogenic memory disorders (secondary to chemotherapy), cerebral palsy, Down syndrome, extremely low birthweight, fragile X chromosome, hydrocephalus, inborn errors of metabolism (e.g., PKU), *in utero* toxic exposure, meningitis, seizure disorders, and many more (Reynolds & Voress, 2009).

Surprisingly, the assessment of memory in children and adolescents has only recently become common practice for clinicians. As pointed out by Reynolds & Voress (2009), the major texts on child neuropsychology of the 1970s and 1980s do not discuss the assessment of memory in children. However, by 1995, assessment of memory function in children was routinely discussed in key textbooks.

The Wide Range Assessment of Memory and Learning (WRAML; Sheslow & Adams, 1990) was the first memory assessment tool designed for use with children. This test consisted of nine subtests that yielded a verbal memory and visual memory score with normative data from children ages five to 17 years. Delayed recall trials could be given for four of the subtests. Four summary indices were provided for interpretation, including the General Memory, Verbal Memory, Visual Memory, and

Learning Index. The Verbal, Visual, and Learning Indices were composed of three subtests each and were derived on the supposition that the dimensions of memory as assessed by the WRAML. While subsequent studies supported the verbal and visual dichotomy as a valid subdivision of the WRAML, data supporting the Learning Factor were equivocal (Aylward, Gioia, Verhulst, & Bell, 1995; Gioia, 1998) with several studies questioning whether subtests may tap into attention/concentration (Burton, Mittenberg, Gold, & Drabman, 1999; Haut, Haut, Callahan, & Frazen, 1992).

The Wide Range Assessment of Memory and Learning—Second Edition (WRAML-2; Sheslow & Adams, 2003) now spans the age range of five to 85+ years. The WRAML-2 comprises six core subtests as well as optional subtests. The screening battery takes approximately 20 minutes to administer, while the administration of the full test to a child takes about 75 to 90 minutes (Hartman, 2007). Administration is flexible, as the authors did not develop the test with an expectation that the entire test would be used. In designing the test in this manner, the authors have satisfied clinicians who adhere to either the fixed or flexible battery (subtest-specific) approach to assessment. The WRAML-2 is composed of three factors: verbal, non-verbal, and attention/concentration. While scores on WRAML-2 subtests contain high reliability coefficients, scores continue to contain error variance. Small studies are cited in the WRAML-2 manual, involving learning-disabled children, suggesting that the WRAML-2 is sensitive to this influence.

The Test of Memory and Learning (TOMAL; Reynolds & Bigler, 1994) consisted of 10 core subtests (five verbal and five nonverbal) that yielded verbal and nonverbal memory scale scores in addition to a composite memory score. The delayed recall index was composed of both verbal and visual subtests. It was also possible to compare the student's learning curve with that of a standardized sample. While some of the subtests appeared similar to other memory measures, additional supplemental indices (e.g., sequential recall attention/concentration, and learning) were unique to this measure and provided useful information. Reynolds and Bigler (1996) examined the latent structure of the TOMAL and found that factor solutions were highly stable across age groups. Interestingly, none of the solutions obtained matched a verbal/nonverbal dichotomy usually represented by the two scales of the TOMAL. Instead, what emerged were components representing various levels of complexity

in memory tasks and processing demands that cut across modalities. Alternative methods of interpretation based on factor-analytic results were provided (Reynolds & Bigler, 1996). In contrast to many neuropsychological measures that combine the forward and backward recall measures, the TOMAL provided separate scores for forward and backward digit and letter recall. The TOMAL included studies of ethnic and gender bias, and items showing cultural bias were eliminated.

The TOMAL-2 (Reynolds and Voress, 2007) is the revised edition of the original TOMAL. The TOMAL-2 can be administered to individuals aged five to 59. For adults ages 55–89, a shorter battery is available. Demographics of the normative sample correspond to 2002 Census Bureau statistics to provide the most updated comparison with the U.S. population. The TOMAL-2 has the broadest range of memory tasks available in a standardized memory battery (Hartman, 2007). The TOMAL-2 consists of eight core and six supplementary subtests. There are two subtests that evaluate delayed verbal memory. There is no index of nonverbal delayed recall; nonverbal recall indices could not be computed due to lower reliability and restriction of range (Reynold and Voress, 2007). The TOMAL-2 reportedly takes less time to administer than the original TOMAL, and the core battery can be given within 30 minutes for most examinees. Results of factor structure studies indicated that there is a clear congruence across the TOMAL and the TOMAL-2, demonstrating the factorial equivalence of the two editions of the TOMAL (Reynolds & Voress, 2009). Results suggested that memory as assessed by the TOMAL and TOMAL-2 is more process-driven than content-driven. Consistently with the original TOMAL, care was taken to control for cultural bias. Following positive feedback from the original TOMAL, forward and backward digit and letter recall scores are computed separately.

The Children's Memory Scale (CMS, Cohen 1997) was developed with connections to the Wechsler Intelligence Scale for Children–Third Edition (WISC-III) built into the standardization process. The CMS consists of six core subtests representing verbal memory, attention/concentration, and visual memory, as well as three supplemental subtests. Subtests allow for evaluation of a student's immediate and delayed recall in both verbal and visual areas. There is a total of seven index scores calculated to examine the differences between immediate/delayed recall, verbal/visual memory, learning, recognition, and attention/concentration. Results of

factor-analytic studies of the standardization sample indicated that a three-factor solution (attention/concentration, verbal memory, and visual memory) provided the “best fit” (Cohen, 1997). To date, the Children's Memory Scale has not been revised.

### ***Language/Communication Abilities***

Language depends on the integrity of the association cortex of both cerebral hemispheres; however, the main language areas are generally located in the left hemisphere for most humans. Broca's area is primarily responsible for planning speech (expressive language) and is located in the inferior temporal lobe. Wernicke's area is involved in representing and recognizing sound patterns of words (receptive language) and resides in the superior temporal lobe. When evaluating the integrity of brain–behavior functioning, both regions should be assessed. While cognitive measures provide language-based measures of general intelligence, information obtained does not provide an adequate measure of listening comprehension that is independent of verbal expression. For this reason, it is imperative to include a measure of receptive vocabulary as part of the neuropsychological evaluation. If language issues appear problematic, a measure of expressive vocabulary may also provide additional useful information.

The Peabody Picture Vocabulary Test–Fourth Edition (PPVT-IV: Dunn & Dunn, 2007) is designed to assess receptive vocabulary by having the examinee select one of four pictures that best represents a target word. The test is untimed and does not require reading ability. The starting and stopping points for the PPVT-IV are determined by the individual's chronological age and basal and ceiling rules. The PPVT-IV is appropriate for individuals ages 2½ to over 90 years of age. The PPVT-IV is the first release that includes color-illustrated pictures. There are two parallel forms of the PPVT-IV. Although the PPVT-IV is limited to the assessment of receptive vocabulary, it is useful in establishing the level of verbal comprehension when expressive communication is not required. The PPVT-IV is co-normed with the Expressive Vocabulary Test–Second Edition (EVT-II: Williams, 2007). The EVT-II evaluates expressive vocabulary and word retrieval in English-speaking individuals age 2½ to over 90 years. Reliability and validity scores reported in the examination manuals ranged from the .80s to .90s.

The Oral and Written Language Scales- Second Edition (OWLS-II: Carrow-Woolfolk, 2011) is an individually administered assessment of receptive

and expressive (oral and written) language for individuals aged three through 21 years old. The OWLS-II consists of four scales: Listening Comprehension, Oral Expression, Reading Comprehension, and Written Expression, which assess listening, speaking, and writing skills, respectively. The Listening Comprehension Scale is designed to measure one's understanding of spoken language. The examinee is required to look at four colorful pictures and select the picture that best depicts the verbal stimulus. The test is untimed, does not require reading ability, and the starting and stopping points are determined by the individual's chronological age and basal and ceiling rules. As the task becomes more difficult, items increase in length, linguistic complexity, and semantic content. Verbal logic, humor, and figurative language are also introduced into items.

To administer the Oral Expression Scale of the OWLS-II, the examinee answers questions, finishes sentences, and generates sentences in response to visual or oral prompts. Due to the recency of the OWLS-II publication, limited research is available; however, the OWLS-II is similar to the original OWLS that exhibited sound psychometric properties.

### ***Perceptual/Sensory and Motor Functioning***

Visual perception and motor functions are complex processes involving many different aspects of brain functioning. The assessment of visual perception is useful in determining the extent to which visual and tactile-kinesthetic information is received and integrated. When clinicians evaluate a child's motor functioning, they usually assess fine motor control and dexterity. The following measures are examples of tests that evaluate visual perception and motor functions.

The Beery-Buktenica Developmental Test of Visual-Motor Integration-6th Edition (VMI; Beery & Beery, 2010) involves copying a sequence of 24 increasingly complex geometric figures. This measure is normed for individuals age two to 100 years old, and takes approximately five to 15 minutes to administer. The VMI measures the extent to which an individual can integrate visual and motor abilities; however, if an individual has difficulties on this measure, it is not possible to ascertain whether it was due to visual, motor, or visual-motor integration problems. As such, if it is determined that further testing is warranted, optional visual perception and motor coordination subtests are available and help compare relatively pure visual and motor performance.

The Developmental Test of Visual Perception—Second Edition (DTVP-2; Hammill, Pearson, & Voress, 1993) and the Developmental Test of Visual Perception—Adolescent and Adult (DTVP-A; Reynolds, Pearson, and Voress, 2002) are comprehensive measures of visual perception that reliably differentiate visual perception problems from visual-motor integration difficulties. The DTVP-2 is designed to be used with children ages four to 10 years and consists of seven subtests, including Visual-Motor Speed, Position in Space, Eye-Hand Coordination, Copying Spatial Relations, Figure-Ground, Visual Closure, and Form Constancy. Subtests are grouped into either the Motor-Reduced Visual Index or the Visual-Motor Integration Index. A General Visual Perception Quotient is also generated. The DTVP-A may be used with individuals 11 to 74 years old and consists of six subtests: Copying, Figure-Ground, Visual-Motor Search, Visual Closure, Visual-Motor Speed, and Form Constancy. Consistent with the DTVP-2, Motor-Reduced Visual, Visual-Motor Integration, and General Visual Perception Index scores are obtained. The DTVP-2 and DTVP-A are especially useful in the evaluation of children and adolescents who have suffered a TBI or stroke where right hemisphere function may be compromised. These measures are well normed and have good internal consistency and validity.

The Children's Halstead-Reitan Neuropsychological Battery (CHRN; Reitan & Wolfson, 1992) for children nine to 14 years, and the Reitan-Indiana Test Battery (RINB; Reitan, 1969) for children ages five to eight are two children's batteries based on the adult version of the Halstead-Reitan Neuropsychological Battery (Halstead, 1947; Reitan & Wolfson, 1985). These batteries contain numerous measures necessary for understanding brain behavior relationships, including assessment of sensory abilities, motor speed, and dexterity. In addition, abilities in the areas of concept formation, attention/concentration, verbal abilities, and memory are evaluated. Both the CHRN and the RINB provide examination of overall performance, patterns of performance, right-left differences, and pathognomonic signs (Reitan, 1986, 1987). The Luria Nebraska Neuropsychological Battery—Children's Revision (LNNB-CR; Golden, 1984) was developed according to neurodevelopmental stages and provides information specific to motor, rhythm, tactile, visual, verbal (receptive and expressive) and memory functioning. Interpretation of the LNNB-CR focuses predominantly on scale patterns

as opposed to levels of performance or pathognomonic signs.

### ***Emotional/Behavioral Functioning***

Children who present with compromised CNS functioning or neurodevelopmental disorders often exhibit problems with emotional or behavior status. In order to adequately provide recommendations in regard to intervention planning, parent and teacher rating scales are often completed that provide information regarding functioning at home and school in a variety of areas. The assessment of emotional and behavior status has lagged behind the methods available for assessing other domains of functioning (Martin, 1988). However, during recent years, the publication of new instruments with improved psychometric properties has emerged.

The Conners' Rating Scale-Third Edition (CRS-3: Conners, 2008) is a widely used behavior rating scale used to assess children aged six to 18 years. The CRS-III was redefined with a focus on ADHD in school-aged children and a strengthened connection with the Diagnostic and Statistical Manual-Fourth Edition- Text Revision (DSM-IV-TR). Parent, teacher, and self-report measures are available. The self-report measure can be used with adolescents aged eight to 18 years. There are short and long forms available for each of the three rating scales. The long form consists of the following scales: general psychopathology, inattention, hyperactivity/ impulsivity, learning problems, executive functioning, aggression, peer relations, family relations, ADHD- Inattentive, ADHD Hyperactive-Impulsive, ADHD Combined, oppositional defiant disorder, and conduct disorder. The Conners 3 Global Index is a measure of general psychopathology. The Conners' ADHD Index 10-item index may be used for screening large groups of children to see if further assessment of ADHD is warranted.

The Behavior Assessment System for Children-Second Edition (BASC-II: Reynolds & Kamphaus, 2004) includes not only teacher and parent forms that can be used from ages two to 25, but also offers a structured observation system (SOS), and for children eight years old and older, a self-report measure that can effectively assess emotional and behavioral status. The primary scales assessed using the Parent and Teacher rating scale include: Adaptability, Activities Of Daily Living, Aggression, Anxiety, Attention Problems, Atypicality, Conduct Problems, Depression, Functional Communication, Hyperactivity, Leadership, Learning Problems,

Social Skills, Somatization, Study Skills, and Withdrawal. Composite score indices are presented for the following: Emotional Symptoms, Inattention/Hyperactivity, Internalizing Problems, Personal Adjustment, and School Problems. The SOS can be used with direct observation that may be more appropriate for monitoring small and gradual changes. Direct observation also provides an objective measure without the potential bias of raters, and can be especially useful when raters (e.g., parents and teacher) disagree in their portrayals of the child. The BASC-2 revision included many improvements from the original BASC that was published in 1992, including improved reliability and standardization the addition of more scales, updated norms, and the age range was expanded to use up through age 21. The BASC-2 also was designed to facilitate differential diagnoses. When adaptive behavior is an identified concern, completion of an adaptive behavior scale such as the Vineland Adaptive Behavior Scales (VABS-II: Sparrow, Cicchetti, & Balla, 2005) or the Adaptive Behavior Assessment System-Second Edition (ABAS: Harrison & Oakland, 2003), may be particularly helpful for intervention planning.

### ***General Organization of the Neuropsychological Assessment of the Child***

The neuropsychological evaluation of a child focuses more directly on CNS functioning, rather than on the identification of strictly neurological disorders. However, assessment can be useful in the diagnosis and identification of subtler conditions (e.g., ADHD, learning disabilities). A neuropsychological assessment of a child differs from that of an adult in that educational considerations are of paramount importance. Furthermore, information obtained from parent and teacher report often provides useful information regarding behavioral functioning.

A thorough history is an important part of a child neuropsychological evaluation. Information about gestation, delivery, postnatal period, and early speech and motor development are important. The length of time and functional changes since the trauma or the disease onset, premorbid levels of functioning, and family history of related problems provide information that will affect how information is interpreted. A review of school records including any special education records, standardized test scores, grades, and information regarding behavioral difficulties will provide additional useful information. If a child has had a previous psychological evaluation, the neuropsychologist must obtain a

copy of that assessment if possible. Once information is obtained from a thorough clinical interview with a parent and school records are reviewed, there are nine guidelines, derived from a variety of sources (Reynolds & Mayfield, 1999; Riccio & Reynolds, 1998; Rourke, Bakker, Fisk, and Strang, 1983), that should be considered in the organization of a neuropsychological assessment.

*1. It is crucial to assess all, or at least a significant majority, of the child's educationally relevant cognitive skills or higher-order information processing skills.* General intellectual functioning via a comprehensive IQ test such as the Wechsler Individual Assessment of Children–Fourth Edition (WISC-IV; Wechsler, 2003) or Kaufman Assessment Battery for Children–Second Edition (KABC-II; Kaufman & Kaufman, 2004) is necessary. Strong measures of *g* that evaluate the efficiency of mental processing provide a baseline for interpreting all other aspects of the assessment (Riccio & Reynolds, 1998). Other areas to be assessed include memory, attention, concentration, and new learning as these are the most common of all complaints following any CNS compromise as well as neurodevelopmental disorders (e.g., ADHD, learning disabilities). Assessment of basic academic skills including reading, mathematics, and written language provide a performance-based measure of learning.

*2. Testing should assess the efficiency of the right and left hemispheres of the brain.* Different brain systems that impact treatment are involved in each hemisphere. In the right-handed majority, language-related processes are usually left-lateralized. The left hemisphere processes rapid sequential recognition, recall and recognition of order information, and the planning of motor and conceptual action skills. Visual-spatial processes, including facial recognition, arousal, and emotional perception, are right-hemisphere functions. Comprehending inferences, metaphors, and humor are also right-hemisphere abilities (Kinsbourne, 2009). Neuropsychological tests, including the Children's Halstead-Reitan Neuropsychological Test Battery (Reitan & Davison, 1974; Reitan & Wolfson, 1992), Reitan-Indiana Test Battery (Reitan, 1969; Reitan & Davison, 1974), and the Luria-Nebraska Neuropsychological Children's Battery (Golden, 1986) are useful in the assessment of brain systems.

*3. Testing should assess both anterior and posterior regions of brain function.* The anterior portion of the brain is generative and regulatory, while the posterior region is principally receptive (Riccio & Reynolds,

1998). Sensory perception should be evaluated. In the area of language, receptive and expressive vocabulary tests may evaluate the posterior and anterior regions, respectively. When care is taken to systematically evaluate both hemispheres as well as anterior and posterior regions, information can be gleamed from all major quadrants of the neocortex.

*4. Testing should determine the presence of specific deficits.* In contrast to many psychological tests, neuropsychological tests tend to be less *g*-loaded and have greater specificity of measurement. This is beneficial when the goal is to determine whether specific functional problems exist. In working with children and adolescents with traumatic brain injury (TBI), strokes, tumors, seizures, or chronic medical disorders, very specific changes in neocortical function are sometimes best addressed by a neuropsychological assessment.

*5. Determine the acuteness versus the chronicity of any present weaknesses.* The duration of a problem is important when formulating a diagnosis and planning treatment interventions. Following an evaluation of a child, a neuropsychologist is called to the task of integrating information from the clinical interview, school records, behavior observations, and testing data. When a comprehensive evaluation is undertaken, it is possible to distinguish chronic neurodevelopmental disorders (e.g., learning disabilities, ADHD) from acute problems resulting from trauma, stroke, or disease with reasonable certainty. The age of the child and the acuteness or chronicity of the problem are important factors to consider when planning treatment or rehabilitation strategies.

*6. The evaluation should locate intact complex functional systems.* While it is imperative in the assessment process to locate weaknesses that are likely to represent permanent or chronic difficulties in functioning, it is even more important to locate the strengths or intact systems of a child. In doing so, it is possible to enhance the probability of designing successful treatments. By identifying intact systems, parents and teachers are provided with useful information to help a child, rather than fostering low expectations. For example, if a child exhibits a weakness with verbal memory but her visual memory is fairly intact, the neuropsychologist can recommend strategies to use in the classroom that draw on her area of strength.

*7. Testing should assess mood, personality, and behavioral functioning.* Neuropsychologists need to be careful not to ignore changes in mood, personality, and behavior that affect a child or adolescent's

functioning. Some of these changes will be temporary, while others will be more permanent. Changes can be directly a result of the CNS compromise at the cellular and systematic levels and others will be more indirect (i.e., the reaction to a loss or change in function, or to how others respond to and interact with the individual). A thorough history can assist in determining direct versus indirect effects. At times, it will likely be an interaction between direct and indirect effects that cause mood disturbances. In adolescents with TBI, anger, and emotional lability are common complaints from six months to a year post-injury. Changes in frontal lobe functioning as a result of the injury, coupled with academic difficulties, social problems, and safety restrictions (i.e., no sports, no driving), collaboratively have an impact on mood and behavioral functioning.

The Behavior Assessment System for Children—Second Edition (BASC-2; 2004) or the Conners' Rating Scales—Third Edition (CRS-3; 2008) contain behavior rating scales and personality inventories that are useful in planning interventions. When planning interventions, it will be necessary to determine whether behavior changes are a direct or indirect result of brain insult or whether premorbid behaviors were evident (Reynolds & Mayfield, 1999).

*8. Evaluations should be written with the primary audience, the school setting, in mind.* Children and adolescents need to be able to function within a school or educational setting, regardless of whether they exhibit a neurodevelopmental disorder or have sustained a brain insult. Results of an evaluation should be presented so that academic and behavior concerns are addressed, as these are primary concerns for educators. Recommendations should provide guidance in determining appropriate services (i.e., special education, content mastery, or a 504 Accommodation Plan) necessary for them to successfully learn. Specific, simple recommendations regarding teaching to a child's strengths through the utilization of intact functional systems will be useful. If behavioral problems are evident, the clinician will need to explain how to best anticipate and diffuse negative situations. A behavior-management plan is often recommended in order to provide positive reinforcement for favorable behavior. Many educators have not had previous experiences with a child who has sustained a TBI, stroke, or other neurological insult. It is the neuropsychologist's role to explain academic and behavioral sequelae so that educators can better understand how to teach these children. For a child with TBI, rapid recovery takes

place during the first six months post-injury, with slower, subtler improvements noted up to two years following insult. Neuropsychologists need to explain this rapid improvement and the need for schools to wait six months before conducting an assessment. It is also necessary to explain that children may not show deficits immediately following their injury but may develop difficulties over time as the demand for new skills emerges (Gronwall, Wrightson, & McGinn, 1997; Taylor & Alden, 1997).

*9. When working directly with the school, the evaluation processes should be efficient.* School districts often do not have a neuropsychologist on staff. Furthermore, they rarely have the time, assessment measures, or funding to provide a comprehensive neuropsychological evaluation. If a neuropsychologist is used to consult with a school to evaluate a child, care should be taken to conduct an evaluation in an efficient manner. The school, with permission from the parents, can provide school records and access to any prior evaluations. Recent intellectual and academic testing by the school district can be incorporated with neuropsychological findings. Behavior rating forms or classroom observations provided by the school may also be obtained and interpreted by the clinician.

## Conclusions

While the field of pediatric neuropsychology is relatively young, neuropsychological assessment of children and adolescents has much to offer toward understanding the functional systems of the brain and the mechanisms involved in learning. Child neuropsychology provides a theoretical framework for understanding patterns of strengths and weaknesses, and the extent to which these patterns may remain stable or change over time (Temple, 1997). Once the clinician identifies the assessment needs of the individual child, he or she must make decisions regarding the most appropriate assessment measures for exploring the dimensions of behavior. In choosing appropriate measures, neurodevelopmental considerations and psychometric properties must be considered. Once an evaluation is completed, understanding the strengths and weaknesses of a child provides the neuropsychologist with needed information to recommend appropriate school modifications and community intervention. When writing neuropsychological reports, the clinician must remember that the audience includes parents, teachers, and other medical professions who are in need of straightforward information that is easily understood and applied. Of paramount importance

is that clinicians must recognize that providing useful, scientifically supported conclusions that contribute to the treatment of the child is the ultimate purpose of assessment. The goal of this chapter is to provide the clinician with the knowledge necessary to make informed choices when evaluating children.

# Memory Assessment

Wayne Adams

## Abstract

The chapter provides an overview of memory assessment of children and adolescents. The importance of memory to a developing organism is noted, and developmental trajectories of verbal and visual memory abilities are described. The relationship of memory with IQ is discussed, along with the additional background that is important for a clinician to understand when undertaking the assessment of memory. Historical roots are summarized, noting the empirical background reflected in contemporary memory tests. After touching on several assumptions made in memory assessment and describing types of memory that are assessed and the model assumed by most tests, five major instruments commonly used with children and teenagers are described in detail, including the WRAML2, TOMAL-2, the CMS, CVLT-C and NEPSY-II.

**Key Words:** memory, assessment, pediatric, children, WRAML2, TOMAL-2, CMS, CVLT-C, NEPSY-II

Memory is fundamental for most human cognitive and emotional functioning, and thus is represented in nearly all day-to-day activities, including intellectual, emotional, academic, social, self-care, vocational, and recreational domains. Memory contributes substantially to who we are and how we perceive ourselves and the world around us. Memory allows us to acquire and later find and utilize skills, feelings and knowledge, so it is an essential ingredient for most of cognitive and emotional developmental change. Simply stated, memory—the ability to acquire and recall information—is ubiquitous in the challenges and delights in the daily lives of infants, children and adolescents. This is true whether we focus on normal or atypical development.

Memory complaints are said to be the most common reason for referral with adults (Lezak, Howieson, Bigler, & Tranel, 2012). It was once thought that a child demonstrating a marked inability to acquire new information and having experienced no acute traumatic event, was likely to be suffering from an

overall cognitive delay. Now it is recognized that there can be discrete to pervasive memory deficits that can range from mild to severe. Table 21.1 is adapted from Reynolds and Voress (2009) and includes a listing of common congenital childhood disorders in which learning and memory, in some form, are probably compromised. Accordingly, psychologists who are referred children for evaluation with any of these conditions, would normally include some kind of evaluation of memory.

While memory is a central cognitive process, it also is a very vulnerable brain function. Various traumas, whether minor or devastating, often affect the efficiency of the brain's laying down of new memories, and/or retrieval of those already stored. Generally speaking, if there is going to be some cognitive compromise resulting from a brain insult, it is most likely that memory will be among those processes negatively affected (Lezak, et al., 2012). Difficulties with memory and attention are the two most common complaints following even mild

**Table 21.1 Chronic and Acute Childhood Disorders or Conditions for Which Compromise in One or More Memory Functions Is Likely**

ADHD
Anoxia and sustained hypoxia
Attention-deficit-hyperactivity disorder
Autism
Cancer, especially brain tumors treated by radiation
Cerebral palsy
Down syndrome
Extremely low birthweight
Fragile X and related syndromes
Hydrocephalus
Intellectual disability
Klinefelter syndrome, XYY, etc.
Learning disability
Lesch-Nyhan disease
Meningitis
Neurodevelopmental abnormalities (e.g., callosal dysgenesis)
Neurofibromatosis
Prader-Willi syndrome
Seizure disorder
Teratogen exposure (e.g., alcohol, lead)
Traumatic brain injury (abuse, falls, motor vehicle accidents, etc.)
Tourette syndrome
Williams syndrome

head trauma (Levin, Eisenberg, & Benton, 1989). Furthermore, it seems that memory is susceptible to congenital insult as well. In fact, contrary to commonly heard assertions, Hebb's (1942) "vulnerability hypothesis" (that early neural insult is more devastating than later) has generally been supported, especially with larger lesions and those affecting white matter tissues (Aram & Eisele, 1992). Other than for more severe acute infection (e.g., encephalitis) and traumatic brain injury from events such

as motor vehicle accidents or falls, amnesias in children are rare (Mattis, 1992).

The importance of memory in estimating overall cognitive ability was assumed by pioneers in cognitive assessment. For example, several memory tasks appeared in the original scale developed by Binet and Simon that was published in 1905, and considered by many as the first test of intelligence (Sattler, 2008). While in one sense, all of the 30 items appearing on that scale required memory, eight made overt memory demands, and are described in Table 21.2. You can see that several have proven their worth, and adaptations of several continue to be included on contemporary IQ and memory tests.

Various assumptions are made when testing memory. First, it is assumed that, like intelligence, memory abilities differ across individuals, and that such variation is normally distributed. Furthermore, based upon research findings related to intelligence, memory is also assumed to gradually increase, in a developmentally linear manner, from birth to adolescence, asymptote in early adulthood, and then begin a decline that is inversely related to age. Also assumed is that the trajectory of developmental change is more rapid in childhood than adulthood, and fairly similar across various memory systems. Some might argue that these are not assumptions, but notions that have empirical grounding based on memory measures. However, it should be remembered that memory tests themselves are substantially created to be consistent with our assumptions (memory is what memory tests measure!). Figures 21.1–21.3 show performance trajectories of individual subtests found on the Wide Range Assessment of Memory and Learning, Second Edition (WRAML2), a memory battery to be discussed later in this chapter. These figures show developmental performance paths for immediate memory in both verbal and visual modalities; sample size for each age grouping is 80. Each point on a given plot represents the total raw score achieved by a given age band, expressed as a percentage of the highest performance achieved across age bands on that subtest. Therefore, the left-most square in Figure 21.1 shown for the Sentence Memory subtest indicates that performance on this subtest by children 5 years 0 months through 5 years 5 months is about 55 percent of the maximum performance on this subtest, that is shown will be achieved around 25 to 30 years of age. (The Sentence Memory subtest is a verbal, immediate memory subtest that requires the client to repeat, verbatim, sentences of increasing length.) At first glance, the plots found

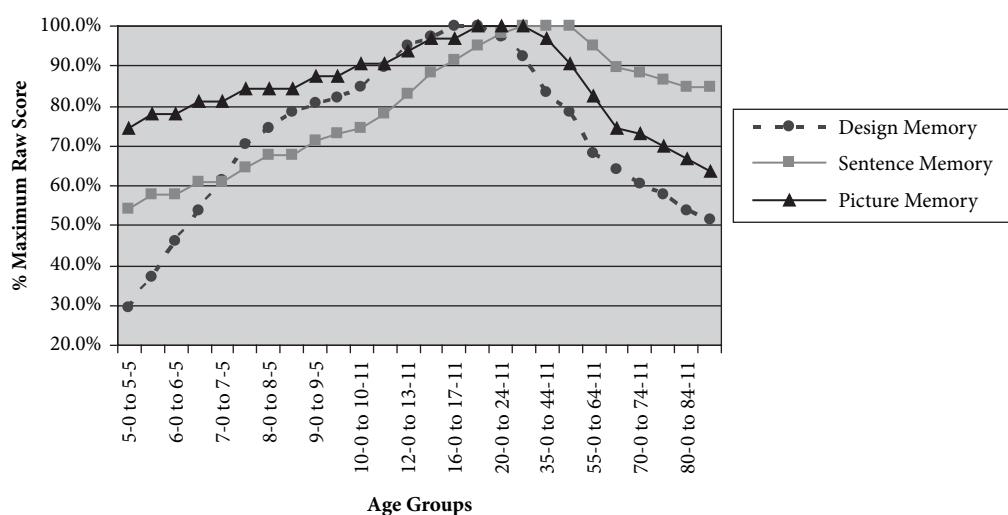

**Table 21.2 Items with Significant Memory Demands Included Within the 1905 Version of Binet and Simon's Measure of Cognitive Ability**

Item Number	Task Name and Requirement
#6	Execution of Simple Orders and Imitation of Gestures. Follow verbal commands and imitate examiner movements.
#7	Verbal Knowledge of Objects. Follow verbal commands to touch specified body parts and find a object among many after a short delay.
#11	Repetition of Digits. Repeat three digits.
#15	Repetition of Sentences. Repeat 15-word sentences.
#17	Memory for Pictures. Shown pictures and then asked to recall their names.
#18	Drawing a Design from Memory. Shown two designs and then asked to reproduce them from memory.
#26	Three Words, One Sentence. Make up a sentence using three words (Paris, gutter, fortune).
#28	Reversal of Clock Hands. State the time if the large and small hands of pictured clock were reversed.

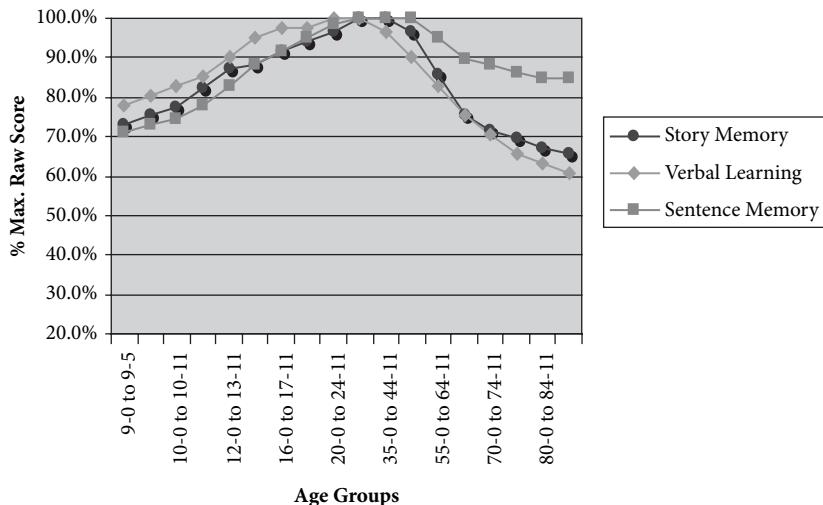

in Figures 21.1–21.3 seem to suggest that memory peaks at about the same age as intelligence, and like intelligence, the verbal modality seems to hold up better than the visual or nonverbal modality.

Inspection of the three figures also indicates several findings that question assumptions often made about memory in childhood and adolescence. First, memory skills do not seem to develop uniformly. For example, Sentence Memory performance gradually improves in a fairly uniform, incremental manner from five to 30 years of age. In contrast, for

the Picture Memory subtest (which assesses visual immediate memory of the content within meaningful scenes), more than 70 percent of the maximum competency in this visual memory task is in place at age five years, and peak performance will occur around 16 to 17 years of age. Yet a different pattern is seen with another visual memory task (the Design Memory subtest requires drawing a pattern of simple shapes from memory). Figure 21.1 indicates that this kind of visual memory is poorly developed at five years (i.e., 30% of the maximum ability that is

**Figure 21.1** Differing developmental trajectories of performance on three WRAML2 subtests from 5–90 years of age. Design Memory and Picture Memory subtests are measures of immediate visual memory; the Sentence Memory subtest is a measure of immediate verbal memory.

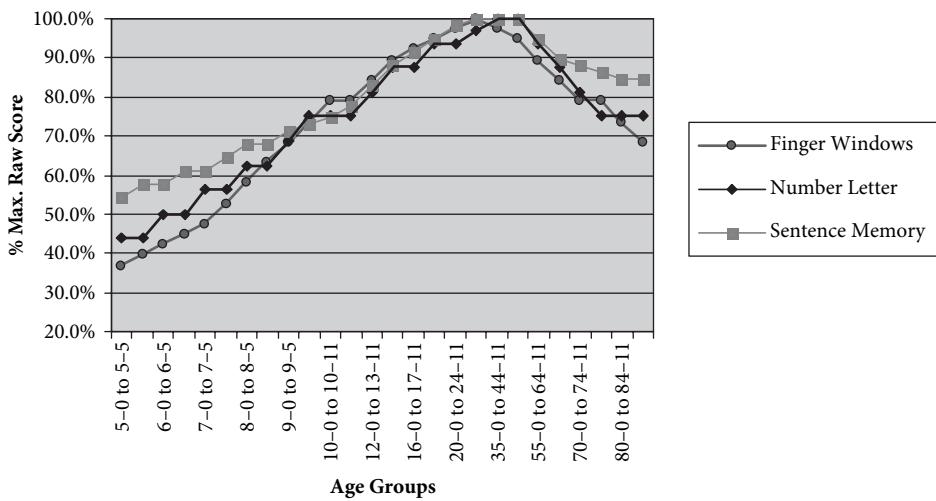

**Figure 21.2** Developmental trajectories of three WRAML2 verbal immediate memory tasks. Story Memory measures highly meaningful verbal material; Sentence Memory measures recall using a less meaningful verbal material; and Verbal Learning is a list-learning task tapping more rote immediate verbal recall.

typically observed around 18–19 years of age), and the growth trajectory is rather steep until age eight, when it then resembles the developmental pace of the Sentence Memory task.

Figure 21.2 shows performance starting at age nine since the two subtests shown (Story Memory and Verbal Learning) use different (easier) items for five- to eight-year olds; therefore, comparison with maximum performance necessitates moving to nine years, at which age the subtest task items are equivalent into the adult years. Sentence Memory performance is again included to serve as a basis of comparison across figures. What is apparent when

comparing Figures 21.1 and 21.2 is the relative consistency in acquisition rates across immediate verbal memory tasks, but relative inconsistency in the decay rates. As reported by many older adults, memory decline seems to begin sooner and drops more dramatically than has been shown with IQ performance. You may remember (!) that the results of the still ongoing Seattle Longitudinal Study (Schaie, 1996) suggested that verbal intellectual skills tend to hold up pretty well, with a decline starting at about age 60. Similar to memory, spatial intellectual skills begin to decline a bit earlier than verbal. However, visual memory shows a more precipitous

**Figure 21.3** Developmental trajectories of two WRAML2 rote, immediate memory tasks, one of which is auditory (Number/Letter) and the other is visual (Finger Windows). Sentence Memory is included for comparison purposes across Figures 21.1–21.3.

drop. Therefore, while verbal memory shows greater resilience than visual, the downward trajectory for each starts considerably sooner than for IQ.

Figure 21.3 provides the performance plots for two WRAML2 subtests demanding rote immediate memory ability (low in meaning) as well as sequencing. The trajectories for these two tasks are rather similar, even though they ostensibly make rather dissimilar immediate-recall demands: one task is aural/oral (hearing and repeating unrelated numbers and letters) and the other is visual/motor (watching and then pointing out demonstrated sequences). While modality-specific memory is a generally accepted concept (Kolb & Whishaw, 2008), it appears that even within a given sensory modality, there are different “subclasses” of memory ability that have developmentally distinctive qualities from each other. Therefore, using tests that assess memory, findings would indicate that memory subsystems develop at different rates, within and across sense modalities. Furthermore, these different kinds of memory abilities peak at different ages that span more than two decades. This kind of variability often gets lost when clinicians are asked questions like, “How’s his memory?” and when those same clinicians try to answer that question using too narrow a range of memory measures. Similarly, when assessing memory in a child who has sustained an acute brain insult, the child may ultimately be differentially impacted in memory, given where that system itself is in its development. That is, a five-year-old sustaining a significant brain injury would more likely demonstrate long-term deficits in those memory processes that are only 30 percent developed compared to other memory functions that are 75 percent developed. Once intelligence was thought to be a unitary trait, then consisting of verbal and nonverbal (or “Performance”) components, and most recently, as something comprising multiple kinds of “intelligences” many of which are quite different from earlier variables that defined IQ. It seems reasonable to expect that our understanding of memory will evolve similarly and our assessment instruments will reflect an increasing sophistication resulting from that evolution.

## Memory and Intelligence

While we would expect memory performance to be related to intelligence, we would not expect it to correlate as highly as intelligence measures inter-correlate. Generally, IQ measures show correlations  $> .70$  with each other. Table 21.3 shows the correlations of scores from the three existing pediatric

memory batteries with the Wechsler Intelligence Scale for Children (versions differ depending on when the research was completed). The WRAML2 has low to moderate correlations with intelligence, with the Test of Memory and Learning—Second Edition (TOMAL-2; Reynolds & Vorees, 2007) and the Children’s Memory Scale (CMS, Cohen 1997) having correlations that are a bit higher, but below the usual range seen for IQ test inter-correlations. The reader should remember that, depending on the edition being considered, the Wechsler Intelligence Scale has at least one memory subtest (such as Information, Digit Span, or Arithmetic) contributing to the FSIQ score. Therefore, the degree of inter-correlation between memory and IQ measures is inflated somewhat because those creating IQ tests believe that short-term memory is an ingredient of intelligence.

It is interesting to note, though, that there is apparently a conceptual wrestling over how much to use memory processes to define intelligence. That is, with the WISC-III (Wechsler, 1991), *intelligence* (as defined by FSIQ) was operationalized as consisting 20 percent of memory (Information and Arithmetic subtests contributed, and Digit Span was non-contributory). With the WISC-IV (Wechsler, 2003), a Working Memory Index appears, as do four memory subtests, although still 20 percent of the FSIQ is derived from memory subtests (but they are different subtests—Digit Span and Letter-Number Sequencing) than contributed to the WISC-III FSIQ. In the most recent adult Wechsler IQ test revision (WAIS-IV; Wechsler, 2008), which may portend changes that will be seen on the WISC-V, Digit Span (in an expanded form), Arithmetic and Information all get the nod to contribute to the FSIQ (now 30 percent comprised of memory—a 50 percent increase!); Letter-Number Sequencing was exiled to supplemental status. So the trend in at least one highly regarded test-development camp accords memory greater involvement in defining IQ than in the past. Nevertheless, as we have already seen, memory is a complex and multifaceted construct, and therefore still demands assessment beyond how it is defined on contemporary measures of intelligence.

Finally, it should be mentioned that there are classifications of functioning assigned to intelligence. *Superior, impaired or average* levels of intellectual functioning are well defined. Such is not the case for memory. While one can use the same classification system for memory as for intelligence, it must be done by mapping onto an IQ framework

**Table 21.3 Correlations of WRAML2, TOMAL-2 and CMS Core Indexes with the Wechsler Intelligence Scale for Children<sup>1</sup>**

IQ Measure	WRAML2 (N = 29)				TOMAL-2 (N = 22)			CMS (N=126)			
	GMI	VMI	ViMI	A/CI	CMI	VMI	NVMI	GMI	VMI	ViMI	A/CI
WISC <sup>1</sup>											
Verbal IQ (or VCI)	.54	.29	.36	.42	.65	.53	.66	.54	.55	.23	.58
Performance IQ (or PRI)	.37	.14	.30	.28	.51	.51	.29	.46	.36	.29	.55
FSIQ	.44	.25	.33	.31	.66	.56	.65	.61	.56	.34	.72

<sup>1</sup>The third edition of the WISC was used for inter-correlations with the WRAML2; the second edition of the WISC for the TOMAL-2, and the WISC-IV for the CMS. The source for these data was the respective tests' manual, except for the CMS, for which the *WISC-IV Technical Manual* was used. Correlations corrected for reliability are used throughout. WISC = Wechsler Intelligence Scale for Children; VCI = Verbal Comprehension Index; PRI = Perceptual Organization Index; FSIQ = Full Scale IQ. WRAML2 = Wide Range Assessment of Memory and Learning, second edition; GMI = General Memory Index; VMI = Verbal Memory Index; ViMI = Visual Memory Index; A/CI = Attention/Concentration Index. TOMAL-2 = Test of Memory and Learning, second edition. CMI = Composite Memory Index; NVMI = Nonverbal Memory Index. CMS = Children's Memory Scale.

of conventional categories. Furthermore, using such classifications of intelligence has clinical utility, since, for example, IQ scores are endowed with meaning by DSM (American Psychiatric Association, 2013) when considering a diagnostic formulation. No equivalent exists for memory scores, especially not within a pediatric population. "Memory" is not even an entry in the index of the DSM (DSM-IV and DSM-V do list "Amnestic Disorders" !) Technically, it is not possible to have a learning disability or be otherwise impaired based on a memory deficit, according to existing diagnostic systems, although I am sure such children exist. True, there is "Cognitive Disorder, not otherwise specified (NOS)," but as for most "NOS" appendages, Cognitive Disorder, NOS, is a very broad, ill-defined category that is not very helpful in focusing on memory impairment per se, and it implies an acute, not congenital etiology. It is hoped that future research efforts in pediatric memory will help us solve such dilemmas, as it has done in contributing a solid foundation for clinical application in the past.

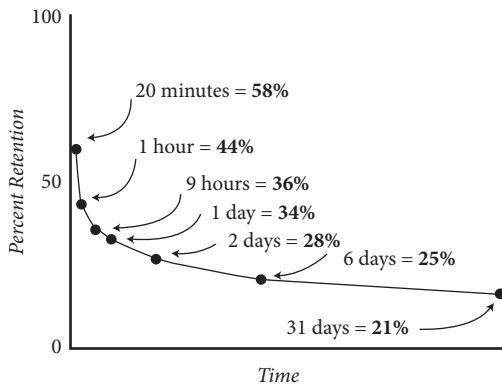

### Historical Roots

A full historical review of memory is beyond the scope of this chapter, but it is important to at least touch on major highlights, since probably more so than most areas assessed by psychological tests, memory had a significant advantage of having a rich legacy of empirical and clinical contributions to inform test content and interpretation. Comprehensive historical reviews of memory and

other cognitive processes are available (see Samuel, 1999; Bower, 2000; Finger, 2000; Finger, 2001, Squire, L., 2004).

While acknowledging the contributions of ancient China or Greece is the typical starting place for most historical overviews of anything, that is not the case for memory (or any brain functioning). One exception was the practice of Hippocratic adherents in the fifth century B.C., who associated epilepsy with the brain. However, this promising start was scuttled by Aristotle, who thought the brain was nearly inconsequential to thinking. Thanks to casualties from the Roman games, the physician Galen (c. A.D. 200) was able to gather evidence supporting his contention that the brain was central to thinking and motor coordination. Unfortunately, he concluded that the ventricles were the structures of greatest importance, a view that continued until the fifteenth century, when Leonardo da Vinci pointed out that ventricles of animals did not vary much in their relative size across species, despite the obviously extreme range of intellectual abilities exhibited (Samuel, 1999).

In the 1880s, Hans Ebbinghaus was the first to systematically study and record his observations of experimental findings with memory in humans (Ebbinghaus, 1913). Almost every introductory psychology text mentions Ebbinghaus and shows a curve similar to that seen in Figure 21.4. Even though these data were primarily based on results from memory tasks he administered to himself and/or his wife, replication using more credible samples

**Figure 21.4** Ebbinghaus' classic learning curve. There is a dramatic loss of learned information within the first hour, after which forgetting occurs at slower and slower rates. Adapted from: [www.psych.purdue.edu/~ben/285su2001/notes/figures/5-forgettingcurve.htm](http://www.psych.purdue.edu/~ben/285su2001/notes/figures/5-forgettingcurve.htm).

substantiated his assertions. The findings represented by the “Ebbinghaus forgetting curve” (i.e., Figure 21.4) immediately suggest clinical applications, such as the appropriateness of testing recall of new learning after a 20- to 30-minute delay, since during this relatively brief interval, more “forgetting” occurs than at any other subsequent interval. This is but one example of how empirical findings from more than a century of research were available to memory-test developers.

Ebbinghaus notwithstanding, it was the twentieth century that witnessed a burgeoning of experimental and clinical evidence that gradually contributed to a modern understanding of memory. Those in the memory “Hall of Fame” include Sherrington (British neurophysiologist who in the 1920s posited an “enriched loom” composed of bioelectric currents in the brain; he also gave us the term *synapse*); Ribot (around 1910, he wrote about three stages of memory that today we would call *encoding, storage and retrieval*); Freud (who started in neuroscience research, and whose debated theory of psychopathology in the 1920s heavily relied upon memory processes); Pavlov (investigating primitive levels of learning and memory); Luria (generating over several decades a still-influential theory of embedded brain systems, using what he learned from injured war victims; he also carefully documented the case of “S,” a man with apparently limitless recall capabilities); William James (in 1890, James noted that recall consisted of what we now call *short- and long-term memory* components); Penfield, in the 1930s, was the first to “map” functional regions of the brain using an electric probe

in epilepsy patients; and Scoville (US neurosurgeon) with “HM” (the patient upon whom Scoville operated in 1953, and who dramatically demonstrated the existence of a brain structure essential for the creation of new memories). Other important contributors include Hebb (Canadian theorist and experimenter who defined the substance of memory in terms of “cell assemblies,” which themselves are established by neural paths that are frequently and regularly “fired” in temporal contiguity); Lashley (U.S. psychologist demonstrating that long-term memory is not localized but distributed throughout a very interactive brain); and ending our historical march we should mention those inventing and using magnetic resonance imaging, which today allows us to actually witness real-time memory activity using computerized estimates of brain metabolism (Rosler, Ranganath, Roder, & Kluwe, 2009). Because of this rich historical legacy, a vocabulary related to memory gradually developed, is generally accepted, and comprises a required knowledge-base for professionals evaluating clients for memory disorders. Table 21.4 lists common terms related to memory phenomena, most of which were generated through research efforts, and most of which can be found today on tests of memory. A solid knowledge of these concepts is important for those engaged in the understanding and interpretation of memory assessment. Detailed discussions of these terms and how they were derived can be found in many advanced texts on cognition (e.g., Leahey & Harris, 2001; Radvansky, 2005), in more clinically oriented volumes (e.g., Reeves & Wedding, 1994; Haberlandt, K., 1999), or in a text dedicated to discussing memory terminology (Dudai, 2004).

Despite impressive growth in understanding many aspects of memory over the last century, the focus of these efforts was primarily on adults; other than studies using infants, few memory investigations focused on a pediatric population. Amazingly, “memory” does not appear as an entry in *Child Development Abstracts and Bibliography* until 1965. Even today, it is assumed that the phenomena and the associated mechanisms related to adult memory processing are similar or identical to that found in children (a variant on the idea that “children are just little adults”). Some memory phenomena clearly are not the same in children as adults, such as Miller’s (1956) “magic number” of  $7 \pm 2$ . Those working with children know, as did Binet a century ago, that most “normal” seven-year-olds cannot repeat seven digits; their magic number is five (and probably not  $\pm 2$ ). Similarly, it is assumed that executive

**Table 21.4 Vocabulary of Memory: Terms in Use That Emerged from Research, Are Common Terms in Current Clinical or Research Efforts with Memory Impairment, and Describe Components Found in Memory Test Batteries**

Memory Term	Phenomenon Described
Anterograde Amnesia	Impaired ability to remember information <i>following</i> the onset of memory difficulties
Consolidation	Strengthening of the informational “engram” while it is stored
Declarative (Explicit) Memory (“knowing what”)	Memory that is available to the conscious self (including episodic and semantic memory)
Episodic Memory	Autobiographical memory for events, including content, place, and temporal aspects (the “what,” “when” and “where” of an event)
Learning/Forgetting Curve	A plotted measure representing degree of recall of a set of material over a series of equivalent learning episodes (usually multiple “teaching” sessions or “trials” with that material); conversely, a plotted measure representing loss of material once learned, obtained by assessment periodically over time, is a forgetting curve
Long-term (Delayed) Memory	Storage of information after hours or days, with seemingly unlimited capacity, and a slow rate of decay. Presumably all information in long-term memory started as part of short-term memory and was “transferred” into storage
Primacy/Recency Effect	When learning new information (especially of a relatively rote nature), the material at the beginning and end of the learned material is retained best, with the end material (most recent exposure) being retained better than that found at the beginning; material in the middle is least well retained
Procedural memory (“knowing how”)	Remembering focused skill sets, usually learned through much practice, and upon mastery are relatively automatic (non-conscious)
Recognition Memory vs. Retrieval	The ability to correctly recognize information previously encountered vs. being able to retrieve that information volitionally. Evidence of recognition suggests the information is stored, even if not retrievable
Retrograde Amnesia	Impaired ability to remember information <i>prior</i> to the onset of memory difficulties (often resulting from an acute brain insult)
Rote vs. Meaningful Memory	Remembering rote material (relatively meaningless to the learner, such as a foreign word or unfamiliar term) is more difficult than remembering meaningful material (a concept, sentence, story)
Semantic Memory	Knowledge of the world, like facts, concepts, and vocabulary (content is preserved but without a temporal marker (when it was learned)
Short-term (Immediate) Memory	Limited-capacity storage for a brief period (seconds) with rapid decay
Working Memory	Capacity to briefly utilize information in short-term storage without disrupting that information while working with it

functions are involved with working memory and learning over trials, and yet we are aware that frontal lobe myelination is relatively slow in development, continuing even into young adulthood (Giedd et al., 1996). Nevertheless, the impact of frontal lobe immaturity on memory performance has not been methodically explored. Despite these gaps in our knowledge of memory in children, results from

existing memory batteries provide reasonable proof that memory phenomena found in adults can also be documented in children, and is probably one reason that child and adult memory tests are more alike than different.

Table 21.5 provides an abbreviated chronology of major memory tests. While parts of various adult memory procedures were adapted for use

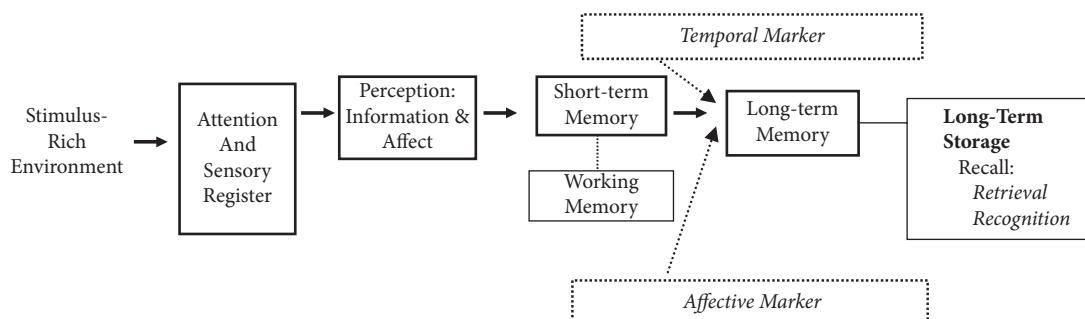

**Table 21.5 Chronology of the Emergence of Memory Tests**

Year Introduced	Test Name and Author
1941	Complex Figure Test (Rey)
1945	Wechsler Memory Scale
1987	—2nd Edition
1997	—3rd Edition
2009	—4th Edition
1946	Benton Visual Retention Task
1963	Recurring Figures Test (Kimura)
1964	Rey Auditory-Verbal Learning Test
1974	Selective Reminding Task (Buschke)
1978	Judgment of Line Orientation Test (Benton, Varney, & Hamsher)
1991	Rivermead Behavioural Memory Test for Children (Wilson, Ivani-Chalian, & Adrich)
1987	California Verbal Learning Test (Delis, Kramer, Kaplan & Ober)
2000	—2nd Edition
1990	Wide Range Assessment of Memory and Learning (Sheslow & Adams)
2003	—2nd Edition
1994	Test of Memory and Learning (Reynolds & Bigler)
2007	—2nd Edition (Reynolds & Voress)
1994	California Verbal Learning Test—Children's Version (Delis, Kramer, Kaplan, Ober)
1997	Children's Memory Scale (Cohen)

with children, no set of memory tasks designed for children and co-normed using a pediatric sample existed until 1990 when the Wide Range Assessment of Memory and Learning (Sheslow & Adams, 1990) was released. Since then, two other child-focused memory batteries have been introduced, including the Test of Memory and Learning (Reynolds & Bigler, 1994) and the Children's Memory Scale (Cohen, 1997). Also, in 1994, the California Verbal Learning Test—Children's Version (Delis, Kramer, Kaplan, & Ober, 1994) was made available. These tests and others that are commonly used and/or psychometrically sound will be discussed later in this chapter.

## Models of Memory

While numerous models of human memory have been proposed and have generated enthusiastic debate emphasizing disparities, generally there is more similarity than difference across models. The tests described later in this chapter generally understand memory in a manner characterized by Figure 21.5, which is reminiscent of a long-standing model of remembering originally advanced by Atkinson and Shiffrin (1968). Each memory test assumes an external world that impinges upon human sensory systems. Through selective attention, which itself is a function of evolving cognitive schemas, environmental stimulation is, usually, incompletely taken in. The incomplete encoding of information in one or more sensory systems is available (i.e., the person is aware of it) for a brief interval (short-term memory) of several seconds. Again, because of incomplete processing, a portion of that perceived information is stored in long-term memory, depending on many variables, including prior information stored, conscious effort of the learner to remember (e.g., rehearsal), and state of alertness. Longer-term memory storage is less evanescent than short-term, but still, as Ebbinghaus demonstrated, there is

**Figure 21.5** A common model used to conceptualize the human memory system (adapted from Atkinson and Shiffrin (1968)).

significant information loss with normal learning. Frequent and/or “emotionally strong” exposure to that and related information establishes a trace or *engram*, which should allow conscious (intentional) retrieval of that information at a later time (via semantic and episodic memory). The information seems to be stored in primary (probably related to the sensory system[s] perceiving the information) as well as secondary locations. In addition to the content of the information that gets stored, an affective valence is often stored as well, allowing the person to obtain an emotional weighting of the information along with the content being retrieved. For most events, a temporal marker is also stored with the informational and affective content allowing memories of events to be distinguished from each other using an internal calendar. Normally, with enough exposure (which can vary from one or more exposures), the information is stored or “laid down” in a relatively robust “memory bank.” More vulnerable and/or inefficient is the retrieval mechanism, a conscious (i.e., intentional) memory component used to find the stored information when needed. Even if retrieval is not successful, the person can still, through a different and more basic memory system mechanism, recognize the information being sought if it or aspects of it are made available. Accessing the information successfully (i.e., remembering it) may or may not result in any observable output by the person.

While it is a oversimplification, the heuristic value of this model allows one to understand that a breakdown anywhere along the path can create recall problems. So, for example, either blindness or hearing impairment would lead to deficits in the sensory register that, in turn, would create distortions or omissions in the information being passed along, well before it gets to the actual memory processing devices. Likewise, at the other end of the route, deficits in short-term memory may contribute to the relaying of incomplete or faulty information into long-term storage. Weaknesses in long-term storage can exist because information was “misfiled,” or filed but then lost partially or completely.

Therefore, memory assessment consists of evaluating the efficiency of various parts of this kind of system, using history, client report, observer report, the examiner’s observations, as well as test results to assess functioning everywhere along the route just described. Medical status including sensory defects and/or knowledge of medications (taken or not), may be as important in this sequential process as are the memory test results—perhaps more so in

some conditions, such as hypothyroidism. Likewise, through test results, identifying isolated problems with short- or longer-term memory can be very helpful in developing an effective remediation plan for the client.

It should be mentioned that it is common to establish a level of memory expectation based upon intellectual functioning. So, if a client is functioning in an extreme range, it is reasonable to expect memory skills to also reflect a similar extreme level, and for the examiner to form impressions of “atypical” based upon the degree of discrepancy based on this expectation. As noted earlier, memory and IQ are only moderately related, so exceptions are common, and therein is the justification for memory testing. However, if, for example, a child is functioning in the mildly impaired range of intelligence, and has memory test results falling within this same range, that child would not be considered having a memory deficit *per se*, since memory performance is consistent with his/her overall cognitive level.

### **Requisites for Clinicians Measuring Memory in Children**

Most clinical training programs prepare students in individual assessment, especially intellectual assessment. Knowledge of and experience with intelligence testing provide an important foundation upon which one builds broader evaluation competencies including memory assessment. Important skill sets that should readily generalize include efficiently obtaining a thorough and focused history, establishing and maintaining rapport, being alert to make keen observations, adhering to standardized test administration and scoring details, being able to integrate information from a variety of sources, applying multicultural awareness and sensitivity to a given client and/or presenting problem, and providing informed feedback in an effective but caring manner. In addition, a clear understanding of the psychometric aspects related to item measurement, standardization, sampling, bias, reliability, and validity, are essential for test selection and interpretation. Furthermore, knowing what tests are available and their relative strengths and weaknesses for common referral or research questions are central to assessment mastery. While all of these assessment skills are important for any cognitive testing, there are some unique competencies important for memory assessment generally, and for assessing memory in children and teenagers, specifically.

## ***Neuroanatomical Understanding of Memory***

There have been major advances in our understanding of the neuroanatomical substrates involved with forming and laying down new memories, as well as retrieving and forgetting them. Almost monthly, findings from functional magnetic resonance imaging (fMRI) and related imaging techniques enhance our understanding of brain-behavior functions, with memory commonly a focus. An appropriate treatment of the neuroanatomy of memory is well beyond the scope of this chapter, but excellent reviews exist (e.g., Squire & Schacter, 2002; Kolb & Whishaw, 2008; Moscovitch et al., 2005). Those working with memory assessment and clients with memory disorders should remain knowledgeable of neuroscientific developments, since client understanding and test interpretation are becoming increasingly more informed by neuroanatomical findings related to remembering and forgetting, as well as cognition and emotion in general (e.g., Stark & Squire, 2000; Smith & Squire, 2009).

## ***Psychological Understanding of Memory and Learning***

There is an extensive literature that focuses on how humans (and animals) learn and remember. Courses entitled “Cognition” or “Learning and Memory” are found in most undergraduate and graduate psychology curricula, and use texts that provide excellent discussions of the terms listed in Table 21.4. Many aspects related to these descriptors of “normal” memory and learning phenomena are found within tests of memory abilities, therefore the examiner working with memory assessment should be knowledgeable about phenomena such as those listed in the table. Having a developmental appreciation of the client vis-à-vis expected memory change is also a real asset in relating to and understanding the client being evaluated.

## ***Clinical Understanding of Common Referral Problems***

Memory assessment tends to be especially important with certain conditions, many of which are listed in Table 21.1. Those to whom such referrals are made clinically, or those using a memory measure for research purposes, should directly or through a supervisor have an informed background of the clinical condition and its likely impact on cognition generally, and memory specifically. Knowing when there is no associated cognitive “profile” is important as well. Such background often requires some knowledge outside of the traditional domains

associated with psychology, pushing the minimum competency boundary into other fields such as language pathology, endocrinology, genetics, occupational therapy, nuclear imaging, or pharmacology. To make an accurate interpretation of test results, those working with children must be able to rule out conditions that can confound memory scores. More so in childhood than adulthood, these confounding conditions may not have been identified yet, such as expressive language impairment, ADHD, and peripheral acuity or hearing deficits, and so require greater examiner vigilance and diagnostic acumen.

Also, in contrast to those working with adults, psychologists working with children tend to omit specific memory inquiries when obtaining a comprehensive history. Accordingly, parent (and child) interviews or history questionnaires should invite responses to questions such as the ones that follow: Does your child:

- (1) need reminders to do things and seems frustrated with him/herself because they were left undone?
- (2) have the ability to be sent into another room and be asked to return with several things from that room?
- (3) remember to bring home the correct materials for homework assignments? (or frequently need to phone or text friends to get a homework assignment?)
- (4) easily memorize sets of facts like state capitals or new scientific terms? Are those still remembered a week or two later?
- (5) usually locate his/her own belongings around the house?
- (6) forget to take things to or bring things home from school (or a friend’s house) even when he/she wants to?
- (7) forget things important to him/her, such as invitation to a party or sports event?
- (8) get temporarily lost, like in a store or when biking to a nearby friend’s neighborhood?
- (9) remember the rules of new games?
- (10) remember the names of teachers from prior years or prior vacation spots?
- (11) demonstrate impressive remembering, like being able to direct you to a location you have both driven to once or twice before?
- (12) show the ability to repeat stories they read or have been read?
- (13) have problems participating in sports because your child forgets things related to the game being played?

Note how, unlike in clinical work with adults, the professional working with children needs to make various developmental adjustments in expectations when asking and interpreting parents' responses to these questions. The relatively modest relationship between memory and academic achievement (Dehn, 2008) causes one to question whether obtaining teacher ratings on memory while at school supplies misleading information that is confounded by the many other factors required for school performance. Likewise, it is important to focus on memory facets embedded within tasks. Memory is involved in almost any task, but its importance on overall level of performance can vary considerably. For example, remembering a short list of afternoon chores or the details of a homework assignment each has memory demands, but only taking a history carefully can tease out whether the deficit in performing this multidimensional tasks is, in fact, memory-related, and/or more related to motivation, overall intellectual level, executive functioning, parental or sibling

involvement, distractibility, and unique aspects associated with task demands. Table 21.6 lists examples of "everyday procedures" that commonly make memory demands on children and teens, and may be useful to include during history-taking when assessing for memory deficits.

### ***Psychometric Expectations***

As noted at the outset of this section, a solid psychometric understanding of what makes a test a "good" test is important for any psychologist involved in assessment. And while an appreciation of what constitutes psychometric integrity of a given instrument is important in assessment generally, there are some ways memory assessment is unique. For example, it is not unusual in reading reviews of memory tests to see it pointed out that test-retest reliability is lower than "levels normally acceptable" for cognitive tests. Sometimes reviewers seem to forget that by their very nature, memory assessment involving new learning (which is a part of most all

**Table 21.6 Examples of Everyday Tasks Involving Memory Components and Meriting Focus When Obtaining a Child's or Adolescent's History**

**Compared to Age Mates, Does the Child/Teen Remember:**

Names of familiar people? new acquaintances?	Math tables?
Phone number(s), street address, locker combination?	Spelling words past the weekly test?
How to find somewhat new places in the neighborhood or at school?	What was for supper last night?
Remember where things are located (e.g., can opener, batteries supply, soap replacement)?	A series of two or three directions related to a novel request? Or a homework assignment?
Parts of new chore assignments (utensil positions when setting the table)?	A phone message with reasonable accuracy?
The time and day of a favorite TV show?	The name for new object whose label has been given once or twice before?
Jokes or stories heard at school, at a party, etc.?	The rules and terms related to a relatively new game?
Things the parents forgot?	The plot and details of a novel story heard or read?
How to operate a new gadget after one or two interactions with it?	Poetry assignments? Memorizing lines of a play or speech?
Time and day of a social date, party or other "appointments" like meeting after school?	A few items to obtain while shopping in a store?
Lists of facts after originally mastered (e.g., state capitals, list of presidents, etc.)?	factual information, rather than looking to a parent or older sibling to provide the information?
Where important possessions are stored at home or school?	To which team he/she has been assigned during a daily or weekly phys. ed. class or intramural sports team?

memory measures) cannot be readministered to establish reliability. The task being used is different at the second test administration than it was for the first. The variable it is attempting to measure (i.e., memory) may, in fact, lower the test-retest reliability if the test is valid! Instead, what may be a better index of reliability are “person separation” and “item separation” statistics derived from Rasch item analysis (Wright & Stone, 1979). While some psychometrics courses include this within their syllabi, many do not, and for those that do, most students have forgotten this background by graduation.

Another example of the need for some psychometric adjustment in one’s thinking about memory measures is found in maintaining an exacting demand for a full range of normed scores across the ability spectrum. For some tests, such as those measuring intelligence, detecting strength is often important. For other tests, however, measurement of strength is less important, or not really meaningful. For example, personality tests are not expected to have enough sensitivity to detect those whose positive self-esteem is at the 95th percentile. Generally, low self-esteem is the clinical interest and focus. Likewise, for some aspects of memory assessment, sensitivity to strength is often unimportant. For example, recognition memory is so robust in healthy individuals that sensitivity in detecting strengths in this area is very difficult, because few participants miss recognition items. As with some personality constructs, demanding test sensitivity to detect average, above average, and superior recognition memory probably has little clinical meaning or worth. While it is possible that tasks could be devised to achieve such discrimination, the expense and effort would not be deemed justified by an investing publisher, given the limited usefulness of the resulting data. While some components of memory tests do require a wide range of psychometric sensitivity (e.g., comparing visual vs. verbal memory abilities in the same child), generally, the focus is on sensitivity to weakness. That is where high psychometric sensitivity should normally be expected of a given instrument: “How good is the floor of the scale?” Seldom, if ever, has a referral been received to determine if a child is memory-gifted! The point being made is that assessing psychometric integrity of memory measures will at times require some adjustment in the traditional demands made for demonstrating psychometric adequacy. An otherwise useful tool might be erroneously dismissed because of inappropriate psychometric expectations.

## ***Choosing an Instrument***

Knowing the tools available to address a specific diagnostic focus is an essential competency for any psychologist doing comprehensive assessments. This is especially so for those undertaking an evaluation of memory deficits. It is typical to add memory tasks to supplement other “key” tests of a comprehensive assessment, such as intelligence, academic achievement, and/or personality. And while entire memory batteries are often administered, it is also common in today’s managed healthcare environment for psychologists to choose how to fill an extra half hour that has been salvaged in order to screen for memory deficits. Many of the most common tests used to assess memory in children are listed in Table 21.7. The list is far shorter than what would appear for assessing memory in adults. The section that follows is intended to provide a useful examination of testing options for those wanting to develop a more thorough knowledge of those memory assessment tools available when working with children and teens. Measures that were created for use with adults and then imposed downward extensions to accommodate older children have not been included. The majority of such measures have task expectations, scoring modifications, directions, and/or norms that result in inadequate measurement precision to detect any but those children with gross memory impairments. Instead, particular attention will be given to the three comprehensive memory batteries that were specifically designed for use with a pediatric age group, plus a few additional measures that clinicians may want to consider having available on the memory shelf of their “test pantry.”

Generally speaking, most global memory measures assess verbal and/or visual memory modalities, and such is the case with the three batteries receiving attention below. The focus, structure and contents of each battery will be examined along with a look at the psychometric grounding of each. In some ways, there is considerable similarity across the batteries; for example, each uses the recall of stories and a list-learning task to assess verbal memory. The batteries are also fairly comparable in terms of administration time. But there are also differences across the measures, and these are usually found in how visual memory is assessed as well as how various supplemental tasks provide the means to achieve greater diagnostic clarity. This section should be especially helpful to those new to memory assessment as well as to those who want to compare their current methods with what else is available for evaluating the domain of memory in their pediatric clients.

**Table 21.7 Common Tests Used to Assess Memory in a Pediatric Population**

Test	Age Range (yrs.)	Scope of Memory Measurement	Administration Time
Benton Visual Retention Test, 5th Edition (Sivan, 1991)	8 and up	Visual Memory: (drawing) copy, recall, and recognition	15–20 minutes
Buschke Selective Reminding Task (Buschke, 1973)	5–15	Verbal memory (list learning) recall, and recognition	10–15 minutes
California Verbal Learning Test; Children's Edition (Delis et al., 1994)	4–16	Verbal Memory (list learning) Immediate, delayed, and recognition	15–20 minutes
Children's Memory Scale (Cohen, 1997)	5–16	Verbal memory, Visual Memory; Immediate, delayed recall, and recognition.	30–60 minutes
NEPSY-II (Korkman, Kirk, & Kemp, 2007)	3–16	Verbal Memory, Visual Memory, Immediate Memory, Delayed Memory (4 tasks), Cued Recall (1 task)	15–30 minutes (age dependent)
Rivermead Behavioural Memory Test, Children's Edition (Wilson et al., 1991)	5–10	Tasks intended to mimic everyday memory demands; Verbal Memory, Visual Memory Immediate memory, delayed (2 tasks)	25–30 minutes
Test of Memory and Learning, 2nd Edition (Reynolds & Voress, 2007)	5–59	Verbal memory, Non-Verbal Memory Immediate and delayed; rote and meaningful	30–40 minutes
Wide Range Assessment of Memory and Learning, 2nd Edition (Sheslow & Adams, 2003)	5–85+	Verbal Memory, Visual Memory Immediate, delayed, and recognition memory; rote and meaningful	20–25 minutes for screening; 40–60 for full battery

## Memory Measures

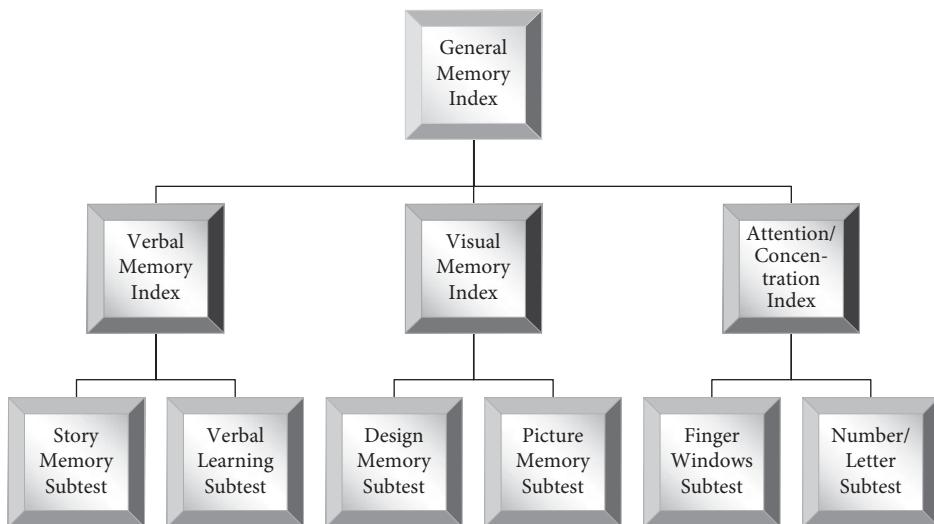

### *Wide Range Assessment of Memory and Learning, Second Edition (WRAML2)*

#### OVERVIEW

The WRAML (Sheslow & Adams, 1990) was released in 1990 and was the first standardized and well-normed memory battery for children (ages 5–17 years of age). A second edition became available (Sheslow & Adams, 2003) containing significant revisions, chief of which was a significant extension of the age range (5–85+ yrs. vs. 5–17 yrs). Reviews of the test have been completed (e.g., Strauss, Sherman, & Spreen, 2006; Hartman, 2007a) and most include a discussion of the changes between the original and second edition. Given the child/adolescent focus of this volume, this chapter will focus primarily on child and adolescent aspects and applications of this measure.

**Core Indexes/Subtests.** As shown in Figure 21.6, the “core” components of the WRAML2 are its three

memory indexes (Verbal, Visual and Attention/Concentration). Combined, these three indexes form the General Memory Index, which is a composite estimate of immediate memory ability. Each of the core indexes is formed by two core subtests. Therefore, administering six subtests yields the three core indexes and an overall memory composite score. All of the core indexes contain subtests that assess immediate memory, and together take 30 to 40 minutes to administer, depending on the child's age and the examiner's familiarity with the instrument. The Verbal Memory Index assesses immediate recall of verbal information, with one subtest focusing on retention of meaningful material (as found in real world conversations or brief stories) and the other focusing on less meaningful material (as found in remembering the names of the seven dwarfs or the 13 original colonies). The Visual Memory Index assesses immediate retention of visual information, with one subtest focusing on retention of

**Figure 21.6** WRAML2 Core Indexes and Core Subtests.

contextually meaningful material (like a classroom photograph) and the other focusing on less meaningful material (like remembering a diagram from a workbook). Lastly, the Attention/Concentration Index assesses immediate retention of relatively meaningless information that is visual (like remembering a rote pattern on a map) and auditory (like retaining a phone number). More detailed information related to each of the core subtests is found in Table 21.8. Indexes use the familiar units of a mean of 100 and SD of 15; likewise, subtests have a mean of 10 and SD of 3. Percentiles and confidence intervals are also available.

**Optional Subtests.** In addition to the WRAML2 core components, there are 11 optional subtests, which are designed to complement and extend the interpretive value of the core subtest findings. Figure 21.7 shows various “sets” of these optional subtests. One set allows examination of performance on tasks emphasizing working memory. The Working Memory Index subtests allow the clinician to compare performance on, for example, a rote repetition task (sometimes mistakenly labeled “working memory”) such as found with a subtest like Number Letter, with the more demanding Verbal Working Memory subtest. For example, on the latter subtest, the examiner asks a client to listen to a list of nouns which consist of an assortment of animals and non-animals. The client is asked to first report the animals in order of their sizes, followed by the non-animals also in order of size. Sometimes, children who do adequately with Number Letter rote recall do very poorly with the rote task when

the manipulation of information component that defines working memory is added. This may have important clinical implications as one considers the task demands of a classroom discussion or a reading assignment.

Another set of important optional subtests are the Delay and Recognition subtests. The former allows for assessment of retention of Core subtest material after a 10- to 15-minute delay. The Recognition subtests allow the examiner to assess memory recognition (vs. retrieval using the Delay subtests). Comparing immediate (core) with delay performance allows for examination of storage of newly learned information. Comparing delay with recognition performance allows for evaluation of retrieval. An example may make this clearer. A child who is read two short stories (i.e., the Story Memory subtest) is asked to recall each, thus providing a measure of immediate memory of meaningful verbal information. The examiner can then evaluate a longer-term recall (following a 10–15 minute delay) to assess forgetting of the material. If, compared to age mates, the client does more poorly on the longer-term free recall task than with the immediate free-recall task, recognition components can be used to distinguish between difficulty retrieving the information vs. difficulty storing the information. Retrieval is assessed by the examiner’s asking about various aspects of the story, each of which is followed by three options from which the child can choose. If the information cannot be retrieved but is stored, performance, using this multiple-choice recognition format, should be done well above chance

**Table 21.8 Description of WRAML2 Core Index and Subtest Components**

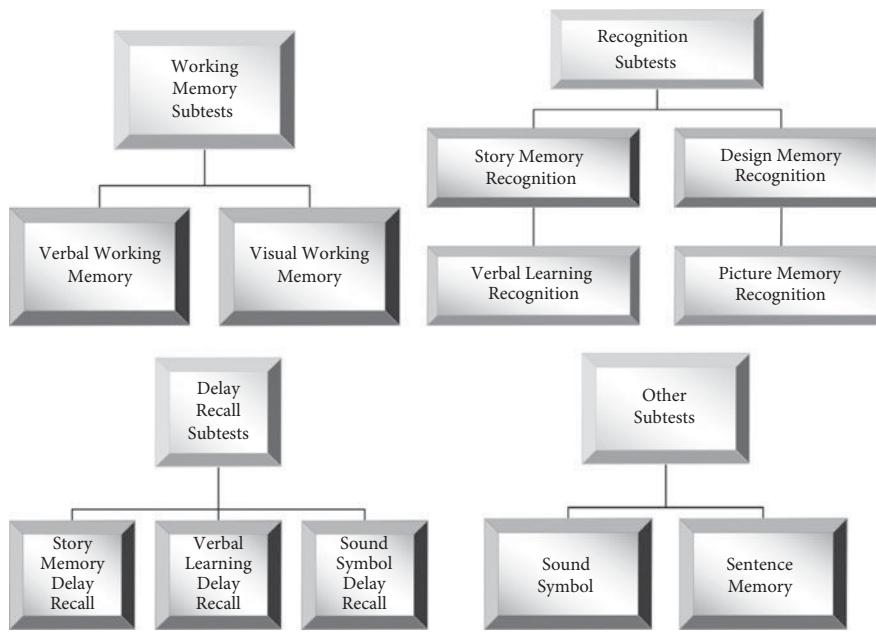

Core Index	Core Subtest <sup>1</sup>	Subtest Description	Administration Time
Verbal Memory Index (Immediate, Delayed and Recognition components exist for each subtest of this index)	Story Memory (1)	After each of 2 stories is read, client repeats as much of the story as can be remembered.	7–10 minutes
	Verbal Learning (3)	A list of unrelated nouns is read; client repeats as many as can be remembered. This is repeated 3 more times, resulting in a learning acquisition curve.	6–8 minutes
Visual Memory Index (Immediate and Recognition components exist for each subtest of this index)	Design Memory (2)	Client looks at a configuration of simple geometric shapes for 5-sec, and must then draw what is remembered. Five configurations are included.	6–8 minutes
	Picture Memory (4)	Client looks at a colorful everyday scene for 10-sec and then inspects a facsimile trying to identify elements that have been “changed, moved or added.” Four scenes are used.	5–8 minutes
Attention/Concentration Index	Finger Windows (5)	The examiner places a pencil through holes found on a vertical board, and client is asked to replicate the pattern.	5–8 minutes
	Number Letter (6)	A series of digits and letters is read and the client is asked to repeat the span.	4–6 minutes

<sup>1</sup>Order in the administration sequence appears in parentheses.

levels of performance (i.e., 33%). However, if there is a problem with storage, both the delay and the recognition tasks will be performed poorly. In this way, use of the optional subtests can provide diagnostic clarity when compared to performance on the core subtests. Details related to these many core-optimal interpretive comparisons can be found in a recent volume by Adams and Reynolds (2009). There are also numerous “qualitative” observations that can be meaningfully interpreted, because each can be given quantitative meaning in supplementary tables provided, such as comparing relative level of performance on the first story vs. the second (e.g., to assess relative consistency of performance), or comparing

performance in retaining the gist of the stories vs. specific details.

**Memory Screening Index.** Because of time constraints, a clinician may want to screen a client's memory skills in order to decide if more in-depth assessment is needed. For such instances, scores from the WRAML2's first four subtests can be combined to derive a Memory Screening Index (MSI). Performance on the MSI subtests alone is also tabled with a mean of 100 and an SD of 15. The four contributing subtests allow two samplings each of verbal and visual memory abilities. In addition, Verbal and Visual Memory Indexes can also be obtained. The two Attention/Concentration

**Figure 21.7** Optional WRAML2 subtests in domains of Working Memory, Recognition, Delay, and Other.

subtests are omitted, but some of this rote recall information has sometimes already been obtained, such as from a digit span task from an IQ test. By omitting the Attention/Concentration component of the WRAML2, the examiner saves about 10 minutes. The psychometric integrity of the MSI is strong since, the entire standardization sample was used in its creation (i.e., the first four subtests of the complete core WRAML2 administration). The MSI correlates .92 with the General Memory Index, and the average mean difference between the GMI and MSI is less than one standard score point (100.01 MSI vs. 99.98 GMI).

**Technical Information.** The standardization of the WRAML2 was based on the 2000 U.S. census and used a sample of 1,200 persons, stratified by age (15 age groups, each with 80 participants), gender, ethnicity (African-American, Hispanic, Caucasian, and other), educational attainment (four levels), and U.S. region of residence (four regions). The reliability statistics using Person and Item Separation coefficients range from .85 to .94 for core subtests, and those for the other subtests are similarly high other than for the recognition subtests, which, like all recognition formats, tend to have little variability because most persons do very well. Coefficient alphas (a measure of internal consistency) are also provided for the Indexes (ranging from .86 to .93), core subtests (.81 to .92) and optional subtests (.80 to .92, other than for the Recognition subtests, for

the reason just mentioned). As noted earlier in this chapter, a test-retest stability coefficient can be a misleading statistic for a memory test. Nevertheless, a subsample of 142 individuals ranging in age from 5 to 84 years was chosen and readministered the WRAML2 with a test-retest median interval of 49 days. Test-retest correlations ranged from .53 to .85. Of greater clinical relevance are the gains noted in Index and subtest performance, and reported in the WRAML2 *Manual*. One often hears the question, “When can the test be readministered without significant practice effects being encountered?” Practice effects may be more of an issue for IQ tests than for memory tests. Generally, clinicians are using memory tests to detect memory impairment (vs. strengths). That being the case, if one obtains no practice effect after a reevaluation a month or two following the original session, that may be diagnostic, since Index gains for the interval are reported as 6.3, 7.2, and 1.7 points (in a nonclinical sample) for Verbal, Visual, and Attention/Concentration Indexes, respectively. Documenting a practice effect is, in fact, strong evidence that information is being remembered for long-term retrieval, which is often the purpose of administering the battery in the first place! Likewise, finding no improvement (or lower performance) in a readministration a month or two later may be diagnostic evidence of memory impairment.

With respect to validity, the usual subtest and index inter-correlations are provided in the *Manual*,

along with results from both Exploratory and Confirmatory factor analyses. A three-factor solution was found (Verbal, Visual, and Attention/Concentration) with the expected core subtests contributing mostly to their respective Indexes. Factor loadings are provided for five different age sub-groupings, as well as for the entire sample. Goodness-of-fit analyses are also described. Overall, there is strong support for the factor structure of the battery.

Especially important to test users is a presentation of Item Bias data using DIF (differential item functioning) analyses, correlating item calibrations from Rasch analyses for gender and ethnicity (African-American and Hispanic subgroupings). DIF analyses are provided for each core subtest. From the discussion found in the *Manual*, it should be reassuring to know that the WRAML2 shows little bias in item calibrations for both the ethnic and gender subgroups analyzed across all core subtests.

Convergent validity data are provided with comparisons with the following tests: Wechsler Memory Scale-III, Test of Memory and Learning, Children's Memory Scale, California Verbal Learning Test-II, Wechsler Adult Intelligence Test-III, Wechsler Intelligence Scale for Children-III, Wide Range Achievement Test-3, and the Woodcock-Johnson Tests of Achievement-III. Clinical studies of WRAML2 performance are provided for samples that included alcohol abuse, Alzheimer's disease, Parkinson's disease, traumatic brain injury, and learning disability. For each of these clinical groups, means and SDs are provided on WRAML2 Index and subtest performance, as well as indications of statistical difference and effect sizes.

Subsequent to the release of the WRAML2, an interesting study was conducted by Weniger (Weniger & Adams, 2006) using children with reading disorder; attention deficit-hyperactivity disorder, combined type; children with both disorders; and a fourth group of children chosen randomly from the standardization sample, after being matched for age and gender. Because these diagnoses are very common referrals to those working with children, details of that study are provided here.

Table 21.9 provides relevant identifying information about the three clinical groups. Table 21.10 includes the WRAML2 Index scores for those groups along with the matched non-clinical contrast group; indicators of statistical significance are provided. Figure 21.8 provides a corresponding bar graph of index performance for the four groups. It can be noted that children with ADHD generally resembled the standardization sample more than the samples with reading problems. Across most indexes, children with reading problems tended to show immediate memory impairment, whereas children with ADHD did not. One exception to this generalization was the performance of the ADHD group on Working Memory tasks. In this case, it seemed that the concentration demands and greater immediate memory load became too great for children with ADHD to adequately compensate. What is also striking is that children with both attention and reading disorders, generally estimated to be about half of those with ADHD (Barkley, 1998; Lyon, Fletcher, Fuchs, & Chhabra, 2006), achieved the lowest memory scores, regardless of index—generally .65 SD lower than IQ would predict. So, from a memory processing perspective, reading disorder

**Table 21.9 Characteristics of Subgroups of Children with ADHD and Reading Disorder**

Variable	ADHD Group (n = 23)	Reading Disorder Group (n = 24)	ADHD + Reading Disorder Group (n = 23)
T-score Mean (and SD), Connors Rating Scale, Inattention Index	74.1 (11.2)	54.1 (5.6)	74.6 (8.1)
T-score Mean (and SD), Connors Rating Scale, ADHD Index	76.8 (10.9)	55.1 (5.3)	75.5 (8.8)
Reading standard score	88.1 (3.48)	78.9 (9.2)	70.8 (7.3)
Intelligence Quotient	95.6 (8.8)	95.9 (8.5)	92.5 (6.1)

*Note:* ADHD = Attention Deficit-Hyperactivity Disorder

**Table 21.10 WRAML2 Index Means and (SDs) of Children with ADHD, Reading Disorder, Both Disorders, and a Non-Clinical Group**

	<b>ADHD</b>	<b>Reading Disorder</b>	<b>ADHD &amp; Reading Disorder</b>	<b>Non-Clinical</b>
Verbal Memory Index	102.5 (12.0) <i>b</i>	92.0 (8.0) <i>a</i>	86.2 (11.1) <i>a</i>	102.5 (12.7) <i>b</i>
Visual Memory Index	97.8 (13.9) <i>b</i>	92.4 (11.9) <i>a</i>	91.0 (10.9) <i>a</i>	100.4 (11.7) <i>b</i>
Attention/Concentration Index	94.3 (11.6) <i>a</i>	94.1 (10.6) <i>a</i>	85.2 (10.6) <i>b</i>	99.7 (13.7) <i>a</i>
General Memory Index	97.4 (12.0) <i>b c</i>	90.0 (8.9) <i>a b</i>	84.3 (9.5) <i>a</i>	101.0 (12.9) <i>c</i>
Working Memory Index	92.9 (13.6) <i>a</i>	90.8 (12.4) <i>a</i>	82.7 (11.9) <i>a b</i>	102.9 (15.1) <i>c</i>
General Recognition Index	106.0 (13.7) <i>b</i>	90.8 (12.3) <i>a</i>	89.7 (8.9) <i>a</i>	99.9 (15.9) <i>b</i>

*Note:* ADHD = Attention-Deficit Hyperactivity Disorder. Means within a row with different italicized letter subscripts are statistically different from one another,  $p \leq .05$ .

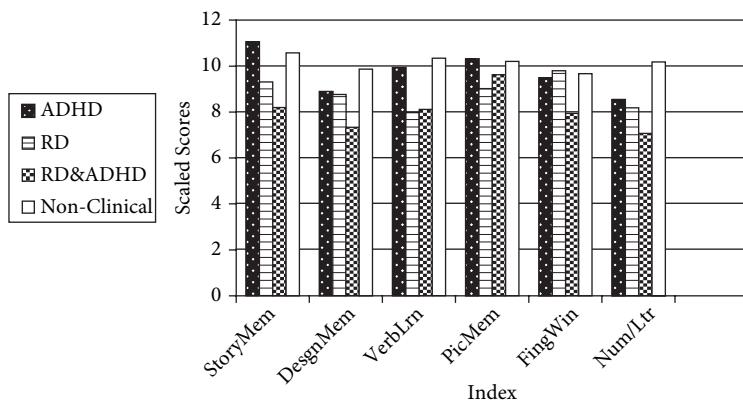

is associated with greater deficit than ADHD, and having both disorders is associated with even greater memory deficit than having only one. An additional interesting finding was performance on the recognition tasks. Overall, children with ADHD have recognition scores equivalent to or slightly higher than the non-clinical sample, suggesting that children with ADHD struggle more with retrieval, whereas children with reading problems seem to have more difficulty with the storage component (or storage and retrieval). The WRAML2's Verbal Recognition Index was alone shown to be a reliable predictor of

group membership, accurately classifying 82 percent of children with reading disorders and 80 percent of children with ADHD.

Figure 21.9 illustrates the study's findings at the subtest level. Only one of the core subtests fell significantly below average for children with ADHD; namely, Number Letter (ADHD group scaled score = 8.6). (Performance on the Number Letter subtest contributed to the Attention/Concentration Index appearing to be lower; the other subtest contributing to the Index, Finger Windows, was performed as well as the non-clinical sample, possibly because of

**Figure 21.8** WRAML2 Index performance by children with ADHD, Reading Disorder, both disorders, and a non-clinical sample.

**Figure 21.9** WRAML2 core subtest, scaled score performance by children with ADHD, Reading Disorder, both disorders, and a non-clinical sample.

its apparent novelty.) Design Memory performance tended toward significance (scaled score = 8.9) although the effect size for this difference was relatively small. However, slight delays in tasks making perceptual-motor demands are a common finding for children with ADHD (Litton, 2003; Yochman, Ornoy, & Parush, 2006). Therefore, taken overall, children presenting with lower Number Letter and Design Memory subtest scores as well as lower Working Memory Index scores, but with “normal” performance in the other Core subtests and all recognition memory tasks, are far more likely to be children with ADHD than reading disorder. This becomes even more probable if performance on the Verbal Learning subtest tends to be average, since that subtest was consistently poorly performed by children with reading disorder (average scaled score = 8.0). Subgroup placement sensitivity and specificity using these criteria each approached 80 percent.

The reader should not infer from this discussion that the WRAML2 can be used as a means to diagnose ADHD. However, when used with other well-chosen measures, WRAML2 results can provide additional useful information in the overall formulation of that diagnosis. Clearly, more research is needed in examining memory inefficiencies in children with various learning, emotional, and attention deficits.

### ***Test of Memory and Learning, Second Edition (TOMAL-2)***

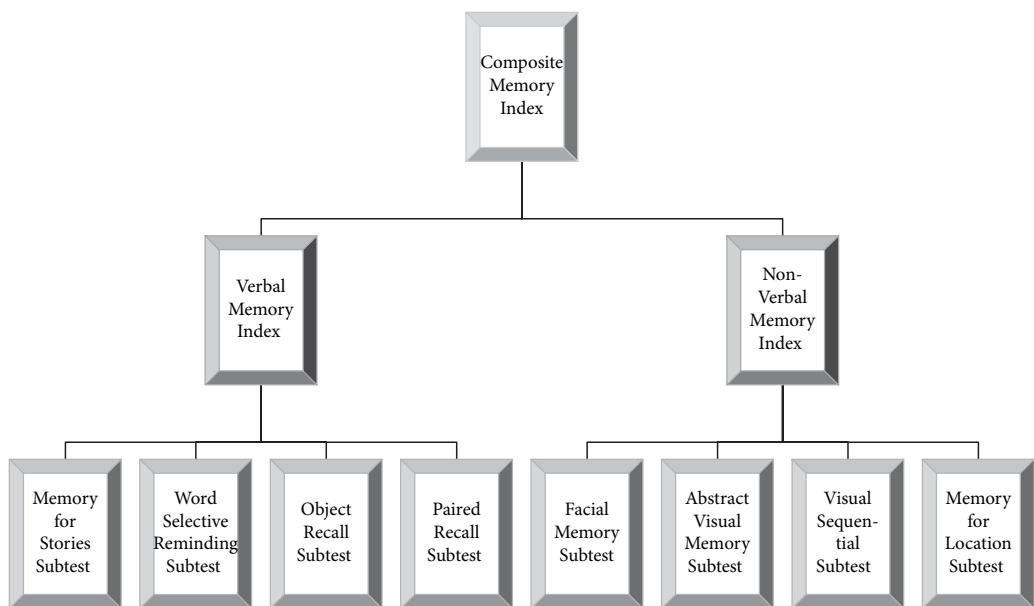

#### **OVERVIEW**

The TOMAL-2 (Reynolds & Voress, 2007) was released as a revision of the original battery, TOMAL (Reynolds & Bigler, 1994). Like the WRAML2, the TOMAL revision extended its age range (5 to 59

years), although, unlike the WRAML2, there was little change in the structure or items of the battery. An extra story was added to the Memory for Stories subtest in order to better span the adult range. Reviews of the test have been completed: a brief though lively analysis by Hartman (2007b), and another that is more in-depth by Schmitt & Decker (2009). Also, an extended discussion of TOMAL-2 procedures and interpretation is also available (Adams & Reynolds, 2009).

**Core Indexes/Subtests.** There are eight core subtests, taking 30 to 40 minutes to administer. Four subtests contribute to each of the two core indexes, which themselves combine to define the overall Composite Memory Index, as shown in Figure 21.10. All of the core subtests assess immediate memory and each is described in Table 21.11 along with time estimates for administration. The Verbal Memory Index assesses immediate recall of meaningful verbal information (words) and comprises four subtests. The Non-Verbal Index is also composed of four subtests requiring immediate recall of visual material, some of which is meaningful (faces); some of which relatively non-meaningful (non-familiar abstract designs); and some of which is spatial.

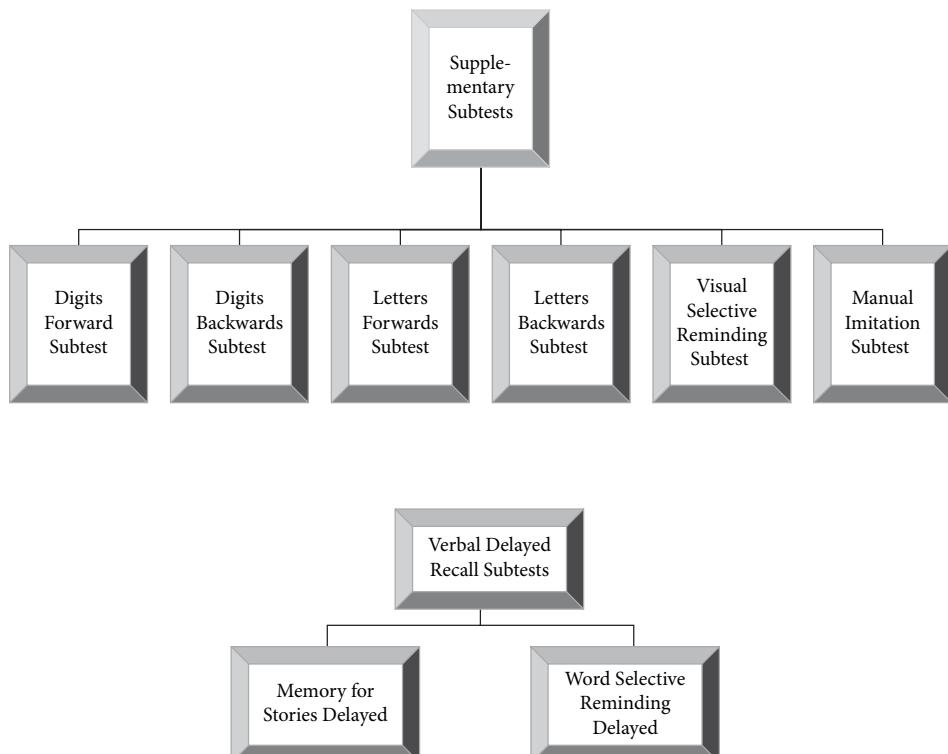

**Supplementary Subtests.** In addition to the core components, there are eight optional subtests designed to complement and extend the interpretive value of the core findings. They are identified in Figure 21.11, and the name of each amply describes its content. The Visual Selective Reminding subtest is intended to parallel the Verbal Selective Reminding Task found within the Core subtests section, using visual materials. The examiner touches a grouping of dots found within each area of a 2 x 3 (5- to 8-year-olds) or 2 x 4

**Figure 21.10** TOMAL-2 Core Indexes and their subtests.

(9 years and older) grid. Similar to the procedure in its verbal counterpart, the examiner informs the client of the dots that were omitted, ignoring the dots touched in error. A maximum of five learning trials are administered. The remaining supplementary

subtest is Manual Imitation, which resembles a task found on other tests in which the examiner demonstrates various hand sequences (palm down, fist, palm up, side of hand), ranging from two identical hand positions to a series of eight varied positions.

**Figure 21.11** TOMAL-2 Supplementary subtests and Verbal Delayed-Recall subtests.

**Table 21.11 Description of TOMAL-2 Core Index and Subtest Components**

Core Index	Core <sup>1</sup> Subtest	Subtest Description	Administration Time
Verbal Memory Index (An Immediate component exists for each subtest of this index)	Memory for Stories (1)	After each of two 1-paragraph stories is read, client repeats as much of the story as can be remembered.	3–6 minutes
	Word Selective Reminding (3)	Client is asked to repeat a list of words (8 for 5–89 year olds; 12 for 9 years old and older). Only the words not recalled are repeated to the client. Six such learning trials are administered or until client succeeds with the entire list.	3–7 minutes
	Object Recall (5)	On a single page, pictures of 15 common objects are labeled. The page is removed, and the client is asked to recall the verbal labels. Five such exposures are administered or until the client recalls all the labels.	3–7 minutes
	Paired Recall (7)	A paired associate task with 6 (5–8 years old) or 8 (9 years and older) pairs to be learned. Up to four trials are allowed. For each trial, the examiner reads all word pairs, and then, using a different order, tests by giving the first word of each pair. Half the pairings are “easy;” half are “hard.” Errors are corrected.	3–6 minutes
Non-Verbal Memory Index (An Immediate component exists for each subtest of this index)	Facial Memory (2)	Client looks for a set time at a stimulus page showing 2–12 black and white faces (children and adults of both genders and differing ethnicities), and then is shown a response page with 2–3 times as many foils. The client is asked to identify the stimulus faces.	4–7 minutes
	Abstract Visual Memory (4)	One abstract design is displayed on the stimulus page for 5 sec., after which the client is to find it on a response page amongst 5 foils.	4–8 minutes
	Visual Sequential Memory (6)	2 to 7 abstract shapes are viewed for 5 sec. on a stimulus page. Then on a response page the client is to point to the designs in the same order as they appeared on the stimulus page.	3–7 minutes
	Memory for Location (8)	For 5 sec. the client views an 8 x 11 inch page on which appears a large square or rectangle within which there is one or more large black dots. The page is turned, dots are gone, but a grid work appears within the square or rectangle. The client is asked to identify the location of the dot(s) by placing circular plastic chips within the grid work. Grids range from 3 x 3 (9 locations) to 4 x 4 (16 locations).	6–10 minutes

<sup>1</sup>Order in the administration sequence appears in parentheses.

In addition, two memory-delayed subtests are provided, to be administered approximately 30 minutes after their immediate recall exposure. Memory for Stories Delayed has clients repeat the two stories they heard earlier in the session. Word Selective Reminding Delayed asks the client to repeat all the words that can be remembered from the original list presented earlier. No recognition measures are part of the TOMAL-2. However, use of various supplemental subtests, by themselves or with core subtests, allows the derivation of several additional indexes: Attention/Concentration, Sequential Recall, Free Recall, Associative Recall, and Learning. As would be expected, all indexes have a mean of 100 ( $SD = 15$ ) and subtests have a mean of 10 ( $SD = 3$ ). Percentiles and age equivalents up to 14 years are also provided.

**Technical Information.** The standardization sample for the TOMAL-2 consisted of data gathered from the TOMAL and a supplemental sample ( $n = 579$ ) that allowed an updating of the child subgroups, so their demographics were comparable to the 2002 U.S. census data, and as well, provided norms for the new adult subgroups. The resulting combined sample numbered 1,961 and was stratified based upon geographic area, gender, race (Black, White, Other), family income, educational attainment, and age. Coefficient alphas are reported for subtests and indexes. Median subtest alphas across age groups ranged from .67 to .96; median index alphas across age groups ranged from .90 to .98. Test-retest stability is reported for both a pediatric ( $n = 47$ ) and an adult subsample ( $n = 35$ ), based upon testing separated by one to three weeks. For children (ages 5–18 years), core subtest scaled score test-retest correlation coefficients ranged from

.63 to .82; core index standard score correlations ranged from .71 to .83. The obtained index scores for children differed by 11 standard score points for the Verbal Memory Index, and by 4 points for the Nonverbal Memory Index. With respect to validity, while no subtest or index inter-correlation tables are provided, a table of standard errors of measurement is. Findings from a factor analysis were discussed, using the entire sample, although the manual states that “the factor solutions were stable across the four age groupings studied.” Results from two- vs. four-factor solutions are reported, with the four-factor solution found to be superior; the factors were described as General Memory, Spatial, Sequential Recall and Attention, and a Digits Forward vs. Backward separator. Percentages of the explained variance were not reported. Of interest, Alexander and Mayfield (2005) factor-analyzed TOMAL performance using a large sample of children who had sustained traumatic brain injury. A two-factor model provided a better fit than did the four-factor model; a large general factor was found along with a smaller but stable factor that was thought to capture sequential memory processing.

In the *Manual*, TOMAL-2 performance is compared to performance on several other measures including reading fluency tests, tests of expressive and receptive vocabulary, the WISC-R (Wechsler, 1974), the Test of Nonverbal Intelligence-3 (Brown, Sherbenou, & Johnsen, 1997), and the WRAML2, but the WRAML2 comparison used adults. Table 21.12 reports the degree of similarity between performance on the WRAML2 Core Index scores and those of the TOMAL, using a pediatric sample with learning disabilities (mean age = 9.3 years), and reported in the WRAML2 *Manual*

**Table 21.12 Comparison Between WRAML2 and TOMAL Performance (N = 50)**

WRAML2 Indexes	WRAML2 Means (SDs)	TOMAL Indexes <sup>1</sup>		
		CMI	VMI	NVMI
Verbal Memory	92.6 (17.0)	.50	.50	.34
Visual Memory	87.4 (18.0)	.46	.26	.58
Attention/Concentration	80.7 (16.6)	.50	.61	.24
General Memory Composite	80.6 (17.9)	.69	.62	.58
TOMAL Index Means (SDs)		86.7 (12.0)	83.3 (13.3)	90.8 (12.4)

<sup>1</sup>Corrected for reliability. WRAML2 = Wide Range Assessment of Memory and Learning, Second Edition; TOMAL = Test of Memory and Learning; CMI = Composite Memory Index; VMI = Verbal Memory Index; NVMI = Nonverbal Memory Index.

(Sheslow & Adams, 2003). As can be seen, the two memory measures yield standard scores that are near a half SD of each other, but with correlations of only moderate strength. The correlations using an adult sample and reported in the TOMAL-2 *Manual* are noticeably higher (Reynolds & Voress, 2007). Therefore, with a pediatric sample, it appears that the TOMAL-2 and WRAML2 are measuring somewhat different constructs.

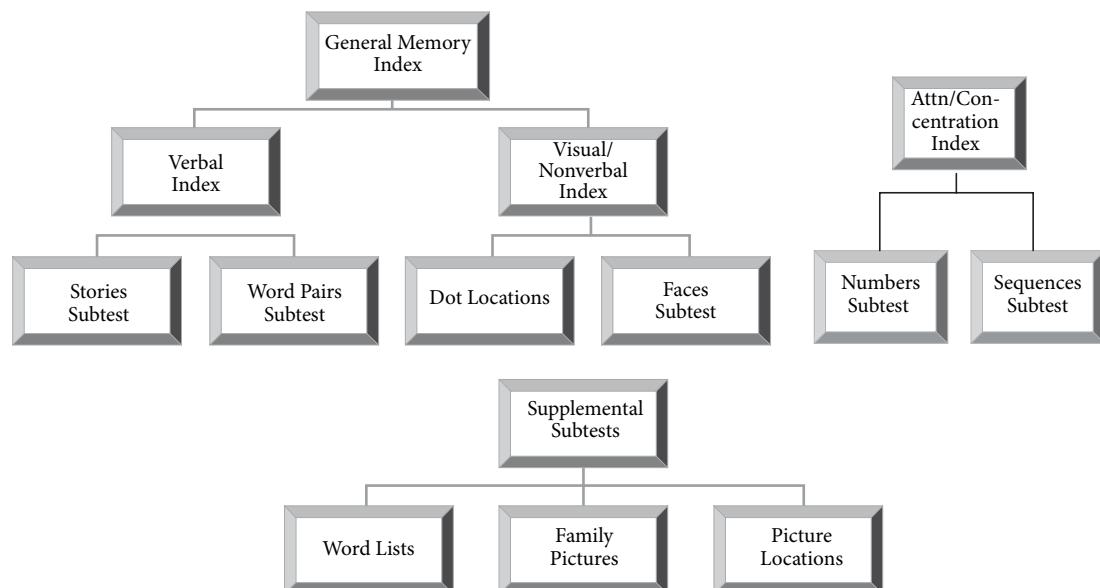

Like the WRAML2, the TOMAL-2 reports analyses of potential item-bias by gender and ethnicity. No item bias was demonstrated for male vs. female, White vs. Non-White, or Anglo vs. Non-Anglo.

No new clinical studies are included in the TOMAL-2 *Manual*, although several studies that used the TOMAL are briefly mentioned. The TOMAL-2 authors felt that since there was little difference in content between the TOMAL and TOMAL-2, all prior study findings can be assumed to generalize to the new version. A study by Lowther & Mayfield (2004) is cited as showing children and adolescents who had sustained brain injury perform almost a standard deviation lower on the TOMAL than a sample of non-injured children. Children with various learning disabilities were reported in the TOMAL manual (Reynolds & Bigler, 1994) to perform less well on all of the subtests but one. Lowest performance was found on the Attention/Concentration

Index and Sequential Recall Index. The TOMAL-2 *Manual* cites an investigation using children with reading disabilities. Compared to a control group matched for age and IQ, those with reading problems scored lower than controls on all TOMAL subtests (Howes, Bigler, Lawson, & Burlingame, 1999). A study of children with 22q11.2 Deletion Syndrome (known as “velocardiofacial syndrome”) using the TOMAL showed higher verbal than non-verbal memory abilities and a particular weakness, as found in children with autism, on the Facial Memory subtest (Lajiness-O’Neill, Beaulieu, Titus, Asamoah, Bigler, Bawle, & Pollack, 2005).

### Children’s Memory Scale (CMS) Overview

The Children’s Memory Scale (Cohen, 1997) is a third comprehensive memory battery developed for children and available to clinicians. Good reviews of the test are available (e.g., Skaalid, Dunham, & Anstey, 1999; Hildebrand & Ledbetter, 2001; Monahan & Fennell, 2001). The age range is five through 16 years, and in many ways the scale is a downward extension of the subtests found on the Wechsler Memory Scale–III (Wechsler, 1997). The structure of the CMS is similar to that found on the WRAML2 and TOMAL-2, and is illustrated in Figure 21.12.

**Figure 21.12** Structure of the Children’s Memory Scale. The Verbal and Visual/Nonverbal Indexes are composed of both Immediate and Delayed Indexes generated from immediate and delayed components of their respective subtests. Verbal and Visual Indexes combine to form the General Memory Index. Supplemental tests are intended to map on to Verbal, Visual, and Attention /Concentration Index subtests.

## CORE INDEXES/SUBTESTS

The GMI is a composite statistic derived from immediate and delayed memory aspects of the subtests comprising the Verbal and Visual/Nonverbal Indexes. The subtests associated with the Verbal and Visual/Nonverbal Indexes each have Immediate and Delayed components. The verbal subtests also have Delayed Recognition components. The Attention/Concentration subtests have only an Immediate/Working Memory component. Consequently, there are eight Index scores: Verbal Immediate, Verbal Delayed, Visual Immediate, Visual Delayed, General Memory, Attention/Concentration, Learning, and Delayed Recognition. The six core immediate memory subtests take 30 to 40 minutes to administer. The four delayed and two recognition subtests add 10 to 20 minutes more and should follow the immediate presentations by about 30 minutes, which is expected to be filled with other assessment tasks if the examiner chooses not to administer the entire core battery in the recommended sequence. There are two record forms (5–8 and 9–16 years). The traditional conversion of raw scores to scaled scores with means of 10 (SD = 3) is utilized; raw scores are also used to derive memory indexes with

a mean of 100 (SD = 15). Percentiles are also provided. Scoring software is available. A description of each subtest appears in Table 21.13.

## TECHNICAL INFORMATION

The normative sample includes 1,000 children, 100 in each of 10 age groups ranging in age from five through 16 years. The sample was stratified, based on 1995 U.S. census data, according to race/ethnicity (White, African American, Hispanic and Other), four U.S. geographic regions, and five parent-education levels. An equal number of each gender was used. Unique to the CMS, the scale was linked with the WISC-III and WPPSI-R, providing, an empirically grounded basis for predicting level of memory performance from IQ; with the subsequent release of newer Wechsler editions, this asset is less relevant.

Split-half reliability, across all age groups, for the eight Index scores ranged from .76, to .91. Internal consistency statistics for core subtests ranged from .71 to .91; supplemental subtest coefficients ranged from .54 to .86. Using a two-month average interval, test-retest reliabilities are reported, ranging from .29 to .89 across the age groups; the CMS *Manual*

**Table 21.13 Description of CMS Core Index and Subtest Components**

Core Index	Core Subtest	Subtest Description	Administration Time
Verbal Memory Index (Immediate, Delayed, and Recognition components exist for each subtest of this index)	Stories	Two of three stories (age-dependent) are read, immediately after which client repeats as much of the story as can be remembered.	6–10 minutes
	Word Pairs	A list of 10 or 14 (age-dependent) related and unrelated word-pairs are read; thereafter the stem is read and client recalls the associate. Three learning trials are administered.	5–8 minutes
Visual/Non-Verbal Memory Index (Immediate, Delayed, and Recognition components exist for each subtest of this index)	Dot Locations	Child is shown dots located in an empty rectangle. This page is replaced by a 3 x 4 or 4 x 4 (depending on age) rectangular grid and dot positions are to be indicated by client by placing circular chips. Three learning trials administered.	5–8 minutes
	Faces	16 (9- to 16-yr-old) human faces are displayed followed by 48 test photos by which immediate recognition is assessed.	5–8 minutes
Attention/Concentration Index	Numbers	A digit span forward and backwards task (identical to the WISC-III subtest).	4–6 minutes
	Sequences	12 series of orally presented numbers and months of the year must be properly sequenced. Accuracy and speed earn points.	5–7 minutes

does caution about practice effects, with readministration “practice effects” that approach a standard deviation in magnitude on some of the subtests (Cohen, 1997). The Dot Locations and Faces subtests may be problematic with the youngest children because of an insufficient floor to discriminate between deficits of varying severity.

With respect to validity, the results of confirmatory factor-analysis yielded a three-factor solution consisting of verbal memory, visual/nonverbal memory, and attention/concentration. Performance on both the CMS and WRAML2 is reported in the latter test’s Examiner’s *Manual* (Sheslow & Adams, 2003), and shows a correlation of .49 between general memory indexes. While there was a low moderate correlation between the Verbal Memory (Immediate) Indexes (.36) as well as the Visual and Visual/Non-Verbal (Immediate) Indexes (.37), the Attention/Concentration Indexes correlated at a noticeably higher level (.58). Overall, the two tests seem to measure somewhat different aspects of memory and appear to be less related than the TOMAL-2 and WRAML2 (e.g., the general composite indexes between these tests are reported to correlate .76, and the range of correlations across core subtests is .34 to .82 (Reynolds & Voress, 2007). Inter-correlations with a number of intellectual, executive, linguistic, memory, and achievement test measures are included in the CMS *Manual*. Also, mean performance scores are provided for a number of small clinical samples, including children with ADHD (inattentive and combined types), learning disability (combined reading and mathematics disorder), language impairment, temporal lobe epilepsy, traumatic brain injury, and brain tumor.

### **California Verbal learning Test—Children’s Version (CVLT-C)**

The CVLT-C (Delis, Kramer, Kaplan, & Ober, 1994) is a memory task that provides the clinician a means of evaluating various components of verbal-auditory learning, recall, and recognition. Its structure is similar to the California Verbal Learning Test (CVLT; Delis, Kramer, Kaplan, & Ober, 1987) and its predecessor, the Rey Auditory Verbal Learning Test (Rey, 1964). The CVLT-C is appropriate for children five to 16 years of age. A Spanish version has also been developed (Rosselli et al., 2001). An extensive review of the CVLT-C was written by Strauss, Sherman, and Spreen (2006).

In administering the CVLT-C, the child initially hears and is asked to repeat, in free-recall format, a

list of 15 words. The child’s responses are recorded, and the recitation-recall procedure is repeated four additional learning/recall trials. Although not mentioned to the child, the words can be sorted into three categories: clothes, fruits, and toys, with an equal number of words associated with each category.

Following administration of the first list of words (List A, the “Monday list”), a second list of words is then presented (List B, the “Tuesday list”). The second list consists of 15 different words that can be sorted into the categories of furniture, fruits, and desserts (fruits being an overlapping category, desserts a partially overlapping category). Following a single learning/recall trial using the second list, the child is again asked to repeat the *first* shopping list. At this point, the child is told the three categories into which the words of the first list could be grouped. With this cue available, recall for each category is then elicited.

A 20-minute interval then elapses during which other nonverbal testing should be completed. At the end of this interval, the child is again given a free-recall trial of the first list, followed by a cued-recall trial. Finally, the child is asked to listen to a list of words that includes items from both learning lists as well as distracter words. The child is asked to identify those words from the first shopping list. The entire procedure requires approximately 30 minutes to complete, not including the 20-minute delay.

Care was exercised in determining item inclusion. The words chosen for the shopping lists were selected based on their frequency of occurrence in the English language as well as by how often they were reported by children. To address the possibility that children would only report the most common words in a category rather than those learned from the list, the three most commonly used words for each category were excluded. The two words lists were designed to be comparable in difficulty.

Perhaps the greatest strength of the test is that it allows a detailed examination of learning strategies. About two dozen age-normed scores can be generated from a child’s performance. Examples of scores available include variables such as total recall, performance for trials 1 and 5 of List A, semantic clustering, serial clustering, primacy/recency recall, learning slope (the average number of new words recalled per learning trials), intrusion errors (reporting of words not on the list), short-term and long-term recall, and recognition. For ease of comparison, most of these scores are provided as

*z* scores. Some of the variables are only meaningful at older ages; for example, semantic clustering is not typically observed until about nine to 10 years of age. While hand scoring is possible for most of the scores, because of the number of variables generated, use of available scoring software is desirable, plus it provides normative data for all the variables. Donders (1999a) has provided data on four additional variables: proactive interference, retroactive interference, rapid forgetting, and retrieval problems.

### **Technical Information**

The CVLT-C used the 1988 U.S. Census to guide subject-inclusion. A sample of 920 children was stratified by age (12 subgroups), gender, ethnicity (White, African American, Hispanic and Other), geographic region (four) and parent education (four levels). Details of the standardization, including sampling statistics, are found in the CVLT-C *Manual* (Delis et al., 1994). Norms for four-year-olds were subsequently provided by Goodman, Delis, and Mattson (1999).

Reliability calculations for the CVLT-C are reported as measures of internal consistency, as well as test-retest reliability. Across the five trials for the first shopping list, the average internal consistency correlation is .88 with a range from .84 to .91. Reliability across categories yields an average internal consistency coefficient of .72 across all age groups. Test-retest measures were obtained from 106 8-, 12-, and 16-year-olds. The interval between test periods averaged 28 days. Total recall performance on the second CVLT-C administration increased by 5, 6, and 9 words for the 8-, 12-, and 16-year-olds, respectively. Reliability coefficients derived from the first and second administration scores ranged from .31 to .90, which the authors considered acceptable for the nature of this auditory-verbal memory assessment tool, especially given the contamination introduced into the readministration by giving the child the organizing strategy of categories during the first testing.

With respect to validity, an exploratory principal component analysis is reported in the test's *Manual*. Given that entire test batteries generally have fewer than three or four factors, the analysis with the CVLT-C surprisingly yielded a six-component solution, a result similar to the adult version of the measure. Donders (1999b) reanalyzed the standardization data and reported a five-factor solution. Also surprising is the apparent lack of concurrent validation data comparing the CVLT-C with other memory measures. The WRAML2 (Sheslow &

Adams, 2003) only reports correlations with the CVLT (Delis et al., 1987) and CVLT-II (Delis, Kramer, Kaplan, & Ober, 2000). The WRAML2 Verbal Memory Index score was found to correlate .68 with the CVLT-II Trials 1–5 Total score (vs. .03 with the Visual Memory Index). When compared to the WISC-III, using a psychiatric outpatient sample, the greatest amount of unique variance was found shared with the Perceptual Organization Index and CVLT-C short- and long-delay free recall; the Verbal Comprehension Index was a poor predictor explaining only 1.5%–4.5% of the variance) (O'Jile, Schrimsher, & O'Bryant, 2005).

There has been extensive reporting of CVLT-C use with various clinical populations, and these studies are nicely reviewed by Strauss, Sherman, & Spreen (2006) who cite investigations with samples as varied as those with head injuries, spina bifida, phenylketonuria, dyslexia, leukemia, epilepsy, stroke, and low birth weight. Because there are so many variables to examine, it is hard to easily summarize the results, although, in general, the principal CVLT-C variables indicated deficits compared to non-clinical groups. Surprisingly, while performing less well than controls, no lateralized differences were found when the CVLT-C was used with stroke victims with predominantly right- vs. left-hemisphere insults (Lansing, Max, Delis, Fox, et al., 2004). Overall, however, using a relatively simple format, the authors of the CVLT-C have deeply mined traditional and nontraditional learning and memory variables in a remarkable way that has demonstrated valuable clinical utility.

### **NEPSY-II**

While the NEPSY-II (Korkman, Kirk, & Kemp, 2007) is a more general, pediatric-focused neuropsychological assessment battery, nonetheless, a substantial portion of the battery consists of memory subtests. Because many psychologists performing assessments supplement a basic set of measures with additional subtests dictated by the referral question and initial test findings, the memory components of the NEPSY-II are included here as another option that is available.

### **Overview**

The NEPSY-II is a neuropsychological battery appropriate for children from age three to 16 years of age. Of its 32 stand-alone subtests, six are identified as memory subtests, and are described in Table 21.14. All the subtests were part of the original NEPSY other than Memory for Designs and Word List Interference, which are new to the

revision; however, modifications in administration, scoring, and/or item content were undertaken for most of the tasks. The tasks include both verbal and visual memory demands, and most have both immediate and delayed recall components. The normative sample includes 1,200 children, 100 in each of 12 age groups ranging in age from 3 through 16 years. The sample was stratified, based on 2003 U.S. census data, according to race/ethnicity (White, African American, Hispanic and Other), four U.S. geographic regions, and four parent-education levels. Equal numbers of each gender were included. Starting and stopping points, along with discontinue rules, were empirically derived and are used to make the testing more streamlined and less burdensome for both client and examiner. The traditional conversion of raw scores to scaled scores with means of 10 ( $SD = 3$ ) is utilized, but no overall memory score or verbal/visual composites are provided. Base rates, cutoffs, and other data grouping techniques are provided for numerous "Process Scores" that provide a normative basis for qualitative observations often made. Test-retest reliabilities for the memory subtests listed in Table 21.14 were determined using six sub-samples differing in age, each group consisting of about 30 children; correlations (corrected) generally ranged from .50 to .86 with the difference between first and second test (separated by about 3 weeks) differing by one to three scaled score points. Mean performance scores are provided for a number of clinical groups, including children with ADHD, Reading Disorder, Mathematics Disorder, Language Disorder, Mild Intellectual Disability, Autistic Disorder, Asperger's Disorder, and Hearing Impairment. Strangely, a group of only 10 children with TBI were evaluated, and because of the variability within that sample, no performance data were reported. Hand scoring templates as well as Scoring and Interpretive software are available for the entire battery.

### Concluding Comment

Given what was available to evaluate memory in children twenty-five years ago, we have made enormous strides in the ensuing years. Specific tests and entire batteries are now available for clinicians, and most of these measures have reasonable psychometric integrity and reflect the growing sophistication in the neuroscience of memory. A literature examining the technical merits and clinical utility of these measures is gradually growing. One aspect that seems to have been overlooked, though, is tests' "ecological validity." That is, if a child does poorly

or well on a given task or set of tasks, what does that mean in terms of real-world performance? This lack of careful mapping between our tests and a client's everyday world is not unique to memory assessment. Even though tasks like block design or digit span have been around for more than 70 years, do we really know what it means "in the real world" if a child or teenager does well or poorly on these tasks? Often in the Recommendations sections of our reports, we write like we know. However, there is scant research that gives clinicians a reasonable empirical foundation for interpreting a subtest's uncovered deficit (or strength), let alone for justifying diagnostic pronouncements or well-intentioned recommendations.

There have been attempts to bridge the gap between test findings and everyday functioning, such as the Rivermead Behavioural Memory Test for Children (RBMT-C; Wilson, Ivani-Chalian, & Aldrich, 1991). The RBMT-C is designed for children five through 10 years of age and takes about a half hour to complete; children generally like its tasks. Children are asked to perform "everyday memory" requests, such as remembering the first and last name of an unfamiliar person in a picture, remembering what to do when reminded later in the session, and finding an object hidden earlier in the session. Despite its generating a relatively truncated range of scores, its questionably appropriate British norms when applied to American children, and its marginal reliability (Aldrich & Wilson, 1991), this measure clearly has more face-validity to support claims that it is related to real-world memory demands. However, there does not seem to be much of a research basis upon which to support any such ecological claims more than the more traditional tests that purposely steer clear of tasks that might have been differentially practiced by children coming to be evaluated. The RBMT-C has shown clinical utility with children with more pronounced impairment, but has not fared so well with children with subtler deficits. Nevertheless, the RBMT-C test authors are to be applauded for attempting to create a more ecologically grounded instrument.

Perhaps one reason findings from memory measures do not have a clearer connection with the "real world" is because we are not altogether sure what the comprehensive memory demands are in children's everyday lives. There have been several instruments designed to provide something like a task analysis of "typical" memory demands made of children, employing a survey format (Hickox

**Table 21.14 NEPSY-II Memory and Learning Subtests**

NEPSY-II Subtest (and Administration Time Estimate)	Age Range (yrs.)	Subtest Description
List Memory (7 minutes)	7–12	A list-learning task using 15 common nouns, and 5 learning trials. A different 15-noun interference trial is then administered with recall, after which recall of the original list is requested. Several “Process Scores” are normed (e.g., number of non-list word intrusions).
List Memory Delayed (1 minute)		Recall of original list is asked after 25–35 minutes’ delay.
Memory for Designs (10–15 minutes)	5–16	Spatial memory for novel visual content is assessed. A grid with 4–10 designs is displayed for 10 seconds, and immediately followed with a set of 1 x 2-inch cards from which the child selects the designs just viewed, placing them in the proper grid location. Both content and spatial criteria contribute to the scoring.
Memory for Designs Delayed (3–4 minutes)		Recall of original designs and their positions on the last page seen are assessed 15–25 minutes following initial task.
Memory for Faces (4–5 minutes)	5–16	Facial Recognition task. 5-sec. exposure to each of 16 single target faces (photographs), followed by 16 3-picture groupings, each of which contains a previous target face to be identified.
Memory for Faces Delayed (2–3 minutes)		The 16 3-picture groupings are again shown, and the one target face is to be identified in each.
Memory for Names (6 minutes)	5–16	6–8 2 x 3-inch cards of line drawings of children’s faces are presented along with the child’s name. The client is to remember which name goes with which face. Three paired-associate learning trials are administered. The presentation order remains invariant.
Memory for Names Delayed (2 minutes)		After a delay of 25–35 minutes, the cards are again presented and recall of each name requested.
Narrative Memory (6–11 minutes)	3–16	A single story is read (selection determined by age) and is immediately followed by a recall trial, and then a cued recall trial for any omitted content. A binary choice recognition task concludes this subtest for those under 11 years of age.
Sentence Repetition (4 minutes)	3–6	Single sentences are read and the child repeats each.
Word List Interference (6–8 minutes)	7–16	A verbal working memory task. One to three words are said and then repeated by the child. A second series of the same number of different words is said and repeated. Then the child is asked to repeat the first series, and then the second. The child’s ability to repeat the words is contrasted with his/her ability to recall the words.

& Sunderland, 1992). Unfortunately, the results have not been encouraging, psychometrically or ecologically. Accordingly, should not psychologists be somewhat less focused on pathology, and instead include wellness within our research interests, such as characterizes the “positive psychology” movement (Compton, 2005)? It would be interesting to explore whether our memory measures can discriminate among those who can and cannot perform impressive “everyday” memory feats such as easily memorizing theater lines, quickly learning a new piece of piano music, and winning spelling or geography bees. Working with strengths as well as deficits might allow us to better evaluate our assumptions related to good or bad scores on a particular memory subtest or index.

At the same time, we must continue to learn about the effects on memory from not-so-positive happenings, like traumatic brain insults from car accidents, strokes, and tumors. Hopefully, in two more decades we will have even better memory tools that will allow us to correctly identify and functionally map corresponding memory deficits in children who deserve more than another page of test scores enlarging their medical records. Instead, we hope that our tests will become more useful in generating diagnostic insight and effective recommendations that will prove valuable to children and their families, as well as assist those engaged in research trying to understand this nearly magical cognitive process.

# Formal Methods in Assessing Child and Adolescent Personality and Affect

Patricia A. Lowe, Erik L. Fister, Susan M. Unruh, Jennifer M. Raad, Justin P. Allen, Tiffany L. Arrington, Skylar A. Bellinger, Liesl J. Edwards, Belinda N. Kathurima, Jeaveen M. Neaderhiser, Christopher R. Niileksela, Jessica Oeth Schuttler, Matthew J. Grumbein, and Stephen W. Loke

## Abstract

This chapter reviews established, newly developed, and updated structured personality inventories broad and narrow in scope used to assess children and adolescents' personality and affect. The psychometric properties of these structured personality inventories are discussed as well as their strengths and limitations. In addition to the structured personality inventories, informal methods, including clinical interviews and observations, used to assess children and adolescents' affect are discussed.

**Key Words:** structured personality inventories, norms, reliability, validity, clinical interviews, observations, children, adolescents

In an effort to develop a comprehensive definition of personality, scientists and researchers have defined personality in many different ways over time. These numerous definitions have led to the development of multiple assessment instruments that measure different aspects of personality. Personality inventories consist of objective or structured personality inventories, projectives, and other techniques (Drummond & Jones, 2010). For the purpose of this chapter, structured personality inventories will be reviewed.

Structured personality inventories are usually standardized, self-report measures with a selected response format that facilitates quick responding to the items, quick and reliable scoring, and accurate and efficient interpretation. Structured personality inventories may be broad in scope and assess multiple dimensions of personality or they may be narrow in scope and measure specific aspects of personality. Measures that are broad in scope tend to be comprehensive, consist of many items, are time-consuming to complete, and provide multiple scores on different scales and subscales. In contrast, measures that

are narrow in scope tend to be brief, address specific symptoms, take less time to complete, provide fewer scores to interpret, serve as screeners, and may prove invaluable in monitoring client progress and evaluating treatment outcomes (Drummond & Jones, 2010).

This chapter will review established, newly developed, and updated structured personality inventories broad and narrow in scope used in the assessment of children and adolescents, followed by a review of less formal methods or techniques, including clinical interviews and observations, used to assess children and adolescents' affect.

## Structured Personality Inventories

Structured personality inventories broad in scope provide a global assessment of children and adolescents' personality and affect. Comprehensive self-report measures are generally well standardized and yield reliable and valid scores. These measures assist clinicians in identifying those children and adolescents who are at risk or may have

a diagnosable disorder. In this section of the book chapter, selected established, newly developed, and updated structured personality inventories broad in scope will be introduced and discussed.

### ***Adolescent Psychopathology Scale***

The Adolescent Psychopathology Scale (APS; W. M. Reynolds, 1998a) is an innovative, comprehensive measure based on Achenbach and McConaughy's (1992) and W. M. Reynolds' (1992) conceptual distinction between externalizing and internalizing symptom presentation. The APS is a 346 item, multidimensional self-report measure and was developed to assess psychopathology, personality, and socio-emotional problems and competencies in adolescents, ages 12 to 19. The APS consists of three broad factors (Externalizing, Internalizing, and Personality Disorder) and 40 scales. The 40 scales include 20 Clinical Disorder scales and five Personality Disorder scales consistent with symptom specification of 20 Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition (DSM-IV, American Psychiatric Association, 1994) Axis I clinical disorders and five DSM-IV personality disorders, respectively, 11 Psychosocial Problem Content scales, and four Response Style Indicators. The Psychosocial Problem Content scales assess social and emotional adjustment in adolescents, and the Response Style Indicators measure inconsistent and truthful responding as well as endorsement of low frequency or unusual behaviors, and significant symptoms and problems. The Diagnostic and Statistical Manual of Mental Disorders-Third Edition-Revised (DSM-III-R; American Psychiatric Association, 1987) served as the conceptual basis for the development of the APS items and scales, and these items and scales were re-evaluated and modified when the DSM-IV was published in order for the items and scales to be consistent with the most current version of the DSM diagnostic criteria. The APS items were written at a third grade reading level. Multiple response formats are used on the APS, and these response formats were developed with the DSM-IV symptom criteria in mind. Multiple response formats are used on the APS to best understand the nature of each symptom or each problem being evaluated. The response formats used include a true/false format, general frequency or general duration format, specific frequency format, and frequency of use format. The multiple response formats also allow clinicians to evaluate symptoms across different time periods. The multiple response formats are a unique feature of the APS. The

administration of the APS is straightforward and a test administrator reads the instructions aloud to one or more examinees. Test administrators should be trained in the administration of self-reports to individuals and groups in order to administer the APS. However, those who are not qualified professionals should be under supervision when they administer the APS to an individual or a group of individuals. Once test administrators complete reading the instructions, examinees read each item and record their responses in a 12-page booklet. The APS takes approximately 45 to 60 minutes to complete. APS scoring is accomplished through the use of a computerized scoring program. Interpretation of the APS involves a seven-step process clearly articulated in the administration and interpretation manual, but the interpretation should be done by a qualified professional. The administration and interpretation manual along with the technical manual are clearly written and well organized. The APS should be used to obtain information on the severity of symptoms associated with the DSM-IV clinical and personality disorders, but it should not be used to provide any formal diagnoses (W. M. Reynolds, 1998b).

The final standardization sample for the APS consisted of 1,827 adolescents (900 males and 927 females), 12 to 19 years of age ( $M = 14.96$ ,  $SD = 1.66$ ), in grades 7 through 12. The socioeconomic status (SES) of the sample was described as heterogeneous with a mean SES value of 8.16 ( $SD = 2.91$ ) on the Hollingshead (1975) Occupational Index, indicating that the sample's SES was in the lower-middle class range. Racial/ethnic composition of the sample was 73.6% Caucasian, 18.6% African American, 5.4% Hispanic, 1.0% Asian, and 1.4% Other. The majority of the adolescents in the standardization sample were living with both parents (61.8%) and residing in suburban locations (74.5%). The demographic characteristics reported for the standardization sample are quite detailed and approximate the 1990 U.S. Census for gender, race/ethnicity, and age. The APS also has a clinical sample consisting of 506 adolescents (293 males, 211 females, and 2 individuals' gender was not reported), with a mean age of 15.57 years ( $SD = 1.41$ ), which is slightly higher than the standardization sample. Grade in school for the clinical sample ranged from 7 to 12th grade. However, 10.1% of the sample reported not being in school. Racial/ethnic composition of the sample included 81.6% Caucasian, 6.4% African American, 5.8% Hispanic, 1.0% Asian, and 5.2% Other. The majority of the clinical sample (87%) was diagnosed with a Conduct Disorder based on

the DSM-III-R diagnostic criteria. The adolescents in the clinical sample were recruited from 31 clinical sites in 22 states (W. M. Reynolds, 1998b).

Extensive work has been conducted to examine the reliability and validity of the APS scores. The majority of internal consistency reliability estimates for the standardization and clinical samples for the scores of the APS clinical, personality, and psychosocial scales were .80 or higher. Also, the majority of the test score stability coefficients for the scores of these same scales over a 14 day test-retest interval were .80 or higher (W. M. Reynolds, 1998c). These findings suggest that the item content on the different APS Clinical Disorder, Personality Disorder, and Psychosocial Problem Content scales are relatively homogeneous in content, and the scale scores show consistency over a relatively short period of time.

Evidence supporting the validity of the APS scores was examined through content analysis, concurrent validity studies, contrasted group studies, and factor analyses (W. M. Reynolds, 1998c). This information is reported in the technical manual. The content validity of the APS was ensured with the inclusion of items representing symptom descriptions of psychopathology, personality disorders, and social and emotional adjustment difficulties supported in the DSM-IV. Different APS clinical, personality, and psychosocial scale scores showed good convergent validity with the scores of the Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1943) and the scores of other established measures of anxiety, depression and self-esteem. In addition, the APS clinical, personality, and psychosocial scale scores demonstrated good divergent validity with the scores of measures of cognitive ability and social desirability. Results of a contrasted group study comparing the scores of the standardization group and the clinical group on the 40 APS scales with age and gender serving as covariates also provide support for the discriminant validity of the APS scores. Finally, a series of principal component analyses were performed, and the findings from these analyses provide support overall for the factor structure of the APS.

In sum, the APS is an innovative, multidimensional self-report measure designed to assess psychopathology, personality, and socio-emotional problems and competencies in adolescents. The APS is a comprehensive measure and it was designed specifically to assess psychopathology in adolescents. These are two of the many strengths of the measure. Other strengths include the extensive evidence

supporting the technical adequacy of the measure, well written and detailed manuals, clear seven-step process to interpret the APS scores and profiles, and multiple response formats to better understand the symptoms and problems being evaluated. In contrast, several weaknesses or limitations of the APS include the length of the measure (however, a short form has been developed), representation of the clinical sample (a large majority of the clinical sample had been diagnosed with a conduct disorder), and research on the specificity and sensitivity of the measure (more information is needed in this area).

### ***Behavior Assessment System for Children, Self-Report of Personality***

The Behavior Assessment System for Children-Self-Report of Personality (BASC-2-SRP; C. R. Reynolds & Kamphaus, 2004a) is a multidimensional self-report measure designed for use with children, adolescents, and college students, ages 6 to 25. The BASC-2-SRP is designed to elicit an individual's perceptions of his or her own behavioral and emotional functioning across several domains, as well as identify specific areas in which the individual exhibits strengths and weaknesses. According to the manual, the results of the BASC-2-SRP are intended to help identify emotional and behavioral difficulties, as well as guide intervention and treatment plans. However, the authors also list several other possible uses of the BASC-2 rating system, including educational classification, manifest determination, program evaluation, forensic/legal proceedings, and research (C. R. Reynolds & Kamphaus, 2004b).

According to C. R. Reynolds and Kamphaus (2004b), the BASC-2 composite scales were based on the factor structure of the original Behavior Assessment System for Children (BASC; C. R. Reynolds & Kamphaus, 1992) then modified to reflect the results of exploratory and confirmatory factor analyses. The item content of the composite scales and individual scales reflect the diagnostic criteria from the DSM-IV-TR (American Psychiatric Association, 2000), as well as information gathered from teachers, parents, children, and mental health professionals (C. R. Reynolds & Kamphaus, 2004b). Several versions of the BASC-2-SRP are available, a child form, the BASC-2-SRP-C, an adolescent form, the BASC-2-SRP-A, and the college form, the BASC-2-SRP-COL. However, the focus of this review will be on the child and adolescent forms. Detailed information about the college form can be found in the BASC-2 manual. The BASC-2 child

and adolescent forms contain several validity scales to identify inaccuracies, inconsistencies, biases, and otherwise invalid responses. Each version is written at a third grade reading level, and can be completed in approximately 20 to 30 minutes. The BASC-2-SRP may be hand-scored or computer-scored (C. R. Reynolds & Kamphaus, 2004b).

Normative data were gathered for the BASC-2-SRP between 2002 and 2004 (C. R. Reynolds & Kamphaus, 2004b). Data were collected from 375 sites across the U.S., and included 3,400 children and adolescents, ages 8 to 18. The authors controlled for gender, race/ethnicity, geographic region, socio-economic status, and inclusion of special populations in the normative sample, in an effort to reflect the 2001 U.S. population. Clinical norms were also gathered from a group of 1,572 children, ages 8 to 21, identified as having a clinical diagnosis or special education classification. The clinical group was not considered a random stratified sample, and therefore demographic characteristics were not controlled (C. R. Reynolds & Kamphaus, 2004b).

Extensive reliability and validity studies have been conducted with the BASC-2 scores. Test score stability was examined, with intervals ranging from 13 to 66 days (C. R. Reynolds & Kamphaus, 2004b). In addition, the convergent and discriminant validity of the BASC-2-SRP scores were assessed in comparison to the scores of several other behavioral and emotional scales. Specific reliability and validity estimates for the BASC-2 scores for the different forms based on the general normative group are discussed below. In addition, information on a supplementary form to the child form, the BASC-2-SRP-Interview is also discussed.

*Self-Report of Personality—Interview (SRP-I).* The Self-Report of Personality-Interview (SRP-I) is available for children, ages 6 to 7. The SRP-I consists of 64 items read aloud by an examiner, to which children respond in a yes/no format. The SRP-I contains one composite scale: the Emotional Symptoms Index, as well as the following individual scales: Anxiety, Attitude to School, Attitude to Teachers, Atypicality, Depression, Interpersonal Relations, and Social Stress (C. R. Reynolds & Kamphaus, 2005).

Based on the normative group of 250 children, the SRP-I scores demonstrated strong to very strong internal consistency reliability for the composite scale scores ( $\alpha = .94$ ) as well as the individual scale scores ( $\alpha = .72 - .82$ ). The SRP-I also exhibited moderate to strong test score stability for the composite scores ( $r = .85$ ) and the individual scale

scores ( $r = .56 - .79$ ) over a three-week test-retest interval. These reliability estimates were adjusted for restriction of range (C. R. Reynolds & Kamphaus, 2005). Exploratory and confirmatory factor analyses were also performed on a sample of 315 children, and the results of these analyses supported a one-factor solution/model for the SRP-I. A moderate correlation of .53 was found between the SRP-I Anxiety scores and the Revised Children Manifest Anxiety Scale (RCMAS; C. R. Reynolds & Richmond, 1978) Total Anxiety scores, supporting the convergent validity of the SRP-I scores. In contrast, overall the correlations between the scores of comparable scales on the SRP-I and the scores of the BASC-2-TRS and BASC-2-PRS were relatively weak (C.R. Reynolds & Kamphaus, 2005). According to Reynolds and Kamphaus, additional studies are needed to assess the validity of the SRP-I scores.

*Self-Report of Personality—Child Form (SRP-C).* The SRP-C is designed for use with children, ages 8–11. The SRP-C contains a total of 139 items. Fifty-one items are presented in a true/false format, while 88 items are answered using a 4-point Likert scale, ranging from 1 (*never*) to 4 (*almost always*). The SRP-C includes five composite scales: Inattention/Hyperactivity, Internalizing Problems, Personal Adjustment, School Problems, and the Emotional Symptoms Index. In addition, each composite scale contains a number of individual scales. The SRP-C includes the following individual scales: Anxiety, Attention Problems, Attitude to School, Attitude to Teachers, Atypicality, Depression, Hyperactivity, Interpersonal Relations, Locus of Control, Relationship with Parents, Self-Esteem, Self-Reliance, Sense of Inadequacy, and Social Stress (C. R. Reynolds & Kamphaus, 2004b).

The SRP-C normative group included 1,500 children, ages 8 to 11. Based on the general normative group, the SRP-C exhibited strong to very strong internal consistency reliability for the composite scale scores ( $\alpha = .85 - .96$ ) as well as the individual scale scores ( $\alpha = .71 - .86$ ). Test score stability was assessed in a sample of 113 children, with a median test-retest interval period of 25 days. The SRP-C demonstrated moderate to strong test score stability for the composite scale scores ( $r = .75 - .83$ ) and the individual scale scores ( $r = .63 - .82$ ; C. R. Reynolds & Kamphaus, 2004b). Convergent and discriminant validity have also been examined between the scores of the SRP-C and the scores of established self-report measures, such as the Children's Depression Inventory (CDI; Kovacs,

1992), the RCMAS and the original child form of the BASC-SRP.

*Self-Report of Personality-Adolescent Form (SRP-A).* The SRP-A is designed for use with adolescents, ages 12 to 21. The SRP-A contains a total of 176 items. Sixty-nine items are presented in a true/false format, while 107 items are answered using a 4-point Likert scale, ranging from 1 (*never*) to 4 (*almost always*). The SRP-A contains the same composite scores as the SRP-C. However, the SRP-A also includes individual scales relating to Sensation Seeking and Somatization (C. R. Reynolds & Kamphaus, 2004b).

The SRP-A normative group included 1,900 adolescents, ages 12 to 18. Based on the normative group, the SRP-A exhibits strong to very strong internal consistency reliability for the composite scale scores ( $\alpha_s = .83 - .96$ ) and moderate to strong internal consistency reliability for the individual scale scores ( $\alpha_s = .67 - .88$ ). Test score stability was assessed in a sample of 107 adolescents, with a median test-retest interval time of 20 days. The SRP-A demonstrated moderate to strong test score stability for the composite scale score ( $rs = .74 - .84$ ) and the individual scale score ( $rs = .61 - .84$ ; C. R. Reynolds & Kamphaus, 2004b). With regard to validity, strong correlations were reported between the scores of the SRP-A scales and the scores of conceptually-similar scales on the Youth Self-Report of the Achenbach System of Empirically-Based Assessment (ASEBA; Achenbach & Rescorla, 2001d). Specifically, strong correlations were found among the inattention ( $r = .76$ ), internalizing ( $r = .80$ ), and overall emotional functioning ( $r = .75$ ) scores of the ASEBA and the SRP-A. Evidence supporting the discriminant validity of the SRP-A scores with conceptually-dissimilar ASEBA scale scores is noted in the BASC-2 manual (C. R. Reynolds & Kamphaus, 2004b). Evidence supporting the convergent and discriminant validity of the SRP-A scores and the scores of other established self-report measures, including the CDI, the RCMAS, and the adolescent form of the original BASC is also reported in the manual (C. R. Reynolds & Kamphaus, 2004b).

The BASC-2-SRP is a widely-used and respected instrument, and is supported by a wealth of research data. The normative sample and procedures for the BASC-2-SRP represents a clear strength. The general normative group consists of a large sample, collected from many sites across the U.S., and appears representative of the general population. In addition, although the clinical

sample is smaller than the normative sample, the inclusion of several clinical groups increases the utility and applicability of the instrument to diverse populations. As with the inclusion of a clinical sample, the expanded age range of the BASC-2-SRP (ages 6 to 25) increases the instrument's utility from a developmental perspective, and allows for its use among a wide age range. Similarly, the availability of Spanish versions of each of the BASC-2-SRP forms establishes the BASC-2-SRP as a useful tool when working with populations of increasing diversity. In addition, the inclusion of a 4-point Likert response format within the BASC-2-SRP improves upon the previous version, which relied solely on true/false responses. The expanded response range allows for greater sensitivity and specificity of responses and interpretation.

Limitations of the BASC-2-SRP include the relatively lower internal consistency reliability estimates of the individual scale scores in comparison to the composite scores. However, this is not unexpected, as reliability estimates often improve with the addition of items on scales. Therefore, the scores of the composite scales (based on multiple scales) appear to be a more reliable indicator of an individual's strengths and needs, and caution should be exercised when interpreting or making decisions based on individual scale results.

### ***Minnesota Multiphasic Personality Inventory-Adolescent***

The Minnesota Multiphasic Personality Inventory—Adolescent (MMPI-A; Butcher, Williams, Graham, Kaemmer, et al., 1992), designed for use with adolescents between the ages of 14 and 18, provides an estimate of psychopathology and adjustment in youth populations (Butcher, Williams, Graham, Archer, et al., 1992). The MMPI-A is a downward extension of the MMPI and the MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer 1989); however, the MMPI-A underwent item revision, testing format redesign, and norming procedures with the adolescent population in mind (Conoley & Impara, 1995). In accordance with the MMPI's history of empirical test development, the MMPI-A continues this tradition. The MMPI-A consists of 478 items and 10 clinical scales (Hypochondriasis, Depression, Hysteria, Psychopathic Deviate, Masculinity-Femininity, Paranoia, Psychastenia, Schizophrenia, Hypomania, and Social Introversion), three broad validity scales (Lie, Infrequency, and

Defensiveness), and four validity subscales (two Infrequency, Variable Response Inconsistency, and True Response Inconsistency). In addition to these scales and subscales, there are 15 adolescent content scales, six supplementary scales, 28 Harris-Lingoes subscales, and three social introversion subscales (Butcher, Williams, Graham, Archer, et al., 1992).

Test administration of the MMPI-A takes approximately 1–1/2 hours to complete. The MMPI-A assessment comes in three formats: a standard booklet format, computer-assisted format (which facilitates scoring), and audio administration format for the visually impaired. Adolescents respond to the statements on the MMPI-A using a true/false format. The complexity of the questions on the MMPI-A requires respondents to have at least a fifth to seventh grade reading level (Butcher, Williams, Graham, Archer, et al., 1992). The MMPI-A testing format allows respondents to complete the assessment in more than one administration period.

Scoring of the MMPI-A is rather easy. Practitioners completing hand-scored assessments do so by summing responses identified using the provided templates that match the appropriate items with the identified scale. Once scale scores are summed, the practitioner then transfers the scores to a profile sheet. However, interpretation of the MMPI-A is somewhat complex. Practitioners must be familiar with the various scale descriptors, as well as the number of interplays of profile representations before they attempt to interpret the measure for their clients.

The normative sample for the MMPI-A consisted of 1,620 adolescents (805 males and 815 females), ages 14 to 18. The adolescents were recruited from eight states. These states were selected to provide a balance in the demographic characteristics of the sample with regards to race/ethnicity, geographic region, and urban and rural settings (Butcher, Williams, Graham, Archer, et al., 1992). The normative sample was fairly representative of the U.S. population of adolescents in 1980, with a few exceptions. These exceptions include under-representation of Hispanics, SES distribution skewed toward the higher SES levels, fewer individuals in the higher age groups, and under-representation of school drop-outs (Butcher, Williams, Graham, Archer, et al., 1992; Kamphaus & Frick, 2002; Rowe, 2003). In addition to the normative sample, a clinical sample of 713 adolescents (420 males and 293 females), ages 14 to 18, were recruited from treatment facilities in the Minneapolis area (Butcher, Williams, Graham, Archer, et al., 1992).

Studies have been conducted to examine the reliability and validity of the MMPI-A scores. Butcher, Williams, Graham, Archer, et al. (1992) reported test score stability coefficients for the scores of the validity scales and subscales and the clinical scales over a one-week test-retest interval. Reliability estimates for the scores of the validity scales and subscales ranged from .49 to .75, and test score stability coefficients for the scores of the clinical scales ranged from .65 to .84. Internal consistency reliability estimates for the scores of the validity scales and subscales and clinical scales ranged from .35 to .91. These reliability estimates are in the moderate to very strong range.

Evidence supporting the validity of the MMPI-A scores has been found. Butcher, Williams, Graham, Archer, et al. (1992) conducted a factor analytic study of the responses of adolescents to the validity and clinical scale items on the MMPI-A. Results of the factor analysis indicated a four-factor solution provided the best fit for the data. These factors were named General Maladjustment, Overcontrol, Social Introversion, and Masculinity-Femininity. However, follow-up factor analytic studies reported different factor structures for the MMPI-A (Archer, Belevich, & Elkins, 1994; Archer, Bolinskey, Morton, & Farris, 2002; Bolinskey, Arnau, Archer, & Handel, 2004). Similarly, some studies have demonstrated evidence of predictive validity for the content scale scores over the basic clinical scale scores (e.g. Forbey & Ben-Porath, 2003; McGrath, Pogge, & Stokes, 2002). While other researchers (e.g. Rinaldo & Baer, 2003) found that the clinical and content scale scores were both useful in predicting clinical and non-clinical group membership. Interestingly, recent studies (Hand, Archer, Handel, & Forbey, 2007; Hilts & Moore, 2003) have demonstrated that the MMPI-A produces normal profiles among some adolescents who experience significant psychological distress. In examining sensitivity and specificity rates, Fontaine, Archer, Elkins, and Johansen (2001) discovered that the accuracy of the MMPI-A classification rates improve when the cut score is raised from a T score of 60 to a T score of 65, thus arguing that a grey area of classification exists. Furthermore, convergent and discriminant validity studies found that the MMPI-A scores demonstrate adequate validity when compared to scores of other scales that purport to measure similar and dissimilar constructs (Arita & Baer, 1998).

Even among current assessment systems, the MMPI-A remains a peerless assessment system. Years of empirical research continue to support its

effectiveness and refined administration and interpretation procedures. Yet the original MMPI, of which the MMPI-A is based, was developed using the same test development methods that were continued in the development of the MMPI-A. Thus, while the assessment remains useful, the MMPI-A is not as psychometrically sophisticated as it once was (Lanyon, 1995). For example, many test items overlap on a number of scales and this redundancy reduces the amount of unique variance the scores of each scale contributes to the overall assessment (Kamphaus & Frick, 2002). Additionally, the convergence of items across scales brings the results from factor-analytic studies into question (Kamphaus & Frick, 2002). Though maintaining fidelity to the original MMPI and MMPI-2 is commendatory in many respects, revising some of the scales and subsequent scale names would have proved useful. For example, the superannuated Psychasthenia and the sensational Psychopathic Deviate scales would have benefited from such revisions, reducing confusion and shock among practitioners and clients alike (Claiborn, 1995). While certain scales would have benefited from revisions, the overall assessment would have benefited from the removal of the Masculinity-Femininity scale. It is unclear why Butcher, Williams, Graham, Kaemmer, et al. (1992) maintained this scale. The Masculinity-Femininity scale provides a poor measure if presented as an assessment of interests and the contribution of this scale to the overall assessment remains questionable at best (Claiborn, 1995). The MMPI-A paper-and-pencil format allows practitioners to access a broader view of their clients; however, administration is rather long for adolescents. To counter this, practitioners must either utilize the computer adaptive assessment or remain cognizant of client fatigue in cases where it may affect the quality of responses. The low internal consistency reliability estimates and instability of some of the clinical scale scores are also of concern and suggest the need to interpret some MMPI-A scale scores with caution (Kamphaus & Frick, 2002).

### ***Personality Assessment Inventory-Adolescent***

The Personality Assessment Inventory-Adolescent (PAI-A; Morey, 2007a) is a 264-item, self-report measure designed to assess personality and psychopathology in adolescents, ages 12 to 18. The PAI-A consists of 22 non-overlapping scales, 11 clinical scales (Alcohol Problems, Antisocial Features, Anxiety, Anxiety-Related Disorders, Borderline Features, Depression, Drug Problems,

Mania, Paranoia, Schizophrenia, and Somatic Complaints), five treatment consideration scales (Aggression, Suicidal Ideation, Stress, Nonsupport, and Treatment Rejection), two interpersonal scales (Dominance and Warmth), and four validity scales (Inconsistency, Infrequency, Negative Impression, and Positive Impression). In addition, most of the clinical scales of the PAI-A have three conceptually driven subscales each, with the exception of the Alcohol Problems and the Drug Problems scales, which have no subscales, and the Borderline Features scale, which has four subscales, designed to provide full coverage of the clinical constructs assessed on the PAI-A and to assist in clinical interpretation. The clinical syndromes assessed by the PAI-A were chosen based on current views of nosology and diagnostic practice. The PAI-A parallels closely the adult version of the scale, the Personality Assessment Inventory (PAI; Morey, 1991). The structure of the PAI-A is similar to the PAI, and most of the items developed for the PAI were retained on the PAI-A; however, the items were modified to make them more applicable to adolescents and their experiences. Items were written at a fourth grade reading level. The instrument can be administered on an individual basis or in a group setting in either a paper-and-pencil format or on a computer. Minimal differences have been found when measures have been administered in these two different formats (Finger & Ones, 1999). Administration time for the paper-and-pencil and the computer versions of the PAI-A is approximately 30 to 45 minutes (Morey, 2007b).

The standardization sample for the PAI-A consists of two groups, a community-based sample and a clinical sample. The community-based sample consisted of 707 adolescents (361 males and 346 females), ages 12 to 18, with a mean age of 15.00 years ( $SD = 2.00$ ). Racial/ethnic composition of the sample included 61.5% Caucasian, 15.4% African American, 16.3% Hispanic, and 6.8% Other. The adolescents were recruited from urban and rural settings in 21 states in the U. S. The sample was comparable to the 2003 U.S. adolescent population with regards to age, gender, and race/ethnicity. The clinical sample included 1,160 youths, 58.4% males and 41.6% females, seen in 78 different clinical sites in the U.S. The mean age of the clinical sample was slightly higher than the community-based sample ( $M = 15.29$  years,  $SD = 1.59$ ). Racial/ethnic composition of the clinical sample consisted of 72.3% Caucasian, 19.8% African American, 4.5% Hispanic, and 4.4% Other. Approximately half (49.7%) of the clinical sample

was assessed in outpatient facilities, with the majority of the adolescents having a primary diagnosis of conduct disorder (23.6%), drug/alcohol abuse or dependence (19.3%), attention-deficit/hyperactivity disorder (18.8%), major depressive episode (15.9%), or oppositional defiant disorder (13.4%; Morey, 2007b).

Detailed information is provided in the PAI-A manual on the reliability and validity of the PAI-A scores. Internal consistency reliability estimates for the scores of the PAI-A clinical scales, validity scales, treatment consideration scales, and interpersonal scales ranged from .70 to .90 and .63 to .90 for the total community-based and clinical samples, respectively. Only one reliability estimate fell below .70 in the clinical sample. Coefficient alphas for the clinical subscale scores ranged from .47 to .80 and .47 to .85 for the total community-based and clinical samples, respectively. Test score stability coefficients for the scores of the PAI clinical scales, validity scales, treatment consideration scales, and interpersonal scales for a sample of 100 adolescents from the community-based standardization sample ranged from .65 to .89 over a 9 to 35 day test-retest interval. For the clinical subscale scores, test score stability coefficients over the same test-retest period with the same adolescents from the community-based standardization sample ranged from .59 to .88 (Morey, 2007b).

Internal structure of the PAI-A scores was examined through principal component and confirmatory factor analyses. Principal component analyses were performed separately on the responses of the community-based and clinical samples. Results of the principal component analysis indicated that a four-factor structure provided the best fit for the data for the community-based and clinical samples. The four factors appeared to assess subjective distress and affective disruption, egocentricity and exploitation in interpersonal relationships, substance involvement and abuse, and interpersonal detachment and alienation. In addition, confirmatory factor analyses were performed to examine the hypothesized conceptual subscale structures in relation to the actual subscale structures. Results indicated acceptable fit for all subscale structures. However, the fit was not as good for the PAI-A in comparison to the PAI. Morey indicated that the difference in the findings may be due to fewer indicators for each factor on the PAI-A in comparison to the PAI or the structure of these constructs is not as distinct in the adolescent population. Overall, strong evidence supporting the convergent and

discriminant validity of the PAI-A scores is provided in the manual. The PAI-A scores were compared to scores of appropriate scales that measure similar and dissimilar constructs on the MMPI-A, the APS, the Personality Inventory for Youth (PIY; Lachar & Gruber, 1995a), the NEO Five Factor Inventory (NEO-FFI; Costa & McCrae, 1989), the Symptom Assessment-45 (SA-45; Davison et al, 1997), the College Adjustment Scale (CAS; Anton & Reed, 1990), the Clinical Assessment of Depression (CAD; Bracken & Howell, 2004a), the Adolescent Anger Rating Scale (AARS; Burney, 2001), the Conners' Adult ADHD Rating Scale (CAARS; Conners, Erhardt, & Sparrow, 1999), the Beck Depression Inventory (BDI; Beck et al., 1996a), and the State-Trait Anxiety Inventory (STAI; Spielberger, 1983) (Morey, 2007b).

The PAI-A is a promising new measure designed to assess personality and psychopathology in the adolescent population. Strengths of the PAI-A include its comprehensiveness, ease of administration, well organized and well-written manual, and detailed information in the manual on the psychometric properties and technical characteristics of the measure. Limitations of the PAI-A include its newness, the need for more independent studies to examine the reliability and validity of the PAI-A scores, moderate reliability estimates for the subscale scores, suggesting these scores should be interpreted with caution, and the length of time to complete the measure. Although there are some limitations associated with the PAI-A, it has the potential to become a major rival of the MMPI-A in the future.

### ***Personality Inventory for Youth***

The Personality Inventory for Youth (PIY) is a comprehensive, multidimensional, self-report measure used to assess behavioral and emotional adjustment, family interactions, school adjustment, and academic ability in children and adolescents, ages 9 to 18. The PIY consists of 270 items or true-false statements (Lachar & Gruber, 1995b). The items for the PIY were adapted from the Personality Inventory for Children-Revised (PIC-R; Lachar, 1982), with the majority of the items reworded to be age appropriate and rewritten in the first person. The PIY items were written at about a third grade reading level. An audio recording of the statements is also available for students who may have difficulty reading the items. Administration of the PIY takes 30 to 60 minutes and is completed independently with appropriate supervision. Group administration of the PIY is also possible. A shorter screening

assessment called the Classroom Screening (CLASS) can also be administered using the first 80 items of the PIY and provides a general measure of adjustment (Lachar & Gruber, 1995b).

The PIY consists of nine clinical scales as well as four validity scales. The nine clinical scales are Cognitive Impairment, Impulsivity and Distractibility, Delinquency, Family Dysfunction, Reality Distortion, Somatic Concern, Psychological Discomfort, Social Withdrawal, and Social Skills Deficits. Each scale is comprised of two or three subscales, resulting in 24 subscales that provide more detailed information. The validity scales are Inconsistency, Validity, Dissimulation, and Defensiveness, which are designed to indicate whether the PIY results of children and adolescents are inaccurate or atypical. Both hand-scoring and computer-scoring are available for the PIY. However, due to the complexity in transferring clusters of item responses from the response sheet to the profile form, computer scoring is recommended for accuracy and efficiency. Standard scores (i.e. *T* scores) are reported for the different scales and subscales. Interpretation of the PIY scores involves a five-step process (Lachar & Gruber, 1995b).

The standardization sample of the PIY consisted of 2,347 children and adolescents, ages 9 to 18. The students were all in regular education in 13 public school districts across five states. In addition, a sample of 1,178 clinically-referred students was assessed to establish a clinical research base for the PIY (Lachar & Gruber, 1995b). While the demographics of the standardization sample did differ from those of the general U.S. population, according to the authors a study of a demographically representative subsample of 709 children and adolescents from the normative sample indicated it was unlikely that the differences in demographic characteristics reported significantly affected the test scores (Destefano, 2001).

The PIY includes a technical guide which provides extensive information regarding the reliability and validity of its scores (Lachar & Gruber, 1995c). The median internal consistency reliability coefficient for the PIY clinical scale scores was .82 for the regular education sample and .85 for the clinical sample. Median internal consistency reliability coefficients for the subscale scores were .70 for the regular education sample and .73 for the clinical sample (Merrell, 2008). Test score stability coefficients for the clinical scale scores ranged from .80 to .91 for the regular education sample and from .76 to .84 for the clinical sample over a 7- to 10-day test-retest

interval. For the subscale scores, test score stability coefficients ranged from .66 to .90 for the regular education sample and .59 to .88 for the clinical sample over the same test-retest interval (Lachar & Gruber, 1995c).

Results of factor analyses support the structure and design of the PIY (Lachar & Gruber, 1995c). Evidence supporting the convergent and discriminant validity of the PIY scores was demonstrated through correlations with the scores of such measures as the PIC-R, the MMPI, and the Peabody Picture Vocabulary Test-Revised (PPVT-R; Dunn & Dunn, 1981) (Lachar & Gruber, 1995c). The PIY scores have also shown adequate sensitivity in distinguishing between clinical and non-clinical samples of children and adolescents (Merrell, 2008). Lachar, Harper, Green, Morgan, and Wheeler (1996) conducted a contrasted group study and found that the PIY scores were able to differentiate children with a major depressive disorder from children with a conduct disorder. These findings provide additional support for the discriminant validity of the PIY scores.

The PIY has the potential to make significant contributions in both research and clinical practice. Because the PIY was developed from the PIC-R, which is a well-established measure, the PIY has a significant theoretical and statistical base. The PIY allows for children and adolescents to supply information from their perspective. Due to its length, which can be a hindrance, the PIY may not be suitable as a general screening instrument; however, the abbreviated 80-item format may be useful for large-scale administrations (Marchant & Ridenour, 2001). Although the authors conducted a special study using the normative sample and a demographically representative subsample and reported that differences in the demographic characteristics were unlikely to affect the test scores, the authors did proceed and did create separate norms for males and females (Destefano, 2001). Additional research is needed in this area to examine issues of potential test bias. Overall, the research evidence supports the reliability and the validity of the PIY scale scores; however, lower reliability estimates reported for the PIY subscale scores suggest these scores should be interpreted with caution (Marchant & Ridenour, 2001).

### ***Youth Self-Report***

The Youth Self-Report (YSR; Achenbach & Rescorla, 2001d) is one component of the Achenbach System of Empirically Based Assessment

(ASEBA; Achenbach & Rescorla, 2001a) aimed at assessing competencies and problematic behaviors in adolescents. The YSR is a comprehensive self-report measure intended for adolescents, ages 11 to 18. This latest version is a revision of the popular and widely used 1991 YSR (Achenbach, 1991) and 1987 YSR (Achenbach & Edelbrock, 1987). Under ideal circumstances, the YSR is administered along with the Child Behavior Checklist (CBCL; Achenbach & Rescorla, 2001a) and the Teacher's Report Form (TRF; Achenbach & Rescorla, 2001c) of the ASEBA to acquire multiple raters' perceptions of an adolescent's problematic behaviors and competencies/adaptive functioning. The ASEBA consists of eight syndrome scales (Anxious/Depressed, Withdrawn/Depressed, Somatic Complaints, Social Problems, Thought Problems, Attention Problems, Rule-Breaking Behavior, and Aggressive Behavior). The raw scores from these various syndrome scales are summed together in different combinations to obtain an Internalizing Problems score and an Externalizing Problems score. The ASEBA also has a Total Problems score, computed by summing the raw scores from the Internalizing Problems, Externalizing Problems, Social Problems, Thought Problems, Attention Problems, and Other Problems scales. The Total Problems score provides an overall measure of problematic behavior. In addition, there are two competence scales on the YSR—the Activities and Social scales. The raw scores of these two scales are summed and added together to obtain a Total Competence score, which provides a measure of overall competence. A new feature of the latest YSR is the six DSM-oriented scales (Affective Problems, Anxiety Problems, Somatic Problems, Attention Deficit/Hyperactivity Problems, Oppositional Defiant Problems, and Conduct Problems). These scales consist of items developed to assess problematic behaviors found on the syndrome scales. The YSR protocol requires adolescents to complete demographic information, provide information on competencies in six categories, and respond to open-ended questions regarding strengths and concerns. In addition, the adolescent responds to 112 statements that describe his or her behavior in the past six months. Each statement is rated on a 3-point Likert scale, ranging from 0 (*not true*) to 2 (*very true or often true*). The items on the ASEBA were written at or above a fifth grade reading level. The YSR can typically be completed in 15 to 20 minutes. The measure can be either hand- (provided in detail in the manual's appendix) or computer-scored. If hand-scored, raw scores are summed on the different

scales and converted to standard scores (i.e. T-scores) and percentiles (Achenbach & Rescorla, 2001b).

The YSR was standardized on two samples to create norms for the competence and syndrome scales. Representative of the 1999 U.S. population, the standardization sample for the competence scales consisted of 1,057 adolescents, ages 11 to 18. The standardization sample was comprised of 52% males. Ethnic/racial composition of the sample was 60% NonLatino White, 20% African American, 8% Latino, and 11% Mixed or Other. Regional characteristics included adolescents from 40 states and the District of Columbia, with 17% from the Northeast, 19% from the Midwest, 41% from the South, and 23% from the West. Socioeconomic status of the normative sample consisted of 32% upper SES, 53% middle SES, and 16% lower SES. This sample consisted of non-referred adolescents (Achenbach & Rescorla, 2001b).

The standardization sample for the syndrome scales consisted of 1,057 adolescents from the norming sample for the competence scales and 1,494 adolescents who were receiving treatment in inpatient and outpatient facilities. These 2,551 adolescents (1,429 males and 1,122 females) were from 40 states, the District of Columbia, one Australian state, and England. Ethnic/racial composition of this sample was 47% NonLatino White, 23% African descent, 17% Latino, and 13% Mixed or Other. The SES of this normative sample was described as middle class (Achenbach & Rescorla, 2001b).

Evidence supporting the reliability and validity of the ASEBA scores has been found. Internal consistency reliability estimates for the Total Problems, Internalizing and Externalizing Problems, and syndrome scale scores ranged from .71 to .95. For the DSM-oriented scale scores, coefficient alphas ranged from .67 to .83 and for the Total Competence, Activities, and Social scale scores, coefficient alphas ranged from .55 to .75. A sample of 1,938 referred and non-referred individuals were assessed in determining these reliability estimates. Temporal stability coefficients of the YSR scores were examined over an 8-day test-retest interval with a sample of 89 adolescents. Test score stability coefficients ranged from .67 to .89 for the YSR scores. Temporal stability of the YSR scores was also assessed over a 7-month test-retest interval in a sample of 144 adolescents, ages 11 to 14. As one would expect, test score stability coefficients across all scales tended to decrease and ranged from .34 to .63 (Achenbach & Rescorla, 2001b).

Evidence supporting the construct validity of the YSR scores has been reported. A principal component analysis was performed on the responses of the 2,551 adolescents in the norming sample for the YSR syndrome scales, and the analysis produced an eight factor solution. An eight factor solution was also determined to be the best fit for the YSR data drawn from another sample of adolescents using confirmatory factor analysis (Achenbach & Rescorla, 2001b). These findings were comparable to the factor analytic results reported for the 1991 version of the YSR (Achenbach, 1991). Correlations reported between the scores of the YSR syndrome scales and the scores of the adolescent form of the BASC-2 clinical scales support the convergent validity of the YSR scores. Reynolds and Kamphaus (2004b) reported moderate to strong correlations between the scores of conceptually similar scales on the YSR and BASC-2. Correlations were also examined between the YSR scores and the CBCL scores and were found to be moderate ( $r_s = .37$  to  $.60$ ; Achenbach & Rescorla, 2001b). Discriminant analyses were also performed to determine whether the YSR scores could differentiate adolescents who were referred from adolescents who were not referred. Using unweighted combinations of scale scores, the average percentage of correctly classified adolescents ranged from 68% for the syndrome scale scores to 83% for the scores of the competence and problem behavior items combined (Achenbach & Rescorla, 2001b). These findings support the discriminant validity of the YSR scores.

The YSR is an excellent self-report measure that has been extensively studied and well reviewed (Flanagan, 2005; Watson, 2005). Used in conjunction with the CBCL and TRF, the YSR is on a short list of measures able to provide valuable multi-rater information. The psychometric properties have proven to be strong overall throughout the years and the accompanying manual is meticulously written and user friendly. Considering its length in comparison to other structured personality inventories, the YSR is a cost effective measure that provides a global assessment of the behavioral, emotional, and social functioning of adolescents.

Besides comprehensive measures, structured personality inventories may be narrow in scope. Although these measures do not provide a global assessment of children and adolescents' behaviors, they assess specific aspects of individuals' personality and affect. In this section of the book chapter, selected established, newly developed, and updated structured personality inventories narrow in scope will be reviewed.

### ***Beck Depression Inventory-Second Edition***

The Beck Depression Inventory-Second Edition (BDI-II; Beck, Steer, & Brown, 1996a) is a 21 item, self-report measure used to assess the severity of depressive symptoms in adolescents and adults, ages 13 and older. The BDI-II's predecessors, the Beck Depression Inventory—Amended (BDI-IA; Beck, Rush, Shaw, & Emery, 1979), and the original Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) have been the most popular and widely used instruments for detecting depression in non-referred populations over the past 35 years. The BDI-II was developed to be consistent with the diagnostic criteria in the most recent edition of the DSM, the DSM-IV (Beck et al., 1996b). A Spanish version of the BDI-II is also available.

Administration of the BDI-II takes five to ten minutes to complete. However, individuals with severe depression or obsessive symptoms may take longer to complete the instrument. Individuals are required to read each statement and select the best statement out of a group of four statements for each item that describes how they have felt over the last two weeks. Items may be read aloud to accommodate non-readers or those with reading difficulties. The response options for each item on the BDI-II are arranged on a 4-point Likert scale, ranging from 0 (symptom is absent) to 3 (symptom is most severe or is most frequent). Item 16, which pertains to sleep patterns, and Item 18, which pertains to appetite changes, both have unique options (i.e. for each statement within the group of four statements, there are two options). Although the BDI-II can be administered by individuals who have received little training, interpretation is reserved for trained professionals (Beck et al., 1996b).

Scoring of the BDI-II involves summing the weights of the 21 items to obtain a Total score. Possible BDI-II Total scores are grouped by levels of severity— 0–13, 14–19, 20–28, and 29–63, which correspond to minimal, mild, moderate, and severe levels of depression, respectively. Cut scores for these ranges were derived by receiver operating characteristic curves (ROC) that differed across four groups of mild, moderate, severe and non-depressed responders. The cut scores were designed to be sensitive to depression while reducing the number of false positives. Researchers in need of a “true” depression score are encouraged to use a raw score of 17 as their cut score. A cut score of 17 was the score in the BDI-II clinical sample

that yielded a 93% positive and 17% false positive rate (Beck et al., 1996b).

A college student sample ( $n = 120$ ) and a psychiatric outpatient sample ( $n = 500$ ) were used to examine the psychometric properties of the BDI-II. The demographic characteristics reported for these two samples are lacking in detail. The mean age of the student sample was 19.58 years ( $SD = 1.84$ ) and the mean age of the psychiatric outpatient sample was 37.20 years ( $SD = 15.91$ ; range 13–86 years). Sixty-three percent of the psychiatric outpatient sample and 56% of the college student sample was female. Racial/ethnic composition of the psychiatric outpatient and college student samples was predominately White (Beck et al., 1996b).

The manual reports on the alpha levels for the BDI-II Total scores for the psychiatric outpatient ( $\alpha = .92$ ) and college student ( $\alpha = .93$ ) samples. In addition, corrected item-total correlations for the outpatient and college student samples ranged from .39 to .70 and .27 to .74, respectively. All corrected item-total correlations were statistically significant. Test score stability for the BDI-II scores was established with a subsample of psychiatric outpatients ( $n = 26$ ) during their first and second therapy sessions, one week apart. A strong test score stability coefficient of .93 was found (Beck et al., 1996b).

Validity of the BDI-II scores was established on several fronts. Support for the content validity of the BDI-II came through the writing of items that captured the diagnostic criteria for depressive disorders in the DSM-IV. New items were added and nearly all items were reworded to reflect the latest criteria. Convergent validity was assessed by comparing the BDI-II scores with the scores of the Beck Hopelessness Scale (BHS; Beck, 1988;  $r = .68$ ), the Scale for Suicide Ideation (SSI; Beck, Kovacs, & Weissman, 1979;  $r = .37$ ), the Hamilton Psychiatric Rating Scale for Depression-Revised (HRSD-R; Riskind, Beck, Brown & Steer, 1987;  $r = .71$ ), and the Hamilton Anxiety Rating Scale-Revised (HARS-R; Hamilton, 1959;  $r = .47$ ) in psychiatric outpatient samples of various sizes. In contrast, discriminant validity of the BDI-II scores was supported based on the difference between the strong correlation of the BDI-II scores with the HRSD-R scores and the moderate correlation of the BDI-II scores with the HARS-R scores (Beck et al., 1996b).

Results of factor analyses for the responses of the psychiatric outpatient sample and college student sample to the BDI-II items differed across samples. Both factor analyses produced a two-factor

solution for the BDI-II items, but the dimensions and the number of items loading on those dimensions were different. In the outpatient sample, the two factors were named Somatic-Affective and Cognitive. Twelve items loaded on the Somatic-Affective dimension while the remaining 9 items loaded on the Cognitive dimension. In the college student sample, the two factors were named Cognitive-Affective and Somatic. Fourteen items loaded on the Cognitive-Affective dimension and five items loaded on the Somatic dimension (Beck et al., 1996b). Independent studies have also reported variations in the BDI-II factor structure (e.g. Buckley, Parker, & Heggie, 2000).

Criticisms of the BDI-II include absence of ROC development procedures in the BDI-II manual, inconsistent findings in the factor structure across populations, and optimal information on the research samples used to examine the psychometric properties of the BDI-II (Farmer, 2001). Farmer's review of the BDI-II highlights the lack of detailed information on the samples in the manual, including missing information on the education level, geographic patterns, and family income of the responders. Strengths of the BDI-II include a strong empirical foundation, innovative methods to determine cut scores (Farmer, 2001), excellent reliability, and ease of administration, scoring, and interpretability. Based on these strengths, the BDI-II remains a popular instrument among many clinicians and researchers.

### ***Beck Youth Inventories-Second Edition***

The Beck Youth Inventories-Second Edition (BYI-II; Beck, Beck, Jolly, & Steer, 2005a) is a measure designed to assess socio-emotional functioning in children and adolescents, ages 7 to 18. The BYI-II is composed of five scales or inventories (Beck Depression Inventory for Youth (BDI-Y), Beck Anxiety Inventory for Youth (BAI-Y), Beck Disruptive Behavior Inventory for Youth (BDBI-Y), Beck Self-Concept Inventory for Youth (BSCI-Y), and Beck Anger Inventory for Youth (BANI-Y)) that can be completed independently or in aggregate in the combination booklet. Each scale is composed of 20 items. The items were constructed based on the DSM-IV-TR criteria. Respondents self-report using a 4-point Likert scale, ranging from 0 (*never*) to 3 (*always*) regarding the frequency of various behaviors and feelings experienced. The time to complete the entire BYI-II is 30 to 60 minutes (5 to 10 minutes per scale). Once completed, raw scores for each BYI-II scale are tallied, converted to T-scores,

and plotted on a profile (Beck, Beck, Jolly, & Steer, 2005b).

Norming and development of the BYI-II was accomplished in two phases. In the first phase, data were collected from a community sample of youth, ages 7 to 14, and analyzed for the first edition of the Beck Youth Inventories of Emotional and Social Impairment (Beck, Beck, & Jolly, 2001). The second phase focused on obtaining data from a community-based sample of adolescents, ages 15 to 18, and this data and the data from the first edition of the BYI were combined in the second edition. In both phases, data from clinical samples were also collected (Beck et al., 2005b).

The community-based sample of children and adolescents, ages 7 to 14, consisted of 1,100 individuals living in the four major geographic regions of the U.S. The children and adolescents were recruited through churches, community groups, public and private schools, and national mailing lists. For the standardization sample, 800 children and adolescents were selected from the community-based sample, stratified to match the 1999 U. S. Census data by race/ethnicity and parent education level. Age-by-gender norms were developed for the standardization sample based on the analyses of age and gender effects. A special education sample was also identified, comprised of 89 children between the ages of 8 and 12. The clinical sample included 107 children who were receiving outpatient mental health services in a state in the Northeastern region of the U.S. (Beck et al., 2005b).

The community-based sample of adolescents, ages 15 to 18, included 252 adolescents from the four major geographic regions in the U.S. The sample was recruited through advertising, school districts, and professionals who conduct evaluations. For the standardization sample, 200 individuals were selected from the community-based sample to match the 2002 U.S. Census data for age, gender, ethnicity, and parent education level. Adolescents were excluded from the standardization sample if there were any indication they were currently receiving psychiatric services. The clinical sample of adolescents, ages 15 to 18, consisted of 178 individuals (Beck et al., 2005b).

Overall, the reliability and validity of the BYI-II scores are solid. Internal consistency reliability estimates for the scores of the five inventories for the norming sample ranged from .86 to .96. Standard errors of measurement ranged from 2.04 to 3.00 for the norming sample across inventories. Test score stability coefficients based on a sample of

170 children and adolescents ranged from .74 to .93 for the scores of the BYI-II Inventories (Beck et al., 2005b). Principal components factor analysis indicated the presence of an underlying negative affect principal factor, as well as factors for negative self-concept and negative behavior. Convergent and discriminant validity studies for the BYI-II scores were conducted with the scores of the CDI, the RCMAS, the Reynolds Bullying and Victimization Scales for Schools (RBVSS; Reynolds, 2003), the Conners-Wells Scales (CASS:S; Conners, 1997), and the Piers-Harris Children's Self-Concept Scale (PHCSCS; Piers, 2002). Relationships were found among the expected scale scores in the expected directions, supporting convergent and discriminant validity, with stronger relationships for the adolescent sample. Convergent validity for the BDI-Y scores and the scores of the CDI was indicated by a strong validity coefficient of .72 for a sample of 128 children, ages 11 to 14. The BDI-Y scores and the CDI scores were moderately correlated ( $r = .67$ ) in a sample of 26 adolescents. The BAI-Y scores were moderately to strongly correlated with the RCMAS anxiety scores for children and adolescents ( $r = .70$ ;  $r = .64$ , respectively), while the scores of the RCMAS anxiety scores did not correlate as highly with the BDBI-Y ( $r = .21$ ) and BANI-Y ( $r = .36$ ) scores for adolescents, providing some support for the discriminant validity of some of the BYI-II scale scores. The BAI-Y scores also correlated strongly with the RBVSS Bully Victimization Distress Internalizing scores ( $r = .72$ ) for a sample of 111 children. Moderate to strong correlations ( $r = .69$ ,  $n = 108$  children, and  $r = .76$ ,  $n = 89$  adolescents) between the BDBI-Y scores and the CASS:S Conduct Problems scale scores were found. For adolescents, the BDI-Y scores were most strongly correlated with the RCMAS anxiety scores ( $r = .70$ ; Beck et al., 2005b), suggesting a strong overlap between the two constructs in the area of negative affectivity (Watson & Clark, 1984). The BDBI-Y scores were strongly correlated with the CASS:S Conduct Problems scores for a sample of 108 children, ages 7 to 14 ( $r = .69$ ) and for a sample of 108 adolescents, ages of 12 to 14 ( $r = .76$ ). Moderate to strong correlations between the BANI-Y scores and the CASS:S ADHD Index scores ( $r = .73$ ) and the Hyperactive Impulsive scores ( $r = .68$ ) for children were reported, suggesting that the BANI-Y scores may be sensitive to the externalizing characteristics of ADHD. The BSCI-Y scores were moderately to strongly correlated with the PHCSCS Total scores ( $r = .61$  for children and

$r = .77$  for adolescents; Beck et al., 2005b). Group differences were also evaluated using a sample of children receiving special education services and a sample of children presenting for treatment at an outpatient mental health clinic compared to a sample of matched controls. Students receiving special education services scored statistically significantly higher on the BDI-Y, BAI-Y, BDBI-Y, and BANI-Y scales and significantly lower on the BSCI-Y scale than children not identified. For the clinical sample, statistically significant differences between the outpatient sample and the matched controls were found for the scores of three of the five inventories: BSCI-Y, BDBI-Y, and BANI-Y, with the BSCI-Y scores showing the largest differentiation between the groups (Beck et al., 2005b).

Beck and colleagues (2005b) outlined four reasons for evaluators to use the BYI-II over other measures. First, each separate inventory is quite brief, taking only 5 to 10 minutes to complete. It's suggested that children and adolescents may be more compliant in completing one or a combination of these shorter inventories over longer, more traditional self-report scales. Of particular note, the scores of the BANI-Y and BDBI-Y scales, of which few of these types of scales are available, are reliable and valid. The BYI-II covers a broad scope of potential difficulties experienced by youth and adolescents. Additionally, the measures were developed and co-normed with a sample of U.S. youth stratified in accordance with the U.S. Census data. The manual provides extensive validity information for the BYI-II scores. However, Henington (2007) noted that there is a lack of information on item development of the BYI-II. Overall, the BYI-II is a well-calibrated instrument that provides quality information in combination with other measures and methods for evaluations of children and adolescents as well as for research purposes.

### ***Children's Depression Rating Scale-Revised***

The Children's Depression Rating Scale—Revised (CDRS-R; Poznanski & Mokros, 1996) is a rating scale based on a 20- to 30-minute semi-structured interview designed to evaluate children, ages 6 to 12, for depression and dysthymia. The CDRS-R addresses 14 different areas of symptomatology (Impaired Schoolwork, Difficulty Having Fun, Social Withdrawal, Sleep Disturbance, Excessive Fatigue, Physical Complaints, Irritability, Excessive Guilt, Low Self-Esteem, Depressed Feelings, Morbid Ideation, Suicidal Ideation, Excessive Weeping, and Appetite Disturbance) and three areas of observable

behavior (Depressed Facial Affect, Listless Speech, and Hypoactivity). A clinician provides a rating from 1 to 7 for each symptom and observable behavior. Higher scores indicate more severe symptoms or behaviors. For Sleep Disturbance, Appetite Disturbance, and Listless Speech, a rating from 1 to 5 is used, also based on severity. The raw scores for each symptom or behavior are then summed and converted to a T-score, the CDRS-R Summary score, to provide a standardized score for comparison to the norm group, as well as percentile rank. Besides the child, parents, significant other adults, and peers can also be interviewed regarding the presentation of symptoms by the targeted child (Poznanski & Mokros, 2005).

A nonclinical sample consisting of 223 children and their parents from an urban public school in Chicago, Illinois served as the norming sample. These students were selected using a stratified random sampling procedure, and they participated in a one-time evaluation. However, not all of the children who participated had parents who were interviewed. Only about 50% ( $n = 109$ ) of the parents also participated in the interviews. Of the 223 children participating, approximately 33.3% were African-American, 27.3% were of other (primarily Hispanic) ethnicity, and 60.6% were White. Mean age of the respondents was approximately 10 years. In contrast, the clinical sample consisted of 78 children recruited from affective disorder clinics at two University medical centers in the Chicago area. Of these 78 children, 64% were male, 35% were Black, 7% were from other (primarily Hispanic) backgrounds, and 58% were White. Sixty of these children were identified as having depression, 90% ( $n = 54$ ) with a Major Depressive Disorder. Of the remaining 18, 19% ( $n = 15$ ) were identified as having another psychiatric diagnosis other than depression. Of the 60 children identified as having depression, 46.7% had another comorbid disorder. Mean age of the clinical sample respondents was 10 years (Poznanski & Mokros, 2005).

Three types of reliability (inter-rater, test-retest, and internal consistency) were examined for the clinical and nonclinical samples based on the CDRS-R ratings. Inter-rater reliability for the CDRS-R ratings was .92 for a sample of 25 children. A test score stability coefficient of .80 was reported for the CDRS-R Summary scores based on an intake and 2-week follow-up assessment. A coefficient alpha of .85 was found for the CDRS-R Summary scores in the nonclinical sample consisting of 223 children (Poznanski & Mokros, 2005). These reliability estimates are in the strong to very strong range.

Evidence supporting the validity of the CDRS-R Summary scores has been found. A moderate validity coefficient of .48 was reported between the CDRS-R Summary scores and the Hamilton Rating Scale for Depression (Warren, 1994). Total scores in the clinical sample. The validity of the CDRS-R Summary scores was also examined in relation to the Dexamethasone Suppression Test (DST; Carroll et al., 1981), a measure used to evaluate the biological markers of depression, in the clinical sample. Results of an analysis of variance (ANOVA) indicated significantly higher scores on the CDRS-R Summary scores for children displaying DST results indicative of depression. A contrasted group study was conducted to also evaluate the discriminant validity of the CDRS-R Summary scores using data from two groups of children from the clinical sample, one group of children with major depression or dysthymia ( $n = 60$ ) and the other group of children diagnosed with other disorders other than depression ( $n = 18$ ), and the group of children from the nonclinical sample ( $n = 223$ ). Children in the major depression and dysthymia group scored significantly higher on the CDRS-R Summary scores than those in the other clinical and nonclinical groups, and the nonclinical sample had the lowest mean CDRS-R Summary scores of the three groups. Other evidence supporting the discriminant validity of the CDRS-R Summary scores for the clinical and nonclinical samples is provided in the manual (Poznanski & Mokros, 2005).

The CDRS-R has the advantage of being a revised version of the original Children's Depression Rating Scale (CDRS; Poznanski, Cook, & Carroll, 1979) that has been used in clinical and nonclinical settings for over 20 years. This most recent version of the CDRS has been updated in the following ways: the addition and renaming of symptom areas, revised rating scale anchors, additional interpretive and usage considerations, including development of suggested interview prompts and providing a means for integrating information from multiple informants, and revision of the calculation of the Summary score. It has a flexible method of administration, with emphasis on empathy with the child and fluidity in interviewing, appears to require more extensive training in administration than more traditional interviews or measures. Additionally, reviewers note that the manual is quite dense and could be organized in a more easily understood format (Dowd, 2001). One reviewer noted concerns about the diversity and representation of the sample, completely lacking of children

from Asian-American and Native American backgrounds (Stovall, 2001).

### ***Clinical Assessment of Depression***

The Clinical Assessment of Depression (CAD; Bracken & Howell, 2004a) is a 50-item, multidimensional, self-report measure designed to assess depression in children, adolescents, and adults, ages 8 to 79. The CAD consists of eight scales – a Total scale, four Symptom scales (Depressed Mood, Anxiety/Worry, Diminished Interest, and Cognitive and Physical Fatigue), three validity scales (Inconsistency, Negative Impression, and Infrequency), and six critical item clusters (Hopelessness, Self-Devaluation, Sleep/Fatigue, Failure, Worry, and Nervousness). The purpose of the validity scales on the CAD is to assist clinicians in assessing the veracity of the rater's self-report, whereas the purpose of the six critical item clusters is to assist clinicians in addressing specific issues in therapy or in taking specific action to help their client (Bracken & Howell, 2004b).

The CAD is a comprehensive measure with application across a large portion of the child, adolescent, and adult life span. The authors of the CAD believe based on clinical practice and the literature in the area of depression that there are more symptoms of depression in common than not common across the life span and thus, they developed a measure (i.e. a single form) to assess depressive symptomatology found across the child, adolescent, and adult life span. However, the measure also assesses those unique features of depression found in specific age groups. The CAD's items were written to reflect the diagnostic criteria found in the DSM-IV-TR, as well as the current literature on depression in children, adolescents, and adults. The CAD's items were written at a third-grade reading level. The CAD is easy to administer and it can be administered on an individual basis or in a group setting. Little training is needed to administer and score the CAD. However, individuals with little training should receive professional supervision. During the administration of the measure, children, adolescents, and adults respond to the CAD items by indicating how they have felt lately. Respondents rate their responses on the CAD on a 4-point Likert scale, ranging from 1 (*strongly disagree*) to 4 (*strongly agree*). The CAD takes approximately 10 minutes to complete. Once completed, the CAD can be hand scored or computer scored and interpreted. Interpretation of the CAD scores and profiles involves a five-step process articulated

in the manual and should be done by qualified professionals (Bracken & Howell, 2004b).

The standardization sample for the CAD consists of 1,900 individuals, 300 children (150 females and 150 males), ages 8 to 11, 400 adolescents (200 females and 200 males), ages 12 to 17, 400 older adolescents/young adults (200 females and 200 males), ages 18 to 25, and 800 young, middle, and older adults (400 females and 400 males), ages 26 to 79. These demographic characteristics of the standardization sample for the CAD matched closely the U.S. population demographics. Of those individuals, ages 18 to 79 in the standardization sample, 1.3% had eight or fewer years of education, 4.3% had 9 to 11 years of schooling, 18.9% had 12 years of education, 37.1% had 13 to 15 years of schooling, and 38.4% had more than 16 years of education. Based on these percentages, Bracken and Howell (2004b) noted that the standardization sample was slightly more highly educated than the U.S. population. The racial/ethnic composition of the sample was 70.2% Caucasian, 12.9% African American, 8.3% Hispanic, and 8.6% Other. The racial/ethnic composition of the standardization sample was comparable to the U.S. population. The standardization sample was recruited from 22 states in the U.S., 44% from the Midwest, 8.7% from the Northeast, 31.4% from the South, and 15.5% from the West. According to the authors of the CAD, the Midwest was oversampled and the Northeast was undersampled (Bracken & Howell, 2004b).

Overall, the reliability and validity of the CAD scores are solid. Internal consistency reliability estimates are reported for the standardization sample by age group, gender, and race/ethnicity. Coefficient alphas for the CAD Total scale scores and the four Symptom scale scores for the different groups ranged from .96 to .98 and from .78 to .96, respectively. Internal consistency reliability for the scores of the Total scale and the four Symptom scales for a clinical sample of 99 children were comparable to the coefficient alphas reported for the standardization sample and ranged from .85 to .98. The consistency of the CAD scores was also examined over a 7–36 day test-retest period for children and adolescents. Corrected test score stability coefficients for a sample of 40 children and adolescents, ages 8 to 18, ranged from .64 to .81 for the Total scale scores and the four Symptom scale scores, with only one test score stability coefficient falling below .70 (i.e. the Diminished Interest scale scores; Bracken & Howell, 2004b). Overall, the majority of these

reliability estimates are in the strong to very strong range.

Evidence supporting the validity of the CAD scores was examined through content analysis, convergent validity studies, contrasted group studies, and factor analyses (Bracken & Howell, 2004b). Bracken and Howell note that the content validity of the CAD was ensured with the inclusion of items representing symptoms of depression supported in the literature and the DSM-IV-TR. Examination of the mean scores of a combined clinical sample of 30 children and adolescents, ages 8 to 18 and 37 adults, ages 19 to 79, and a non-clinical control sample of 66 children and adolescents, and 123 adults of comparable ages revealed that the clinical subsamples had mean CAD scores above the normative mean and the clinical control subsamples had mean CAD scores below the normative mean in all cases except two. These findings support the discriminant validity of the CAD scores. Convergent validity of the CAD scores was supported in studies conducted with scores of measures external to the test. Bowers (2004) administered the CAD and the BDI-II to 119 adolescents and reported moderate to strong validity coefficients ( $rs = .64$  to  $.77$ ) between the scores of the two measures. Likewise, Tinsley (2004) administered the CAD to 121 adolescents along with the Reynolds Adolescent Depression Scale (RADS; Reynolds, 1986) and found strong validity coefficients ( $rs = .71$  to  $.88$ ) between the scores of the two measures. Confirmatory factor analyses were also performed. The normative sample was divided into two age groups, ages 8 to 17 and 18 to 79, to form a child/adolescent and adult analysis groups. In addition, the entire normative sample served as a third analysis group. One-, two-, and four-factor models were compared and contrasted using the data. Results of the confirmatory factor analyses indicated that the four-factor model provided the best fit for the data for all groups. The four factors were Depressed Mood, Anxiety/Worry, Diminished Interest, and Cognitive and Physical Fatigue (Bracken & Howell, 2004b).

The CAD is a promising relatively brief, multidimensional measure used to assess depressive symptoms in children, adolescents, and adults. Several strengths of the CAD include the use of a single measure to assess depressive symptoms across the life span, the inclusion of validity scales for clinical interpretation, the ease of administration and scoring of the measure, a user-friendly manual, a large, fairly representative standardization sample, and good psychometric properties overall. In contrast,

some weaknesses or limitations of the measure include limited description of the clinical normative sample, a low test score stability coefficient for the Diminished Interest scale scores in the child/adolescent sample, and possible breadth of coverage of depressive symptoms on the measure in comparison to some existing measures of depression. Furthermore, additional research is needed with the CAD to examine the reliability and validity of its scores and its clinical utility in treatment planning and progress monitoring (Kavan, 2007).

### ***Fear Survey Schedule for Children—Revised***

The Fear Survey Schedule for Children—Revised (FSSC-R; Ollendick, 1983) is a self-report measure designed to assess several types of fears and anxieties in children and adolescents. The FSSC-R was created as a revision of Scherer and Nakamura's (1968) Fear Survey Schedule for Children (FSS-FC), in an attempt to increase the scale's utility among younger children. The FSSC-R scale contains 80 items assessing children's fears and anxieties, to which raters respond using a 3-point Likert scale, ranging from 1 (*none*) to 3 (*a lot*). The normative sample consists of 126 children, ages 7 to 18 (Ollendick, Matson, & Helsel, 1985). In addition, data were gathered from 25 children, ages 7 to 12, who had received referrals for treatment of school phobia. These individuals make up the clinical sample of the FSSC-R (Ollendick, 1983).

Using a sample of 217 children, ages 8–11, Ollendick (1983) reported very strong internal consistency reliability for the FSSC-R scores, ranging from .92 to .95. In an independent study conducted by Muris, Merckelbach, Ollendick, King, and Bogie (2002), the FSSC-R scores demonstrated moderate to very strong internal consistency reliability across the Total scale ( $\alpha = .96$ ) and five subscales – Fear of Failure and Criticism ( $\alpha = .91$ ), Fear of the Unknown ( $\alpha = .87$ ), Fear of Animals/Minor Injuries ( $\alpha = .85$ ), Fear of Danger and Death ( $\alpha = .89$ ), and Medical Fears ( $\alpha = .65$ ). With regard to test score stability, Ollendick (1983) reported reliability estimates ranging from .81 to .89 over a 1-week test-retest interval and .55 to .62 over a 3-month test-retest interval.

A factor analysis of 217 children's responses on the FSSC-R supported a five-factor structure. The five factors are: Fear of Failure and Criticism, Fear of the Unknown, Fear of Injury and Small Animals, Fear of Danger and Death, and Medical Fears (Ollendick, 1983). These factors are similar to the factors found on Scherer and Nakamura's (1968) original FSS-FC scale and provide support for the

construct validity of the FSSC-R scores. The factor structure of the FSSC-R has proven to be relatively stable across gender, age, and nationality among American and Australian youth (Ollendick, King, & Frary, 1989).

In addition, researchers have examined the convergent and discriminant validity of the FSSC-R scores. Ollendick (1983) reported moderate correlations ( $rs = .32$  to  $.56$ ) between the FSSC-R scores and the scores of the State-Trait Anxiety Inventory for Children (STAIC; Spielberger, 1973)—Trait Scale, supporting the convergent validity of the FSSC-R scores. In contrast, Ollendick reported negative, moderate to strong validity coefficients between the FSSC-R scores and scores of a measure of self-esteem ( $rs = -.62$  to  $-.79$ ) and between the FSSC-R scores and the scores of a measure of internal locus of control ( $rs = -.42$  to  $-.74$ ) among female participants, providing support for the discriminant validity of the FSSC-R scores. Although the FSSC-R scores also demonstrated negative correlations with the scores of these two measures among male participants, they were not significant. Ollendick also reported the results of a contrasted group study in which children with school phobia had significantly higher scores on the FSSC-R than children without phobias. In contrast, Last, Francis, and Strauss (1989) reported mixed results in their contrasted group study with children with different types of anxiety disorders. Specifically, the FSSC-R scores appeared unable to detect differences in mean scale and subscale scores among children with different types of anxiety disorders. However, qualitative analysis of the data indicated that children with different types of anxiety disorders may be differentiated based on the number of intense fears reported.

The FSSC-R has been translated by researchers into several different languages to allow for clinical and research use with culturally and linguistically diverse populations, including Swedish (Svensson & Ost, 1999), Dutch (Bokhorst, Westernberg, Oosterlaan, & Heyne, 2008), Greek (Mellon, Koliadis, & Paraskevopoulos, 2004), Turkish (Erol, 1995), and Spanish-speaking children (Valiente, Sandin, Chorot, & Tabar, 2002). In addition, several new measures have been designed based on the FSSC-R, to allow its use in ethnically and culturally diverse populations. The Fear Survey Schedule for Children and Adolescents-II (FSSC-II; Gullone & King, 1992) is a 75-item self-report measure that includes updated item content, and it was normed on a sample of 918 Australian children and adolescents, ages 7 to 18. Gullone and King examined the

technical adequacy of the measure, and the results suggest the measure has good psychometric properties. Gullone and King's FSSC-II was adapted for use with children in the U.S. (Burnham, 2005; Burnham & Gullone, 1997). The resulting American Fear Survey Schedule for Children (FSSC-AM; Burnham, 2005) contains 98 items and was normed on 720 U.S. children, ages 7 to 18. The psychometric properties reported for the FSSC-AM are similar to those of the FSSC-II (Burnham, 2005). Finally, Shore and Rapport (1998) developed a third revision of the FSSC-R, the 84-item Fear Survey Schedule for Children–Hawaii (FSSC-HI). The FSSC-HI's culturally diverse normative group includes 385 Hawaiian children, ages 7 to 16. Similar to the FSSC-R, the psychometric properties of the FSSC-HI are good. However, factor analysis of the FSSC-HI produced a seven-factor structure rather than the five-factor structure reported for the FSSC-R, FSSC-II (Gullone & King, 1992), and FSSC-AM (Burnham, 2005).

The FSSC-R is a useful instrument for both research and clinical purposes. Unlike other measures of general anxiety, the FSSC-R appears able to tap anxiety associated with fears and phobias found in children. In addition, qualitative data provided by the FSSC-R (i.e., numbers of intense fears) may be especially helpful in identifying children with or at risk for different types of anxiety disorders. An additional strength of the FSSC-R is its versatility, as it has been translated into other languages and normed on diverse populations. However, the multiple variations of the Fear Survey Schedule for Children may also represent a drawback. Specifically, the multiple variations of the scale may make it difficult for researchers and clinicians to identify the most appropriate instrument and normative data for use with various research and clinical populations. A review of the literature indicates that the FSSC-R, FSSC-II, FSSC-AM, and FSSC-HI each continue to be used in current research, and it is unclear what makes one scale more suitable for use than another (e.g. each instrument has updated norms, solid psychometric properties, and has been used successfully with diverse populations).

### ***Internalizing Symptoms Scale for Children***

The Internalizing Symptoms Scale for Children (ISSC, Merrell & Walters, 1998) is a 48-item, self-report measure for children in grades 3 through 6, ages 8 to 12. The instrument is used to assess children's perceptions of internalizing

symptoms (i.e. depression, anxiety, social withdrawal, and somatic problems) and positive and negative affect. The ISSC was developed based on the behavioral dimension approach, an innovative, alternative approach, for classifying behavioral, social, and emotional problems. In this approach, externalizing and internalizing problems are viewed as representing large general behavioral clusters that account for many of the problems children experience. The ISSC assesses one of those general behavioral clusters (i.e. internalizing problems). The ISSC can be administered on an individual basis or in a group setting. Children may complete the ISSC independently or have the items read aloud to them by a test administrator. Children respond to the items on the ISSC using a 4-point Likert scale to indicate how "true" the items are for them: never true, hardly ever true, sometimes true, and often true. The ISSC takes approximately 10 to 15 minutes to complete. Scoring of the ISSC results in three scores: the Total score, the Negative Affect/General Distress score, and the Positive Affect score. The Positive Affect items are reverse scored, thus higher scores are associated with greater levels of distress. The Total, Negative Affect/General Distress, and Positive Affect raw scores are converted to percentile ranks, standard deviations, and standard scores (Merrell, 2008). Qualified professionals should only interpret the ISSC scores, using a four-step process articulated in the manual (Christopher, 2001).

The ISSC normative sample consisted of 2,149 students (1,109 boys and 1,040 girls), ages 8 to 13, in grades 3 through 6. The students were from several states, representing the four geographic regions of the U.S. The sample included a large percentage of children with learning disabilities. There are differing opinions as to whether or not the normative sample adequately represents the racial/ethnic composition of the general U.S. population as well as the distribution of students' special education status (Christopher, 2001a; & Merrell, 2008).

Extensive information is presented in the manual and literature on the reliability and validity of the ISSC scores. Internal consistency reliability for the ISSC Total scores ( $\alpha = .91$ ), Negative Affect/General Distress scores ( $\alpha = .90$ ), and Positive Affect scores ( $\alpha = .86$ ) were in the strong to very strong range (Merrell, 2008). Michael and Merrell (1998) reported on the test score stability of the ISSC scores over a 2-week, 4-week, and 12-week test-retest interval. For the ISSC Total scores, test score stability

coefficients were .84, .76, and .74 over a 2-, 4-, and 12-week test-retest period. The test score stability coefficients for the Negative Affect/General Distress scores and the Positive Affect scores were .81, .73, and .70 and .79, .79, and .72 over a 2-, 4-, and 12-week test-retest interval, respectively. Michael and Merrell reported a general attenuation in symptom endorsement after the first administration of the ISSC.

Evidence supporting the construct validity of the ISSC scores has been found (Merrell, Crowley, & Walters, 1997). Merrell and colleagues used exploratory and confirmatory factor analytic procedures to examine the factor structure of the ISSC. Results of the factor analyses indicated that a two-factor structure provided the best fit for the data. The two factors were named Negative Affect/General Distress and Positive Affect.

Studies investigating the convergent and discriminant validity of the ISSC scores with scores of other measures have been conducted. Moderate to strong correlations with the RCMAS anxiety subscale scores ( $rs = .36$  to  $.68$ ) and the Reynolds Child Depression Scale (RCDS; W. M. Reynolds, 1989) scores ( $rs = .68$  to  $.78$ ; Crowley & Merrell, 2000), and strong correlations with the YSR Internalizing scale scores ( $rs = .71$  to  $.86$ ; Merrell, Anderson, & Michael, 1997) have been found, lending support to the convergent validity of the ISSC scores. In contrast, negligible correlations between the ISSC scores and the RCMAS Lie scale scores ( $rs = .08$ – $.10$ ), and negative, negligible to moderate correlations between the ISSC scores and the Social Skills Rating Scale Social subdomain scores ( $rs = -.51$  to  $-.14$ ; Crowley & Merrell, 2000) have been reported, supporting the discriminant validity of the ISSC scores. Sanders (1996) reported additional evidence of discriminant validity of the ISSC scores in differentiating students with emotional disturbance from students in regular education programs.

The ISSC has been shown to be a good measure for clinical and research purposes, with evidence supporting the reliability and validity of its scores (Merrell, 2008). The ease of administration and scoring of the ISSC make it a useful and attractive instrument to use in a variety of settings, including the schools. The ISSC is unique in that it was designed to assess a broad range of internalizing symptoms and positive and negative affect in the child population rather than assessing symptoms associated with specific disorders. However because the ISSC is a broad assessment tool, it should be used as a screening tool and used in conjunction with other measures for diagnostic purposes

(Christopher, 2001a). At the present time, the ISSC is being updated.

### ***Multidimensional Anxiety Scale for Children***

The Multidimensional Anxiety Scale for Children (MASC; March, Parker, Sullivan, Stallings, & Conners, 1997) is one of the most commonly used measures of childhood anxiety. The MASC is a 39 item, self-report measure designed for use with children and adolescents, ages 8 to 19. The MASC consists of four scales (Physical Harm, Harm Avoidance, Social Anxiety, and Panic/Separation Anxiety) and six subscales (Tense, Somatic, Perfectionism, Anxious Coping, Humiliation Fears, and Performance Fears). In addition, a Total Anxiety scale (consisting of all 39 items), an Anxiety Disorders Index (reflecting diagnostic criteria from the DSM-IV-TR), and a validity scale (assessing response inconsistency) are also available. Children and adolescents respond to the items on the MASC by indicating how “true” the items are for them using a 4-point Likert scale, ranging from 0 (*never*) to 3 (*often*). The MASC is written at a fourth grade reading level, and can be completed in approximately 15 minutes (Christopher, 2001b).

The MASC was normed on 2,698 children and adolescents. The norming sample included children of several racial/ethnic backgrounds: 53.5% Caucasian, 39.2% African American, .7% Hispanic/Latin American, 1.4% Asian American, 2.4% Native American, and 3% classified as Other. Hispanics and Asian Americans were underrepresented in the MASC norming sample and African Americans were overrepresented in the norming sample (Christopher, 2001b).

According to the test developers, moderate to very strong internal consistency reliability estimates ( $\alpha_s = .60$ – $.90$ ) for the MASC scale scores were found. However, some MASC subscale scores, such as Perfectionism, Performance Fears, and Anxious Coping, had much lower internal consistency reliability estimates ( $\alpha_s = .62$ ,  $.60$ , and  $.66$ , respectively; March et al., 1997), indicating that the items on certain subscales may not be homogenous in content. This may be due to the wide range of symptoms and characteristics inherent in some anxiety disorders, but it may also indicate a need for caution when interpreting the assessment results. March, Sullivan, and Parker (1999) examined the test score stability of the MASC scores among a community sample of 142 school children and reported strong to very strong test score stability coefficients over a 3-week test-retest interval ( $rs = .71$ – $.92$ ).

During the development of the MASC, two confirmatory factor analyses were conducted. The results of the two confirmatory factor analyses indicated that a four-factor structure provided the best fit for the data for the norming sample of 2,698 children and adolescents as well as a clinical sample of 390 individuals. The four factors are Physical Anxiety, Harm Avoidance, Social Anxiety, and Panic/Separation Anxiety (March et al., 1997). Further analyses identified six sub-factors, including Tense, Somatic, Perfectionism, Anxious Coping, Humiliation Fears, and Performance Fears. Independent studies have replicated the four-factor structure of the MASC among various clinical, racial, and ethnic groups (Baldwin & Dadds, 2007; Fincham et al., 2008; March, Conners, et al., 1999; Olason, Sighvatsson, & Smari, 2004; Rynn et al., 2006). In contrast, research involving African American adolescents did not support the four-factor structure, and instead supported a three-factor structure (Kingery, Ginsburg, & Burstein, 2009). These results suggest that the MASC factor structure may not be invariant across certain racial/ethnic groups.

Evidence supporting the convergent and discriminant validity of the MASC scores has been examined in relation to the scores of measures external to the test. March and colleagues (1997) reported that studies have compared the MASC scores with scores of other measures of anxiety, depression, and disruptive behaviors, with higher correlations found between the MASC scores and scores of other measures of anxiety overall and lower correlations reported between the MASC scores and the scores of measures of depression and disruptive behaviors. Furthermore, March and Sullivan (1999) conducted a contrasted group study with anxious children, non-anxious children, and children with other psychiatric disorders and found that the MASC scores were able to differentiate between children who were anxious and children who were non-anxious or who had other psychiatric disorders.

Limitations of the MASC include underrepresentation of Hispanic/Latino and Asian-American children and over-representation of African American children in the norming sample. The MASC scores demonstrate adequate reliability and validity in some areas, but exhibit low internal consistency reliability estimates for some of the MASC subscale scores, suggesting the need to interpret the MASC scores with caution. In addition, although the MASC scores demonstrate good discriminant validity, more data are needed to examine differences in the MASC scores among children

with different types of anxiety disorders (rather than simply differentiating between children with and without anxiety disorders). Furthermore, with the emergence of a three-factor structure in a sample of African American adolescents, the MASC scores may need to be interpreted with caution with certain racial/ethnic groups of children and adolescents.

### ***Revised Children's Manifest Anxiety Scale-Second Edition***

The Revised Children's Manifest Anxiety Scale-Second Edition (RCMAS-2; C. R. Reynolds & Richmond, 2008a) is a 49-item, self-report measure used to assess anxiety symptoms in children and adolescents, ages 6 to 19. Written for children and adolescents at a second-grade reading level, individuals respond to the items by simply circling "yes" or "no" to each statement. The RCMAS-2 is comprised of three anxiety subscales (Physiological Anxiety, Social Anxiety, and Worry), a Total Anxiety scale, and two validity indexes (Inconsistent Responding and Defensiveness). The Total Anxiety score is obtained by summing the raw scores from the three anxiety subscales and provides an overall measure of chronic, manifest anxiety. The RCMAS-2 can be administered on an individual basis or in groups, and the time to complete the measure is 10 to 15 minutes (C. R. Reynolds & Richmond, 2008b).

New additions to the RCMAS-2 from the original version of the RCMAS include the Inconsistency index and a Performance Anxiety scale. The Inconsistency index consists of nine pairs of items, eight of which are usually endorsed by the respondent in a similar manner and one pair of items endorsed in a dissimilar manner. The Inconsistency score indicates the number of incongruent response pairs. A high Inconsistency score may suggest careless responding, unfavorable testing conditions, or a reading barrier. The Performance Anxiety scale measures anxiety in performance situations. In contrast to the other scales and subscales, the Performance Anxiety scale does not provide a standard score. If the majority of the items are endorsed on this scale, follow-up assessment is encouraged. High scores on the Performance Anxiety scale may indicate anxiety that hinders academic or test performance. In the latest version of the RCMAS, the Social Anxiety subscale has replaced the Social Concerns/Concentration subscale and it assesses anxiety in social and performance situations. The new Social Anxiety subscale includes six items from the original RCMAS Social Concerns/Concentration subscale

and six new items. Another new feature found on the RCMAS-2 is the Short Form Total Anxiety scale comprised of the first 10 items on the RCMAS-2. This scale provides a brief measure of chronic, manifest anxiety (C. R. Reynolds & Richmond, 2008b).

The RCMAS-2 standardization sample, which consists of 2,368 individuals, came from the full reference sample of over 3,000 children and adolescents. Demographic characteristics of the standardization sample are fairly representative of the U.S. population in 2000. The standardization sample includes roughly equal numbers of males and females (1,201 females and 1,185 males) and it consists of individuals from all major regions of the U.S. Ethnic/racial composition of the standardization sample includes 3.5% Asian, 14.8% Black, 17.1% Hispanic, 1.0% Native American, 61.5% White, and 1.9% Other. Parents' educational level is also reported and is fairly consistent with the educational level of the U.S. adult population in 2000. The RCMAS-2 also includes a clinical sample of 341 children and adolescents with Attention Deficit Disorders, Autism Spectrum Disorders, Anxiety disorders, Depression, Oppositional Defiant Disorders, and Conduct Disorders (C. R. Reynolds & Richmond, 2008b).

The strong correlations between the scores of the RCMAS and RCMAS-2 scales and subscales may portend to the psychometric properties of the RCMAS-2. Correlations between the scores of similar dimensions on the RCMAS and RCMAS-2 ranged from .88 to .96. The internal consistency reliability estimates for the RCMAS-2 scores ranged from .75 to .92 and test score stability coefficients over a one-week test-retest interval ranged from .64 to .76. Test score stability coefficient over the same one-week test-retest interval for the Short Form Total Anxiety scale scores was .54 (C. R. Reynolds & Richmond, 2008b). Overall, the test score stability coefficients are not strong, but the magnitude of these correlations may be due to the small sample size ( $n = 100$ ) used to assess the consistency of the RCMAS-2 scores over time. Additional research with larger samples is needed in the future to explore the test score stability of the RCMAS-2 scores across different test-retest intervals.

Evidence supporting the validity of the RCMAS-2 scores is limited and additional research is needed. However, an exploratory factor analysis of the responses of the individuals in the full reference sample to the RCMAS-2 items produced a five-factor structure (C. R. Reynolds & Richmond, 2008b). The five factors include three anxiety factors (Physiological Anxiety, Social Anxiety, and Worry)

and two Defensiveness factors. The RCMAS-2 factor structure is similar to the RCMAS factor structure reported in the RCMAS manual in which the Lie factor split into two factors (C. R. Reynolds & Richmond, 1985). The three anxiety factors on the RCMAS-2 are comparable to the three anxiety factors found on the RCMAS (C. R. Reynolds & Richmond, 1979). A three-factor structure of anxiety has been consistently reported in the literature, not only for the RCMAS (e.g. Paget & C. R. Reynolds, 1984; C. R. Reynolds & Richmond, 1979; Scholwinski & C. R. Reynolds, 1985), but its predecessor the Children's Manifest Anxiety Scale (CMAS; Castaneda, McCandless, & Palermo, 1956; Finch, Kendall, & Montgomery, 1974).

The RCMAS-2 scores were further evaluated by convergent and discriminant validity comparisons with the scores of three separate measures: the Children's Measure of Obsessive-Compulsive Symptoms (CMOCS; C. R. Reynolds & Livingston, 2010), the Children's Depression Inventory-Short Form (CDI-Short Form; Kovacs & Multi-Health Systems, 2003), and the parent and teacher forms of the Conners' Rating Scales (CRS; Conners, 1989). The CMOCS scores correlated the highest with the RCMAS-2 Total Anxiety scale scores and the scores of conceptually similar subscales of the RCMAS-2 among 2,550 children and adolescents from the reference sample. The CDI-Short form scores were moderately correlated ( $rs = .45$  to  $.68$ ) with the RCMAS-2 anxiety scores in a sample of children with ADD (C. R. Reynolds & Richmond, 2008b). Moderate correlations were expected as the constructs of depression and anxiety overlap in the area of negative affectivity (Watson & Clark, 1984). In contrast, the correlations between the scores of the Conners' Parent and Teacher rating forms and the scores of the RCMAS-2 anxiety scale and subscales in the same sample of children with ADD ranged from  $-.37$  to  $.32$ , supporting the discriminant validity of the RCMAS-2 scores (C. R. Reynolds & Richmond, 2008b). Finally, evidence supporting the discriminant validity of the scores of the RCMAS-2 comes from comparisons of children diagnosed with various clinical disorders and children in the standardization sample. Children with anxiety disorders had higher mean raw scores on the RCMAS-2 anxiety scale and subscales than the children in the standardization sample, and the children in the standardization sample had higher mean raw scores on the RCMAS-2 anxiety scale and subscales than children with externalizing disorders (C. R. Reynolds & Richmond, 2008b).

The RCMAS-2 provides encouraging evidence of improvement from the previous version of the measure. The standardization sample is exemplary and the manual provides excellent information regarding administration and interpretation. However, in some instances, the psychometric properties of the RCMAS-2 could be stronger, especially with regards to the test score stability coefficients. Additional research with larger samples of children and adolescents is needed to address the stability of the RCMAS-2 over time. Furthermore, replication of the factor structure of the RCMAS-2 is needed with large independent samples. Considering its brevity, the RCMAS-2 is a good measure, with the Total Anxiety scale scores providing the most sensitive and accurate indication of elevated levels of anxiety in children and adolescents.

### ***Reynolds Adolescent Depression Scale-Second Edition***

A self-report measure of depressive symptoms, the Reynolds Adolescent Depression Scale-Second Edition (RADS-2; W. M. Reynolds, 2002a), is the most recent iteration of the original 1986 Reynolds Adolescent Depression Scale (RADS; W. M. Reynolds, 1986). As a measure of adolescent depression, the RADS-2 is age inclusive, allowing administration among individuals, ages 11 to 20. The design of the 30 item RADS-2 is based upon converging depressive symptomatology across a number of formalized diagnostic paradigms (i.e. the DSM-IV, 1994; and the International Classification of Diseases-Tenth Edition, ICD-10; World Health Organization, 1992). Though based upon conceptual nosology of depressive symptoms, the RADS-2 is a measure that assesses the severity of depressive symptoms and should not be used as a diagnostic tool. Yet as a measure of symptom severity, the measure taps the following domains: Dysphoric Mood, Anhedonia/Negative Affect, Negative Self-Evaluation, and Somatic Complaints. In addition, the RADS-2 includes a Depression Total Scale. The RADS-2 is designed for use in individual or group settings. Respondents choose from one of the four available response options (*almost never, hardly ever, sometimes, or most of the time*) to describe the frequency of occurrence of depressive symptoms. Completing the RADS-2 requires approximately five minutes for most adolescents, though those who have difficulty reading may require additional time. However, most respondents will have little or no difficulty completing this measure, as the RADS-2

was written at a third grade reading level (W. M. Reynolds, 2002b).

The school-based restandardization sample of the RADS-2 was drawn from a sample of 9,052 adolescents from seven states and the Canadian province of British Columbia. The regional sampling method included states from the Eastern seaboard, the Midwest, and the Northwest. Test developers reduced this total sample to 3,300 participants (the school-based restandardization sample) using a stratified sampling procedure based on the 2000 U.S. Census to reflect the then current ethnic population rates. The three age groups described in the RADS-2 manual include 11 to 13, 14 to 16, and 17 to 20 year olds. Each of these three groups comprises 1,100 participants and contains an equal number of male and female adolescents (W. M. Reynolds, 2002b).

Reliability studies revealed strong to very strong reliability coefficients for the RADS-2 scores. Internal consistency reliability estimates for the RADS-2 Depression Total scores ranged from .91 to .96. Coefficient alphas for the RADS-2 four subscale scores ranged from .78 to .92. Test score stability coefficients for the RADS-2 Depression Total scale scores over a two-week test-retest interval ranged from .85 to .89. Temporal stability coefficients for the RADS-2 four subscale scores over the same test-retest period ranged from .77 to .85 (W. M. Reynolds, 2002b).

The RADS-2 manual provides extensive validity evidence for the scores of the RADS-2 and the original RADS. W. M. Reynolds (2002b) reported the results of a factor analysis of the responses of the total school sample to the RADS-2 items, producing a four-factor structure. The four factors were named Dysphoric Mood, Anhedonia/Negative Affect, Negative Self-Evaluation, and Somatic Complaints. The strong factor scores and organization of the items in the factor analysis provided additional nosological evidence supporting the use of the RADS-2 as a measure of depression. Strong evidence was also found for the convergent validity of the RADS-2 Depression Total scale scores. The RADS-2 Depression Total scale scores were compared to the scores of a number of other scales and interviews measuring psychological distress, including the Hamilton Depression Rating Scale (Hamilton, 1960) interview ( $r = .82$ ), the MMPI Depression scale ( $r = .78$ ), and the APS Major Depression ( $r = .76$ ) and Dysthymic Disorder ( $r = .74$ ) scales. In contrast, the RADS-2 scores were compared to scores

of academic achievement and social desirability, and negligible to small validity coefficients of  $-.25$  to  $.11$  were reported (W. M. Reynolds, 2002b), lending support to the discriminant validity of the RADS-2 scores. Furthermore, the results of a study conducted by the author of the measure clearly demonstrated the clinical efficacy of the RADS-2 Depression Total scores in a group of 214 adolescents, 107 individuals with a primary diagnosis of a Major Depressive Disorder and a matched group of 107 non-referred individuals. The author considered several cutoff scores to differentiate the two groups. Ultimately, a RADS-2 Depression Total T score of 61 was selected and produced a hit rate of 88%, and a specificity and sensitivity level of 84% and 92%, respectively (Carlson, 2005).

The RADS-2 is an exemplary measure and serves as an excellent model for test developers to follow in designing future screening instruments to assess symptom severity in the adolescent population. The RADS-2 has many strengths including its brevity, efficient administration and scoring procedures, a clear and concise manual containing information and caveats about the scale's use and interpretation, a strong norming sample, and well-documented evidence in support of the RADS-2 psychometric properties and few, if any weaknesses or limitations. The RADS-2 is an excellent addition to the group of narrow-band instruments designed specifically to assess certain aspects of an adolescent's affect.

### ***Reynolds Child Depression Scale-2nd Edition***

The Reynolds Child Depression Scale-2nd Edition (RCDS-2; W. M. Reynolds, 2010a) is a brief paper-and-pencil measure used to assess depressive symptomatology in children. The RCDS-2 is suitable for children, ages 7 to 13, in grades 2 through 6 (W. M. Reynolds, 2010b). The items on the RCDS-2 consists of all 30 items found on the original RCDS and assesses the severity of a range of depressive symptoms, such as cognitive, vegetative, somatic and social-interpersonal symptoms. Children respond to 29 of the 30 items using a 4-point Likert scale, ranging from 1 (*almost never*) to 4 (*all of the time*). The other item consists of five smiley-type faces, with a very sad and a very happy smiley face serving as anchors. Children select the face that best represents how they have felt during the past two weeks. Seven of the 30 RCDS-2 items are reverse scored to provide a check for inconsistent responding. There are also

seven critical items on the RCDS-2 that discriminate between children who are depressed and not depressed. Items on the RCDS-2 were written at the second-grade level. However, for children in grades 2, 3 and 4, as well as children with learning difficulties, the RCDS-2 should be administered verbally. The RCDS-2 is suitable for individual and group administration and takes approximately 10 minutes to complete. Scoring of the RCDS-2 involves the use of built-in scoring keys and simply summing the raw scores of the items to obtain a Total raw score. A standard score and percentile rank can also be derived. Although the RCDS-2 does not provide for a formal diagnosis of depression, an empirically tested cutoff score (i.e. a T score of 65) is available to offer an indication of clinically relevant levels of depression (W. M. Reynolds, 2010b).

The RCDS-2 also comes with a shortened version, the Reynolds Child Depression Scale—2nd Edition: Short Form (RCDS-2:SF; W. M. Reynolds, 2010c). Similar to the RCDS-2, the RCDS-2:SF assesses the severity of depressive symptomatology in children between the ages of 7 and 13 and in grades 2 through 6. The RCDS-2:SF, which takes approximately 2 to 3 minutes to complete, is billed as a quick screener for childhood depressive symptomatology. The RCDS-2:SF requires a second-grade reading level to complete. However, it is permissible for children with reading difficulties to be administered this measure verbally. The 11 items on the RCDS-2:SF were selected from the 30-item RCDS-2. The response format is similar to the RCDS-2, with children responding to 10 of the 11 items using a 4-point Likert scale, with 1 (*almost never*) and 4 (*all the time*) serving as anchors. Children respond to the last question by circling one of the five smiley-type faces, with a very sad face and a very happy face serving as anchors. Four items on the RCDS-2:SF were identified as critical items that discriminate between children who are depressed and not depressed. Two items on the RCDS-2:SF were reverse scored to reduce response pattern bias. A Total raw score (including a standard score and percentile rank) is derived by summing the raw scores for each item. This Total raw score is then compared with an associated cutoff score (i.e. a T score of 62) to identify children who might be exhibiting clinically significant levels of depressive symptomatology. Despite this metric, the RCDS-2:SF is emphasized as not being a diagnostic tool for depressive symptoms (W. M. Reynolds, 2010b).

The standardization sample for the RCDS-2 and RCDS-2:SF consists of 1,100 children (550 boys

and 550 girls) between the ages of 6 and 13 (with 99% of the children between 7 and 12 years of age) and in grades 2 through 6. The sample approximates the 2007 U.S. Census in both gender and ethnic backgrounds. Approximately 43% of the standardization sample consists of children from different ethnic minority backgrounds (W. M. Reynolds, 2010b).

Studies on the reliability and validity of the RCDS-2 scores have been conducted. The internal consistency reliability estimates for the RCDS-2 Total scores for the standardization sample was .90. Coefficient alphas were also reported for the RCDS-2 Total scores in the standardization sample for children by gender ( $\alpha = .89$  for boys and  $\alpha = .91$  for girls), grade level ( $\alpha_{\text{S}} = .85$  to  $.92$  for grades 2 through 6) and ethnicity ( $\alpha_{\text{S}} = .87$  to  $.93$ ; W. M. Reynolds, 2010b). These internal consistency reliability estimates are in the strong to very strong range. To our knowledge, there is no study that has been conducted to examine the test score stability of the RCDS-2 scores.

For the RCDS-2:SF, the internal consistency reliability estimate for the Total scores was strong ( $\alpha = .85$ ). The internal consistency reliabilities were also reported for children by gender ( $\alpha = .85$  for boys and  $\alpha = .86$  for girls), grade level ( $\alpha_{\text{S}} = .74$  to  $.89$  for grades 2 through 6) and ethnicity ( $\alpha_{\text{S}} = .82$  to  $.90$ ; W. M. Reynolds, 2010b). These reliability estimates are in the strong to very strong range. Like the RCDS-2, temporal stability for the RCDS-2:SF scores has not been examined.

Evidence supporting the construct validity of the RCDS-2 and RCDS-2:SF scores has been found. Principal component analysis followed by the varimax rotation procedure of 1,100 children's responses on the RCDS-2 resulted in a four-factor solution—emotional or emotional self-directed cognitions factor, anhedonia factor, cognitive-behavioral factor, and somatic-vegetative factor (W. M. Reynolds, 2010b). Convergent and discriminant validity of the RCDS-2 scores have been examined in relation to scores external to the test. W. M. Reynolds reported moderate correlations of .44 to .60 between the scores of the RCDS-2 and RCDS-2:SF and the scores of the APS, the BVS Victimization scale and the Revised Body Esteem Scale for Children (Mendelson & White, 1993). These findings support the convergent validity of the RCDS-2 and RCDS-2:SF scores. In contrast, W. M. Reynolds (2010b) reported low validity coefficients between the RCDS-2 and RCDS-2:SF scores and the BVS

Bullying Scale scores ( $r = .29$  and  $r = .24$ , respectively), and self-reported average school grades ( $r = -.30$  and  $r = -.27$ , respectively). These findings lend support for the discriminant validity of the RCDS-2 and RCDS-2:SF scores.

Like its predecessor, the RCDS, strengths of the RCDS-2 and the RCDS-2:SF include the ease of administration and scoring, low reading level for younger children, and brevity of the measures. Limitations of the measures include the number of independent research studies conducted to date to address the psychometric properties of the measures. In addition, no studies are reported in the RCDS-2 manual on the test score stability of the RCDS-2 and RCDS-2:SF scores. Independent research studies need to be conducted in the future on these newly published, brief measures that assess the severity of depressive symptomatology in children.

### ***Social Phobia and Anxiety Inventory for Children***

The Social Phobia and Anxiety Inventory for Children (SPAI-C; Beidel, Turner, & Morris, 1998) was developed to screen for and measure the behavioral, cognitive and somatic aspects of social phobia in children and young adolescents in a variety of settings, including outpatient clinics, inpatient clinics, schools, juvenile detention facilities, and residential treatment settings. The SPAI-C is a 26 item self-report inventory for children and adolescents, ages 8 to 14. For those adolescents 14 and older who are socially anxious, the Social Phobia and Anxiety Inventory (SPAI; Turner, Beidel, Dancu, & Stanley, 1989) may be used. To complete the SPAI-C, children and young adolescents need to be able to read at least at a third-grade reading level. Individual test administration is recommended for the measure. However, the SPAI-C may be administered in a group setting. Test administrators can be clinical or non-clinical staff. In the administration of the measure, children read each statement on the SPAI-C and respond by circling how frequently each place or activity makes them feel nervous or scared. The SPAI-C uses a 3-point Likert scale, ranging from 0 (*never or hardly ever*) to 2 (*most of the time or always*). The SPAI-C takes approximately 20 to 30 minutes to complete. Scoring of the SPAI-C is relatively easy and involves the summing of the raw scores for each item. The SPAI-C Total score is obtained from the summing of these raw scores, and a SPAI-C Total score of 18 is recommended as the cut score for screening purposes. Qualified professionals should interpret

the SPAI-C. While the SPAI-C Total score provides an overall assessment of symptom intensity across settings, clinicians may examine response patterns on the protocol to determine important aspects of children's fears in different social situations. Using this information qualitatively may assist in developing effective treatment plans (Beidel, Turner & Morris, 2000).

The normative sample for the SPAI-C included 154 children, ages 8 to 17 ( $M = 11.5$ ). Fifty-three percent were female and 47% were male. Racial/ethnic composition of the sample included 83% Caucasian, 14% African American, 2% Asian American, and 1% Native American. A large portion of the normative sample included children and adolescents with psychiatric disorders, particularly children and adolescents with anxiety disorders (Beidel, Turner, & Morris, 1995).

Reliability and validity of the SPAI-C scores have been examined. Coefficient alphas for the SPAI-C Total scores in a sample of 148 children and adolescents and the normative sample of 154 children and youth were .92 (Beidel, Turner, & Fink, 1996) and .95 (Beidel, Turner, & Morris, 1995), respectively. Beidel and colleagues (1995) reported test score stability coefficients for the SPAI-C scores of .86 over a two-week test-retest interval among 62 individuals in the normative sample and .63 over a 10-month test-retest interval among 19 individuals in the normative sample who participated in the two-week test-retest session.

Beidel et al. (1995) conducted a number of studies to evaluate the validity of the SPAI-C scores. A principal-component factor analysis with varimax rotation of the responses of the 154 children and adolescents in the norming sample to the SPAI-C was performed. Results of the factor analysis indicated that a three-factor solution produced the best fit. The three factors (Assertiveness/General Conversation, Traditional Social Encounters, and Public Performance) together accounted for 60% of the variance. The Assertiveness/General Conversation factor consisted of items that measured negative assertion and general conversation skills, the Traditional Social Encounters factor included items that assessed fears of particular situations, and the Public Performance factor consisted of items that measured fears of performance situations. These findings provided support for the construct validity of the SPAI-C scores. Beidel and colleagues (1995) also found support for the convergent and discriminant validity of the SPAI-C scores. The authors reported a moderate validity

coefficient of .50 between the SPAI-C scores and the STAI-C Trait scale scores in a subsample of 38 children from the normative sample. In addition, the SPAI-C scores were compared to the scores of the five subscales (Fear of Failure and Criticism, Fear of the Unknown, Fear of Injury and Small Animals, Fear of Danger and Death, and Medical Fears) of the FSSC-R, and moderate correlations ( $rs = .41-.53$ ) were noted in a subsample of 59 children from the normative sample. Also, children's scores on the SPAI-C were compared to parents' ratings on the CBCL in a subsample of 74 children from the normative sample. The SPAI-C scores correlated moderately with the CBCL Internalizing scale scores ( $r = .45$ ), moderately and negatively with the CBCL Social Competence scale scores ( $r = -.33$ ), and negligibly with the CBCL Externalizing scale scores ( $r = .18$ ; Beidel et al., 1995). These findings provide support for the convergent and discriminant validity of the SPAI-C scores. Furthermore, a contrasted group study comparing children with social phobia to children with externalizing disorders and children without a diagnosis was conducted using the SPAI-C. Beidel and colleagues (1996) reported the mean score on the SPAI-C for children with social phobia ( $M = 24.6$ ) was significantly higher than the mean score for children in the externalizing group ( $M = 12.8$ ) and the no diagnosis group ( $M = 11.05$ ), supporting the discriminant validity of the SPAI-C scores.

The strengths of the SPAI-C include a strong conceptual basis and theoretical rationale, assessment of a wide range of social fears across different settings, brevity of the measure, convenience and ease of use, quick administration and scoring (Allen, 2003), and availability of the measure in several different languages (English, French-Canadian, and Spanish; Spenciner, 2003). In contrast, limitations of the measure include a lack of detailed description of the test development sample (Spenciner, 2003), and few reliability and validity studies in comparison to comparable instruments presented in the manual (Allen, 2003), especially studies conducted by independent researchers. Overall, the SPAI-C has a number of strengths as a screener of children and young adolescents' social fears in a variety of settings and situations.

### Clinical Interviews

Along with structured personality inventories, less formal (i.e. informal) methods such as clinical interviews are available to assess the personality

and affect of children and adolescents. In this section, information on some of the most common semi-structured and structured interviews used with children and adolescents will be discussed.

### ***Diagnostic Interview for Children and Adolescents—Fourth Edition***

The Diagnostic Interview for Children and Adolescents-Fourth Edition (DICA-IV; Reich, Welner, & Herjanic, 1997) is a semi-structured instrument which assesses the psychiatric status of 6 to 18 year old children using the DSM-IV criteria. The purpose of the DICA-IV is to make psychiatric diagnoses; it can also be used in epidemiological and clinically-oriented research. Barbara Herjanic initially developed the DICA in the early 1970s. The original version of the DICA was highly structured and was designed to be administered by lay interviewers (Reich, 2000). The current computerized version was published in 1997 by Multi-Health Systems (Reich, Welner, & Herjanic, 1997). It can be administered by highly-trained lay persons or, if the respondent has adequate reading skills, can be self-administered.

There are two versions of the DICA-IV—one for the child/adolescent and one for the parent. The child/adolescent version assesses a wide variety of clinical diagnostic categories, including ADHD, substance use, depressive disorders, anxiety disorders, conduct disorders, eating disorders, gender identity, etc. There is also a critical items feature to aid in highlighting high-risk responses such as suicidal ideation, violent tendencies, and drug abuse. Scoring consists of linking the interviewee's responses to relevant diagnostic categories which, in turn, allows the clinician to determine the focus of a follow-up interview (M. Marocco, personal communication, June 30, 2009). In terms of response format, respondents can answer with a "firm yes" or "firm no." Less firm answers—or "evasive" answers—are probed (Reich, 2000). The DICA-IV format allows interviewers to probe responses with pre-defined probes; interviewee requests for information and clarification are answered with scripted material (Orvaschel, 2006). The child/adolescent version has 26 clinical diagnostic categories. A branching question structure is employed; the interview offers over 1,600 possible questions. Interviewers can choose to administer either some or all of the categories (M. Marocco, personal communication, June 30, 2009). The time required to administer the DICA-IV is between one and three hours, depending upon the number of categories of pathology that are probed.

For the self-administered computerized version, the child or adolescent must have at least a fourth-grade reading level. Interviewees with beginning reading skills and skill deficits need to have the material read aloud to them (Reich, Cottler, McCallum, Corwin, & VanEerdewegh, 1995). It is also recommended that a nearby assistant be available to answer questions for those interviewees who can read the material themselves.

Several limitations of the DICA-IV include no norming sample and no reliability and validity data for this version of the instrument (M. Marocco, personal communication, June 30, 2009). To its credit, the DICA-IV can be used to aid clinicians in their attempts to diagnose their clients. It is widely used in both research and clinical settings and can be used with both younger children and adolescents. The computerized version has been found to be acceptable to children and adolescents (Reich et al., 1995).

### ***National Institute of Mental Health—Diagnostic Interview Schedule for Children Version IV***

The National Institute of Mental Health Diagnostic Interview for Children Version IV (NIMH DISC-IV; National Institute of Mental Health, 1997) is a structured diagnostic interview instrument that addresses more than thirty psychiatric diagnoses possibly present in children and adolescents, ages 6 to 17 (Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000). It can be used in clinical studies for research purposes, in mental health settings to aid in diagnosis, and in schools as a prevention/screening instrument. It has six diagnostic sections based on the criteria of the DSM-IV and the ICD-10. These sections cover anxiety disorders, mood disorders, disruptive disorders, substance-abuse disorders, schizophrenia, and miscellaneous disorders such as eating and elimination disorders (National Institute of Mental Health, n.d.). The instrument includes parallel parent and child versions and is available in English and Spanish. It has been in development since 1979, was the product of an initiative by the NIMH Division of Biometry and Epidemiology, and was developed to be used for large-scale surveys whose purpose was to determine the prevalence of mental disorders and the need for related services for children (Shaffer et al., 2000).

The questions on this instrument are designed to be read exactly as written. Responses are typically limited to "yes," "no," and "sometimes" or "somewhat." The questions are organized in a branching-tree

question structure. The categories of questions for the child version include: (1) 358 “stem” questions asked of everyone; (2) 1,341 contingent questions asked only if the previous stem question were answered positively; (3) 732 questions about age of onset, degree of impairment, and treatment; and (4) 499 “whole-life” questions—or questions that pertain to a past history of symptoms—which also employ a stem-contingent structure (National Institute of Mental Health, n.d.). The administration time for the NIMH DISC-IV is dependent upon the number of symptoms that are endorsed, and the interview averages approximately 70 to 120 minutes. Computers are utilized in the administration and scoring of the NIMH DISC-IV.

Depending on the disorder, informant, and sample tested, kappa test-retest reliability estimates range from .05 to .93 (Shaffer et al., 2000). For combined (parent and child) informants in community samples, kappa statistics fall within the moderate range for some common disorders: ADHD ( $k = .48$ ), Oppositional Defiant Disorder ( $k = .59$ ), Conduct Disorder ( $k = .66$ ), and social phobia ( $k = .44$ ; Orvaschel, 2006). Orvaschel notes that there is a lack of validity studies for this instrument.

In listing advantages of the NIMH DISC-IV, Shaffer and colleagues (2000) indicate that it is relatively inexpensive to use in a research setting and it is standardized and thus minimizes the possibility of measurement error. The NIMH DISC-IV has a variety of parallel versions and translations and is widely used throughout the world, which allows international comparisons of prevalence and incidence data (Orvaschel, 2006). In terms of limitations, Shaffer and colleagues (2000) state that the instrument is unable to address invalid responses of an interviewee who misunderstands a question, and—since it is restricted to assessing the symptoms of the DSM and ICD systems—it is unable to allow atypical presentations to be revealed. Additionally, some researchers and clinicians consider it to be too structured, thus discouraging clinical judgment in a diagnostic instrument (Orvaschel, 2006).

### ***Kiddie Schedule for Affective Disorders and Schizophrenia for School-Aged Children***

The Kiddie Schedule for Affective Disorders and Schizophrenia for School-Aged Children (K-SADS; Orvaschel, 1995) is a semi-structured interview designed to aid in the identification and diagnosis of psychopathology in children and adolescents (Orvaschel, 2006). The interview format is designed

to allow for the collection of information from children and adolescents, ages 7 to 18, and their parents in order to determine both present and lifetime versions of thirty-two DSM-IV Axis I psychiatric disorders (Reynolds, 2006). The initial version was designed in the late 1970s to provide a systematic method for identifying symptoms of depression in children who participated in a research program (Orvaschel, 2006). Various versions have been developed since that time.

The K-SADS is intended to be administered by trained clinicians rather than lay interviewers. It requires a brief (five minutes) unstructured time for the interviewer to develop rapport with the interviewee. The interviewer then moves on to sections on history of treatment and medication for emotional problems, then proceeds to specific topics of psychopathology, including mood disorders, psychoses, anxiety disorders, and so on (Orvaschel, 2006). The primary caregiver is interviewed before the child/adolescent. Responses of each are recorded and summary ratings for each symptom are made during the child’s interview. Diagnoses are then based on the summary ratings of both respondents. The interviews of each informant may take from 30 to 60 minutes, depending upon the nature and extent of the symptoms of psychopathology endorsed.

Whereas reliability was initially established with patient populations in New York and Pittsburgh, there is no norming sample and the expectation is that reliability will be established at the research site (Orvaschel, personal communication, July 23, 2009). Orvaschel (2006) reported an interrater reliability mean kappa coefficient of .66 for version 5 of the K-SADS-Epidemiologic Version. Kappa coefficients for specific disorders range from .45 to .81. An important advantage of the K-SADS is that it has been widely used throughout the world in clinical and epidemiological research studies. The K-SADS is considered the “gold standard” among diagnostic interview instruments (Kessler et al., 2009). There are versions available in different languages throughout the world, not only in widely used languages such as Spanish (Ulloa et al., 2006) but also in less widely used languages such as Korean (Kim et al., 2004) and Icelandic (Lauth, Magnússon, Ferrari, & Pétursson, 2008). The various versions generate helpful data on “episode duration, age of onset, treatment characteristics, and syndrome-specific impairment” (Ambrosini, 2000, p. 56). Disadvantages include limited data on reliability and validity.

## **Anxiety Disorders Interview Schedule for DSM-IV**

The Anxiety Disorders Interview Schedule for DSM-IV (ADIS; Silverman & Albano, 1996) is a semi-structured clinical interview derived from the DSM-IV. The purpose of the ADIS is to aid clinicians in diagnosing anxiety and related disorders in children, ages 6 to 18. The ADIS consists of two versions – a child version and parent version. The interview should be conducted by a trained clinician and it takes approximately one hour per respondent to administer.

The ADIS utilizes a yes/no response format for each diagnostic category, with follow-up probes used to obtain clarification. Endorsement of a “yes” response to an interview question directly corresponds to the DSM-IV diagnostic criteria. Scoring occurs by summing the number of “yes” responses. If a sufficient number of “yes” responses warrant a possible diagnosis, the clinician asks the respondent to rate the level of impairment or interference caused by the symptoms. Children rate the level of impairment of their symptoms on a 9-point “feelings thermometer”, ranging from 0 (*no impairment*) to 8 (*severe impairment*). Parents respond on the same 9-point scale (0 to 8), as to the degree to which the child’s symptoms interfere or “mess things up.” Child and parent interviews are considered jointly when issuing a diagnosis as well as determining the level of impairment. When impairment ratings vary between the child and parent, the clinician defers to the higher rating.

The ADIS is an excellent and renowned tool for clinicians wanting corroborating evidence for diagnostic purposes, and researchers concerned with the psychometrics of instruments. Silverman, Saavedra, and Pina (2001) reported kappas of .61 to 1.00 and interclass correlations of .81 to .95 for the ADIS. Test-retest reliability coefficients over a 7 to 14 day test-retest interval for the child and parent impairment ratings ranged from .60 to .84, with one correlation coefficient falling below .60, and from .56 to .84, respectively (Silverman et al., 2001). Additionally, the ADIS has been shown to produce high agreement between the child and parent. However, research has shown that child-parent agreement and agreement consistency over time (child-child, parent-parent) varies across specific anxiety disorders diagnosed, research studies, and motivational level of the child (Reuterskiöld, Öst, & Ollendick, 2008; Silverman et al., 2001). Despite these differences, the ADIS is an important tool in the field for evaluating childhood anxiety (Orvaschel, 2006).

## **Behavioral Observations**

Besides structured personality inventories and clinical interviews, there are other methods to assess children and adolescents’ affect. Informal methods such as behavioral observations can be used to identify behavioral indicators of negative affect or emotion in children and adolescents. In this section, the use of informal methods to assess children and adolescents’ affect will be reviewed. In addition, this chapter will close with a brief discussion of functional assessment and analysis and how this informal method of assessment can be used possibly in the future to gain a better understanding of the development and maintenance of negative affect and maladaptive thoughts in children and adolescents.

According to a recent survey by Shapiro and Heick (2004), behavioral observation is one of the most common assessment tools used by mental health professionals in the schools. Observations inform the assessment and treatment process through the gathering of baseline information, assisting in the determination of benchmarks for setting treatment goals, and validating of information from semi-structured and structured interviews and objective questionnaires. Martin and Pear (2003) outline two types of observation, direct and indirect. For issues of affect, direct observation can be problematic because of the covert nature of many symptoms, but some methods of observation for problems related to affect provide helpful information and will be discussed.

### **Direct Behavioral Observations**

One way to gain a better understanding of a referal problem is to observe the behaviors of concern in the natural environment. Several observational techniques can be used depending on the problem behavior, the environment, or the time constraints involved. Direct informal observations involve writing down a description of behaviors and environmental events in sequence without any systematic measurement. While this technique is helpful in gathering descriptive information, it is not a reliable technique for gathering quantitative information (e.g. frequency or duration of behavior). However, direct informal observation can help the clinician better understand the behaviors of concern and the potential environmental factors that may trigger or maintain the behavior, and this may be an important step in designing a more systematic observation for future use.

A second way to record behavior in the natural environment is to create a systematic behavioral

measurement system. This kind of direct observation requires an observable and measurable definition of the behavior in order to achieve consistent results over time. Guidelines outlining the development of reliable observation protocols are beyond the scope of this chapter, but these can be found in most books on behavior modification (e.g. Cooper, Heron, & Heward, 2007; Martin & Pear, 2003). Systematic behavioral observation is commonly used for externalizing disorders, but several researchers have indicated that there are observable behaviors related to problems of affect. For example, Kazdin (1988) identified several broad categories that may indicate symptoms of depression, including social activity, solitary behavior, and affect-related facial expression. Using these broad categories, it would be possible to create an observation form to record the amount of time a child spends interacting with others, the amount of time the child spends alone, and the frequency of different facial expressions. It is important for the clinician to also observe other same-sex peers who are in the vicinity. This allows the clinician to compare the behavior of the child to other peers in the same situation (Merrell, 2008).

Glennon and Weisz's (1978) work provides another example of using observable behaviors for affect related disorders. The authors designed a coding system for 30 anxiety-related behaviors in preschool children, including verbal expressions (e.g. physical complaints), affect-related expressions (e.g. facial expressions of fear), gratuitous bodily movements (e.g. moving of feet), and other behaviors such as nail-biting, chewing on other objects, and eye contact avoidance. Glennon and Weisz found that these behaviors could be reliably coded by independent observers, with interobserver agreement ranging from .66 to .99, with a .92 level of agreement across all categories.

### ***Behavioral Avoidance Tasks***

Observing behavior in the natural environment is not always an option, especially for affect-related problems. Another method to directly observe these behaviors is to create controlled analogue situations which will induce the behaviors of concern. One method that has been used frequently in research and practice is the Behavioral Avoidance Test (BAT; Schniering, Hudson, & Rapee, 2000). In a BAT, the clinician introduces the child to a stimulus or situation which brings about avoidance or anxious behaviors in the individual. It is then possible to record aspects of the child's behavior in the situation. For example, if a child is afraid of dogs, the

clinician could have a small, tame dog in a room and have the child enter the room with the dog. Several types of measures can then be taken, such as length of time the child spends in the room, how close the child comes to the dog, how long it takes before the child begins to approach the dog, or percentage of steps completed in a standardized protocol that brings the child into more intimate interactions with the dog (Ollendick et al., 2009; Woodruff-Borden & Leyfer, 2006). In addition to the behavioral measures, BATs often include subjective scales, such as a fear thermometer, to assess the level of fear a person is experiencing (Walk, 1956). This allows the clinician to gather both observable measures and ratings of the child's subjective feelings in the feared situation. BATs can also be designed to include several different types of tasks which also have several graded steps to be performed (Steketee, Chambliss, Tran, Worden, & Gillis, 1996).

BATs have been used in research to assess behavioral symptoms of several disorders, including social anxiety (Compton, Grant, Chrisman, Gammon, Brown, & March, 2001), phobias (Ollendick et al. 2009), and obsessive compulsive disorders (Barrett, Healy, & March, 2003). Because BATs are not standardized, Schniering et al. (2000) suggests that BATs are most useful for assessing simple phobias because the nature of other anxiety disorders usually include a complex set of variables that would be difficult to recreate in a clinical setting. Also, because many of these tasks are often tailored to individual children, there has not been extensive research into the psychometric properties of BATs, but studies which have used them have reported acceptable levels of reliability and concurrent validity. For instance, Hamilton and King (1991) completed a test-retest reliability study using a BAT for children diagnosed with a phobia for dogs. In this study, the assessments were seven days apart and the reliability was .97 between the two administrations of the BAT, which indicates very strong temporal stability. Ollendick et al. (2009) also examined the reliability of the BAT over a one-hour test-retest interval and reported stability coefficients of .87 for the behavioral avoidance tasks and .92 for ratings of subjective levels of distress among a group of children with phobias. Although these coefficients are in the strong to very strong range, the test-retest period was relatively short and it is difficult to determine whether the BAT would have shown adequate temporal stability over extended periods of time. Steketee et al. (1996) found evidence to support the convergent validity of the BAT with individuals,

adults not children, with obsessive-compulsive disorders. Moderate correlations were reported for the BAT and scores of the Maudsley Obsessional Compulsion Inventory (MOCI: Hodgson & Rachman, 1977) Composite scale ( $r = .46$ ), and the Yale-Brown Obsessive Compulsive Scale (YBOCS; Goodman et al., 1989) Composite scale ( $r = .49$ ), Avoidance subscale ( $r = .61$ ) and Compulsions subscale ( $r = .63$ ). These findings indicate that the BAT measures aspects of obsessions and compulsive behaviors that are similar but different from those assessed by standardized questionnaires.

One advantage of a BAT is that it allows the clinician to ask about subjective levels of fear or anxiety while the child is in the situation, which is not something that can happen easily with observations in the natural environment. Also, this helps the clinician view behaviors that may be difficult to observe in the natural environment because of their low frequency, such as a phobic reaction to animals. Each task should be tailored for the individual child based on his/her specific fears or anxieties, making this method most useful for pre/post-treatment assessment of behavior change. However, because BATs are analogue situations, the clinician must always keep in mind that it is possible that the child's behavior may differ if the individual was in the same situation, but in the natural environment. Because they are controlled situations, the child may feel more able to perform in the feared situation than he/she would outside of a clinical setting.

### ***Family Anxiety Coding Schedule***

The Family Anxiety Coding Schedule (FACS; Dadds, Ryan, Barrett, & Rappee, n.d.) is an observational coding system that assesses child and parent reactions to ambiguous situations. It includes interviews for both the child and parents, and then it includes four discussions between family members about ambiguous situations and issues that may concern family members, also called "hot" issues (Dadds et al., n.d.). The purpose of the FACS is to analyze the way parents and children talk with each other when they are attempting to come up with solutions to problems they are presented with during a session. Initially, Barrett et al. (1996) found that children who are anxious tend to view ambiguous situations as threatening, and choose avoidant solutions to cope with those situations. They also found that parents contributed to their child's avoidance behavior when interacting with the child by rewarding or reciprocating avoidant verbal statements of the child, leading to avoidant solutions to

problems. Little research has been completed on the FACS psychometric properties, but Dadds et al. (1996) found adequate agreement between raters, with mean kappa indices for content and affect codes of .78 and .72, respectively.

The FACS can be helpful because it allows the clinician to observe how the child and parent interact when resolving problems. Previous research has shown that parents with anxiety disorders tend to have children with anxiety disorders (Beidel & Turner, 1997; Turner, Beidel, & Costello, 1987), and this procedure allows clinicians to investigate the possibility of familial contribution and maintenance of affect disorders, especially anxiety disorders.

### ***Functional Assessment of Affective Symptoms***

Similar to the research on direct observation, the use of functional assessment and functional analysis have been used mostly to analyze externalizing behaviors, but recent advances in behavioral theory (Hayes, Barnes-Holmes, & Roche, 2000) and therapy (Hayes, Strosahl, & Wilson, 1999) have provided a basis for gaining a better understanding of the development and maintenance of negative affect and maladaptive thoughts from a behavioral perspective. Merrell (2008) points out the possible importance of examining the antecedent events related to the development of affective issues such as depression and anxiety, as well as how the consequences of behaving in an anxious or depressed manner may maintain those behaviors. With further research, it may be possible to develop reliable methods to assess affective states from a functional perspective. Using a function-based assessment method for affective issues can help in the design of function-based interventions as well. For instance, an understanding of the antecedent conditions that predict anxious symptoms may help an individual recognize those situations and possibly implement a relaxation intervention on their own. Additionally, gaining an understanding of the consequences of the behaviors related to the internalizing symptoms may help with the design of interventions that help alter the maintaining consequences, such as removing aversive stimuli or providing social attention for appropriate behaviors. While there is still much work to do in this area, an effective and reliable function-based approach could provide promising outcomes for the treatment of affect-related disorders.

In summary, there are several helpful methods for observing the behavior of children who experience affective problems. There are specific overt

behaviors that can be assessed through typical observation measures, and analogue sessions can be created to help determine how children may behave in natural environments. These methods are essential to the assessment process to help provide additional information beyond verbal reports, and they can help validate and extend upon the information gathered using other forms of assessment.

## Conclusion

Over the years structured personality inventories designed for children and adolescents have increased in numbers and have become more sophisticated and more psychometrically sound. In this chapter, a wide array of established, newly developed, and updated objective personality inventories broad and narrow in scope were reviewed. Informal methods of assessing children and adolescents' affect were discussed, as well as methods not commonly used to assess affect but may have the potential in the future to contribute invaluable information in the assessment process. The use of and information gleaned from structured personality inventories, clinical interviews, and behavior observations assist professionals in their understanding of children and adolescents' behavior and in making sound decisions about the appropriate course of action to take to help children and adolescents lead healthy and productive lives. Future research directions include the development of more sophisticated and psychometrically sound instruments specifically designed to assess the personality and affect of children and adolescents and adapting structured personality inventories for use with children and adolescents from diverse cultural backgrounds.

# Methods of Assessing Academic Achievement

Michelle A. Drefs, Tanya Beran, and Meghann Fior

## Abstract

Academic assessment is a complex and intricate process owing to the various factors that need to be taken into consideration. Within this chapter, an overview is provided of the skills and knowledge areas that are typically viewed as essential to successful reading, writing, and mathematics achievement. Moreover, additional factors that are important to examine in explaining poor academic achievement are reviewed. Attention is given to more recent work linking various neuropsychological processes (e.g., executive functions, memory) to academic performance. The goal of this chapter is to provide a framework of the skills, knowledge, and cognitive processes that are essential to reading, writing, and mathematics achievement. It is the intent that this framework will assist the reader in making important decisions regarding methods of academic assessment and, relatedly, appropriate areas to target for intervention.

**Key Words:** academic assessment, reading, writing, mathematics

The assessment of academic achievement has been of longstanding interest within the field of psychology. Along with cognitive and personality tests, academic assessments have long been considered a core component of psychological assessment (Halpern, 1960). At the same time, the attention and thoroughness given to the assessment of academic skills within the extant psychological assessment literature has lacked in comparison to that given to the assessment of such latent traits as cognition (Kamphaus, 2009). In particular, achievement testing has traditionally been addressed primarily within the field of education, serving as only a minor footnote within the psychology literature. Academic testing when completed by psychologists has tended to focus on large-scale standardized measures that provide an indication of one's status, progress, or accomplishments in relation to others, whereas detailed assessment of specific academic skills and knowledge has more commonly been viewed as

falling within the domain of classroom and special education teachers.

Interest in the measurement of academic achievement has heightened over the past number of years, however, owing to several factors. Among these are the increased emphasis placed on teacher and school accountability (Rury-Smith, 2001) and greater adoption of response-to-intervention (RTI) practices (e.g., universal screening and progress monitoring). Relatedly, considerable research has amassed to support the importance of the assessment and intervention for learning difficulties during the early grades. Young children with less developed skills in reading and mathematics, for example, are at-risk for continuing to underperform and struggle academically throughout their schooling without adequate assessment, intervention, and support (Duncan et al., 2007; Jordan, Kaplan, Ramineni, & Locuniak, 2009; Judge & Bell, 2011; Romano, Babchishin, Pagani, & Kohen, 2010; Vellutino, Scanlon, Small,

& Fanuele, 2006). Identifying early learning difficulties and providing appropriate remediation requires the assessment of specific academic skills and subskills. Also contributing to the increased attention on academic achievement are recent advances with respect to the tests and assessment procedures used. Academic assessments have long been used to identify *how* a child is performing, relative to other students or a set criterion. Contemporary methods and approaches to achievement testing are beginning to be developed that help to better understand *why* a child is performing at a particular level and, consequently, how best to intervene.

Within this chapter we provide an overview of what is currently known regarding the essential skills, knowledge, and cognitive processes important to consider in the assessment of academic achievement. At the outset, defining what is entailed in achievement testing appears to be a relatively simple task. Simply stated, achievement testing involves the assessment of an individual's understanding of information and proficiency with specific skills in accordance with established learning objectives within a specific academic domain (e.g., reading, writing, and mathematics) (Ebel & Frisbie, 1986) and/or in relation to other students. A distinction that is commonly made is between measures of academic achievement and measures of general abilities, such as intelligence, memory, and spatial skills. In fact, a significant discrepancy between an individual's performance on ability versus achievement tests has long served as an indicator of a specific learning disability (see Gridley & Roid, 1998). While the ability-achievement discrepancy model of diagnosis has been heavily criticized, the model is representative of the contrasts that have been and continue to be drawn between achievement and ability testing. Achievement testing is generally presumed to measure a domain of skills or knowledge that can be fully articulated and described (e.g., single-digit addition and subtraction) and that can be impacted by teaching and schooling. In contrast, ability measures are viewed as underlying traits that cannot be directly observed and, in general, are believed to be less amenable to intervention (Kamphaus, 2009).

In reality, such ability-achievement distinctions are overly simplistic. Ability and achievement are better viewed along a continuum (Hogan, 2007) or as interrelated skills and processes that are coordinated in optimal academic performance (Busse, Berninger, Smith, & Hildebrand, 2001). For example, the task of reading requires the execution of learned letter-sound correspondence skills (decoding), as well

as the recruitment of more general comprehension skills. Among the cognitive factors that have been identified as integral to an individual's ability to achieve academically are attention, memory, language skills, processing speed, and intelligence (see Alloway, Gathercole, Adams, Willis, Eaglen, & Lamont, 2005; Berg, 2008; Bull, Espy, & Wiebe, 2008; Monette, Bigras, & Guay, 2011; Park, 2011; von Aster & Shalev, 2007). Such capacities determine not only the rate and extent of learning, but also influence an individual's ability to successfully demonstrate the knowledge he or she possesses. As such, the assessment of academic achievement requires consideration of both domain-specific (e.g., decoding) and domain-general (e.g., attention, memory) capacities.

Aside from knowledge-based skills and neuropsychological factors, a comprehensive assessment of academic achievement must also give consideration to a number of individual (e.g., motivation, self-efficacy, behavior), educational (e.g., teacher-student relationship, instructional practices, teacher knowledge), and broader contextual (e.g., parent-child interactions, attitudes towards education) factors (Berninger & Hooper, 1993; Blevins-Knabe & Musun-Miller, 1996; Klibanoff, Levine, Huttenlocher, Vasilyeva, & Hedges, 2006; LeFevre et al. 2009; Ma, 1999). Of these, educational factors have garnered increased attention as of recent. In adopting response-to-intervention practices, practitioners are being encouraged to examine the quality of instruction, the breadth, pacing, and sequencing of the curriculum, and the school environment (e.g., classroom rules, school discipline policies) as possible factors impacting student academic performance (Upah, 2008). Multidirectional relationships exist between these various factors, resulting in both direct and indirect influences on student achievement. Using modeling methods, for example, Ellefsen and Beran (2007) found children's behaviours in terms of conscientiousness, homework completion, conduct, and attention to be directly related to academic achievement, whereas family factors were significant, albeit more distal factors. Related factors involved may also include a family history of particular academic problems, limited exposure to the language the child is learning in, and limited educational history. Consideration also needs to be given to the developmental aspects of academic achievement, with some academic problems resolving with time and others remaining more persistent (Geary, Hamson, & Hoard, 2000). Moreover, the hierarchical nature of academic learning, with later skills building upon and extending earlier skills,

can result in the demonstration of varying skill levels across an individual's development. Comorbid conditions, such as attention deficit hyperactivity disorder (ADHD) and conduct disorder (CD), also factor into understanding a child's current level of academic performance (American Psychological Association, 2000; Klein & Mannuzza, 2000; Kooistra, Crawford, Dewey, Cantell, & Kaplan, 2005). Best practice entails an examination of these multiple processes and factors.

When determining what approach to take towards academic assessment, it is also imperative to identify the purpose for conducting the assessment. In general, academic achievement is used to evaluate: (a) overall achievement, (b) student growth, and/or (c) specific strengths and weaknesses in and across content domains. Once ascertained, such information is used for a variety of purposes, including screening, assisting with eligibility decisions and diagnoses, and informing the planning, design, and evaluation of educational interventions and individualized instructional plans (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, AERA, APA, NCME, 1999; Rury-Smith, 2001). The results can also be more broadly used to evaluate the quality and effectiveness of instruction and educational programming, as is often the case with system-wide testing programs. The amount and complexity of assessment data required are linked to the purpose for which they are being collected. Screening and program evaluation tend to require less comprehensive and involved procedures and fewer sources of information than is required for eligibility and intervention decisions (AERA, APA, & NCME). Clearly, academic assessment is a more complex and intricate process than it may at first appear.

The remainder of this chapter will focus on outlining specific areas that should be examined in the assessment of academic abilities, particularly as they relate to informing instructional practices. Certain delimitations exist with respect to the scope of this chapter that require discussion at the onset. First, this chapter is organized in accordance with the three most commonly assessed academic areas of reading, writing, and mathematics. Acknowledgement is given, however, to the importance of assessing content knowledge and skills in curricular areas, such as language arts, science, and history, as well as vocational areas particularly in the later elementary, middle, and high school grades (McLoughlin & Lewis, 2008).

Second, this chapter is not intended to be a comprehensive review of all relevant academic achievement instruments and methods. Given that there are more achievement tests than all other types of tests combined (Hogan, 2007), this should be a welcome relief to the reader. Rather, the intent is to provide a framework by which the reader can subsequently review and consider the adoption of various instruments and methods. Examples are also provided in the Appendix of assessment instruments that fit within the proposed framework. While these examples are primarily from standardized tests due to their prominent use within the field and familiarity amongst most readers, the skills and processes detailed within this chapter can readily be assessed through various formal and informal academic measures and approaches. As well, the reader should remain cognizant while reviewing this chapter that a comprehensive assessment of academic ability requires the additional consideration and attention to the full range of individual, educational, and broader contextual factors, as noted above.

## **Reading Assessment**

Of the various academic skills, reading skills have undoubtedly received the majority of attention. This is perhaps owing to the significant contributions reading offers to learning and achievement across all subject areas as well as to successful functioning within society. It is generally acknowledged that reading is a complex cognitive activity, with successful reading involving the ability to identify words in text, know their meaning, connect represented ideas to prior knowledge, and retain this information long enough to comprehend the intention of the author. That is, requisite in the reading task is both the ability to successfully recognize the printed words on the page and the ability to make sense of those words. This section begins with a focus on core skills required in both decoding and reading comprehension. In particular, we discuss phonological awareness, which has received considerable attention in the research and is supported by many empirical findings. Three other important skills, orthographic awareness, morphological awareness, and linguistic comprehension, will also be discussed as will other skills that have received more recent attention. Finally, considerations and methods of assessing these various reading skills are discussed.

### ***Core Processes: Decoding and Comprehension***

Most researchers who have studied reading development agree that mastery of phonological

awareness is critical (Adams, 1990; Bradley & Bryant, 1983). Phonological awareness entails “an understanding of the different ways that oral language can be divided into smaller components and manipulated” (Chard & Dickson, 1999, p. 261). Moving from larger to smaller speech units, this includes dividing sentences into words, (e.g., Billy / really / likes / to / sing), words into syllables (e.g., /real/, /ly/), onset-rime units (e.g., /s/ and /ing/), and individual phonemes (e.g., /s/, /i/, / /). It relies, in part, on an individual’s ability to attend to the intonation, stress, and timing of speech. Individuals who have strong phonological awareness are readily able to rhyme words, segment words into syllables or individual sounds, omit sounds in the beginning, middle, and end of words, and substitute or blend sounds to form new words. This ability to distinguish and manipulate various parts of language is an important requisite skill in connecting oral sounds to written letters. Referred to as alphabetic knowledge, this awareness that certain names and sounds are associated with printed letters or combinations of letters allows an individual to begin to decode or “sound out” words (Reading & Deuren, 2007).

Successful readers also create and store visual representations of whole words, letters, or letter clusters (e.g., prefixes, suffixes; Apel, 2009; Berninger, 1990). Once formed, these visual mental representations permit the rapid recognition and decoding of words, in absence of sounding out. An example here is the preschool child who can readily recognize his or her own name and can visually distinguish it from similar looking words. Such representations are based on an orthographic awareness, “a specific understanding or knowledge of the rules and patterns that govern how individuals represent words in print” (Apel, Wilson-Fowler, Brimo, & Perrin, 2011, para. 5). For example, a pseudoword such as “blark” appears more plausible than a word “zjke” based on stored mental representations of commonly occurring letter combinations. Although it has been less examined, morphological awareness is another linguistic skill that has been linked to reading achievement (Apel et al., 2011; Berninger, Abbott, Nagy, & Carlisle, 2010). It refers to an understanding of the units of meaning within words (root words, compound words, prefixes, suffixes) and the relations between them (e.g., word derivations; Apel et al., 2011). Morphological awareness permits, for example, an individual to identify the difference between a “bicycle” and a “tricycle” due to knowledge of how the prefixes “bi” and “tri” contribute to the meaning of a word.

Together, these three metalinguistic factors (phonological awareness, orthographic awareness, morphological awareness) help foster reading development, although it is important to consider their relative influence. While prominence is often given to phonological awareness, all three kinds of linguistic awareness have been found to be important developments during the primary grades (Berninger et al., 2010) and to be associated with word-level reading at later grades (Roman, Kirby, Parrila, Wade-Woolley, & Deacon, 2009). Combined, it appears that the coordination of phonological, orthographic, and morphological awareness is required at both the initial stages of reading acquisition and throughout its development in order to optimize reading achievement.

Although necessary, word-level literacy skills are not sufficient for effective reading. As stated earlier, reading comprehension is also a key component of the reading process and is viewed by some as the “essence of reading” (Durkin, 1993, p. 4–1). Beyond deciphering the literal meaning of the passage, reading comprehension also refers to the higher-level processes in which an individual interprets, evaluates, synthesizes, infers, predicts, critically analyzes text, and considers alternative interpretations (Klinger, 2004; McLoughlin & Lewis, 2008).

According to the *simple view of reading* (Hoover & Gough, 1990), reading comprehension is the result of an interaction between decoding skills (i.e. word-level reading ability) and accurate linguistic comprehension. As such, reading comprehension relies heavily on the mastery of the word-level reading skills of phonological, orthographic, and morphological awareness, particularly at the younger ages when children are first learning to read (Betjemann et al., 2008). In terms of linguistic comprehension, successful reading relies on the ability to make meaning from and interpret language. It is viewed as a multidimensional construct involving awareness and interpretation of oral sounds, focused attention, and active participation (James, 1984). It is commonly assessed through listening comprehension tasks in which information is presented orally. This skill, in combination with decoding, has been found to be significantly related to reading comprehension (Hoover & Tunmer, 1993, see also Høien-Tengesdal, 2010).

### ***Core Processes: Not So Simple View of Reading***

More recent research has identified a number of additional skills and cognitive processes that account

for variance in both reading comprehension and decoding. Among the most commonly identified are: vocabulary, fluency, naming speed, and working memory. An unresolved question is to whether these additional candidate skills are best subsumed within the simple view of reading model (e.g., vocabulary viewed as a subskill of language comprehension, see also Vellutino, Tunmer, Jaccard, & Chen's (2007) Convergent Skills Model of Reading Development) or whether they constitute distinctive components (see Pressley et al., 2009). Although this remains a debated area, there is accumulating evidence to support a *not-so-simple view of reading* in which these wider range of factors need to be considered as determinants of reading ability. In other words, although necessary, decoding and linguistic awareness may not be sufficient for effective reading (Blachman, 2000; National Reading Panel, 2000; Snow, Burns, & Griffin, 1998). In support of a less simple view of reading are, for example, longitudinal and factor analytic studies in which a number of factors have been found to account for variance in reading comprehension above that explained by either decoding or linguistic comprehension (e.g., Conners, 2009). Interventions targeting such candidate factors have also proven effective in improving reading comprehension (e.g., fluency interventions as reviewed by the National Reading Panel, 2000). It is also the case that individuals can have deficits in reading comprehension despite intact decoding and listening comprehension skills (e.g., Georgiou, Das, & Hayward, 2009). The importance of these additional factors may be greater in explaining individual differences in comprehension skills within the higher grades, as individuals become more proficient readers and text complexity increases, and within populations with more intransient reading problems (e.g., reading disabilities).

Of these additional skills, vocabulary has consistently been identified as an important factor in reading achievement. Vocabulary refers to knowledge of words and their corresponding meanings (Verhoeven & Perfetti, 2011). It has been found to be strongly associated with reading comprehension and also, albeit somewhat weaker, with decoding skills (Ouellette & Beers, 2010; Verhoeven, van Leeuw, Vermeer, 2011). With respect to the latter, a rich vocabulary is believed to aid in the successful identification of common words and helps facilitate the decoding processes of new or novel words when encountered in print (Simmons & Kame'enui, 1998). In turn, greater fluency and skill in the reading process assists in the acquisition of new

vocabulary (for further discussion of the relationship between lexical growth and reading skills, see Verhoeven et al., 2011). Both vocabulary breadth (number of words one knows) and vocabulary depth (how well one knows attributes, functions, and features of words) are important to examine (Ouellette & Beers, 2010; Tannenbaum, Torgesen, & Wagner, 2006).

It also appears that it is not just the ability to decode that is important for reading comprehension but also the rate at which decoding occurs. Reading fluency occurs when children can quickly and automatically identify words (Snow et al., 1998). Words are read with speed, accuracy, and proper expression (prosody) (National Reading Panel, 2000). While there is some debate regarding the direction of causality between fluency and comprehension, a generally supported view is that fluent or automatic reading frees up attentional resources required for the higher level comprehension of text. In other words, if a child can decode with relative ease he has more resources to divert towards understanding what he is reading. In addition to the rapid recognition of words, fluency at both the syntactic level (adeptness in processing phrases and sentences as syntactic units) and passage level (appropriate expressiveness and consistent mood and tone) have been linked to increased reading comprehension (Klauda & Guthrie, 2008).

In examining the underlying mechanisms of reading difficulties, considerable evidence has also amassed to support rapid automatized naming (RAN) tasks as predictive of reading ability (e.g., Barth, Catts, & Anthony, 2008; Compton, 2003; Joshi & Aaron, 2000). Poor performance on both naming speed and phonological tasks has been linked to more severe and intractable reading problems (e.g., Frijters et al., 2011), commonly referred to by the term "double deficit" (Wolf & Bowers, 1999). The proportion of variance in decoding and reading comprehension accounted for by RAN tasks has been found to vary depending upon the type of RAN tasks and reading outcomes utilized (Høien-Tengesdal, 2010), developmental factors (Wagner et al., 1997), and degree of reading impairment (e.g., Lervåg, Bråten, & Hulme, 2009 report RAN as an important predictor for the poorest readers). What is not clear at this juncture is the underlying processes that are shared between rapid naming tasks and the reading process. Among the hypotheses to account for the RAN-reading relationship is the importance of processing abilities in reading (Wolf, 1991). For example, speed of

processing may underlie differences in letter naming speed. Researchers have argued that when naming is quick, automatic, and effortless it requires little cognitive load and concentration (Logan, 1988; Stanovich, 1990). This allows the reader to focus attention more on extracting meaning than on decoding. Indeed, difficulty fully automatizing skills may explain reading deficits (Nicolson & Fawcett, 1990; for alternative hypotheses regarding RAN and reading skills, see de Jong, 2011 and Georgiou, Parrilla, Kirby, & Stephenson, 2008).

In addition to the above processes, both short-term and working memories are cognitive processes that have been widely studied and are associated with poor reading ability (Dahlin, 2010; Ni, Crain, & Shankweiler, 1996; Swanson, Zheng, & Jerman, 2009). Deficits in these areas have been found to persist over time (Swanson et al., 2009) and to contribute to reading abilities independent of other reading skills and processes (Crews & D'Amato, 2009). It may be that difficulty retaining word information in memory while extracting meaning interferes with fluency and comprehension (Bayliss, Jarrold, Baddeley, & Leigh, 2005). Additional executive functions associated with the concurrent processing, monitoring, and storage of information have also been implicated in the reading process, such as attentional/inhibitory control processes (Conners, 2009), planning (Das, Georgiou, & Janzen, 2008), visual attention span/memory (Bosse, Tainturier, & Valdois, 2007; Vellutino et al., 2007), and (verbal) IQ (Frijters et al., 2011; Hulslander, Olson, Willcutt, & Wadsworth, 2010).

At present, consensus is lacking with respect to the neuropsychological factors of most importance to the reading process and the exact mechanisms by which they exert their influence. What is known, however, is that the reading process is multicomponential and relies on the integration of multiple linguistic and cognitive factors. Difficulty in any one can affect the understanding of text. Although all of these skills play a necessary role in comprehension, not one guarantees that comprehension will occur (Pressley, 2000). Clearly, reading is complex. There are a variety of skills and cognitive processes that comprise reading ability, and it is each one, along with their coordination that influences reading performance (Berninger, Abbott, & Stage, 1999).

### ***Assessment Methods and Considerations***

As reading is one of the most assessed academic skills (McLoughlin & Lewis, 2008), the large

variety of tests and methods available to assess reading should not be surprising. They range from single-word decoding tasks to a wide-range of comprehension tasks on passages of varying length. Typically, word-level measures are used to assess accuracy and fluency and consist of words or pseudo-words presented in list or text form. They can also include tasks that focus on certain components of a word, such as in the rhyming, sound blending, or sound deletion tasks commonly used in the assessment of phonological skills. Word reading measures tend to be highly correlated with each other. In contrast, lower correlations found between measures of reading comprehension suggest that they tap a broader range of cognitive skills (Johnston, Barnes, & Descrochers, 2008). Among the more diverse methods for assessing reading comprehension are the reading of a passage followed by short-answer, multiple-choice, cloze tasks (fill in blanks of omitted words), interviews and questionnaires, anecdotal records and observations, oral retelling, freewriting, and think-aloud procedures (for a review of advantages and limitations of these methods, see Klinger, 2004). In selecting such measures, it is important to ensure that the items assess both concrete (direct) ideas (e.g., word meaning, recognition of relevant information) and abstract (higher-level) thinking (e.g., inferences, critical analysis; Svetina, Gorin, & Tatsuoka, 2011). Also, the reading material must be within an individual's instructional reading level (Klinger, 2004).

While the focus of reading assessment is typically limited to decoding (accuracy and fluency) and reading comprehension, the following areas, as outlined in the foregoing review, are also important to examine in the assessment of children's reading ability: letter identification (orthography), listening comprehension, vocabulary, speed of processing, working memory, general knowledge, verbal ability, and intelligence. Provided in the Appendix is a listing of subtests from four commonly used standardized test instruments that assess these various skills and cognitive processes. As mentioned at the onset of this chapter, this listing is not intended to be exhaustive. It does not include all of the subtests from the four selected instruments nor does it reflect the wide range of available formal and informal measures. Rather, the chart is intended to serve as a guide in helping to select appropriate measures required for the comprehensive assessment of academic abilities. Specifically, it provides examples of the types of measures that can be used to examine the broader range of skills, knowledge, and cognitive processes

detailed in this chapter. The reader is encouraged to add to this framework additional formal and informal measures and procedures. Since many of the skills and processes used in the reading process are also used in other academic areas, the example measures provided for reading, writing, and mathematics have been compiled into one chart for ease of reference and comparison.

In assessing these areas it is also important to stress that attention should not only be given to the various skills and cognitive processes listed in the Appendix, but also more broadly to the interaction between the reader and text (McLoughlin & Lewis, 2008). There are many factors about the text itself that may influence how children read. For example, clues in the text passage can be used meaningfully and systematically as aids to reading. Also, the context and meaning of the passage can assist in interpreting text (Baumann, Font, Edwards, & Boland, 2005). Successful reading also requires metacognitive awareness and control of strategic processes in planning, monitoring, and evaluating what is being read. Skilled readers effectively deploy a number of reading strategies, dependent on the goals of reading and the nature of the text being read, to make reading meaningful (e.g., establishing a purpose for reading, making predictions) and to deal effectively with difficult text (Mokhtari & Reichard, 2002). Such areas are most readily assessed through informal measures, such as interviews, questionnaires, and think-aloud procedures, but can also be observed during the administration of more standardized measures. For example, observations of a student reading aloud can provide immediate information on fluency and decoding skills, but can also provide invaluable information on self-monitoring and self-correction (Westwood, 2009). While a thorough review of the use of informal measures is beyond the scope of this chapter, more detailed discussion is given to this topic within the remaining writing and mathematics sections.

## **Written Expression**

Similar to reading, writing is a complex process involving the integration of multiple requisite skills and mental processes. Among these, for instance, are oral language and visual-motor integration skills, background and discourse (e.g., story elements) knowledge, ability to generate and organize ideas and adhere to established writing conventions (e.g., spelling, punctuation, grammar), and self-monitoring strategies (Espin, Weissenburger, & Benson, 2004; Olinghouse & Graham, 2009).

Writing well involves a complex progression from ideation through to execution of an organized, planful, and compelling discourse. While a number of models exist by which to examine the manner in which these various skills and processes contribute to the writing process (for review of models, see Wagner et al., 2011), a useful division from an assessment perspective is between transcription (e.g., spelling, handwriting) and text generation skills (e.g., writing down one's ideas) (Berninger, 2009). In alignment with this approach is the considerable attention that has been given to the tri-fecta areas of handwriting, spelling (transcription), and written composition (text generation) in terms of the instruction and assessment of written expression (Berninger, Garcia, & Abbott, 2009; Berninger et al., 2002). This section outlines the core writing skills and processes within this simplified division of transcription and text generation skills before attending to methods for assessment.

### ***Core Processes: Transcription Skills***

Transcription skills, such as spelling, handwriting, and keyboarding, are considered lower-order text production skills that support a student's ability to successfully produce written work. The majority of research in this area supports handwriting and spelling as differentially impacting upon the quality and length (compositional fluency) of the written product (Graham, Berninger, Abbott, Abbott, & Whitaker, 1997). A commonly accepted position is that impairments in the mechanics of writing (e.g., handwriting, spelling) limit the attentional and cognitive resources available for other aspects of the writing process, such as idea generation, planning, and revising (Graham, Harris, & Chorzempa, 2002). There is some evidence to suggest that these constraints are particularly relevant for the beginning writer (Graham et al., 1997), although researchers have found both spelling and handwriting to continue to exert influence on the writing process well into the high school years (Dockrell, Lindsay, & Connelly, 2009).

In general, it appears that spelling skills are a common area that differentiates poor writers from more capable writers. While highly correlated with reading abilities (Ehri, 1989; 2000), spelling remains a separate and distinct process. For example, students with unimpaired reading abilities can struggle with spelling (Treiman, 1993), and although less common, the reverse also holds true (Bryant & Bradley, 1980). Moreover, "deficits in spelling tend to be more tenacious [and can] persist long after reading

deficits have been ameliorated" (Joshi & Carreker, 2009, p. 113). This is likely owing to the fact that whereas reading is a recognition task in which context and word features may be of assistance, spelling constitutes a more complex recall task that requires the accurate production and sequencing of each letter (Joshi & Carreker, 2009).

Due to its close association with reading, it is not surprising that spelling shares with reading many of the cognitive and linguistic skills aforementioned in the reading section. Of these, phonological, morphological, and orthographic word-level skills are considered salient skills underlying competent spelling ability (Joshi & Carreker, 2009; Silliman, Bahr, & Peters, 2006). Phonemic awareness, in particular, has been identified as playing a strong role in spelling development (across the grades—early to high school, first and second languages) (Sparks, Patton, Ganschow, Humbach, & Javorsky, 2008), with arguments made for spelling as a phonologically guided process (Treiman, 2004).

While phonological awareness is an important contributor to spelling skills, it is not sufficient. Spellers must also be able to effectively use certain strategies and memory skills. Knowledge of the morphemic structure of words and how to manipulate that structure allows students to correctly spell words (Apel et al., 2011; Carlisle, 1995), particularly those that do not appear to adhere to a regular phoneme-grapheme correspondence pattern (Mather, Wendling, & Roberts, 2009). For instance, students are aided in the spelling process when they know that the suffix /ed/ denotes past tense in words that have a final end sound of /d/, /t/, or /id/ as in called, helped, and waited (Leong, 2009).

Likewise, an understanding of the basic orthographic properties of language, the way in which spoken language is visually represented, is also needed in spelling (Abbott & Berninger, 1993; Berninger et al., 2002). These visual representations of words or parts of words are of particular importance given the alternative spellings for the same phoneme, such as the /long e/ phoneme which can be spelt as *e* (be), *ee* (meet), *ea* (leaf), or *y* (baby). Once formed, they allow for the rapid recognition or retrieval of whole words, letters, and letter clusters (e.g., prefixes, suffixes) and can assist in the production of spellings that are consistent with commonly occurring letter patterns (Apel, 2009). In summary, although the order of acquisition and developmental processes are not well understood, learning to spell consists of the amalgamation of phonological, morphological,

and orthographic knowledge (Joshi & Carreker, 2009).

Turning to handwriting, both legibility (quality) and speed have been shown to be important components of handwriting (Berninger, Yates, Cartwright, Rutberg, Remy, & Abbott, 1992; Rosenblum, Weiss, & Parush, 2003). Quality measures include examination of such areas as letter size and proportion, line quality (pressure consistency), consistency of slant and style (manuscript, cursive), spacing between letters and words, and general merit (Mather et al., 2009; Rosenblum et al., 2003). Measures of speed are concerned with the number of letters or amount of text that can be generated within a set time period (Rosenblum et al., 2003). Reviews of comparative studies identify a number of spatial, pressure, and temporal characteristics that differentiate the handwritten output of typical children from those with writing difficulties (Engel-Yeger, Nagauker-Yanuv, & Rosenblum, 2009; Rosenblum et al., 2003). The general consensus is that writing tends to be a slower process and result in less legible product for the struggling writer.

Processes that contribute to handwriting competency include both intrinsic and extrinsic factors (Feder & Majnemer, 2007). The former of these appear to be largely related to fine motor coordination and visual motor integration (Van Hartingsveldt, De Grott, Aarts, & Nijhuis-Van Der Sanden, 2011), with some support also for visual perception/memory and kinesthesia<sup>1</sup> (Feder & Majnemer, 2007). There is also some initial evidence to suggest that handwriting is dependent upon an underlying mental representation of written words and letters to hand movements. These areas have been assessed through orthographic coding tasks, successive finger movements, and the automatic retrieval and production of legible letters (Berninger, 2009; Graham et al., 1997). Extrinsic considerations relate to the environment and biomechanics, such as sitting position, distance from copy source, lighting, and writing volume (Feder & Majnemer, 2007). It may be the case that early deficits in psychomotor skills persist over time (Smits-Engelsman & Van Galen, 1997) or, as suggested by the work of Overvelde and Hulstijn (2011), notable improvements occur over the primary grades with a general stabilization of handwriting quality towards the beginning of the third grade. What is clear, however, is that poor handwriting skills contribute to decrements in both compositional fluency and quality (Graham et al., 1997).

## Core Processes: Text Composition

A second area for consideration in writing assessment is that of text composition, the process of selecting and organizing words “to convey and represent ideas for a particular purpose” (Mather et al., 2009, p. 23). To write well is an involved process in which higher-order attentional and cognitive skills are recruited in the recursive processes of planning, text generation (i.e., translating ideas into written words), and reviewing and editing (Scott, 2009). Also required is requisite verbal and background knowledge (e.g., established semantic and syntactical components of a particular text structure; Mather et al., 2009), an understanding of the writing goals (e.g., audience), and ability to evaluate and revise goals and strategies as required to meet one’s writing objectives (Butler, Elaschuk, & Poole, 2000). “Because proficiency in written expression requires the integration of multiple skills, the assessment of writing is a complex endeavour. In fact, some view writing assessment as the most difficult domain in achievement testing” (Espin et al., 2004, p. 55). This fact is further compounded by a lack of concreteness in determining what constitutes successful text composition. While one can readily determine if a child has successfully summed “4 plus 6” or correctly read the word “circumference,” a more challenging task is to determine the quality of an individual’s written work.

Text composition is commonly assessed by evaluating the written product or *what* has been produced, most typically in response to a writing prompt or picture. In general, struggling writers tend to write less and have more poorly constructed composition than their typically developing peers (Amato & Watkins, 2011). When examining the writing product, measures can be qualitative, “requiring an assessor to rate a text as a whole (holistic assessment) or to rate several traits of at a text (organization, sentence fluency, etc.) according to a predetermined rubric” (Scott, 2009, p. 359). Measures can also be quantitative, with common indicators being compositional fluency (amount written under specific time conditions), lexical diversity (number of different words used), and accuracy measures (percentage of grammatically correct sentences produced) (Scott, 2009).

In assessing the written product, the primary concern is with the linguistic characteristic of the text (e.g., the extent to which the text includes rich vocabulary, varied sentences, a clear message, etc.). Recent work in this area points to the importance of the assessment of text composition at several

linguistic levels, namely at the word, sentence, and text/discourse levels (Scott, 2009; Wagner et al., 2011). These levels appear to be somewhat dependent on separate processes (Whitaker, Berninger, Johnston, & Swanson, 1994), with performance in any one area not entirely predictive of performance in the others (Berninger, Mizokawa, Bragg, Cartwright, & Yates, 1994). Word-level measures tend to provide an assessment of an individual’s vocabulary size and control, e.g., lexical diversity (number of different words used), word length, density (content words to total words), and word choice (maturity, interest, and variety). The emphasis in sentence-level measures is on the extent to which a thought can be effectively expressed in terms of the syntax, grammatical accuracy, and semantic relations (Scott, 2009). Simple fluency measures (total number of words written) have consistently been found to be valid indicators of writing proficiency at the elementary level; with more limited support for the use of complex fluency and accuracy measures (e.g., number of correct word sequences) at higher grade levels (for review, see Weissenburger & Espin, 2005, see also Amato & Watkins, 2011). At the discourse-level, attention is given to determining how effectively the author translates ideas into words to achieve the purpose and effectively communicate to the intended audience. In general, discourse-level measures tend to demonstrate effects of age and language ability more consistently than do word- and sentence-level measures (Scott, 2009).

Breaking text composition down further, what is receiving increased attention is the *process* by which the text is developed. Here, attention is given to the types of cognitive activities in which a writer is engaged (e.g., planning ideas, formulating sentences, revising the text) and the extent to which movement between these activities is done in a recursive and ongoing process throughout the writing process (Berninger, Mizokawa, & Bragg, 1991). Additional constraints include a writer’s content knowledge (specific topic knowledge) and knowledge of the specific writing organizational structures (e.g., discourse/genre forms, such as narrative, descriptive, compare/contrast, and persuasive; Beers & Nagy, 2011; see also McCutchen, 1986). Studies examining differences between adept and struggling writers have identified a number of differences with respect to these processes. When compared with adept writers, struggling writings tend to spend less productive and uninterrupted time on these tasks (Garcia & Fidalgo, 2008; Troia, 2007). They also

demonstrated a less sophisticated understanding of the purpose and goals of writing, defining quality writing in terms of lower order skills (handwriting, spelling, neatness) as opposed to its communicative importance (Lin, Monroe, Brandon, & Troia, 2007).

While there is general agreement that skilled and struggling writers differ in terms of both the writing product and processes, less is known regarding the factors that contribute to these differences. Certainly, as earlier detailed, there is evidence to support the important contributions of lower order transcription skills, such as spelling and handwriting, to the writing process (Graham et al., 1997; Wagner et al., 2011). Language and linguistic functions also impact text generation and are broadly recruited throughout the writing process. These include vocabulary, phonological processing, orthographic coding, word finding, sentence syntax, language pragmatics, and reading capabilities (see Hooper et al., 2011). This association begins early, with expressive vocabulary and other oral language skills already linked with fluency and productivity measures at the kindergarten years (Kim, Otaiba, Puranik, Folson, Greulich, & Wagner, 2011). This should not be surprising given that, pragmatically speaking, writing is language production (Kellogg, 2001).

More recent attention has been given to the importance of executive functions as an early and consistent neuropsychological contributor to written language expression (Berninger, 2009; Hooper et al., 2011, see also Berninger, Garcia, & Abbott's (2009) Not-So-Simple View of Writing). These include self-regulation of attention, inhibitory control, and planning (Berninger et al., 2009; Hooper et al., 2011). Subsumed within this category are also the various memory functions that are central to a functional writing system. Long-term memory processes influence the writing process by allowing access to the aforementioned content and discourse-specific knowledge. Working memory allows such information along with the writing goals to be held in an active state during the planning, reviewing, and revising processes (Alamargot, Caporossi, Chesnet, & Ros, 2011; Kellogg, 2001).

### ***Assessment Methods and Considerations***

There are considerably fewer assessments available for the assessment of writing skills than for reading and mathematics; with the majority of those available constituting more informal measures (McLoughlin & Lewis, 2008). Considerable

diversity also exists with respect to the types of writing tasks utilized. Spelling and handwriting are commonly assessed as isolated skills (e.g., spelling lists, figure and letter formations) or examined within larger writing samples. Joshi (1995) suggests the inclusion of spelling tests that consist of familiar words, those words an individual can read, in order to allow for the examination of more than phonological skills within spelling production.

Text composition measures can vary from the production of a single sentence to the generation of longer text with opportunities for planning and revision (Scott, 2009). It is also the case that writing tasks can consist of "machine-scored multiple-choice judgment tasks that do not require writing *per se*" (p. 359). A common approach to word- and sentence-level measures is the use of curriculum-based measures (CBMs) of writing. The most common of these measures include counts of the total number of words written (TW), number of correct word sequences (CWS), and number of correct minus incorrect word sequences (CWS-ICWS) (Weissenburger & Espin, 2005). These areas are also indirectly measured on standardized assessments that examine, for example, word choice and varied sentence structure (Scott, 2009).

For discourse-level measures involving the generation of longer passages, effort should be given to ensuring that the writing task is authentic with a clear purpose and audience (Calfee & Miller, 2007). This transforms the writing task from a "test" to a substantive "real life" exercise with value to the student. Opportunities for support and feedback allows for greater insight into how an individual transitions between the planning, formulating, and revising stages. While discourse-level text can also be evaluated through such quantitative measures as fluency and productivity, it is more common for a composition to be assessed through the aforementioned holistic and analytic approaches. Of these, the analytic approach is viewed as having greater diagnostic utility as it provides a breakdown of the various writing features (trait) that are required for communicative competence. Commonly examined areas include; ideas, organization, voice, word choice, sentence fluency, conventions, and presentation (Calfee & Miller, 2007). It should be noted that some criticism has been levied against available writing rubrics as lacking a strong basis in a theory or model of language or writing development (see Knoch, 2011). Finally, it is important to mention that the assessment of

writing skills should also be conducted across a number of diverse genres (e.g., narrative, expository, compare-and-contrast) given that the organization and components may vary, thus resulting in differing cognitive demands (Kellogg, 2001). The reader is again referred to the Appendix for a listing of the various skills and processes detailed above and corresponding measures.

## Mathematics Assessment

Compared to reading and writing, limited consensus exists regarding the componential parts or processes of mathematics knowledge. This is likely owing, in large part, to the fact that mathematics is a broad discipline encompassing a wide range of concepts, skills, and procedures. At the broadest level, learning math requires an understanding of knowledge and skills across a number of content areas or strands, such as algebra or geometry. Students may demonstrate deficits within one or more of these strands, or with respect to a set of competencies within a given strand (Geary, 2004; see also Dowker, 2005). Even a seemingly simply task, such as determining the sum of two numbers, requires a number of diverse cognitive skills. These can include retrieving arithmetic facts from semantic memory, applying arithmetic procedures to solve multi-digit numbers, accessing a cognitive system of arithmetic signs, and possessing a conceptual understanding of what addition means (see Denes & Signorini, 2001).

Further contributing to the lack of consensus regarding what constitutes mathematical knowledge and how best to assess such abilities is the limited research attention that has traditionally been given to this area in comparison to that given to the development and assessment of reading skills (Donlan, 1998; Wilson & Dehaene, 2007). In general, research into mathematics abilities has almost exclusively focused on the development and assessment of basic numerical competencies (counting, number comparisons) and computational skills of children (Geary, 2004). While we know a great deal about the types and sophistication of children's strategies in solving single-digit addition problems (Siegler & Shrager, 1984), for example, considerably less is known about the processes and skill that contribute to poor performance in geometry or algebra.

Against this backdrop, the following section outlines two complementary orientations to assessing mathematics. The first, based primarily on psychological and educational perspectives, focuses on a general

framework in which *types* of mathematical thinking and skills are detailed. The second, arising more from the cognitive neuropsychology field, focuses on the *processes* which underlie mathematical cognition. Methods of assessing these various math skills are also discussed.

### Core Skills: Types of Mathematical Knowledge

As stated, the assessment of mathematics achievement at the broadest level is concerned with a student's current level of skills and abilities across content and domain areas. According to the National Council of Teachers of Mathematics (NCTM; 2000) these areas include: number and operations, algebra, geometry, measurement, and data analysis and probability. General consideration is given to ensuring that a child can demonstrate those skills and abilities that are in line with the curricular objectives for a particular grade level. An individual's level of mathematical development can be examined in terms of mastery of broad skills areas (e.g., arithmetic operations) or further examined in terms of more discrete skills and competencies (e.g., single-digit addition, double-digit addition). Given that math learning is generally considered a developmental process, in which higher-level mathematics skills and knowledge are predicated on the successful acquisition of rudimentary abilities (Duncan et al., 2007), central here is the determination and assessment of mathematical proficiency within a hierarchical sequence, as outlined within a curriculum resource or the research literature.

Another distinction that is commonly made for both assessment and intervention purposes is between an individual's procedural and conceptual knowledge (Burns, 2011). Procedural knowledge is defined as *knowing how* in terms of specific sequences, steps, or rules required for solving problems (e.g., the FOIL method to multiply polynomials). It is not only a student's ability to successfully execute a particular procedure, but the assessment of strategy selection and efficiency which can vary as a result of individual factors (e.g., age, cognitive processes, arithmetic skills) and problem features (e.g., format, problem type) (Imbo & Vandierendonck, 2007; Lemaire & Callies, 2009). While most students tend to employ a variety of strategies, children with math disabilities may be more limited in their range and flexible use of appropriate strategies (Ostad, 1997). Conceptual knowledge, in contrast, is an individual's *knowing why* in terms of implicitly or explicitly understanding the meaning of

mathematical principles, facts, or procedures (e.g., understanding the FOIL method in terms of the distributive and commutative rules used to distribute the terms from one of the polynomials being multiplied to the other) (Rittle-Johnson & Siegler, 1998; Rittle-Johnson, Siegler, & Alibali, 2001).

While procedural and conceptual knowledge comprise the two most commonly identified types of mathematical knowledge, a number of additional types of mathematical knowledge have been proposed. A comprehensive psychological framework advanced by Byrnes (2007), for example, identifies three additional types of mathematical competencies: declarative knowledge, estimation skills, and ability to graphically depict and model mathematical relationships and outcomes. The former of these areas, declarative knowledge, is defined as an extensive storehouse of math knowledge, inclusive of basic number facts (e.g.,  $8 \times 8 = 64$ ) and more general mathematics information (e.g., number of sides in a triangle). A related skill, math fluency has also been linked to math achievement and refers to the “fast, accurate, and effortless computation with basic operations as well as appropriate and flexible application” (Jordan & Levine, 2009, p. 63).

When these various types of math knowledge are examined, areas of deficit may be identified in one or more of these areas. For those with math disabilities, the research supports impairments in fact retrieval and calculation fluency (Chong & Siegel, 1998; Jordan & Levine, 2009; Mabbott & Bisanz, 2008) and differences in retrieval strategy usage, rate, and accuracy (e.g., Geary, Hoard, Byrd-Craven, & DeSoto, 2004; Wu et al., 2008). Such weaknesses in basic arithmetic knowledge and computation skill may in turn impair the development of conceptual structures needed for advanced mathematics learning (Passolunghi, 2011), although conceptual deficits have not been found to be a constant feature of math disabilities (see Mabbott & Bisanz, 2008).

### ***Core Processes: Not So Simple View of Mathematics***

In contrast to the types of mathematical knowledge detailed above, a number of models have emerged primarily from the cognitive neuropsychology field that detail the brain structures and processes that underlie numerical and mathematical cognition (see Dehaene & Cohen, 1995; McCloskey, Caramazza, & Basili, 1985). One of the most influential of these, the triple-code theory, asserts mathematical knowledge as being influenced by linguistic, quantitative, and spatial processes

(Dehaene & Cohen, 1995; Dehaene, Piazza, Pinel, & Cohen, 2003). The application of this model to children has identified links between children’s success on a range of mathematical outcomes with measures of linguistic (vocabulary and phonological processing), quantitative (rapid recognition of small number sets) and spatial attention processes (LeFevre et al., 2010). The research in this area remains tentative largely due to the relatively restrictive focus on arithmetic skills and impairments within adult populations. However, what is emerging is a cursory listing of core skills and processes in mathematics that is similar to those detailed earlier in the area of reading. Of these, number sense (supported by the core quantity system within Dehaene’s model) has received heightened research interest and attention as of late.

Number sense refers to an awareness of what number means and the relationship between numbers (Malofeeva, Day, Saco, Young, & Ciancio, 2004). Children who have a well-developed number sense are able to count, compare quantities, estimate, do simple mental-computations, and use number flexibly (Politylo, White, & Marcotte, 2011). Children with less well-developed number sense than their same-aged peers by grade one are at risk of experiencing serious delays and performing below their peers through their schooling (Case & Griffin, 1990; Griffin, 2004; Griffin, Case, & Capodilupo, 1995; Griffin, Case, & Siegler, 1994; see also Jordan, 1995). Additional arguments have been made for the links between the obtainment of number sense and children’s self-confidence and low anxiety in mathematics performance (Malofeeva et al., 2004). In general, it appears that number sense is one potential source of deficit for children who are experiencing difficulties in mathematics learning (Geary, 2010). In fact, Gersten and Chard (1999) draw an analogous comparison between phonemic awareness in reading and number sense in mathematics.

As with reading and writing, a number of additional cognitive processes have been identified as explanatory of differences in math achievement. Of these are measures of fluency (e.g., Methe, Hintze, & Floyd, 2008), rapid naming (e.g., Lago & DiPerna, 2010), processing speed (Bull & Johnston, 1997), visual spatial memory (e.g., Bull, Espy, & Wiebe, 2008), working memory (e.g., Fuchs, Geary, Compton, Fuchs, Hamlett, & Bryant, 2010; Wu et al., 2008), executive attention (e.g., LeFevre et al., 2013), and inhibitory processes (e.g., Passolunghi, 2011). It seems that “doing”

mathematics, such as calculations and problem solving, requires involvement of the executive functions in the representation and manipulation of information and the inhibition of irrelevant associations. In alignment with this view, the retrieval errors commonly observed among children with math learning difficulties are not viewed as simply a storage-retrieval problem, but rather may be contributed to more general cognitive deficits, such as difficulties in inhibiting irrelevant number associations (Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007). Geary et al. found that the number and extent of cognitive deficits is greatest for children with the most pervasive and severe math difficulties, although subtle differences in a more limited number of processes were also found for low achieving students. While our understandings of the contributions of cognitive functions to math achievement are still fairly modest, there is evidence to suggest that such domain-general processes may differentially impact the acquisition and growth of certain types of mathematical knowing (e.g., fluency versus procedural). For example, recent work by LeFevre and colleagues (2013) supports executive attention as playing a larger role in the initial acquisition of novel procedures as opposed to the execution of well-learned procedures. In sum, it appears that there are a number of underlying skills and cognitive processes that contribute in diverse ways to mathematical competence.

### ***Methods of Math Assessment***

As demonstrated in the foregoing review, there is less consensus and less presently known regarding key areas to examine in the assessment of children's mathematical abilities. It should not be surprising to the reader, therefore, to know that there is limited correspondence between the areas of mathematical knowledge detailed above and the types of tasks included within contemporary measures. The majority of assessment items have been designed to measure mastery of specific skills and mathematical abilities. Those that do so for a wide range of skills and across different mathematics strands (e.g., number and operations, algebra, geometry, measurement) are referred to as survey or diagnostic instruments (e.g., KeyMath-3; Connolly, 2007). While diagnostic instruments have not been included in the Appendix, selection of such tests should be done with attention given to the range of math content areas assessed and the number and type of items within each strand.

The correspondence between other types of mathematical knowledge and assessment subscales

and headings may be somewhat obscure. That is, many of the available math instruments are not organized in terms of procedural, conceptual, and declarative knowledge (although fluency is a commonly assessed area). Rather, mathematical tasks are routinely organized within standardized measures in accordance with the broad headings of mathematical concepts, numerical operations/computation, application, and problem solving (Taylor, 2009). It is thus necessary to make determination as to how and the extent to which these knowledge types are assessed on various instruments. Dowker (1998), for example, extends the procedural-conceptual distinction as akin to the numerical facility and mathematical reasoning distinction commonly made on many standardized assessment instruments. In support of this comparison is the typical assessment of procedural knowledge through computational tasks (e.g., exact calculation, written problems, forced retrieval), with conceptual knowledge more often assessed through novel or applied tasks (e.g., approximate arithmetic, place value, calculations principles, story problems; see Jordan, Mulhern, & Wylie, 2009).

Finally, it should be noted that measures associated with some of the outlined neuropsychological processes (e.g., number sense) remain largely restricted to the research arena. Although additional instruments and methods are forthcoming (e.g., REMA, Clements et al., 2008) and items can be selected from larger batteries to assess particular competencies (e.g., quantity comparison and estimation tasks as indicators of early number sense), the instruments available to practitioners at this juncture remains limited. Again, the Appendix is provided to assist the reader in identifying measures that correspond to the skills and processes identified above as contributing to math achievement.

Echoing similar discussions in the preceding reading and writing sections, ascertaining a child's level of mathematical understanding and best informing instructional activities additionally requires attention to informal measures. Returning to the procedural and conceptual distinction, determining the extent of a student's mathematical understandings often requires extension beyond standardized measures to the use of informal techniques. That is, a response of  $54 + 28 = 82$  is not sufficient to conclude that a student has procedural proficiency in regrouping. Rather, observation of and discussion with the student with respect to the manner in which the problem was solved is required in identifying a student's level of conceptual and procedural knowledge. While

of importance in the assessment of any academic area, informal techniques are essential in the assessment of mathematics given the wide range of steps, strategies, and thought processes that undergird both successful and unsuccessful responses.

Two informal assessment techniques that are widely used as part of a mathematics assessment are *error analysis* and *clinical interviewing*. With error analysis, the goal is to, first, identify if there is a pattern to an individual's incorrect responses and to, second, determine if such errors are due to systematic misunderstandings (McLoughlin & Lewis, 2008). Error analysis requires a sufficient number of items to permit the identification of an error pattern and subsequent classification of the type of errors being made. Within the math clinical interview, students are encouraged to "talk through" the processes they use while completing math tasks, either during or following task completion. When students are provided with manipulatives (i.e., coins, base-ten blocks, calculator, paper and pencil) greater insight can be gained regarding the individual's mathematical thinking, in addition to broader strategy approaches, attitudes about math, and perseverance. Both these techniques require substantive mathematics knowledge on behalf of the examiner to ensure a correct analysis and assessment of mathematical thinking (Fleischner & Manheimer, 1997).

## Conclusion

Academic assessment is a complex and intricate process. Within this chapter we provided an overview of the skills, knowledge, and cognitive processes that are currently viewed as important contributors to academic achievement with the goal being to better inform academic assessment as well as intervention practices. A general direction that was taken in writing this chapter was to give less attention to the domain-general versus domain-specific distinctions that are often made within the literature. It is likely the case that many of the neuropsychological factors discussed may more broadly exert influence on learning and academic achievement (Fuchs et al., 2010). We share the view of Bull et al. (2008), however, that a "good estimate of a child's ability to learn and hence their future academic success" requires a combination of knowledge-based plus cognitive measures (p. 225). Awareness of cognitive limitations allows for modifications to be made to learning activities that reduce the cognitive demands and permits more targeted interventions to be delivered.

In review of the outlined skills, knowledge, and processes it is clear that significant advances have been made over the last 20 years with respect to our knowledge of and ability to assess those factors that contribute to both typical and atypical academic development. It is also the case, however, that research, particularly with respect to neuropsychological correlates, remains in its infancy. While a considerable amount is known about processes involved in the reading process, considerably less is known in the areas of writing and mathematics. Moreover, across all academic areas, continued work is needed to better explicate the specific neuropsychological processes of influence and the mechanisms by which they exert such influence. At present, moderate to strong correlations between assessment tasks and more global measures of academic achievement appear sufficient for their inclusion within academic models and theories, in absence of a clear understanding of what constructs are being measured by such tasks. An example of this is the rapid automated naming (RAN) tasks in which debate continues as to whether the underlying processes involve phonological processing, general or more specific processing speed skills, response inhibition, or other as of yet indeterminate processes (Savage, Pillay, & Melidona, 2007). In other words, while evidence continues to accumulate regarding which neuropsychological factors influence performance on a variety of academic tasks, considerably less is known about the exact mechanisms or manner of the influence. It is likely that continued work in this area and refinement of assessment measures will reveal more nuanced relationships, with the various skills and processes contributing in both domain-general and domain-specific ways. Although continued research is needed to more fully understand and articulate such areas, this chapter serves as a roadmap based on the extant research in identifying essential areas to consider in the comprehensive and thorough examination of reading, writing, and math achievement.

Several cautionary notes are worth mentioning. It is generally acknowledged that insightful interpretation is dependent upon examination of interindividual differences in academic performance, as well as consideration for an individual's pattern of performance and processes used to arrive at a particular answer (Fiorello, Hale, & Snyder, 2006). Given that reading, writing, and mathematics are multicomponential, in terms of both the component parts (e.g., reading consists of word-level reading and comprehension) and diverse skills and processes required for successful performance, it is not uncommon to

find asynchronous patterns of development within an academic domain. Jordan, Mulhern et al. (2009), for example, found typically achieving children to demonstrate marked variations in their learning trajectories across seven arithmetical tasks (e.g., exact calculation, story problems, and place value). As a greater number of factors are considered, it is possible that a greater number of discrepancies between such factors at the individual level will also be observed. In concert with examining the range and/or severity of discrepant performance within and across certain tasks, it is also important to examine whether such patterns of low achievement extend across successive academic years (Geary, 2004).

It is important to reiterate that the comprehensive assessment of academic achievement requires consideration of broader factors than were the focus of this chapter. In addition to both formal and informal tests, academic assessment should also include observing the student in and out of the classroom, interviewing the student, teacher, and parents, analyzing parent and teacher behavioural rating scales, reviewing work products and samples, as well as reviewing records for developmental, educational, and family history. These combined results, and their appropriate interpretation, provide a wealth of information about children's academic abilities. As mentioned at the onset of this chapter, a comprehensive and thorough academic assessment requires attention to a number of individual, educational, and broader contextual factors.

In writing this chapter, a decision was made to organize it along subject areas (in accordance with the three Rs), as is often the case in review and discussion of academic assessment. While helpful in highlighting skills and processes contributing to typical and atypical development within each academic area, such an approach attenuates the extent to which skills and processes common across subject areas are emphasized. For example, children with certain types of writing difficulties may also experience difficulties with such math specific writing skills as legible numeral writing and the visual-spatial placement of numerals during computation (Berninger, 2009). An alternative organizational approach that provides greater emphasis on common areas of deficits (e.g., orthographic coding) is to organize in terms of specific learning disabilities and hallmark phenotypes. For example, Berninger (2009) has categorized dyslexia as "a writing and reading disorder in which spelling is the persisting feature...and the gender differences are related to the writing problems rather than the reading problems" (p.75).

The reader interested in further examining specific phenotypes associated with such specific learning disabilities as Dysgraphia, Dyslexia, and Oral and Written Language Learning is referred to the works of Berninger and her colleagues (e.g., Berninger, 2009; Berninger & May, 2011).

Finally, it is important to return to the issue of the place of academic assessment within the broader context of psychology and psychological assessment. As mentioned in the introduction, academic assessment is often relegated to more minor status within psychological assessment. It should be evident in review of this chapter, however, that academic achievement is dependent on a complex interplay of domain-specific and domain-general skills and cognitive processes. As such, academic assessment requires more than a simple tally of the number of correct and incorrect responses to academic content questions. Rather, at the core of academic assessment is not only identification of areas of skill deficit, but also an exploration of the neuropsychological factors that are key to understanding an individual's performance and areas to target for intervention.

# Chapter 23: Appendix

Selected subtests from four assessment instruments, the *Weschler Individual Achievement Test-III* (WIAT-III; Pearson, 2009), *Woodcock-Johnson III Tests of Achievement* (WJ-III ACH; Woodcock, McCrew, & Mather, 2001), *The Process Assessment of the Learner—Diagnostic Assessment* (PAL-II; Berninger, 2007) and the *NEPSY-II* (Korkman, Kirk, & Kemp, 2007), and their correspondence with core skills/cognitive processes that should be considered in the assessment of reading (R), writing (W), and mathematics (M).

Core Skills / Cognitive Processes & Example Methods of Assessment		Academic Areas	
Phonological Awareness	Decoding		
WIAT-III	Pseudoword Decoding—read nonsense words	R	W
WJ-III	Sound Awareness (Rhyming)—produce rhyming words	R	W
PAL-II	Syllables- pronounce polysyllabic word with targeted syllable deleted	R	W
Orthographic Awareness			
WJ-III	Spelling Sounds—spell using frequently occurring spelling patterns	R	W
PAL-II	Receptive Coding—recognize letters /words from prior presented words	R	W
Morphological Awareness			
PAL-II	Are They Related—determine if one word is derived from another	R	W
Reading Comprehension			
WIAT-III	Reading Comprehension—read passages and answer questions	R	
WJ-III	Passage Comprehension—identify a key missing word from a passage	R	
Listening Comprehension			
WIAT-III	Listening Comprehension—listen to sentences/passages and respond to comprehension questions	R	W
WJ-III	Understanding Directions—listen to instructions and follow them	R	W
PAL-II	Sentence Sense—identify sentences that make sense based on word choice/ context	R	W
Vocabulary			
WIAT-III	Listening Comprehension Receptive Vocabulary—match pictures to orally presented words	R	W M
WJ-III	Reading Vocabulary—provide synonyms, antonyms, analogies for words	R	W M
Spelling (Transcription Skill)			
WIAT-III	Spelling—write out orally presented words		W
WJ-III	Spelling—write out orally presented words		W
PAL-II	Word Choice—identify correctly spelled word among distractors		W

Core Skills / Cognitive Processes & Example Methods of Assessment		Academic Areas
Handwriting (Transcription Skills)		
WIAT-III	Alphabet Writing Fluency—write the letters of the alphabet (timed)	W
WJ-III	Handwriting Legibility Scale—evaluation of handwriting on the Writing Samples subtest based on legibility and general appearance.	W
PAL-II	Finger Sense (Repetition)—imitate index finger to thumb finger movement	W
Text Composition (Sentence Level)		
WIAT-III	Sentence Composition (Combining)—combine sentences to form one sentence that retains the meaning	W
WJ-III	Punctuation/Capitalization—punctuate and capitalize items	W
PAL-II	Sentence Structure—select plausible sentences based on word order/endings	W
Text Generation (Text Level)		
WIAT-III	Essay Composition—write text in response to a prompt (analytic scoring)	W
WJ-III	Writing Samples—write text in response to a prompt (holistic scoring)	W
PAL-II	Expository Note Taking and Report Writing—write a report from notes	W
Number Sense		
PAL-II	Oral Counting—count forwards/backwards by various increments	M
Math: Procedural		
WIAT-III	Numerical Operations—complete range of calculation tasks	M
WJ-III	Calculation—complete range of calculation tasks	M
PAL-II	Computation Operations—explain steps in solving written calculations	M
Math: Conceptual		
WIAT-III	Math Problem Solving—analyse and solve math problems	M
WJ-III	Applied Problems—analyse and solve math problems	M
PAL-II	Part-Whole (Fractions/Mixed Numbers)—report fraction/mixed number that represents the shaded portion of geometric shapes	M
Math: Declarative		
WJ-III	Quantitative Concepts—identify math terms, facts, and number sequences	M
PAL-II	Fact Retrieval—retrieve basic math facts	M
Fluency		
WIAT-III	Oral Reading Fluency—read passages aloud for comprehension (timed)	R
WJ-III	Writing Fluency—formulate simple sentences quickly (timed)	W
PAL-II	Oral Counting—count forwards/backwards by various increments (timed)	M

Core Skills / Cognitive Processes & Example Methods of Assessment		Academic Areas		
Speed of Processing				
PAL-II	RAS—identify words or numbers	R	W	M
NEPSY-II	Speeded Naming—produce names of colours/shapes/sizes/letters/ numbers	R	W	M
Working Memory				
PAL-II	Spatial Working Memory—recall dot patterns/locations			M
NEPSY-II	Word List Inference—repeat a series of unconnected words	R	W	M
Attention/Executive Functions				
NEPSY-II	Inhibition—quickly read the names of shapes with changing rules	R	W	M

# Methods of Assessing Learning and Study Strategies

Kathy C. Stroud

## Abstract

This chapter seeks to provide an overview of theories of learning strategies and self-regulation. Learning strategies, academic motivation, and related constructs are defined, and their role in fostering academic achievement is discussed. For each construct, specific strategies are highlighted that have been shown empirically to academic performance. Incorporating learning strategies assessment in a battery of tests is crucial to the overall understanding of an individual, and the success achieved from using these strategies can be far-reaching. Only a few measures have been developed for the purpose of measuring learning strategies and/or self-regulated learning, and most have significant limitations in their utility. More commonly, measures are designed to measure one or two constructs, with little consideration given to the possible interactions of the factors measured. Others are developed primarily for research purposes and may change with a given hypothesis. The School Motivation and Learning Strategies Inventory (SMALSI; Stroud & Reynolds, 2006) was developed as means of providing a comprehensive assessment of learning strategies across a broad age range to be used both for assessment and clinical purposes.

**Key Words:** Learning strategies, Academic motivation, Study strategies, Test-taking strategies, School Motivation, and Learning Strategies Inventory

The purpose of psychological assessment in children is to, as accurately and completely as possible, describe the whole child in a way that is meaningful. For this reason, no assessment can be considered truly complete without giving consideration to school functioning. Academic achievement is an essential accomplishment of childhood, and success or failure is tied to numerous outcomes, including emotional adjustment, self-esteem, and self-efficacy. It is interesting that, given its importance, standard practice in measuring academic achievement has often reduced to the comparison between a standardized achievement test and an intellectual instrument. While the information obtained from these measurements can be invaluable, they fail to account for many of the other variables affecting student performance. Just as cognitive functioning is no longer considered

a one-dimensional entity, a more multifaceted approach is necessary in understanding the process of learning and ultimately academic achievement.

A universal definition of learning strategies has remained elusive, often being used interchangeably with similar but different terms (i.e., study skills, learning styles, cognitive skills). Understanding the qualitative differences in these terms is important when making inferences about a student. Learning strategies have been defined as “the purposeful behaviors of a learner that are intended to facilitate the acquisition and processing of information” (Stroud & Reynolds, 2006, p. 8). By contrast, learning styles are “characteristic cognitive, affective, and physiological behaviors that serve as relatively stable indicators of how learners perceive, interact with, and respond to the learning environment” (Keefe, 1979, p.4).

Learning style indicates a tendency to use a limited repertoire of strategies for learning (Schmeck, 1988). Learning styles may be more dependent on the preferences of the learner and may or may not be the most efficient means of learning, whereas learning strategies are more universal and necessary in their ability to improve learning. Learning styles imply more passive attributes of the learner whereas learning strategies require the student to actively manipulate and process the information being presented. Most notably for intervention, learning strategies are an empirically supported, objective set of skills that can be taught and engage the student in an active learning process.

### ***Theories of Learning Strategies and Self-Regulation***

Early theories (and measures) of study methods emerged in the mid-twentieth century (Entwistle & McCune, 2004). At that time, the source and responsibility for successful academic achievement was placed solely on the student. One of the first measures of learning strategies included scales measuring effective study procedures, completing work promptly, having positive attitudes about teachers, and adoption of educational objectives (Brown & Holtzman, 1966; Entwistle & McCune, 2004). Entwistle and McCune (2004) provide an interesting perspective on the evolution of “study habits” and differences in conceptualization for American and European researchers. Their discussion includes a comparison of recent inventories and a qualitative discussion of their common factors. A few of the more current conceptualizations of learning strategies and self-regulated learning are presented here.

Weinstein and Mayer (1986) presented a taxonomy of learning strategies with five distinct but related categories, including rehearsal, elaboration, and organization—specific techniques enabling the student to organize and learn information; comprehension monitoring, which is the learner’s metacognitive awareness of learning and ability to control the use of strategies (Weinstein, Husman, & Dierking, 2000); and affective strategies, which are used to “help focus the learner’s attention and maintain the learner’s motivation” (Weinstein et al., 2000, p. 732). Within this model, strategies are viewed in terms of their relationship with variables such as motivation and metacognition.

Weinstein’s more recent “model of strategic learning has at its core the learner: a unique individual who brings to each learning situation a critical set of variables, including his or her personality,

prior knowledge, and school achievement history” (Weinstein et al., 2000, p. 733). This more comprehensive model includes three components: skills, will, and self-regulation. Skills include a learner’s knowledge about himself/herself as a learner, understanding the characteristics of the academic task, learning strategies, prior knowledge, and learning content as well as skills in the use of learning strategies, discerning important information, reading and listening comprehension, listening and note-taking, study and test-taking skills, and reasoning (Weinstein, 1994). The second component, *will*, encompasses the development and use of goals, academic motivation, affect with respect to learning, beliefs, volition, and a positive attitude toward learning. *Self-regulation* incorporates metacognitive components such as concentration, time management, monitoring comprehension, a systematic approach to learning and accomplishing academic tasks, coping with academic stress, and managing motivation (Weinstein, 1994). Will and Self-regulation are particularly important factors in discriminating between high achievers and low achievers (Yip, 2009).

Although they have a different primary emphasis, theories of self-regulation include learning strategies. Self-regulated learning has the same origins in cognitive psychology as learning strategies. Self-regulated learners: monitor and adapt their learning according to the situation; are strategic and goal-oriented in their approach to learning tasks; and rely on intrinsic self-control of the situation rather than simply reacting to external controls (Purdie, Hattie, & Douglas, 1996). Zimmerman (1998) describes the learning process in three cycling consecutive phases: forethought, performance or volitional control, and self-reflection. Each phase is comprised of subprocesses that may be used to understand the differences between skilled and unskilled learners. Processes in the forethought phase include setting goals, strategic planning, self-efficacy beliefs, goal orientation, and intrinsic interest. For example, skilled self-regulators more often adopt a mastery orientation, or an intrinsic desire to improve their ability; non-skilled learners, on the other hand, demonstrate a performance orientation, or learning in response to the threat of evaluation (Pintrich & DeGroot, 1990). During the performance phase learners engage in the tasks of attention focusing, self-instruction, and self-monitoring. In this phase, differences in learning include unfocused or divided focus or a focus on performance, use of ineffective (handicapping) strategies or self-instruction as

well as strategic learning, and monitoring of outcome or monitoring of success. The final phase, self-reflection, provides for self-evaluation regarding performance, including making attributions for success or failure, positive or negative self-reactions, and appropriate adaptation (Zimmerman, 1998). In this third phase, self-reflection for skilled learners involves self-evaluation and ultimately leads to appropriate attributions for the strategies used. The result is a positive self-reaction and an adaptive approach to subsequent tasks and differing situations (Zimmerman, 1998).

Winne and Hadwin (1998) also have proposed a theoretical model depicting self-regulated learning as an event with four phases: 1. defining the task (developing a perception of what factors relevant to the current task), 2. setting goals and devising a strategy for achieving them, 3. using tactics and strategies, and 4. monitoring, evaluating, and making changes as needed either during the task or in preparation for future learning (Winne, 2010). Students monitor themselves through the first three phases, making small or large scale changes to their learning as the task dictates. The fact that the primary measures of self-regulated learning are learning strategies inventories highlights the similarities of the theoretical constructs. Two measures used are the Learning and Study Strategies Inventory (LASSI: Weinstein, Schulte, & Palmer, 1987) and Motivated Strategies for Learning Questionnaire (MSLQ: Pintrich, Smith, Garcia, & McKeachie, 1991; Winne & Perry, 2000). Self-regulated learning as an aptitude has also been measured through structured interviews and teacher judgments or by using think aloud procedures, error detection tasks, and observations. Observations have been used to examine self-regulated learning in children as young as kindergarten (Whitebread, Coltman, Pasternak, Sangster, Grau, Bingham, Almeqdad, & Demetriou, 2009).

More recently, it has been argued that SRL must be considered in relation to context of internal environment and external environment. As such, self-regulated learning is an event that can be measured by traces, or “observable representations of cognitive, metacognitive and motivational events,” during the task itself (Winne, 2010, 267).

Broekkamp and Van Hout-Wolters (2007) conceptualize learning as occurring through strategy adaptation. Strategy adaptability is defined as “the degree to which students are capable of selecting or revising strategies in ways that make these strategies match relevant external and internal characteristics

of study tasks” (Broekkamp & Van Hout-Wolters, 2007, p. 405). External characteristics are task demands or the goals of the task determined by others. Internal characteristics are the personal goals adopted by the student for a given task. For test preparation, the model identifies internal task processes including adaptation of study strategies, task perceptions, and implementation of study strategies. These internal task processes interact with the student’s task dispositions (i.e., metacognitive skills, motivational beliefs, subject matter knowledge) as well as with external factors such as the student’s task environment and contextual factors (i.e., test, teacher’s task demands, test demands).

There has been some confusion regarding differences in the conceptualization of self-regulated learning (Roeser and Peck, 2009). Some view self-regulation in terms of content, including goals and self-efficacy; others describe volition or a self-regulatory process designed to “protect activated belief-goal systems (i.e., *intentions*) from competing demands and to bring them to fruition in action under favorable conditions” (Roeser & Peck, 2009, p. 121). The Basic Levels of Self model seeks to resolve this apparent inconsistency by referring to the I-Self (volitional) and Me-Self (automatic) systems. Roeser and Peck (2009) also introduce the concept of contemplative education which views self-regulated learning as a framework for cultivating “awareness and related volitional modes of attending, thinking, feeling, perceiving, acting, and interacting” in order to enhance functioning in society beyond the school setting.

## Who Needs Learning Strategies?

The short answer—everyone. The assumption is often that students naturally develop learning strategies as they progress through school; this is not always the case however. Some typically achieving students make it through school without learning effective strategies for learning (Nicaise & Gettinger, 1995). Even students who have already developed study strategies demonstrate improved performance with explicit teaching of learning strategies. Students of all abilities benefit academically from learning to be strategic in their academic tasks (e.g., Gall et al., 1990; Weinstein & Hume, 1998; Faber, Morris, & Lieberman, 2000; Bail, Zhang, & Tachiyama, 2008). Children who struggle tend to adopt more passive and ineffective strategies; they fail to monitor their progress in studying and do not consider the purpose of studying (Gettinger & Seibert, 2002). For college students, explicit teaching in self-regulated

learning strategies has been associated with higher cumulative grade point averages four semesters after taking the course, higher odds of graduation, and lower chances of receiving failing a course (Bail, Zhang, & Tachiyama, 2008)

While the routine teaching of learning strategies in regular education classrooms may well allow for incidental learning of some strategies for many children, special populations with particular needs or circumstances will likely require specific attention and intervention. The largest single group of students who have the capacity to benefit from explicit skill instruction would be those with learning disabilities. These students differ from their peers in their use of learning strategies. They lack confidence in their academic self-efficacy (Baird, Scott, Dearing, & Hamill, 2009; Lackaye, Margalit, Ziv, & Ziman, 2006) and their ability to monitor and regulate their learning, termed self-regulatory efficacy (Klassen 2010). Further, students with learning disabilities display significant difficulties with memory on academic tasks, highlighting the great need for instruction in test-taking and study skills, specifically mnemonic strategies (Scruggs & Mastropieri, 2000). Reading comprehension strategies instruction has also helped to improve understanding of science and social studies texts (Bakken, Mastropieri, & Scruggs, 1997). Other special populations for whom educational interventions related to learning strategies have been recommended include children who are survivors of childhood cancer (Jannoun & Chessells, 1987; Peckham, 1989), with traumatic brain injuries, (Powers, Vanetta, Noll, Cool, & Stehbens, 1995), with Attention-Deficit/Hyperactivity Disorder (ADHD) (DuPaul & Stoner, 1994; Harrison, Thompson, & Vannest, 2009) and with other psychiatric disorders (Brackney & Karabenick, 1995; Vannest, Temple-Harvey, & Mason, 2009). Neuropsychological deficits can be wide-ranging, depending on the nature of the illness, disability, or injury for these children making accurate assessment of learning and study strategies is necessary for determining students' strengths as well as their weaknesses.

## **Learning Strategies and Related Constructs**

Topics included in or related to learning strategies include academic motivation (Brophy, 2004; Pajares & Urdan, 2002), note-taking and listening skills (Kobayashi, 2006; Hughes & Suritsky, 1994; Bygrave, 1994; Hamilton, Seibert, Gardner, & Talbert-Johnson, 2000), time management (Boller, 2008; Britton & Tesser, 1991), test anxiety (Cassady

& Johnson, 2002), research strategies (Quarton, 2003), concentration/attention (Reynolds & Voress, 2007; Reynolds & Shirey, 1988, Rabiner & Coie, 2000), organizational techniques (Bakunas and Holley, 2004; Ho & McMurtrie, 1991; Shapiro, DuPaul, & Bradley-Klug, 1998), test-taking strategies (Scruggs & Mastropieri, 1992), study strategies (Kirby, Silvestri, Allingham, Parrila, & La Fave, 2008; Sweidel, 1996), writing strategies (Graham and Perin, 2007) and reading and comprehension strategies (Scammacca, Roberts, Vaughn, Edmonds, Wexler, Reutelbach, & Torgesen, 2007; Gersten, Fuchs, Williams, & Baker, 2001). These constructs provide concrete, distinct areas that can be targeted for intervention. Success in these areas has broad academic implications for increasing academic achievement. The relationship of each of these topics to academic achievement and, in some instances to each other, has been empirically supported, requiring careful and integrated assessment in order to better understand the development and selective use of cognitive strategies.

## **Study Strategies**

Perhaps the heart of learning, study is the process by which information is integrated with existing knowledge and committed to long-term memory. Studying is unique in several ways (Gettinger and Seibert, 2002). First, the act of study is skillful, requiring instruction to acquire and retain important information. Second, studying is a purposeful or intentional task requiring effort. Next, studying is an individual process that is highly dependent on the characteristics of the student. Finally, studying is dependent on a student's ability to self-regulate or monitor his learning. Studying in and of itself is not generally a requirement of high school. Therefore, it is up to the student to determine if it is needed, how much, and how best to accomplish it (Gettinger and Seibert, 2002).

Students receive a vast amount of academic information and must use study strategies that facilitate identifying important information when they study, making associations when learning, using a variety of resources when a concept is not understood, and using strategies for memory and encoding. Teaching students how to use a systematic, strategic approach to studying is important to learning clearly improves academic performance (e.g., Alexander & Murphy, 1999; Paris & Winegrad, 1990). Students need explicit instruction in how to organize information from different sources such as class notes, textbooks, and worksheets or homework, as well as how to use

memory aids. Direct instruction maximizes strategy use and academic potential (Alexander & Murphy, 1999, Kirby et al., 2008). These rehearsal, elaboration, and organizational strategies are necessary to acquire and use information in a meaningful way (e.g., Weinstein & Hume, 1998). Students are then able to adapt and use the most appropriate strategies, given the demands of a particular situation or test (Ross, Green, Salisbury-Glennon, & Tollefson, 2006; Broekkamp & Van Hout-Wolters, 2007).

Evidenced-study strategies that lend themselves to direct teaching include: improving concentration, improving memorization, developing associations with prior learning, learning self-talk, using concept maps, and using multiple sources of information (Vannest, Stroud, & Reynolds, 2011). For example, memorization may be improved by using strategies that aid in storing and retrieving information. Mnemonics (e.g., acrostics, rhyme keys, keyword, image name, chaining) are helpful strategies for remembering information or necessary steps for other types of learning, particularly for special populations such as students with behavioral and emotional difficulties (Mastropieri & Scruggs, 1998, Kleinheksel & Summy, 2003). Mnemonics are valuable tools for transferring information from working memory to long term memory, the main goal of studying (Goll, 2004). Whereas other learning strategies may be learned spontaneously, mnemonic strategies should be taught explicitly (Levin, 1993). Younger children, in particular, are able to categorize information in some way but are much less likely to spontaneously use mnemonics.

Self-testing is also a powerful tool for learning information (Carpenter, Pashler, & Vul, 2006; Karpicke & Roediger, 2007; McDaniel, Roediger, & McDermott, 2007). Its superiority to more commonly used strategies such as rereading information has been documented, however, students are far more likely to use the latter strategy (Karpicke, Butler, and Roediger, 2009), again highlighting the need for explicit instruction, not only in how to use the strategy, but in its effectiveness relative to other strategies.

### **Reading Comprehension Strategies**

The purpose of reading is to take of meaning from the printed word or text (Stroud & Reynolds, 2009). This simple but complete definition highlights comprehension as being the fundamental purpose of reading. The National Institute for Literacy (NIFL) identifies 5 areas of development critical for learning to read: phonemic awareness,

phonics, fluency, vocabulary, and text comprehension (Armbruster, Lehr, & Osborn, 2003). Perhaps the most complex skill, reading comprehension is also ultimately the most important. After all, the goal of reading is to understand the content of what has been written. Therefore, it is surprising that, through classroom observations, Durkin (1979) asserted that less than 1% of instructional time in reading was used for actual instruction in comprehension. More recently, a study of the curriculum of schools in the United States (ACT, 2007) revealed that reading comprehension strategies are still not being taught in elementary and secondary classrooms and that the lack of these skills is a substantial stumbling block to success in post secondary education. A meta-analysis of intervention studies with students struggling in reading indicated that instruction in reading comprehension strategies had the greatest effect in improving comprehension (Scammacca et al., 2007).

In 2000, the National Reading Panel (NRP) released results from a review of more than 100,000 empirical studies of reading (Armbruster et al., 2003). Among their findings, good readers are identified as being purposeful or goal-directed and active thinkers who incorporate previous learning in their reading. Reading is an “active goal-directed problem-solving process in which the reader’s task is to construct meaning from information contained in the text.” (Samuels, 1989, p. 3). Six strategies critical to text comprehension include: monitoring comprehension, using graphic and semantic organizers, answering questions, generating questions, recognizing the structure of the material, and summarizing (Armbruster et al., 2003).

*Monitor comprehension.* Monitoring comprehension allows students to assess what they do and do not understand about what they are reading and to use strategies to adjust their approach to reading when necessary. Self-regulatory behaviors are components of metacognition during comprehension tasks (Baker and Brown, 1984). Students are asked to engage in a variety of self-regulatory behaviors, including comprehension monitoring, or self-checking during reading (to detect errors and monitor understanding) and comprehension regulation (the active use of strategies to help regulate the reader’s comprehension).

Researchers have also studied the effects of working memory on reading comprehension. Students with comprehension difficulties do not demonstrate differences on short term memory measures, but they do have significantly lower performance on

working memory measures (De Beni & Palladino, 2000). De Beni and Palladino (2000) demonstrated that students with poor comprehension made more intrusion errors than their peers. In fact, their recall of irrelevant information was better than their recall of relevant information. Intrusion errors were a predictor of reading comprehension performance one year later.

*Using graphic and semantic organizers.* Graphic organizers, including semantic organizers, are visual tools to help students focus on important concepts and their relationships with each other (Armbruster et al., 2003). The characteristics of text (i.e., representational illustrations, imagery, spatial organization, mnemonic illustrations) are helpful aids for improving comprehension and retention of material (Mastropieri & Scruggs, 1997). These tools may provide an additional mode of information to be encoded and a means of organizing the information for learning (Mastropieri & Scruggs, 1997). Mnemonic illustrations can also be an aid when students need to commit the material to memory (Scruggs & Mastropieri, 1992). Aside from the use of these illustrations, Mastropieri and Scruggs (1997) identified several adjunct aids that appear to improve comprehension. It is believed that these aids, such as study guides, audiotapes, underlining, and semantic feature relationship charts help students to discern more important facts, providing an additional chance for encoding.

*Answering questions.* Providing questions prior to or embedded within the text cues students to attend to the most important information in a text and improves retention (Duchastel & Nungester, 1984; Pressley, Tanenbaum, Mc Daniel, & Wood, 1990). The Question Answer Relationship (QAR; Ezell, Hunsicker, & Quinque, 1997) teaches students the need to use previously acquired knowledge together with information from the text. Students become proficient at (a) locating information, (b) recognizing text structures and how they present important information, and (c) deciding whether an inference is required or invited (Raphael, 1986). Students must be able to understand information that is both explicitly stated and implied. *Generating questions.* Questioning techniques have proven to be effective strategies for both students with learning disabilities and normally achieving students (Mastropieri and Scruggs, 1997; Rosenshine, Meister, and Chapman, 1996). Students are able to monitor their comprehension as well as improve their comprehension by generating questions for themselves before, during, and after reading. Rosenshine et al. (1996)

examined the effectiveness of five types of prompts: signal words, generic question stems/generic questions, main idea, question types, and story grammar categories. Signal words and generic stems/generic questions were the most effective prompts used followed by story grammar prompts, perhaps because these three prompts are easy to use and they provide students with a guide and a way to focus their attention without requiring strong cognitive skills. Rosenshine and his colleagues (1996) felt that more intensive instruction might have led to improved results of the other types of prompts that were less successful but could be more beneficial. Using generic questions would have more value than signal words "because they promote deeper processing, initiate recall of background knowledge, require integration of prior knowledge, and provide more direction for processing than might be obtained through the use of the more simplified signal words" (Rosenshine et al., 1996, p. 200).

*Recognizing the structure of the material.* Recognizing structure includes a learner's ability to identify the setting as well as to determine why he or she is reading the material and its purpose. Students should be taught how to recognize expository text, recognize the structure of text by looking for signal words or phrases, developing goals for understanding based on the purpose of the text, and selecting study strategies best suited for the structure (Bakken & Whedon, 2002). Recognizing structures and using them to comprehend text are more effective strategies than paragraph restatement and retelling the main idea and incidental information (Bakken & Whedon, 2002).

*Summarizing.* Summarization requires that students understand, process, and formulate their own interpretation of the material presented. Summarization and main idea strategies include a student asking questions (e.g., "Who?", "What's happening?") during reading, then summarizing the text in their own words (Gajria & Salvia, 1992; Jenkins, Heliotis, Stein, & Haynes, 1987). Summarization strategies have generally been effective as a singular technique as well as when combined with self-monitoring and attribution training (Mastropieri & Scruggs, 1997).

### **Writing/Research Skills**

Writing is, perhaps, our best means of communicating an understanding of concepts. It is the most common way, from an academic perspective, of expressing one's own ideas or feelings. More than perhaps any other task in school, it is generative and

original in nature. Writing requires coordination of numerous thought processes, including coordination and knowledge of material being presented, strategies of effective writing and revision, and the skills associated with the mechanics of writing (i.e., grammar, vocabulary use). Writing is also a common task carried over to many vocational pursuits. Given these important distinctions, it is frequently used for measuring academic achievement and is often included as part of most state tests required for grade advancement or graduation.

Prior to the 1990s, writing instruction was largely limited to the mechanics of writing (e.g., grammar, spelling) and little attention was given to the process of writing (e.g., planning, organization of ideas). In a meta-analysis, traditional school grammar was determined to have no effect in improving quality of writing (Hillocks, 1986). Writing activities that were more effective than traditional or free writing were building more complex sentences as well as using and internalizing scales, criteria, or specific questions to generate material. The most effective treatments, termed Inquiry treatments, included those of analyzing data, problem-solving, and generating arguments.

A rather dramatic shift to more process-centered approaches to writing was heralded with the widespread adoption of programs such as Writer's Workshop (Troia, 2002, Atwell, 1987, Graves, 1983). The results were impressive, with several differences noted. 1. The amount of time spent writing in school has increased. 2. Writing is seen as more purposeful by teachers. 3. Teachers respond more to content than error correction 4. Students engage in more writing for pleasure 5. Exemplary teachers are encouraging the use of more advanced writing practices such as planning prior to writing and editing during writing, writing journals, and portfolios of writing samples (Troia, 2002; Campbell, Voelkl, & Donahue, 1997; Pressley, Rankin, and Yokoi, 1996). The National Assessment of Educational Progress (NAEP) was conducted most recently in 2007 to assess writing proficiency for American students (Salahu-Din, Persky, and Miller, 2008). 88% of 8th graders obtained scores corresponding with at least basic achievement, defined as partial mastery of necessary skills to perform at grade level. Only 33% of students had proficient achievement, defined as solid academic performance and competency with challenging subject matter. In other words, 67% of 8th graders are not adequately equipped to competently navigate grade-level subject matter. Results for 12th graders are even more disheartening, with only 24%

of students having obtained proficiency in writing at grade level (Salahu-Din et al., 2008). These results represent a best-case-scenario, in that many students with learning and other disabilities (and likely lower writing achievement) are excluded from the results (Salahu-Din et al., 2008). Not all news is bad. These results represent clear trends of improvement from previous assessments. Improvements have also been demonstrated for some minority groups as well as low and middle achieving students. (Salahu-Din et al., 2008). Overall, the findings clearly underscore the need, not only for a widespread process-centered approach, but one that incorporates both writing strategies and self-regulated strategies.

Numerous descriptions of the writing process exist, and they range in levels of specificity (e.g., Harris, Graham, Mason, & Friedlander, 2008; Strichart & Mangrum, 2002; Tompkins, 1994). All include elements describing steps for planning and organizing information prior to writing, creating at least one draft, and revising drafts both for content and grammar prior to producing a final copy. While these models are presented in linear format, many steps may be revisited as needed during the process. During prewriting, students should make a plan for their composition. This may be accomplished by doing some initial reading or conducting interviews (Scott & Vitale, 2003). Then begins the process of collecting information through such means as brainstorming, answering appropriate questions, using software, or reading more information (Roberts, 2002; Scott & Vitale, 2003). Research skills are needed as part of composition during the planning process in order to obtain necessary information. Children are encouraged early in life to use libraries to increase general reading skills and interest in reading; equal attention should be given to learning basic skills to use other aspects of the library (Krapp, 1988). Wooden card catalogs have been replaced in libraries by various resources, including the internet, databases, reference books and materials, audio/video materials, archival documents, and others. College students will need to be able to independently use all of these resources effectively as soon as they start college. Not only must students learn how to find resources, it is important to teach students how to discern which sources are credible as well as how to effectively organize and narrow the information available (Quarton, 2003). These research skills are essential beginning skills in the initial process of writing. After the initial information gathering phase, students must be taught to efficiently organize the information to be used into a

coherent plan or outline for writing (Scott & Vitale, 2003). Strategies utilized during the actual writing process are designed to narrow the topic, recognize the need for new information, or adapt a paper for a specific audience.

Research with students with learning disabilities yields alarming differences in their performance as compared to their normally achieving peers. Students with learning disabilities do not use writing strategies to the extent that nondisabled students do and they are not as purposeful in prewriting or revision activities; instead the majority of their focus is on grammar, spelling, and handwriting (Faigley, Cherry, Jolliffee, & Skinner, 1985; Graham, Schwartz, & MacArthur, 1993). Students with learning disabilities also spend much less time planning their writing prior to beginning a composition and have a tendency to write without pausing to rethink or read what they have written (MacArthur & Graham, 1987; Faigley et al., 1985). They are less likely than normally achieving peers to understand that the process of writing or the use of writing strategies is important (Graham et al., 1993). Students with learning disabilities are more prone to neglecting the more subtle nuances of writing, such as taking the perspective of their audience. When specifically directed to take their audience into account, they are more likely to examine surface level aspects of their writing; by contrast, normally achieving students typically suggest changes to the substance of the material.

Graham and Perin (2007) conducted a meta-analysis to delineate which elements of writing instruction improve student performance. Eleven elements emerged as being independently effective in improving student performance: writing strategies, summarization, collaborative writing, specific product goals, word processing, sentence combining, prewriting, inquiry activities, process writing approach, study of models, writing for content learning.

The effects of teaching writing strategies to normally achieving students and students with learning disabilities can be dramatic. Explicit teaching of skills such as considering their audience, developing a plan, evaluating the impact of content, and continuing to generate new content during the writing process increased their use from 10% of papers written prior to the intervention to 80% afterward (Graham and Harris, 1989). Measures of maintenance and generalization also yielded positive results. Self-regulated learning strategies including how to brainstorm, semantic webbing, setting writing

goals, and revision have produced improvements in word production and quality of writing (Chalk, Hagan-Burke, & Burke, 2005). Combining writing strategies instruction with self-regulation strategies has also been effective (Glaser & Brunstein, 2007; De La Paz & Graham, 2002; Graham & Harris, 1993; Harris & Graham, 1996). Self-regulated strategies during the writing process include goal setting, self-monitoring, and self-instructions. The self-regulated strategy development model (SRSD; Harris & Graham, 1996, 1999) has been designed to offer explicit instruction of writing and self-regulatory strategies. The six stages of instruction include the following: 1. teach any background knowledge needed to learn the strategy, 2. discuss the benefits and purpose of the strategy, 3. model use of the strategy and introduce self-instruction, 4. memorize steps of the strategy, 5. teacher supports or scaffolds mastery of the strategy, and 6. where the students independently use the strategy (Graham, Harris, & MacArthur, 2006).

### ***Test-taking Strategies***

Given the increased use of high-stakes testing emerging across the United States to determine grade promotion and school funding, much more emphasis has been placed on individual student performance on tests. As states transition to requiring passing scores on state tests (e.g., Texas Assessment of Knowledge and Skills, TAKS; Florida Comprehensive Assessment Test, FCAT) to determine school funding and pupil progress, teachers and school personnel are faced with the increasing demands of promoting children and adolescents' academic knowledge, but also their test-taking abilities. Standardized testing remains a part of the requirements for acceptance at most colleges and universities as well, leading educators, parents, and students to place a premium on improving performance on tests.

Evaluating content knowledge is most often the purpose of giving a test; however, several factors may affect a person's score, including the students' level of confidence and motivation for success as well as knowledge and effective use of test-taking strategies. Test-taking strategies are a set of skills that allow a student to recognize differences in test format and the entire testing situation in order to improve his or her score (Millman, Bishop, & Ebell, 1965). Test-taking strategies and self-regulation strategies during tests are not a new concept and have been proven to be effective interventions (e.g., Beidel, Turner, & Taylor-Ferreira, 1999; Schraw, 1994).

The major types of test-taking skills include: time-using strategies, error avoidance strategies, guessing strategies, deductive reasoning strategies, intent consideration, and cue using (Millman et al., 1965). Intent consideration strategies and cue using strategies are skills specific to a particular testing situation or test author. Time-using strategies are the techniques designed to make monitor and make efficient use of time during a test. Students can be taught strategies such as monitoring their time during tests, answering questions they know first, and not spending too much time on one item or one section. Strategies used to minimize wrong answers due to mistakes are error avoidance strategies (i.e., reading and understanding directions, accurately selecting answers, and checking for mistakes). Guessing strategies increase a student's chance of answering a question correctly. Students can use deductive reasoning strategies to arrive at an answer by using the item content, eliminating unlikely answers, and recognizing similar responses. Intent consideration indicates a test-taker's awareness of the intent behind the test as a whole or the individual item. Finally, cue using strategies rely on the test-taker's awareness of the idiosyncrasies of the specific test author (Mastropieri & Scruggs, 1992).

Hong, Sas, and Sas (2006) delineated 3 types of test-taking strategies: structural organization, cognitive strategies, and motivational awareness. Structural organization includes tasks that assess and allocate time and that sequence tasks to be completed. High achievers were more likely to use these strategies than low achievers. Cognitive strategies include checking (for understanding, correctness, or mistakes), externalizing (writing down formulas, definitions), remembering material, repeating (redoing or checking items), eliminating wrong answers in multiple choice items, using memory aids such as mnemonics, and elaborating (relating material to something). High achievers used more cognitive strategies overall, with particular differences noted in checking for correctness. Motivational awareness is having the student make positive self-statements about putting forth effort and adopting a passive attitude with no method (hope). Low achievers tended to adopt a more passive approach to strategy use.

As with other learning strategies, test-taking strategies are essential in helping special populations such as students with learning disabilities, emotional or behavioral difficulties, and minorities (Hughes, 1993; Scruggs & Mastropieri, 1986; Scruggs & Tolfa, 1985). Teaching elementary

students strategies that include "attending to directions, marking answers carefully, choosing the best answer carefully, using error avoidance strategies, and deciding appropriate situations for soliciting teacher attention" (Scruggs & Mastropieri, 1986, p. 65) resulted in significant increases from pretest to posttest on the Stanford Achievement Test Word Study subtest. Similar results were obtained in a much smaller study with middle school students identified as having an emotional behavioral disability; they were taught test-taking strategies using a mnemonic device (Hughes, 1993). Maintenance effects were seen at 11 weeks and generalization to class tests was noted. Research suggests that the effectiveness of an intervention is influenced by several factors, including length of time for instruction (Scruggs White, & Bennion, 1986). Also, when combining age and length of instruction, the performance of older children is much less dependent on length of instruction than younger children, with older elementary children appearing to benefit from even short instruction periods. The effectiveness of test-taking strategies is also likely dependent on the complexity or difficulty of the test design and material (Scruggs & Mastropieri, 1986).

Other variables, including socioeconomic and cultural factors also appear to influence learning and use of test-taking strategies. For example, children of low socioeconomic status appear to benefit from test-taking strategies instruction twice as much as much as their peers of higher socioeconomic status (Scruggs et al., 1986). One of few studies examining cultural factors examined differences in how students prepare for tests, use test-strategies, and self-efficacy and their effects on a cognitive ability test (Ellis & Ryan, 2003). Differences were most apparent between Caucasians and African Americans in their use of ineffective strategies with African Americans reporting much more frequent use of ineffective strategies. Both reported that they use effective test-taking skills. Strategy use can also be affected by motivation (Barnett, 2000) or a failure to understand when to use them (Winne & Jamieson-Noel, 2002). The variability in performance and lack of sufficient research underscore the need for additional study in this area.

### ***Note-taking/Listening Strategies***

"Notes may be defined as short condensations of a source material that are generated by writing them down while simultaneously listening, studying, or observing" (Piolat, Olive, & Kellogg, 2005, p. 292). Note-taking begins in elementary school

and becomes a critical skill in secondary school and college as instruction shifts to primarily teacher lectures. Note-taking skills and text marking strategies are specific learning strategies associated with good listening skills and the ability to discern important versus non-important information (Stroud & Reynolds, 2006). Effective note-taking as a strategy is a higher level skill that requires manipulating information or reconstructing it in a way that is most meaningful for efficient learning (Porte, 2001). It incorporates both comprehension and written production similar in scope to an original composition (Piolat et al., 2005). Piolat et al. (2005) measured note-taking in terms of the cognitive effort it requires.

Early research on note-taking strategies took one of two perspectives: information processing and product perspective. Research adopting an information processing view focuses on the process or actual recording of information (Kiewra, 1985). This focus on the “process” of note-taking is assessed by comparing students who do take notes with students who do not take notes on a given measure (Kiewra, 1985). The “product” or “external storage” perspective evaluates the effectiveness of note-taking according to whether or not it improves achievement by aiding in review of the information recorded. It is typically evaluated by comparing students who review their notes prior to assessment with those who are not given the opportunity to review their notes (Kiewra, 1985).

Many strategies are designed specifically to decrease the amount of time needed to physically write notes. Piolat, Olive, and Kellogg discuss three levels of language that are available to be targeted: abbreviated procedures, syntax, and physical formatting. Examples of abbreviated procedures include end truncation, conservation of the frame of consonants, and suffix contractions (Piolat et al., 2005). These and other procedures serve the same purpose but are often tailored specifically to the individual. Syntax may be changed by leaving out unnecessary words (telegraphic style) or substitutive techniques using symbols. Finally, the physical format of notes involves altering the physical placement of notes on the page from a linear presentation to an organized layout of concepts (Piolat et al., 2005).

Meta-analyses evaluating the effectiveness of note-taking and note-taking interventions have indicated support for the efficacy of taking notes, and in particular taking and reviewing notes (Kobayashi, 2006; Kiewra, 1985; Hartley, 1983). Students appear to benefit more from interventions

that include providing a graphic organizer or the instructor’s notes (Robinson, Katayama, Beth, Odom, Ya-Ping, Vanderveen, 2006; Kobayashi, 2006). Also, students with low ability benefit much more from explicit teaching of strategies than high-achieving students do (Kobayashi, 2006; Shrager & Mayer, 1989; Kiewra & Benton, 1985; Wade & Trathen, 1989).

Note-takers differ in how well they are able to relate new information to that already learned, take effective notes, make note-taking an active process, and determine priorities of relevant information (Faber et al., 2000). Students shift their focus and the learning strategies they choose to employ with repetition of lecture material, suggesting that “students are active learners who have some metacognitive control over their learning strategies” (Kiewra, et al., 1991, p. 123). As might be expected, students with learning disabilities have significant difficulties taking notes, including their ability to record notes with sufficient speed, focus their attention on lectures, and use appropriate strategies such as a shorthand method (Suritsky, 1992; Hughes & Suritsky, 1993).

Acquisition of note-taking skills is a developmental process, particularly with regard to the way that students encode information as they hear and write it (Faber et al., 2000). Both encoding and external storage are important in learning as it relates to note-taking. In the encoding process, the learner processes the new information and assimilates it with previous related knowledge. Self-questioning is an important tool for monitoring comprehension and making associations with other information (Faber et al., 2000). Research suggests that students gradually transition from using notes in a primarily external storage function to a more efficient use of encoding, and younger students of both high and low ability can be taught to use skills such as how to apply prior knowledge to the current subject matter, (b) how to detect and write main ideas, and (c) how to monitor themselves for understanding. (Faber et al., 2000). Other methods used to help students develop complete and effective notes include the following: learning shorthand, writing faster, previewing the subject before class, using guided notes provided by the teacher, and strategic note-taking that cues the student what questions to ask himself about the lecture (Boyle, 2001).

Listening strategies are also important components of learning in the classroom. Perhaps more than any other strategies discussed here, listening is often viewed as a skill that develops naturally and

does not require explicit instruction; alternatively it is viewed as an innate ability that cannot be taught (Opitz & Zbaracki, 2004). Research does not support either of these contentions. Listening strategies are often taught in the context of learning a second language (Field, 2008). Effective listening strategies that lend themselves well to explicit instruction include: preparing to listen, becoming an active listener, listening for teacher cues, and developing a comprehensive plan for listening (Vannest, Stroud, & Reynolds, 2011).

### **Attention/Concentration**

Attention is a precursor to memory and learning (e.g., see Reynolds & Voress, 2007; Riccio, Reynolds, Lowe, & Moore, 2002). Most theories of learning include in their beginning phases the ability to attend adequately to the material or stimulus. Bandura's (1965) Social Learning Theory has four necessary components: attention, retention, reproduction, and motivation. Attention is dependent both on the characteristics of the learner and of the model. For learning to occur, the learner must be able to filter out extraneous information and focus on the salient elements to be learned. The Keller's ARCS Model (Attention, Relevance, Confidence, Satisfaction) integrates concepts, theories, strategies, and tactics related to the motivation to learn (Keller, 1997). According to Keller, learning is facilitated by capturing the learner's interest (perceptual arousal), stimulating inquiry (inquiry arousal), and maintaining attention (variability). Attention is composed of 4 factors: initiating focus or attention, sustaining attention, inhibiting responses to distractions, and shifting attention (Riccio, Reynolds, Low, & Moore, 2002). Concentration is the extended attention required for learning; this "paying attention" is a skill that can be taught to students (Vannest, Stroud, & Reynolds, 2011).

Attention problems relating to learning are often considered synonymous with Attention-Deficit/Hyperactivity Disorder (ADHD). Prevalence rates of ADHD range from 3–7% (American Psychiatric Association, 2000) to 10–20% of school-age children (Shaywitz & Shaywitz, 1992). ADHD is the most common clinical referral concern for children (Barkley & Murphy, 1998). Clearly, ADHD is a common problem in most classrooms; however, inattention is not limited to children with ADHD. In fact, attention problems impact many children suffering from other neurological and psychological disorders, including schizophrenia (Riccio et al., 2002), depression (American Psychological

Association, 2000), anxiety (LaBerge, 2002), acute stress (Hancock & Warm, 1989) and brain injuries or dysfunction (Sohlberg, McLaughlin, Pavese, Heidrich, & Posner, 2000). Environmental or personal factors also impact attention (e.g., fatigue, medication) (Zentall, 2005). Indeed, the relationships between both internalizing and externalizing disorders and academic underachievement appear to be mediated by attention (Barriga, et al., 2002; Hinshaw, 1992). Given the role of attention in learning and the frequency of reported concerns, it is essential to include assessment of attention and intervention, if needed, with children who are struggling academically (Barriga et al., 2002).

Cognitive psychologists see the ability to self-monitor and adjust in a learning environment as an important skill in the development of effective learning strategies (e.g., Alexander & Murphy, 1999). The successful use of strategies is dependent on several processes, including identifying important information, allocating attention, and monitoring comprehension (Reynolds & Shirey, 1988). As a student learns skills in study, note-taking, and test-taking strategies their perception that attention and performance can be controlled is likely to increase.

Research and recommendations for strategies aimed at improving attention typically have been directed toward children with ADHD and are most often multimodal in nature. Numerous classroom strategies appear to be helpful in engaging children with attention problems. Such techniques target tasks including getting attention, focusing attention, sustaining attention, reducing distractions, teaching organizational skills, increasing time management skills, and increasing specific skills in content areas (Teeter, 1998).

### **Organizational Techniques**

The ability to manage learning tasks is integral to academic success. Organization allows a student to be purposeful in the arrangement of his own environment and materials. It is much more than an academic skill; it is a work skill and a life skill. Organizational behaviors may be defined as the ability "to (a) plan and manage activities within a time framework, (b) systematically arrange objects and assignments within space for rapid retrieval, and (c) structure an approach to a task" (Zentall, Harper, and Stormont-Spurgin, 1993, p. 112). In this definition of organizational behavior 3 types of organization are introduced: time (time management which will be discussed shortly), object (a student's

ability to maintain his possessions, including needed supplies), and idea (the management and structure of academic information to be learned). It is object organization that is the focus of this section.

Having weak organizational skills can result in problems with school, work, and personal life (Gureasko-Moore, DuPaul, & White, 2006). Organizational strategies are those techniques which are used to organize materials to be learned (Stroud & Reynolds, 2006). For example, students can be taught specific steps in order to be prepared for class; they may need help learning to keep their assignments in a designated place. Students who often come to class with one binder that has numerous assignments from every subject protruding from it, yet cannot find the one that is currently due will likely need specific instruction, modeling, and practice in order to learn better organization. Teaching students these basic organizational techniques provide students with a skill set for learning more complex organization tasks as adults (Slade, 1986). Students who are strategic in their organization of work in various environments are more apt to be efficient learners and to have more time to devote to academic tasks. They are also more likely to complete homework assignments and to turn in their work (Hughes, Ruhl, Schumaker, & Deshler, 2002). Object organizational strategies are also essential tools for learning other skills including time management (Richards, 1987).

Organizational techniques may be taught with other self-management strategies including filing and having materials accessible at school as well as defining a study space at home (Gall et al., 1990). Teachers can foster organization by requiring the use of a three-ring binder, providing lessons and games regarding organization of students' desks at school, teaching students ways to define and organize a place to study at home, providing incentives for using appropriate skills, and eliciting parent support. Bakunas and Holley (2004) identify specific organizational objectives to teach students. For example, teach students to bring needed supplies through methods such as making a list of supplies for the class and involving parents in making sure students are coming to school prepared. Teachers might also have students learn to organize their desks and lockers, cleaning them regularly. Suggestions include having students draw maps of their desks as they are and as they should be. Using class time allows different ideas to be compared and implementation to begin.

### ***Time Management***

Time management refers to the ability to identify tasks to be completed and to allocate sufficient time to each of those tasks. Most college students identify management of their time more effectively to be their greatest area of need (Weissberg, Berentsen, Cote, Cravey, and Heath, 1982). Having weak time management skills can result in problems with school, work, and personal life (Mauksch, Hillenburg, & Robins, 2001; Peeters & Rutte, 2005). To help address this need, numerous books and learning strategies classes for college students have included efficient time management skills as a focus. Most of these resources have offered very similar suggestions for improving the time management practices (Macan, Shahani, Dipboye, & Phillips, 1990).

While children are at home, their parents often monitor, at least to some degree, their allocation of time. Teachers provide oversight for larger projects in the classroom. As they progress through middle school and into high school, expectations for independent management of work and extracurricular activities gradually increase. That children naturally mature and develop effective time management practices tends to be assumed but not necessarily supported (Boller, 2008). Even children in elementary school benefit from learning time management techniques (Hoover, 1993). Instruction in effective time management, often included as a self-regulatory strategy, has been associated with higher course grades (Brackney & Karabenick, 1995; Zimmerman, Greenberg, & Weinstein, 1994), reduced anxiety (Macan, 1994), increased problem-solving abilities, effort, and self-efficacy (Jung, 2009) and better grades (Gureasko-Moore et al., 2006; Langberg et al., 2008).

Time management as a self-regulatory or self-management technique includes skills such as learning to organize a schedule, setting attainable goals and accurate timelines, deciding on priorities, arriving on time for class or other obligations, completing work on time, providing rewards or incentives for work completion, and breaking an assignment into manageable parts (Gall et al., 1990). To include these in the general classroom curriculum, teachers might teach students to: use an assignment sheet to keep track of tasks to be completed in their various classes, to schedule their time and encourage them to monitor their ability to stay on schedule, and break larger tasks into smaller more manageable ones. Whenever possible, it is important to draw the connection between students' goals

and their academic effort, and incentives may be helpful in reinforcing the use of good skills. Finally, the need for parent involvement, by having them allocate and monitor study time, model good time management behavior, provide tools such as “to do” lists and assignment planners, and reinforce good time management practices at home, is critical, as it provides this reinforcement across settings (Gall et al., 1990).

Time management may also be viewed from an information processing perspective (Britton and Tesser, 1991). Given a limited amount of time and a set of tasks to be completed, it makes sense that a student who is able to efficiently allocate time to prioritized tasks would be able to accomplish more academically. Many different factors of tasks must be taken into account when prioritizing tasks, including task length, complexity, deadlines, and resources needed.

Measures of time management as a behavior have been used primarily for research purposes rather than a means of intervention. As such, they are not standardized measures. They are also almost exclusively designed for college-age students rather than younger students. The Time Management Behavior Scale (TMB; Macan and colleagues, 1990) includes items based on behaviors recommended by various sources on time management. Research with the TMB indicates that students’ report of effective general time management behaviors are significantly correlated with factors including role ambiguity, somatic tension, job and life satisfaction, self-rated performance, and GPA. Greater perceived control over time was associated with less role ambiguity, job induced tension and somatic tension; it was also associated with higher scores on life and job satisfaction measures as well as self-reports of achievement and grade point average (Macan et al. 1990). The TMB also supported the effectiveness of a time management seminar while reading a book on time management was not helpful.

### **Academic Motivation**

Among other things, motivation dictates a student’s investment in the process of learning, which strategies are used, and the amount of effort put into carrying them out (Stroud & Reynolds, 2006). In addition, understanding motivation helps to explain the differential use of learning strategies, both between students and in one student across learning situations. The converse is also true. The effective use of learning strategies leads to academic success which leads to increased academic motivation.

Models of strategic learning include motivation as a key component (Weinstein et al., 2000). Weinstein et al.’s (2000) model has three components: skill, will, and self-regulation, with “Will” meaning the motivation to learn. Given the relationship between learning strategies and academic motivation, no assessment of one should be considered complete without including the other. An exhaustive review of academic motivation is beyond the scope of this chapter. The reader is referred to Brophy (2004) for a comprehensive discussion of theories of academic achievement motivation with a strong emphasis on how teachers can use aspects of each of these theories to adapt their teaching style and classroom environments to maximize student effort.

The definition of motivation differs according to one’s theoretical orientation (Dembo & Eaton, 1996). Descriptions vary according to the frequency, duration, and/or intensity of behavior (behaviorist), as an unconscious drive (psychodynamic), or as a student’s thoughts or feelings about a task (cognitive). Conceptualizations of motivation might also take into consideration the students’ social or cultural experiences (Dembo & Eaton, 1996). In general, motivation can be considered the “process by which the individual’s needs and desires are activated and, thus, directs their thoughts and their behaviors” (Alexander & Murphy, 1998, p. 33) or “an internal state that arouses, directs, and maintains behavior” (Dembo & Eaton, 1996, p. 68). Dembo and Eaton (1996) describe three components of motivation: (a) expectancy, or the student’s attributions and self-efficacy for success/failure, (b) value, or the importance placed on the task, and (c) affective, or the emotional processes associated with the learning situation. Motivation is also a key component of models of self-regulation (Zimmerman, 2002). A student’s beliefs are important in the forethought phase of learning and include self-efficacy, outcome expectations, intrinsic interest or value, and goal orientation.

Academic achievement motivation relates specifically to academic learning. Leading theories of achievement motivation include self-efficacy, attribution, and goal theories as well as self-determination and intrinsic motivation. While each of these has provided new insights into learning, they have similarities as well. Many have argued that much can be learned from integrating the practical points of these theories when the aim is for successful interventions in the classroom (Brophy, 2004; Roeser & Galloway, 2002). Others feel that there is merit in viewing academic motivation as a multidimensional

construct (Bong, 2001). Brophy (2004) asserted that self-efficacy, attribution, and goal theories can all be conceptualized in the expectancy part of expectancy-value theory.

According to expectancy-value theory, an individual's expectations regarding success and the value he or she gives to succeeding are important factors affecting motivation to perform different achievement tasks (Wigfield & Tonks, 2002). Expectancy for success may depend largely on self-efficacy for the task. Self efficacy is defined as "people's judgments of their capabilities to organize and execute courses of action required to attain designated types of performances" (Bandura, 1986, p. 391). It is the culmination of both perceived performance in previous tasks and perceived control that a person feels he has had. Self-efficacy is independent of ability, and it affects numerous factors including students' choice of tasks, persistence, future performance, and their emotional reaction to the task or situation (Collins, 1982). Higher self-efficacy has been associated with both improved coping with stress and academic performance (Chemers, Hu, & Garcia, 2001). Given its independence from ability, it is an exciting consideration for intervention with students of all achievement levels.

Attribution theory refers to one's natural desire to understand why things happen and their beliefs about the causes of success or failure (Dembo & Eaton, 1996). As it applies to learning, attribution theory seeks to explain students' perceptions of the causes of academic success or failure. Weiner's (1979, 1986) achievement motivation theory is the most commonly accepted theory of attribution. Attributes are organized into three dimensions: internal/external, stable/unstable, and controllable/uncontrollable. Students base their beliefs and future actions on their judgment of events in these dimensions, and these attributions affect their expectancy of future performance, persistence in similar tasks, emotional responses, which tasks they choose, and students' self-efficacy (Dembo & Eaton, 1996; Weiner, 1976).

Goal theory has emerged as providing an important conceptualization of academic motivation (Anderman & Wolters, 2006; Elliot, 2005). Goal theory suggests that students adopt one of two distinct goals—performance or mastery (Brophy, 2004). Performance goals, otherwise known as ability or task goals, view learning as a means to an end. These goals focus on "one's ability and sense of self-worth" and pair evaluation of a student's ability with the process of learning (Ames, 1992, p. 262).

Mastery goals, or learning goals, are those adopted in which "individuals are oriented toward developing new skills, trying to understand their work, improving their level of competence, or achieving a sense of mastery based on self-referenced standards" (Ames, 1992, p. 262). Adoption of mastery goals has been associated with perceived lecture engagement and a lack of harsh or evaluative environment (which were associated with performance goals) (Church, Elliot, & Gable, 2001). Mastery goals are associated with a student's investment in tasks, seeking challenges, persisting longer, increased productivity, and increased positive feelings toward the task (Kaplan & Maehr, 2007). In fact, mastery goals are also associated with a more adaptive life orientation, including increased social behavior, positive feelings toward self, and a general sense of well-being (Kaplan & Maehr, 2007).

While Ames asserted that performance and mastery goals are contrasting goals that do not coexist (Ames, 1992), a 2 x 2 model refutes that notion, taking into account approach/avoidance goals as well as mastery/performance (Kaplan & Maehr, 2002). Learning or mastery approach goals appear to facilitate achievement, and performance avoidance goals hinder achievement (Brophy, 2004). The role of performance approach goals is not as clear; it may be that their usefulness or detrimental nature is related to situational factors including the age of the students (Pintrich, 2000). Research on mastery avoidance goals is needed (Kaplan & Maehr, 2002). Mastery avoidance goals may be associated with disorganized learning and test anxiety (Elliot & McGregor, 2001). Many studies suggest that students do not adopt goals in isolation; rather they often adopt multiple goals depending on the situation or context (Kaplan & Maehr, 2002). Obviously lacking in the 2 x 2 model of goal theory is that it does not take into account other goals that students have endorsed, including work completion and social goals. A more recent model takes personal and situational characteristics into account (Kaplan and Maehr, 2002). Three major components comprise what is referred to as a "personal achievement goal": 1. perceived purpose in the situation, 2. self-processes (i.e., self-efficacy, social identity), and 3. the available possibilities for action in the situation.

Developed by Deci and Ryan (1985, 2000), Self-Determination Theory (SDT) has also been a strong presence in academic motivation research. SDT is based on the proposition that humans have an innate desire to learn which is either encouraged

or discouraged by an individual's environment. In order for intrinsic motivation to develop, fulfillment of three basic psychological needs is necessary—competency, relatedness, and autonomy (Deci & Ryan, 1985, 2000). SDT delineates intrinsic and extrinsic motivation but further suggests the existence of amotivation or the absence of any desire to pursue an activity. Rather than a simple dichotomy, these states exist on a continuum, with varying degrees of extrinsic motivation: external regulation, introjected regulation, identified regulation, and integrated regulation. There have been indications, however, that intrinsic motivation decreases as extrinsic motivation increases (Darner, 2009). Intrinsic motivation may be further divided into three categories: intrinsic motivation to know, intrinsic motivation to accomplish, and intrinsic motivation to experience stimulation (Vallerand, Pelletier, Blais, & Briere, 1992). It is intrinsic motivation, which elicits pleasure from the act of engaging in the behavior, that is the most self-determined (Vallerand & Ratelle, 2002). High levels of intrinsic motivation appear to be associated with greater academic motivation (Faye & Sharpe, 2008; Wang, 2008; Turner, Chandler, & Heffer, 2009).

A few measures have been designed specifically to assess academic motivation, primarily for research rather than clinical purposes and for use with college students. The Academic Motivation Scale (AMS; Vallerand et al., 1992) was developed to measure academic motivation for college students based on Self-Determination Theory. The AMS assesses 7 constructs which measure intrinsic motivation, extrinsic motivation, and amotivation. Research has indicated only partial support for the construct validity of the AMS (Cokley, Bernard, Cunningham, & Motoike, 2001; Cokley, 2000). In fact, some researchers have argued that validity studies of the AMS suggest that the constructs of SDT may not fit well along a continuum. A better alternative might be to conceptualize intrinsic and extrinsic motivation in a hierarchical manner (Fairchild, Horst, Finney, & Barron, 2005).

*Interventions.* Motivation is a behavior that can be learned. Which strategies one chooses to use for improving academic motivation largely depend to the theoretical orientation adopted. For example, learning strategies interventions appear to have a positive effect on self-efficacy (Corno & Mandinach, 1983; Pintrich & De Groot, 1990; Zimmerman & Martinez-Pons, 1990). Being able to use a strategy to accomplish a task provides a sense of control over performance outcomes. If the strategy is successful,

then the student's self-efficacy is improved and the learner is more likely to use the strategy again.

Attribution retraining with learning strategies instruction improved use of reading strategies in a group of children with learning disabilities (Borkowski, Weyhing, & Carr, 1988) and significantly increased the passing rate for final exams with a group of college freshmen (Van Overwalle & De Metsenaere, 1990). Attribution retraining has been less effective (Craske, 1985) or not supported by similar studies (Miranda, Villaescusa, & Vidal-Abarca, 1997; Short & Ryan, 1984) that incorporated self-regulation procedures as part of the intervention. It may be that the use of self-regulation strategies generated sufficient self-confidence, circumventing the need for additional training. Individual strategies such as self-talk, goal setting, and time management have been used effectively to increase academic motivation (Dembo & Eaton, 1996). In addition, classroom management strategies employed by teachers have a profound effect on students' academic achievement motivation (Brophy, 2004; Church et al., 2001).

### ***Test Anxiety***

Anxiety may be defined as "the tendency to be nervous, fearful, or worried about real or imagined problems" (Reynolds & Kamphaus, 2004). Anxiety may be described as general or specific. Test anxiety is a situation-specific form of anxiety. Simply put, test anxiety prevents a student from performing on a test at the level he or she is capable of. Assessment of test anxiety dates back to the mid-twentieth century and test anxiety as a construct was proposed much earlier (Sarason & Mandler, 1952; Mandler & Sarason, 1953). The increasing reliance on state-mandated testing in schools and the consequences for individual students as well as schools has transformed the issue of test anxiety from an individual concern to one that is shared by students, parents, and educators alike. As with so many other areas discussed in this chapter, test anxiety has been studied most in college-age students; however, test anxiety can be a hindrance for students of all ages. Test anxiety has been associated with lower test scores as well as lower self-esteem (Marsh, 1990; Newbegin & Owens, 1996). Students who obtain high scores on measures of test anxiety are also more likely to report more pervasive psychological difficulties, including anxiety disorders and depressive symptoms (Beidel, Turner, & Trager, 1994; King, Mietz, Tinney, & Ollendick, 1995) and even suicidal thoughts (Keogh & French, 2001). Awareness of

when students experience test anxiety has expanded as well to include the time before and after the test as well as during the test itself (Raffety, Smith, & Ptacek, 1997; Zeidner, 1998; Stöber, 2004). The incidence of test anxiety appears to be increasing, from estimates of 10 to 20 percent to more recent suggestions of 33 percent (e.g., Methia, 2004).

Models of test anxiety conceptualize the construct in one of three ways: a personality trait, an emotional state, a clinical disorder (Putwain, 2008). Four main theories have shaped the study of test anxiety (Jones & Petrucci, 1995). The *cognitive-attentional model* includes the original worry-emotionality constructs, theorizing that excessive worries, self-coping statements, concern regarding physiological reactions, and other task-irrelevant thoughts interfere with optimal task performance (Naveh-Benjamin, 1991; Wine, 1971). The *learning deficit model* or *skill deficit model* suggests that test anxiety arises from a lack of adequate study and test-taking skills (Birenbaum, 2007; Hodapp & Henneberger, 1983). Although the relationship between poor study habits and test anxiety has been established, this model has not been able to adequately explain how high-achieving students who have good study skills can also experience test anxiety (Tobias, 1985). The *dual deficit* or *information processing model* seeks to bridge the gap between the first two models, proposing that both task-irrelevant thoughts and skills deficits may contribute to feelings of anxiety (Jones & Petrucci, 1995). According to this view, test anxiety is caused by difficulties encoding and organizing material as well as retrieval during an evaluation (Naveh-Benjamin, 1991). Finally, the *social learning model* argues that the origins of test anxiety lie with a student's self-efficacy regarding a task and motivation to perform well.

Another integrative model of test anxiety is the Transactional Process Model, which describes the relationships among antecedents, student dispositions, cognitive processes, and the consequences associated with test anxiety (Spielberger & Vagg, 1995). Antecedents include the subject matter of the test, study skills, and test taking skills. During the evaluation, a student retrieves and processes information, continually assesses his situation, and may respond with an increase in worry and/or emotionality associated with test anxiety. The result of these processes will be behavior that is relevant or not relevant to the task.

The cause of test anxiety differs according to the characteristics of the student. For example, high achieving students and low achieving students may

have test anxiety for very different reasons (Wigfield and Eccles, 1989). High achievers may experience heightened anxiety due to the unrealistic expectations placed on them by parents, peers, or self, while less able students may be anxious due to previous experiences of and future expectations of failure. Also, some anxious students may have good study habits but suffer from the pressure of being evaluated, whereas other students have poor study strategies which inhibit their learning (Naveh-Benjamin, McKeachie, & Lin, 1987).

Students with high anxiety divide their attention between task-relevant and task-irrelevant thoughts (Wine 1971). Children with high anxiety are similar to anxious adults in their increased reporting of negative self-evaluations (Galassi et al., 1981; Zatz & Chassin, 1983; Zatz & Chassin, 1985). Cognitive distortions, including catastrophizing, are particularly detrimental to performance on tests (Putwain, Connors, & Symes, 2010). Unfortunately, the coping statements that test anxious children so often make do not appear to improve their performance (Zatz & Chassin, 1985). Students with high test anxiety report significantly more self-coping statements than their peers, likely because they perceive the situation as stressful (Prins, Groot, & Hanewald, 1994). Research indicates that it is likely the absence of negative thoughts rather than the presence of positive thoughts that improves performance, a finding which highlights the need for intervention programs to decrease all off-task thoughts.

When assessing test anxiety, it should be considered that the relationship between anxiety and performance is likely not linear. Ball (1995) summarized the following points describing the relationship between the two factors: (a) "that test anxiety may be facilitating" (for some students), (b) that moderator variables including test difficulty and "the proficiency of the test taker" may be present, and (c) "the relation between test anxiety and performance may be curvilinear" (p. 109). Also of concern, students with test anxiety demonstrate poor study habits and organizational difficulties which inhibit information processing (Culler & Holahan, 1980; Naveh-Benjamin et al., 1987). Some distinguish between test anxiety, which they consider to always be debilitating and more mild fear of failure that facilitates better performance (Martin & Marsh, 2003).

Self-report methods remain the commonly used method of assessing test anxiety. Preferred for their efficiency and ease of administration, self-report methods are used more often for research than

for diagnostic or intervention purposes. The most commonly used measures for children are the Test Anxiety Scale for Children (TASC; Sarason, Davidson, Lighthall, & Waite, 1958) and the Test Anxiety Inventory (TAI; Spielberger, 1980). The TAI was developed for use with college students but norms have been developed for high school students. The Children's Test Anxiety Scale (CTAS; Wren & Benson, 2004) is a newer measure of test anxiety. Developed for use with children in grades 3 to 6, the CTAS measures three dimensions of test anxiety: thoughts, autonomic reactions, and off-task behaviors.

Hembree's (1988) meta-analysis asserted that a variety of cognitive and behavioral interventions have had lasting effects in reducing anxiety and increasing academic performance. Unfortunately, as with studies regarding the antecedents and correlates of test anxiety, much of what we know about interventions with children and adolescents is inferred from studies with adults (Ergene, 2003).

Effective intervention most often utilizes a multi-component approach. Elements can include training in cognitive restructuring, relaxation, time management, attention control, test-taking, and study-skills (Dendato and Diener, 1986; Decker, 1987; Glanz, 1994; Wilson & Rotter, 1986). Results of teaching these combined skills appear to be decreased test anxiety and improved academic performance. Such multi-component approaches have effectively reduced test anxiety and increased self-esteem and academic performance (Wilson & Rotter, 1986). Teaching students as young as 3rd grade relaxation techniques can effectively reduce test anxiety (Larson, El Ramahi, Conn, Estes, & Ghibellini, 2010). Abbreviated Upright Behavioral Training, which offers explicit instruction in the use of 10 overt relaxed behaviors, has effectively reduced test anxiety for college students as well (2006).

### **Assessment Measures**

The importance of learning strategies and their related constructs is hopefully evident at this point. The next logical consideration should be the accurate measurement of these constructs. Only a few measures currently exist for the purpose of measuring learning strategies and/or self-regulated learning, and most have significant limitations in their utility. More commonly, measures are designed to measure one or two constructs (Child Organization Scale, Zentall, 1993), with little consideration given to the possible interactions of these constructs. Others are developed primarily for research purposes and may

change with a given hypothesis (e.g., Approaches to Learning and Studying Inventory, Entwistle & McCune, 2004). The most widely used and more comprehensive assessment measures are the Learning and Study Strategies Inventory (LASSI, Weinstein, 1987), the Motivated Strategies for Learning Questionnaire (MSLQ; Pintrich, Smith, Garcia, & McKeachie, 1991), and the School Motivation and Learning Strategies Inventory (SMALSI; Stroud & Reynolds, 2006). As is the case with much work on learning strategies, the MSLQ was created to be used for college-age students. The LASSI, which is commercially available, was also originally designed for use with college students (Weinstein, 1987). The LASSI for high school students is a downward extension of a college level version of the instrument. The LASSI is an established method of measuring of learning strategies and a sound clinical tool, however, it and the other measures listed above leave much unanswered about children and the development of learning strategies and their related constructs.

A measure designed to assess learning strategies and study habits serves many purposes. Historic purposes for high school and college level inventories include: predicting academic performance, advising students about their use of strategies, and screening and progress measures for study skills courses (Weinstein, Zimmerman, and Palmer, 1988). Other reasons cited in the development of the LASSI include: assessment of a wide variety of topics related to and including learning strategies with sound psychometric properties, assessment of observable and modifiable behaviors that are reflective of current research in cognitive psychology, and use as a diagnostic instrument (Weinstein et al., 1988).

The Learning and Study Strategies Inventory—High School (LASSI-HS, Weinstein & Palmer, 1990) is a “diagnostic and prescriptive measure that assesses student thought processes and behaviors that impact studying and learning” (5). It is designed for adolescents entering the ninth grade to first year college students. The 76-item questionnaire has students rate themselves on a 5-point Likert scale. Reliability coefficients range from .68 to .82. Validity information was not available in the original manual. The LASSI has 10 scales: (1) Attitude, (2) Motivation, (3) Time Management principles for academic tasks, (4) Anxiety, (5) Concentration, (6) Information Processing, (7) Selecting Main Ideas, (8) Study Aids, (9) Self Testing, and (10) Test Strategies.

The LASSI and, by extension, the LASSI-HS have taught us much about the assessment of learning strategies and have provided invaluable clinical and empirical information; however, as useful as they are, they leave many questions about the nature of learning strategies and related constructs. The SMALSI (Stroud & Reynolds, 2006) was designed to enhance our understanding of the process of learning. For example, little is known about special populations such as children with ADHD, cancer, learning disabilities, or children with Traumatic Brain Injuries, and their individual needs. Perhaps the greatest potential for contribution of the SMALSI is that it covers a more broad range of child development. The ability to measure and compare these constructs across ages provides a greater understanding of the development of certain cognitive skills as well as an understanding of motivational factors and how they change from childhood to adolescence. Educators are able to assess and monitor learning strategies as they develop rather than only targeting them for remediation once difficulties have emerged.

Much of the practice of psychological assessment involves diagnosing the problem. A less tangible, but no less important aspect of the SMALSI is its focus on student strengths along with weaknesses. More than just allowing the clinician to "rule out" issues as being part of the problem, strengths on the SMALSI allow the clinician to tailor recommendations for intervention given the tools they already have for success.

Inventories prior to the SMALSI provided a reasonable understanding of learning strategies, but only from a remedial or reactive perspective. What remained missing was research to help understand the development of learning strategies in younger children (Weinstein et al., 2000). A psychometrically sound means of measuring such strategies and their associated features was necessary in order to accomplish this goal. The SMALSI was intended to help to identify which behaviors are consistent with academic success and how or if these behaviors vary according to age, gender, intelligence, motivation, attributions, and other relevant variables.

Finally, one might assume that learning strategies naturally increase as a student matures, regardless of instruction. This is certainly true for many learning strategies, but is not the case for all. In fact, self-regulated learning strategies appear to change as students progress through school, with some increasing while others increase then decrease over time (Zimmerman & Martinez-Pons, 1990). Research

indicates that very effective reading comprehension strategies such as generating questions while reviewing texts or making visual representations of information do not improve over time (Thomas & Rowher, 1986). Also, how often students use some strategies are related to their use of other strategies (Zimmerman and Martinez-Pons, 1990). For example, during the transition from junior high to high school, students report declines in the practice of reviewing textbooks whereas their tendency to reviewing notes increases during this period. These two trends highlight the relationships among strategies how students base their strategic decisions on the nature of their changing learning activities. The SMALSI provides a means of further exploring such trends.

### ***The Student Motivation and Learning Strategies Inventory***

The SMALSI is comprised of two forms: one for children ages 8–12 (SMALSI-Form C) and one for adolescents ages 13–18 (SMALSI-Form T). The SMALSI-Child has 147 items and the SMALSI-Teen has 170 items. The SMALSI was designed to be a versatile and widely utilized measure. As such, it can be administered in a group or individual setting in a relatively short period of time. Typical administration time is 20–30 minutes.

The SMALSI includes seven strengths scales and three liabilities scales. Student Strengths scales include: Study Strategies, Reading/Comprehension Strategies, Note-taking/Listening Strategies, Writing/Research Strategies, Test-Taking Strategies, Organizational Techniques, and Time Management. Student Liabilities scales include Low Academic Motivation, Attention/Concentration, and Test Anxiety. On the Child Form, the Time Management and Organizational Techniques scales are combined to reflect developing but not yet distinct organizational behaviors. Scales are reported as T-scores, which allows for comparison of performance among constructs as well as for monitoring development or the effectiveness of an intervention. The SMALSI also has an Inconsistent Responding Index (INC) to indicate responses that are inconsistent, perhaps due to noncompliance, poor understanding, or carelessness. Definitions of these scales as used in the SMALSI are given in Table X.X.

Psychometric properties appear to be solid for both the SMALSI Form C and Form T (Stroud & Reynolds, 2006). Internal consistencies for the ten scales yielded estimates consistently above .7, indicating support for the structure of the SMALSI

**Table 24.1 Definitions of the SMALSI Scales**

Scale	Definition
Study Strategies	Selecting important information, relating new to previously learned information, and memory strategies for encoding.
Note-taking/Listening Skills	Discriminating important material when taking notes, organizing notes, efficiency in note-taking.
Reading and Comprehension Strategies	Previewing, monitoring, and reviewing texts, including self-testing to ensure understanding.
Writing-Research Skills	Researching topics in a variety of ways, organizing writing projects as well as monitoring and self-checking for errors.
Test-taking Strategies	Increasing efficiency in test-taking, including eliminating unlikely answers and strategic guessing.
Organizational Techniques	Organizing class and study materials, structuring assignments including homework and other projects.
Time Management	Effective use of time to complete assignments, understanding of time needed for academic tasks.
Academic Motivation	Level of intrinsic motivation to engage and succeed in academic tasks
Test Anxiety	Student's experience of debilitating symptoms of test anxiety, lower performance on tests due to excessive worry
Attention/Concentration	Attending to lectures and other academic tasks, monitoring and adjusting attention to performance, concentrating and the avoidance of distractions.

scales. These findings were consistent across ages and grades with the exception of one scale (SMALSI Form C Writing/Research Strategies). As might be expected, younger children had the most difficulty responding reliably regarding their use of writing strategies. This was the lowest scale in general; however, reliability on this scale tended to increase with age as would be expected from a developmental perspective. With this exception, younger children tended to respond in the same manner as older children to SMALSI constructs, further supporting the assertion that younger children are capable of reliably reporting their own attitudes and behaviors (Reynolds & Kamphaus, 1992, 2004; Reynolds & Richmond, 1985).

The reliability of the SMALSI scales was also generally robust across gender and across ethnicity (Stroud & Reynolds, 2006). The one exception to this was found in the American Indian sample. When ethnicity was taken into account, results were generally commensurate with the exception of the American Indian sample which produced higher reliability coefficients on several scales. This difference was observed to a small but consistent

degree on both forms and was larger with the adolescent sample. Such a small difference alone did not indicate significant implications for individual interpretation; it does suggest that further study of differences in response patterns for different ethnic groups would be beneficial. Overall, the results of the initial standardization and validity studies suggested that the SMALSI has sufficient reliability and they indicate good confidence that the items comprising the SMALSI scales are accurate in estimating a student's current functioning on the constructs measured.

Validity is an equally important consideration when evaluating the utility of the SMALSI. The constructs measured by the SMALSI were determined by conducting a thorough review of literature in education, psychology, and related areas. Each construct was chosen due to empirical evidence establishing its role in fostering academic success. The content validity of the scales and items was also supported by expert review from multiple sources (Stroud & Reynolds, 2006).

Correlations between SMALSI scales supported the structure of the SMALSI as measuring individual

constructs that fall within the two general areas of student strengths and student liabilities (Stroud & Reynolds, 2006). Similar results across forms indicated the presence of both common and distinctive constructs. As expected, student strengths scales were correlated with each other, while student liabilities scales were correlated with each other.

The validity of the SMALSI scales was further indicated by divergence of the SMALSI scales from measured clinical dimensions (i.e., depression) and convergence with academic measures. For example, School Liability (Low Academic Motivation, Attention/Concentration, and Test Anxiety) scales on the SMALSI were positively correlated with measures of clinical, personal, and school maladjustment, whereas the School Strength scales had negative associations with these scales. This pattern was consistent for younger and older students. In particular, academic motivation was highly correlated with students' attitudes toward school and teachers, further supporting previous literature asserting the critical roles that academic environment and characteristics of the teacher play in the level of students' academic motivation (e.g., Brophy, 2004; Pajares & Urdan, 2002). Also of note, children who reported increased depression also reported less frequent use of some strategies including test-taking strategies and note-taking strategies; these students also reported decreased concentration, attention skills, and academic motivation. This finding lends further support to the importance of direct teaching of learning strategies to students with psychiatric disorders (Brackney & Karabenick, 1995).

Of paramount importance was the relationship between SMALSI constructs and academic achievement. For example, student's use of study strategies, writing skills, and time management/organizational techniques were positively linked with reading abilities (Stroud & Reynolds, 2006). In addition, writing skills were associated positively with math abilities, whereas test anxiety impaired math performance. In the adolescent group, though, a shift was observed, with test anxiety playing a more prominent role; for these students, test anxiety negatively impacted reading, social studies, and science academic abilities. Academic motivation was a more prominent factor in the adolescent sample, particularly in the areas of reading and social studies.

The performance of different demographic groups on the SMALSI also produced interesting results. For example, girls consistently scored higher than boys on both the Child and Teen forms for several scales (Note-taking/Listening Strategies,

Writing/Research Strategies, and Test-Taking Strategies. Differences for gender comparison of adolescents were more prevalent, with girls scoring higher on all student strengths scales. Adolescent girls also tended to report higher test anxiety. Effect sizes were all small but consistent and in line with previous research (Reynolds & Kamphaus, 1992, 2002, and 2004).

The SMALSI scores demonstrated reliability and validity across age and grades. In the child sample, scores on the SMALSI were stable, with little deviation aside from minor score fluctuations around the mean T-score of 50. In the adolescent group, a general trend toward increasing study strategies with age and grade was observed. This is to be expected, given that student's study strategies and abilities tend to improve with increased practice and refinement of skills with added exposure to the academic setting. It is worth noting, however, 8th grade students reported decreased study and learning strategies relative to other teen groups, a trend which invites future research and exploration in adolescent samples.

### ***Interpreting the SMALSI***

The SMALSI can be used in two main ways to determine which strategies may be most effective to focus on for an individual student. Individual items should be examined to determine if there appears to be a pattern to the strategies a student is already using. For example, does the student report using a variety of strategies but very infrequently? He or she may benefit from additional practice with these strategies to make their use more efficient and to increase the student's awareness of strategy effectiveness. Alternatively, does the student report relying heavily on just a few strategies, while not using other strategies at all? Some students may rely on the initial process of taking notes but lack essential skills for later review and organization.

After getting an idea of what strategies an individual is using, the results of each scale in relation to scores on other scales should be examined. These may also provide cues in deciding which specific strategies to focus on. For example, a child also demonstrating difficulties on the Organizational techniques scale may need additional help in developing organizational strategies as well as organizing information. On the other hand, a student who appears to have well-developed organizational skills may need less instruction in strategies used to organize information. Also, a student who endorses using note-taking/listening strategies, but relatively

infrequently, and who has low academic motivation may already know the strategies necessary for success, but lack the motivation to use them regularly or effectively.

### ***Implications of the SMALSI as a Measure of Learning Strategies***

The SMALSI opens new doors for research in understanding learning strategies and their related construct. More importantly it is intended for clinical use in individuals and with groups. The SMALSI was intentionally designed to be used in a variety of settings and by different professions. In the school setting, for example, the SMALSI can be applied as a preventive measure at the classroom level. Teachers may use this measure in a group format to identify specific problem areas such as poor study or organizational habits for the class as a whole. Areas of weakness might then be incorporated into the teacher's class curriculum. Progress can then be monitored by re-administering the SMALSI following a specific intervention or later in the school year. Children struggling academically are often referred to school level teams designed to help implement interventions prior to referral for Special Education services. On this individual level, the SMALSI may be used to identify specific areas that may become the focus of pre-referral intervention. Such instruction may improve academic performance without the need for additional levels of academic support. In this venue in particular, the SMALSI is an excellent tool in response-to-intervention models. Further, given the emphasis on state-mandated testing to determine school funding and pupil progress, teachers and school personnel are faced with the increasing demands of facilitating both students' academic knowledge as well as their test-taking abilities. The SMALSI can be a valuable tool for helping teachers identify children's individual strengths and weaknesses in these areas to help tailor interventions to their specific needs. This measure provides teachers and administrators with a user-friendly method of assessing the skills of multiple children at one time, without the need for comprehensive one-on-one testing.

Psychologists and other professionals with formal training in assessment are able to use the SMALSI in a more diagnostic manner, depending upon their level of training. While the SMALSI is a helpful tool for teachers in the classroom, psychologists will likely use it as part of a complete diagnostic battery. The valuable relationships among constructs measured by the SMALSI and more global behavioral and

emotional difficulties have been demonstrated. The child's use of learning strategies as well as the factors of academic motivation, test anxiety, and attention are useful adjuncts to academic achievement and intellectual measures. Results of the SMALSI can add unique insight into possible academic causes, consequences, or correlates of emotional and behavioral disorders.

Results of the SMALSI may be used by clinicians to make meaningful and measurable academic recommendations regarding interventions to use and classroom accommodations to make in the Individualized Education Plan (IEP). Struggling students who do not qualify for additional services under the Individuals with Disabilities Education Act (IDEA) or Section 504 equal access services are particularly susceptible to academic failure. School personnel will need specific and measurable recommendations about what areas to target given the constraints of available general education modifications (i.e., tutoring, reading programs, skill-building programs).

A significant strength of the SMALSI is its focus on strengths. It is easy to focus on "what is wrong" with a child in an assessment. Just as important is what is right, what is working. The importance of identifying a child's strengths cannot be understated. The aim of the SMALSI is to do both, to delineate both strengths and areas for improvement and to offer objective assessment in a comprehensive manner in areas that previously have been difficult to assess. Much can be done with this knowledge to increase students' skills in the classroom. Sound measurement affords us the opportunity to monitor progress in teaching and use of skills. The result is strategic learners who possess the flexibility and problem-solving skills that will lead to long term academic and vocational success.

### **Conclusions**

The purpose of this chapter has been to present an overview of learning strategies and related constructs, emphasizing the need for and methods of assessment. Certainly with younger students, the focus to date has been on assessment of learning strategies for the broader purposes of research intended to understand the process of learning and effective methods of increasing student achievement. While these goals cannot be overstated, equally important is impact on the individual. Much can be discovered about the process of learning in an individual. Much can be done to intervene in specific areas of weakness for an individual. Assessment of children,

in general, reveals many psychological processes that may not lend themselves to easy intervention. Learning strategies, on the other hand, can be quickly improved through direct group or individual instruction (Vannest, Stroud, & Reynolds, 2011). Incorporating learning strategies assessment in a battery of tests is crucial to the overall understanding of an individual, and the success achieved from learning these strategies can be far-reaching.

# Models and Methods of Assessing Creativity

James C. Kaufman, Christina M. Russell, and Jonathan A. Plucker

## Abstract

Creativity assessment has been studied for nearly as long as creativity itself. In this chapter, we review many different ways of measuring creativity. Most common are divergent thinking tests, including the Torrance Tests of Creative Thinking, although they are not without controversy. More recently, expert raters have been used to evaluate creative work, as outlined in the Consensual Assessment Technique. Peers, teachers, and parents have also been asked to assess a child's creativity, and self-ratings can be used as well. Finally, we provide a rationale for including creativity as part of a battery of assessments.

**Key Words:** creativity, assessment, creativity tests, divergent thinking, Consensual Assessment Technique, self assessments

Creativity is a key component of human cognition that is related to yet distinct from the construct of intelligence. Before discussing its measurement, however, we must define it. It is notable that so many studies on creativity do *not* define the construct. Plucker, Beghetto, and Dow (2004) selected 90 different articles that either appeared in the two top creativity journals or were articles in a different peer-reviewed journal with the word "creativity" in the title. Of these papers, only 38 percent explicitly defined what creativity was. For the purpose of this chapter, we will use the definition proposed by Plucker et al. (2004):

Creativity is the interaction among aptitude, process, and environment by which an individual or group produces a perceptible product that is both novel and useful as defined within a social context. (p. 90)

Creativity assessment has been studied for nearly as long as creativity itself. Guilford (1950), one of the early pioneers of creativity research, placed creativity into a larger framework of intelligence in his Structure of the Intellect Model. He attempted to

organize all of human cognition along three dimensions. The first dimension was called "operations," and simply meant the mental gymnastics needed for any kind of task. The second dimension, "content," referred to the general subject area. The third dimension, "product," represented the actual products that might result from different kinds of thinking in different kinds of subject matters. With five operations, four contents, and six products, Guilford's (1967) model had 120 different possible mental abilities. One of Guilford's operations (or thought processes) was "divergent thinking"—the ability to answer open-ended questions with both novel and useful responses. The assessment of divergent thinking remains the source of the most frequently used creativity tests (Hunsaker & Callahan, 1995).

## Divergent Thinking (DT) Assessments

A lot of time, energy, and effort have been invested on developing and researching measures of divergent thinking (Plucker & Makel, 2010). Ironically, there is not much divergence in the history of creativity assessments. Divergent thinking is

the backbone of creativity assessment and has held this position for many decades—many articles have been published on divergent thinking in the major creativity journals, most books on creativity include long discussions of divergent thinking; schools frequently use DT tests to identify the creative potential of students; and DT tests are used extensively around the world to assess creativity. The launching point for serious development efforts and large-scale application of divergent thinking into assessments were Guilford's Structure of the Intellect divergent production tests (1967), Wallach and Kogan's (1965) and Getzels and Jackson's divergent production tests, and Torrance's (1962, 1974) Tests of Creative Thinking (TTCT).

Guilford (1967) proposed the Structure of the Intellect model (SOI), in which he identified 24 distinct components of divergent thinking, one type for each combination of the four types of content (Figural, Symbolic, Semantic, Behavioral) and six types of product (Units, Classes, Relations, Systems, Transformations, Implications). The SOI Divergent Thinking battery consists of several dozen tests that correspond with the 24 distinct components. One example of a Guilford DT task is the Sketches subtest, which assesses the Figural Unit dimension by inviting the student to draw as many objects as possible using a basic figure, such as a circle. Many tests of DT were based on Guilford's SOI assessments, including the most widely studied of the DT assessments: the Torrance Tests of Creative Thinking.

During the 1960s, researchers published results of students that were “Guilford/SOI-like” assessments. For example, the Instances Test required students to list as many things that move on wheels (that make noise, etc.) as possible (Wallach & Kogan, 1965; Wallach & Wing, 1969). Another such example is the Uses Test, in which students provide answers to prompts such as “Tell me all the different ways you could use a chair” (Wallach & Kogan, 1965, p. 31) or bricks, pencils, and toothpicks (Getzels & Jackson, 1962). The greatest difference between the various batteries developed during this time was the conditions under which students take the tests. Wallach and Kogan (1965) preferred a more game-like, untimed administration of divergent thinking tasks, as they believed this allowed creativity to be measured distinctly from intelligence due to the creation of “a frame of reference which is relatively free from the coercion of time limits and relatively free from the stress of knowing that one's behavior is under close evaluation” (p. 24). This test-taking approach

is in contrast to timed, test-like protocols used with most other DT measures, which addressed the concerns of scholars like Torrance (1970), who worried “children are so accustomed to the one correct of best answer that they may be reluctant to think of other possibilities or to build up a pool of ideas to be evaluated later” (p. 86).

### ***The Torrance Tests of Creative Thinking (TTCT)***

The Torrance Tests of Creative Thinking (Torrance, 1966, 1968, 1972, 1974, 1984, 1988, 1990, 2008) remain the most widely used assessment of creative talent (Sternberg, 2006). Torrance focused on divergent thinking as the basis for creativity, and constructed tests that emphasized the assessment of divergent thinking (Sternberg, 2006). Although based on the SOI assessments, Torrance (1968) wrote, these tests “represent a fairly sharp departure from the factor type tests developed by Guilford and his associates” (p. 167; Kaufman, Plucker, & Baer, 2008, p. 25).

The TTCT are the longest-running continually published assessments of DT, the most carefully studied, and the most widely used in educational settings of all tests of creativity (Kaufman et al., 2008). The Torrance Tests are commonly used in efficacy studies and meta-analyses of the impact of creativity training programs.

### **TEST ORGANIZATION**

The TTCT includes a Form A and Form B that can be used alternatively. The test battery includes Verbal tests (thinking creatively with words) and Figural tests (thinking creatively with pictures). The Figural section includes three subtests:

- *Picture Construction*: participants use basic shape and expands on it to create a picture
- *Picture Completion*: the student is asked to finish and title incomplete drawings
- *Lines/Circles*: the participant is asked to modify many different series of lines (Form A) or circles (Form B)

The Verbal section of the TTCT has eight subtests:

- *Ask-and-Guess*: the examinee is asked to look at a picture (Ex.: Form A has a picture of an elf staring into a pool of water) at the beginning of the test booklet to complete three subtasks:
  - Asking: participant asks as many questions as possible about the picture

- Guessing Causes: participant lists possible causes for the pictured action
- Guessing Consequences: participant lists possible consequences for the pictured action
  - *Product Improvement*: participant is asked to make changes to improve a toy
  - *Unusual Uses*: participant is asked to think of as many different uses for an ordinary item (ex. Cardboard box)
  - *Unusual Questions*: participant asks as many questions as possible about an ordinary item (this subtest does not appear in later editions)
  - *Just Suppose*: participant is asked to “just suppose” an improbable situation has happened then list the possible ramifications.

The administration, scoring, and score reporting of the tests and forms are standardized and include detailed norms that were revised accordingly (Torrance, 1972, 1974; Torrance & Ball, 1984). While reading and understanding the manual allows novice raters to produce reliable scores, Torrance recommended that scorers be trained, as untrained raters tended to deviate from the scoring protocol when assessing originality. Novice scorers tended to unintentionally allow their personal judgments to affect scoring of individual responses.

## SCORING

The original test produced scores in the traditional four DT areas. The current TTCT (2008) produces scores in five areas: Fluency, Elaboration, Originality, Resistance to Premature Closure, and Abstractedness of Titles. Revisions to the scoring protocol in 1984 streamlined the scoring process and flexibility was removed as a score, as these were undifferentiated from fluency scores.

Another change in the scoring protocol allowed for the Figural tests to be scored for Resistance to Premature Closure. Resistance to premature closure is determined by a participant’s tendency to not immediately close the incomplete figures on the Figural Picture Completion Test. Torrance believed that this score reflected the examinee’s ability to “keep open and delay closure long enough to make the mental leap that makes possible original ideas. Less creative people tend to leap to conclusions prematurely without considering the available information” (Torrance & Ball, 1984, p. 20). On the Picture Completion task, the responses are scored zero points for finishing the picture with the easiest, most direct route. One point is scored for indirectly finishing the figure. Two points are awarded for

never completing the picture or completing it with irregular lines that form part of the figure rather than with simple straight or curved lines.

Scoring for the abstractedness of the titles test takers give to the figures in the Picture Construction and Picture completion tasks ranges from zero points for common, obvious titles (“Shoe” or “River”), to one point for more descriptive titles (“The Dancing Cat”), two points for more descriptive or imaginative titles that reach beyond concrete labels (“The Giant’s Finger Puppet”) or three points for abstract but appropriate titles that go beyond the picture and tell a story (“The Time of Your Life”).

There are thirteen other criterion-referenced scores that can be calculated, such as emotional expressiveness, humor, internal visualization, richness of imagery, and synthesis of incomplete figures. The Verbal tests can be scored for fluency, originality, and flexibility.

## Remote Associates Test (RAT)

The Remote Associates Test (RAT) is different from traditional DT tests. It is based on the associative theory that “creative thinking...consists of forming mutually distant associative elements into new combinations which are useful and meet specified as well as unforeseen requirements” (Mednick, 1968, p. 213). Basically, more creative individuals tend to make meaningful, useful associations between disparate concepts and ideas to a greater extent than do less creative individuals.

The test consists of 30 items, each with three stimulus words. Examinees must identify a fourth word that links the groupings of words. For example, for one test item may include the three words wheel, electric, high. Potential answers could be “chair” or “wire,” as these link together the three stimulus words. The RAT has been updated to modify out-of-date language. One revision is available for free on the internet: <http://socrates.berkeley.edu/~kahlstrm/RATest.htm>.

## Other Divergent Thinking Assessments

The majority of DT assessments are borrowed from or are very similar to the TTCT and Guilford’s SOI Assessments. One example is that the DT scores from the Profile of Creative Abilities (Ryser, 2007) are derived from Guilford’s work and have tasks similar to those on the TTCT. One departure is real-world divergent thinking items, which are similar to those of Guilford and Wallach & Kogan verbal tasks, but are placed in a realistic, applied context. This format assumes that a more realistic

assessment of DT skills should take place within a realistic context. Plucker, Runco, and Lim (2006) adapted a task from Chand and Runco (1993) and scored it for fluency and originality:

Your friend Pat sits next to you in class. Pat really likes to talk to you and often bothers you while you are doing your work. Sometimes he distracts you and you miss an important part of a lecture, and many times you don't finish your work because he is bothering you. What should you do? How would you solve this problem? Remember to list as many ideas and solutions as you can.

Other DT assessments are more domain-specific, such as the Creative Engineering Design Assessment (CEDA; Charyton, Jagacinski, & Merrill, 2008).

### ***Controversy Regarding Divergent Thinking Assessments***

While DT tests are associated with evidence of reliability and concurrent validity, there is a perceived lack of predictive validity (Baer, 1993a, 1993b, 1994a, 1994b; Gardner, 1988, 1993; Kogan & Pankove, 1974; Weisberg, 1993). This has led researchers and educators to avoid using DT tests, and they continue to draw criticisms of the psychometric study of creativity (Plucker & Renzulli, 1999). Another controversial aspect of DT assessments is that people tend to over-generalize DT test performance to all other aspects of creativity. Potentially the historical focus on divergent thinking tests among academics and educators has had a negative effect on the influence of the field of creativity.

### ***Consensual Assessment Technique (CAT)***

Although divergent thinking is the most common way to assess creativity, it is far from the only way. The best assessment of creativity in a particular field is usually derived from the collective judgment of recognized experts in the field. This type of assessment emphasizes the creative product. One approach to evaluating the creative product is through rating scales (Besemer & O'Quin, 1993; Hargreaves, Galton & Robinson, 1996; Treffinger, 1989). Teacher rating scales, for example, ask teachers to rate the creativity of students' creative products (e.g., Creative Product Semantic Scale; Besemer & O'Quin, 1993). These instruments tend to be reliable; however, their validity remains to be addressed.

Another approach to evaluating the creative product is the Consensual Assessment Technique

(CAT). The CAT is based on the idea that the best measure of the creativity of a work of art, theory, or any other artifact is the combined assessment of experts in that field to judge the work (Amabile, 1996). Subjects are asked to create something (a product) and experts independently evaluate the creativity of those products (Kaufman & Baer, 2012). Poems, collages, and stories are often evaluated in CAT studies. One example of how the CAT was used was in the field of children's writing. Students were given a simple drawing of a boy and a girl and were asked to write an original story involving both the girl and the boy. Experts in this field of children's writings were asked to evaluate the creativity of the stories written by students on a 1.0–5.0 scale. Judges were able to use fractions (e.g., 4.5) and were not asked to defend their ratings (Baer, 1994c).

The CAT does not have standardized scores, rather only comparative scoring among participants. This method is widely used in creativity research but less widely in schools. CAT ratings can be used in classrooms, however, to assess creativity for admission to special programs that look for people who excel in an area of creativity (e.g., poetry, art, inventing).

### ***How to Use the CAT***

1. *Choose an appropriate task:* This method is most appropriate if you are interested in assessing creativity in a specific domain. Consider more specific domains, such as collage-making instead of the more general artistic creativity. In some cases, you may use previously created artifacts.

2. *Collect the artifacts:* Subjects can work independently or in groups, as long as they do not observe competitors approaching the same task. It is important to ensure that the conditions for all participants are as identical as possible (i.e., time constraints, instructions, materials, any possible rewards).

3. *Assemble panel of experts:* This is one of the more challenging and time-consuming portions of the CAT. Judges should have a level of expertise clearly higher than the subjects' and have some familiarity with the populations from which the subjects are drawn. Judges of high school students, for example, should have some familiarity with production from that age range (Baer, Kaufman, & Riggs, 2009; Kaufman, Baer, & Cole, 2009; Kaufman, Baer, Cole, & Sexton, 2008). For most purposes, five to ten judges is adequate. Too few

judges may make inter-rater reliability difficult to produce.

4. *Organize the work of the expert judges:* All judges must receive identical directions and should not know the identity of the students; however, they should know the average age of the participants. Judges should approach the creative products in a different order.

### **Parent, Peer, and Teacher Measures: Assessments by Others**

Whereas the CAT focused on products, Assessments by Others focus on the creative *person* (personality traits, creativity-relevant abilities, motivation, intelligence, thinking styles, emotional intelligence, or knowledge). This method of assessment can be as simple as having a teacher globally rank his or her students based on the teacher's knowledge of the students and implicit beliefs about the nature of creativity. This method emphasizes traits and abilities that are believed to be relevant to creativity and is domain-general (by its nature, CAT is always domain-specific). The assessors using this method are experts on the child (teachers, parents of the child), not experts in creativity.

One common way to assess creativity is via checklists. When using creativity checklists, there is reason to be wary of teacher, parent, and supervisor ratings of creativity based on global impressions of a student due to unintended bias. To limit this bias, raters are given checklists of traits to rate each child separately.

### **Creativity Checklist**

There are many different creativity checklists, most of which were designed for use in schools. Many creativity checklists are sold commercially and copyright-protected. One freely available assessment is the Creativity Checklist by Proctor and Burnett (2004). The Creativity Checklist is composed of characteristics that are thought to be indicative of a creative person, both cognitive and dispositional traits. The items are defined in terms of classroom behaviors for teachers to use on elementary students. A 3-point Likert scale is used to rate whether each characteristic occurs *rarely* (score of 1), *sometimes* (score of 2), or *often* (score of 3). The total score is computed by summing the markings for the characteristics. For example, a *fluent thinker* item has a performance indicator such as, "The student is full of ideas"; and a *flexible thinker* performance indicator is "The student is versatile

and can cope with several ideas at once" (Proctor & Burnett, 2004). There were no norms established for this checklist and therefore it is only appropriate for making comparisons within groups of students. There also has been no criterion-related or predictive validity established.

### **Scales for Rating Behavioral Characteristics of Superior Students (SRBCSS)**

The SRBCSS checklist is widely used in the selection of students for gifted and talented programs (Callahan et al., 1995; Hunsaker & Callahan, 1995). The first of these scales were designed to introduce teacher perspectives into the gifted and talented identification process (Bracken & Brown, 2006). The SRBCSS is based on a multiple-talent approach to identifying gifted students (Renzulli, 1986). The scales include following 14 scales to help identify student abilities: learning, motivation, creativity, leadership, art, music, drama, planning, communication (precision), communication (expression), math, reading, science, and technology. This creativity scale was based on a literature review as well as feedback from educators. Although the publisher reports no criterion-validity, the reliability has been found to be significant if those completing the assessment have been trained (Center for Creative Learning, 2002).

### **Williams Scale of Creativity Assessment Packet**

The Williams Scale is a creativity checklist that is part of a larger assessment package widely used in selection of students for gifted and talented programs (Williams, 1980). It is composed of 48 items related to characteristics of creative students. It can be completed by a teacher, caregiver, or parent in 10 to 20 minutes. There are eight item types on this scale, including Fluency, Flexibility, Originality, Elaborativeness, Curiosity, Imagination, Complexity, and Courageousness/Risk Taking. The raters are instructed to place checkmarks depending on how often a characteristic is present: double checkmark when the characteristic is present most of the time, a single checkmark if it is present some of the time or a blank item if the characteristic is rarely or never present. The publisher of this scale provides neither reliability nor validity information.

### **Ideal Child Checklist**

This checklist is not a measure of individual creativity; rather, it is a measure of attitudes toward creativity. The Ideal Child Checklist was developed

to provide criteria of a productive, creative person and is most often used in research involving perceptions of parents, teachers, and children of what an ideal student is. A factor-analysis of the Ideal Child Checklist revealed four factors that are indicative of an “ideal child”: confident/aggressive/well-adjusted, sociable, not stubborn/dominering/trouble-making, and creative/intuitive. Only the last of these factors relates to creativity, and it has the weakest reliability of the four (Paguio, 1983). While this checklist is appropriate to measure the values of students, teachers, or parents, caution should be exercised when using it as an indicator of creativity.

Several other rating scales outside of the previously mentioned measures exist; however, none has adequately been studied for validity or reliability, nor are they used in creativity literature. One such example is the Gifted Evaluation Scale—Second Edition (GES-2; Henage, McCarney & Anderson, 1998). This scale consists of 48 items. Raters assess areas of intellect, creativity, specific academic aptitude, leadership ability, and performing and visual arts.

### **Guidelines for Using Creativity Checklists**

When using creativity checklists, it is crucial for the assessors to be familiar with the students whose creativity is being assessed. The raters should have had the opportunity to observe and work with the students in a variety of different contexts and domains. The validity of creativity checklists depends on how well the assessors know the students, how well they understand the questions and the theory of creativity that underlies them, the objectivity of the assessors, and the appropriateness of the questions/theory of creativity that underlies them.

There currently is not a creativity checklist that has the criterion-related concurrent and predictive validity one would like in tests being used for decision-making purposes. It is helpful for several people to independently rate students. While checklists may not be the most psychometrically sound assessments, they can serve as a small piece of an assessment when combined with other measures like divergent thinking tests, self-assessments, and rating of creative artifacts to help paint a picture of the student’s creative abilities.

### **Self-Assessment**

Self-assessment is one of the simplest ways to assess creativity—all that one needs to do is ask

people how creative they are. This method, however, seems too easy and good to be true, and depending on the purpose of the assessment, it may be exactly that.

### **Creative Personality Assessment**

Personality inventories are some of the most prevalent forms of self-assessment. The Five-Factor Theory is the leading theory in personality (Costa & McCrae, 1992). It organizes *personality* into five components: neuroticism (emotional stability), extraversion, openness to experience, conscientiousness, and agreeableness. Openness to experience is the personality component most associated with creativity. There is a near-universal finding that openness to experience is associated with creativity, including self-reports of creative acts (Griffin & McDermott, 1998), verbal creativity (King, McKee-Walker, & Broyles, 1996), being in a creative profession (Domino, 1974), analysis of participants’ daydreams (Zhiyan & Singer, 1996), creativity ratings on stories (Wolfraadt & Pretz, 2001), creative activities and behaviors throughout life (Soldz & Vaillant, 1999), self-estimates of creativity (Furnham, 1999), and psychometric tests (McCrae, 1987). The NEO Personality Inventory and the briefer NEO Five-Factor Inventory are the most popular measures of the five-factor personality theory (Costa & McCrae, 1992).

Another type of creativity personality assessment is to assess one’s *creativity style*, which refers to the ways in which people choose their creativity (Hourtz et al., 2003; Isaksen & Dorval, 1993; Selby, Treffinger, Isaksen, & Powers, 1993). One assessment of this nature is the Creativity Styles Questionnaire—Revised (Kumar, Kemmler, & Holman, 1997; Kumar & Holman, 1989). This is a 76-item self-assessed questionnaire with seven subscales: Belief in the Unconscious Process, Use of Techniques, Use of Other People, Final Product Orientation, Superstition, Environmental Control, and Uses of Senses. For example, on the Belief in the Unconscious Process subscale, a sample item is, “I have had insights, the sources of which I am unable to explain or understand” (Kumar, Kemmler, & Holman, 1997). One study examined the Creative Styles Questionnaire (the original survey) and found more creative students used more techniques and were less guided by the goal of the final project (Kumar, Holman, & Rudegeair, 1991).

The Kirton Adaption-Innovation Inventory (KAI; Kirton, 1999) was developed to measure a

personality dimension ranging from adaption (ability to do things better) to innovation (ability to do things differently) (Kirton, 1994b). This assessment is often used in organizations, as it is relevant to organizational change (Kirton, 1994b). This inventory is constructed of 32 items that produce a score ranging from 32 to 160, although the observed range has been 45 to 146, with an average of 96 and a distribution approaching normality (Kirton, 1994a).

### **Creative Behavior Checklists**

Rather than asking people questions regarding personality, another method for self-assessment of creativity is through creative behavior checklists, which ask people to rate their past or current creative accomplishments. The author of the Creative Behavior Inventory argued that self-reports of activities and attainments are among the best techniques for measuring creativity (Hocevar, 1979a, 1979b; Hocevar, 1981; Hocevar & Bachelor, 1989). This inventory is constructed of 90 items that assess creative behavior in literature, music, crafts, art, performing arts, and math/science. The Creativity Achievement Questionnaire is a second creative behavior checklist (CAQ; Carson, Peterson, & Higgins, 2005). This instrument assesses creativity through 96 items across nine domains that load on two factors: the arts (drama, writing, humor, dance, visual arts) and science (invention, science, and culinary). The tenth domain (architecture) did not load on a factor. This test has a test-retest reliability of .81 and internal consistency of .96. CAQ items ask people to mark their highest level of achievement on a scale that ranges from "I do not have recognized talent in this area" to "My XXX has been recognized as a national publication."

The Runco Ideational Behavioral Scale (RIBS; Runco, 2008) was developed in response to Runco's (2007) perceived need for a more appropriate criterion in studies of predictive validity for divergent thinking tests. Runco hypothesized that researchers were using divergent thinking tests to predict inappropriate criteria, such as those traditionally used in studies of the predictive validity of intelligence tests. Runco reasoned that a more appropriate criterion would be one that emphasizes ideation: the use of, appreciation of, and skill of generating ideas. Runco reduced a pool of 100 items to 23 after initial pilot testing. All of the items describe actual overt behavior related to ideation, such as, "I have many wild ideas," or "I come up with a lot of ideas or solutions to problems."

The Kaufman Domains of Creativity Scale (K-DOCS; Kaufman, 2012), is a recent self-report scale that asks people to rate their creativity across multiple behaviors and domains. The K-DOCS is 50 items and covers the broad domains of Self/Everyday, Scholarly, Performance (encompassing Writing and Music), Mechanical/Scientific, and Artistic.

### **Conclusion**

All of the assessments we have covered have several limitations that prevent them from being a perfect test. Some have poor reliability or validity; others are impractical. Given these restrictions, why would anyone want to include a measure of creativity in their battery of assessments?

We believe, however, that there are many compelling reasons and situations where using a measure of creativity could greatly benefit an overall evaluation. For example, we advise the use of a creativity measure when:

- There is reason to think that traditional IQ or achievement tests may not tap all of a person's potential. Divergent-thinking tests may help give a more comprehensive understanding of a person's overall abilities. The same can be said of creativity checklists completed by teachers.
- A test-taker is at risk for a stereotype threat reaction to traditional tests. Almost all measures of creativity show fewer ethnicity and gender biases than standard IQ and achievement tests.
- Parents, teachers, or peers describe an individual as being especially creative.
- A test-taker has a learning disability that may impact their scores on a traditional ability or achievement measure.
- You are trying to assess creative abilities in a particular area, such as creative writing, artistic creativity, or musical creativity. Giving people a chance to show what they can do (using a real-world task such as writing a short story or making a collage, then judging their creations using the Consensual Assessment Technique) can help you spotlight creative talent that might be overlooked in a traditional battery of assessments.
- You need to judge the creativity of a group of artifacts (poems, musical compositions, science fair projects, etc.) as part of a competition, and you want to include (or focus on) creativity in your assessment. This is a perfect opportunity to use the Consensual Assessment Technique.
- You are selecting students for a gifted/talented program and want to follow national guidelines

to use multiple selection criteria (rather than relying solely on IQ and achievement data). Most creativity measures, although not necessarily the only solution for such selections, may serve as part of a broader evaluation that can add to the overall picture of each candidate.

It is important to reiterate that we do not support administering a creativity test instead of a traditional IQ, achievement, or behavior test. We believe that all of these measures can work together to create the fullest possible picture of an individual. Creativity assessment is a work in progress—we know far less about creativity and its measurement than we would like to know—yet there is still a multitude of tools available for a dedicated test administrator.

# Methods of Assessing Behavior: Observations and Rating Scales

Erin Dowdy, Jennifer Twyford, and Jill D. Sharkey

## Abstract

This chapter discusses two primary methods of behavioral assessment: observations and rating scales. The popularity of these behavioral assessment techniques is on the rise, and information is provided to clinicians and clinicians-in-training on the basic tenets of behavioral observations and rating scales. Specifically, the advantages and limitations of behavioral observations and rating scales, key considerations when preparing for and conducting an observation or collecting behavioral rating scales, measurement issues, information on frequently utilized tools, and recommendations for practice are provided. The chapter concludes with possible future directions for the use of behavioral observations and rating scales.

**Key Words:** assessment, behavior, observations, rating scales, measurement

## Introduction

This chapter provides an overview of two primary methods that are frequently used to assess behavior: behavioral observations and rating scales. The necessity of this chapter is reflective of current trends among psychologists toward an increased use of both behavioral observations and rating scales when conducting assessments in the behavioral, social, and emotional domains of functioning (Shapiro & Heick, 2004). In fact, a wide variety of studies surveying psychologists about their assessment practices have demonstrated an increase in the use of both direct observation and behavior rating scales over time (Hutton, Dubes, & Muir, 1992; Shapiro & Heick, 2004; Stinnett, Havey, & Oehler-Stinnett, 1994; Wilson & Reschly, 1996). For example, in a recent survey focused on their last eight social/emotional/behavioral cases, school psychologists reported they administered parent and/or teacher behavior rating scales or checklists 76% of the time, direct observations 69% of the time, and student rating scales 67% of the time (Shapiro & Heick, 2004). As observations and rating scales are gaining

popularity, their methods are also becoming more advanced, structured, and refined. Given the widespread use and growing sophistication of observations and behavior rating scales in the psychological assessment of children and adolescents, it is increasingly critical for practitioners to understand methods and issues concerning their use.

Although conducting an observation or interpreting the results of a rating scale might be treated as simplistic, significant training and practice is needed to become fluent in their use (Hintze, Volpe, & Shapiro, 2008). Clinicians need to be aware of the various types of behavioral information that can be gathered through the use of observations and rating scales, as well as their limitations and when specific techniques are most appropriately used. From defining target behaviors to understanding the psychometric properties of instruments available for use, there are considerable skills that must be learned. This chapter aims to provide clinicians and clinicians-in-training with a solid foundation on the central tenets of both behavioral observations and

rating scales so that clinicians can begin to understand and employ these critical components of a behavioral assessment. Towards this end, we highlight the advantages and limitations of behavioral observations and rating scales, key considerations when preparing for and conducting an observation or collecting behavioral rating scales, measurement issues, frequently utilized tools, and recommendations for practice. To aid clinicians and clinicians-in-training, specific considerations for practice and information on commonly utilized observation systems and rating scales are provided in Tables 26.1–26.5.

## **Preliminary Considerations**

### ***An Ecologically Valid Approach***

The field of psychology has long operated under the medical model, in which the “problem” is viewed as existing within the child and clinicians have been individually focused in case conceptualization as well as intervention. Accordingly, behavioral observations and rating scales have been primarily implemented to determine what are assumed to be client-based behavioral problem(s). However, it is necessary to move beyond simply viewing the problem as existing within the child to taking a more comprehensive, ecological approach (Sheridan & Gutkin, 2000). An ecological approach allows for the examination of the contextual variables that might also be affecting the child’s behavior (Bronfenbrenner, 1992). The transaction between the child and others is considered, as well as an assumption that problems can occur when a child is placed in an environment where unable to meet the expectations of the environment. The problem is therefore not viewed as the client’s, but rather as a problem of “environmental mismatch.” Ecological approaches are also advocated for within the nondiscriminatory-assessment literature that touts the benefits of first assuming that the problem behavior is not due to a child’s characteristic, but is rather due to the environment or an environmental mismatch (Ortiz, 2008). An assessment of the problem behavior within the ecological approach does not conclude with the assessment of the client’s behaviors. Rather, such an approach considers the various contexts in which the client functions.

Although the majority of behavioral assessment tools currently available were designed under the medical model and primarily provide information on the individual’s maladaptive or adaptive functioning, the central techniques of behavioral observations and rating scales can be applied in an ecological approach. Take, for example, the case of

a client who demonstrates significant hyperactivity and inattentiveness within the reading classroom but is calm, attentive, and responsive in a variety of other environments including at home, in church, and at the community center that the family frequently visits. Conducting behavioral observations in a variety of these settings with attention to environmental characteristics, as opposed to solely focusing on the client in the reading classroom, would reveal that the “problem” is not, in fact, the client’s activity level. Perhaps the child is unable to read and is assigned tasks are too challenging. Or perhaps there is an ongoing conflict between the client and the teacher. The approach to treatment is dramatically different depending on the identified problem(s). Within the medical model, perhaps psycho-stimulant medication and behavioral modification would be advocated; while within an ecological approach, the intervention team decides to move the client to a different reading classroom. By adopting an ecological approach to observation, the astute clinician observes the variety of environments in which a client functions, in addition to observing the unique characteristics and behaviors of the client.

Behavioral rating scales also can be utilized within an ecological approach. In fact, collecting information from a variety of sources can provide insight into the likelihood of the problem’s truly existing within the child, or within the environment. Achenbach and colleagues (1987) argued that each informant within a multi-informant system offers a unique and important perspective. Thus, an ecological perspective elucidates those behaviors with higher inconsistency across raters as being more contextually relevant. Taking the aforementioned example, if the teacher, parent, and community center worker each completed a behavior rating scale examining characteristics of inattention, hyperactivity, and impulsivity, the client may have only received scores in the clinical or at-risk range when rated by the reading teacher. This would lend further credibility to the hypothesis that the client does not, in fact, have sufficient symptoms of Attention Deficit Hyperactivity Disorder, Combined Type to warrant a diagnosis, but that the problem appears to be more related to an environmental mismatch. Furthermore, rating scales examining characteristics of classroom climate and/or home environments, when used in combination with behavioral rating scales, can provide a more comprehensive assessment of functioning. When examining rating scales and behavioral observation techniques throughout

this chapter, a focus on applying these techniques within an ecological approach will be provided.

### ***A Strength-Based Approach***

In part due to the influence of the medical model, observations and behavior rating scales have typically focused on risk, problems, and pathology and neglected human adaptation and development (Masten, 2001). However, longitudinal studies have found that strengths are as important as risks to understanding developmental pathways (Garmezy, 1993), encouraging research into resilience and positive psychology. Thus, comprehensive assessment of child behavior should take into consideration both positive and negative aspects of functioning for a complete understanding of child well-being (Huebner & Gilman, 2003). Moreover, understanding strengths may allow for more accurate and effective intervention plans (Jimerson, Sharkey, Nyborg, & Furlong, 2004); help participants feel more empowered and motivated (Epstein, Hertzog, & Reid, 2001); result in a more positive parent-student-professional relationship (LeBuffe & Shapiro, 2004); communicate respect for families and their children (Weick & Chamberlain, 2002); and lead to developing interventions that are more acceptable to children, families, and external service providers (Walrath, Mandell, Holden, & Santiago, 2004). Observations of desired behavior have been increasingly popular, particularly as a way for students to monitor their own success, as they focus attention on the desired goal rather than an undesired behavior. In terms of behavior rating scales, there are far more psychometrically validated problem-based behavior rating scales than strength-based measures. However, as the importance of understanding strengths has become clear, researchers have begun to invest considerable time and resources to develop and psychometrically test strength-based measures in order to balance efforts to understand and treat mental health problems. Clinicians should consider integrating strengths into behavioral observations and identifying psychometrically solid rating scales that include adaptive skills or other strengths.

### ***A Legally Defensible Approach***

Collecting functional information on students' performance and behaviors using techniques and instruments with established validity and reliability is a routine and necessary part of many behavioral assessments. At times, the inclusion of behavioral observational data is a legal requirement. For example, behavioral observations are a requisite part of

psychoeducational assessments as specified in the Individuals with Disabilities Education Act (IDEA). Specifically, IDEA mandates that assessment professionals "review existing evaluation data on the child, including ... classroom-based observations; and observations by teachers and related services providers" (IDEA, 2004, S. 614, c1A). For students with suspected learning disabilities, a trained professional must observe the student and the learning environment to document their academic and behavioral performance in the areas of difficulty. For students with problematic behaviors, school personnel must conduct functional behavioral assessments under specific circumstances, including when determining if a student's conduct is a manifestation of his or her disability. Additionally, no single procedure or assessment tool may be used to make eligibility determinations for special education. While behavior rating scales are frequently utilized as one component of a comprehensive behavioral assessment, the use of rating scales alone is not sufficient. The necessity and utility of understanding how to conduct and interpret behavioral observations and rating scales is clear, not only to obtain valid behavioral data but also to ensure a legally defensible assessment approach.

### ***Features of Observations and Rating Scales***

Observations and rating scales both provide behavioral assessment information, but the information is gathered through different methods. Observations can be conducted in a variety of settings, with the goal of providing a snapshot of what certain behaviors look like, with what frequency they are taking place, and whether they are appropriate under the observed circumstances. With an underlying assumption that behavior is specific to a certain situation, multiple observations over time in diverse contexts are necessary to accurately define the problem (Hintze et al., 2008). On the other hand, behavior rating scales are administered to parents, teachers, or youth to gain information on the youth's current or past functioning from a particular person's perspective. Thus, behavior rating scales allow for a summary of past observations across contexts familiar to the rater. Information on the frequency, duration, or appropriateness of the behaviors is provided in an indirect manner by asking the informant to reflect on past observations. Observations and behavior rating scales are fundamentally different in that observations collect direct information, while behavior rating scales gather information from indirect sources. There are clear

advantages and disadvantages to both observations and rating scales, depending on the situation and information to be obtained. When administered together, behavioral rating scales and observations allow for a more comprehensive view of behavioral

functioning. The following sections will provide more detailed information on the specific features of behavioral observations and rating scales. For practice considerations that align with the content in the following sections, refer to Table 26.1.

**Table 26.1 Considerations for Practice**

Step	Considerations for Practice
1. Collect information on referred behavior	<ul style="list-style-type: none"> <li>Interview others in the setting where the behavior does and does not occur</li> <li>Conduct a narrative recording to gather global data about the environment</li> <li>Define target behavior</li> </ul>
2. Select and disseminate broad rating scales to collect information for differential diagnosis	<ul style="list-style-type: none"> <li>Select rating scales with items which represent behavior, not consequences of behavior, inferences of behavior, or assumptions, or guesses (McConaughy &amp; Ritter, 2008)</li> <li>Use scales that have been psychometrically tested and validated for the purpose intended</li> <li>Ensure normative sample adequately represents the client and is up-to-date</li> <li>Use behavior rating scales, not checklists</li> <li>Consider options for multiple raters</li> </ul>
3. Empirically record behavioral observations	<p><i>Considerations to have before selecting an observation system:</i></p> <ul style="list-style-type: none"> <li>Is the behavior continuous? Or is it discrete?</li> <li>Is the behavior frequent? Overt?</li> <li>When does the behavior occur?</li> <li>Review time and training requirements of the system</li> <li>How many subjects are to be observed at once?</li> <li>Select observer</li> </ul>
4. Systematically collect direct observation data about the behavior, the child, and the environment in settings with and without the targeted behavior	<ul style="list-style-type: none"> <li>Select time and setting for observations</li> <li>Collect information on severity, intensity, frequency, duration, antecedents, consequences, interpersonal interactions, ecological observations, positive behaviors, other problematic behaviors</li> <li>Interpret information in light of potential: <ul style="list-style-type: none"> <li>Observer bias</li> <li>Inter-observer reliability</li> <li>Reactivity</li> </ul> </li> </ul>
5. Analyze behavioral data from observations and rating scales	<ul style="list-style-type: none"> <li>Use patterns from behavioral data and broad rating scales to determine if more assessment is necessary</li> </ul> <p><i>Consider if:</i></p> <ul style="list-style-type: none"> <li>Narrow rating scales are necessary to provide more specific information about an identified problematic behavior or for differential diagnosis</li> <li>More observation or a different system of data collection is needed</li> <li>Collect baseline data about specific targeted behavior(s)</li> </ul>
6. Analyze information from additional observations or rating scales if applicable	<ul style="list-style-type: none"> <li>Establish level of severity for the behavior</li> <li>Establish antecedents triggering behavior</li> <li>Establish consequences maintaining the behavior</li> <li>Determine if there is enough information available to diagnose and create an intervention plan</li> </ul>
7. Create and implement an intervention or treatment plan	<ul style="list-style-type: none"> <li>Use data collected on antecedents, consequences, severity, frequency, intensity, and diagnostics</li> </ul>
8. Collect data during treatment	<ul style="list-style-type: none"> <li>Analyze data to inform treatment planning</li> <li>Adjust intervention as indicated by data collected</li> </ul>

## **Behavioral Observations**

### ***Advantages and Limitations of Behavioral Observations***

The most direct way to assess behavior is through the use of observations in the setting where the behavior naturally occurs (Skinner, Rhymer, & McDaniel, 2000). However, the most direct way may not always be the most desirable or feasible way, and choosing an observation approach as part of a behavioral assessment depends on the reason for referral, the time and resources available, and the behavior that has been targeted for change. A brief review of the advantages and limitations of behavioral observations is provided.

Direct observations have distinct advantages, which probably contribute to, and maintain, their popularity among both clinicians and researchers. Advantages of direct observations include the amount of information that can be collected during an observation, including information on the frequency and duration of behaviors as well as information on the environmental factors that are maintaining or exacerbating the behaviors (Bloomquist & Schnell, 2002). Observations can focus on the psychological and physical characteristics of the setting where the behavior occurs, and provide a particularly thorough ecological assessment (Sattler & Hoge, 2006). The ability to determine the function of the behavior while also allowing an assessment of the environmental contingencies is among the most attractive features of behavioral observations. Additionally, clinicians often view observations as pure measures of behavior and are thus not subjected to bias through someone else's (parent, teacher, youth) ratings and perceptions (Winsor, 2003).

Behavioral observations are also advantageous in that they can have direct implications for treatment planning and they allow for a more authentic or outcome-based assessment (Stein & Karno, 1994). Gathering information that children in one classroom are, on average, out of their seats 10 times over a 40-minute observation period provides specific baseline information that can be utilized in treatment planning. For example, after obtaining this baseline data, a positive reinforcement system could be implemented in which the children are offered reinforcement for every ten minutes that passes without their getting out their seat. Furthermore, direct observation can allow a clinician to evaluate the effectiveness of an intervention and/or monitor progress towards a specified goal. If, following an intervention, the children are observed to get

out of their seats only one time over a 40-minute observation, the effectiveness of the intervention is documented.

Along with distinct advantages, direct observations are replete with disadvantages. Most notably, direct observations are costly both in terms of professional time and labor. Observers must be trained, inter-rater reliability checks often need to be established, and travel to and from multiple settings to conduct observations can be time-consuming. Due to time constraints, it is not possible to sample a comprehensive variety of behaviors or settings, thus the information obtained is limited. In general, direct observation procedures are not useful to gather information about behaviors that occur infrequently or internally (e.g., depressive mood). Furthermore, if the incorrect method of sampling is employed, the information obtained may not be accurate or representative of the behavior being targeted. For example, if an observer chose to implement a time-sampling procedure to observe a child's hitting, and the hitting did not occur during the specified time period, then it might seem as if the target behavior (hitting) was not problematic. Direct observations might also provide inaccurate information if the person or family under observation is aware that an observation is taking place. The act of being observed can cause a reaction or a change in behavior due to an awareness of being observed (Kazdin, 1981). The presence alone of an observer can change the behavior being observed (Reid, Baldwin, Patterson, & Dishion, 1988). Thus, observations are only a "pure" measure of behavior in a particular setting in the presence of the observer. Overall, the results and interpretations of observations must be considered in light of the advantages and disadvantages of behavioral observations.

### ***Preparing for an Observation: Things to Consider***

While the novice clinician might consider starting an observation by simply walking into a classroom with a notepad and watching a child referred for an assessment, there are many things that should be considered prior to conducting an observation. Information on the reason for referral, the target behaviors to be observed, the setting and timing of observations, and who will be conducting the observation must be considered.

#### **REASON FOR REFERRAL**

First, the reason for referral and the referral source are likely to shape decisions regarding types

of observational data collected. The referral question, for example, could lead to a short observation to determine if behaviors are indicative of motor or vocal tics or if a behavior is developmentally inappropriate. Alternatively, the referral question could lead to a more intensive observation in which the intention and the function of the behavior are analyzed and determined. The reason for referral might be related to a problem of frequency (e.g., how often a hand is raised), timing (e.g., when requests for drinks of water are made), or environmental mismatch (e.g., failure to complete tasks in one class) and observations need to be tailored accordingly. The referral source (person) also shapes the observation by labeling the behavior as problematic.

### **TARGET BEHAVIORS**

One of the first key tasks the observer encounters is to identify what to observe. For example, it might be necessary to observe an individual, an interaction between individuals (teacher/student, parent/child), the characteristics of an environment, or the events surrounding the target behaviors or situational context. The target behavior of interest can range from a single, isolated behavior to an interaction between individuals, and it should not be unnecessarily limited. An observation can be structured to collect information about multiple things, including the environment, interactions, and behaviors.

When a behavior is the target of observation, it should be operationally defined with a clear, concise description that is observable, measurable, and specific, to minimize the likelihood of misunderstanding and bias (Winsor, 2003). However, providing too much specificity can also be detrimental to observations. Using too much specificity to define a behavior (e.g., 10 subcategories for “on task” behaviors) can make data recording difficult, and the ultimate goal should be to find a balance between being too global or too specific (Chafouleas, Riley-Tillman, & Sugai, 2007). In general, the ability to provide a clear and operational definition of the behavior will allow for reliable and valid data collection. For example, stating that “aggression” is the target behavior could result in widely varying results during an observation session. One observer might solely indicate that the target behavior occurred only when the child hit another student, while another observer might take “aggression” to encompass a wide range of behaviors, including making fun of another child or refusing to share toys. To provide further clarification, examples of the target

behavior, along with inclusionary and exclusionary criteria, can be considered.

### **SETTING AND TIMING OF OBSERVATIONS**

The setting in which the observation is going to occur and the timing of the observation should also be well thought-out. Observations can be conducted in both naturalistic and controlled settings. Observations conducted in naturalistic settings, such as within a classroom or home environment, can provide contextually relevant information and are generally preferred. The observer can see the behavior in its naturally occurring environment, and information on the environment and interactions between individuals in the environment, in addition to the target behaviors, can be recorded. Controlled observations involve observing a child in a staged environment where conditions can be created to elicit the target behavior. Advantages of this approach include not having to wait for the behavior to occur naturally, and the ability to examine how multiple individuals will respond to the same conditions; disadvantages include participants’ not behaving spontaneously, and not allowing for additional, potentially informative events to take place (Sattler & Hoge, 2006).

When considering the timing of the observation, it is beneficial to observe at a time when the behavior is likely to occur. For example, if a child were referred for off-task behavior that occurs during math class, observing during math class would make logical sense. However, comparison data gathered during a different class period can provide more information from which to draw conclusions. It might be meaningful to indicate that off-task behavior is not problematic throughout the day and in a variety of settings, but rather solely during math class. Another timing consideration involves the length of the observation. Observers should not schedule overly short observational periods, to ensure that there is adequate time to observe the target behaviors (Winsor, 2003). To obtain a more representative sample of the child’s behavior, observations should be conducted within multiple settings and at various times throughout the day. However, it is prudent to remember the resources required to carry out multiple observations at multiple time points and an effort at balance should be sought.

### **THE OBSERVER**

Who is going to conduct the observation is another preliminary question to be answered. Both internal and external observers are frequently

utilized to collect observational data. The personnel resources required to collect observational data might lead to having an internal observer, such as a teacher or a peer, collect data. Alternatively, observations are collected by external observers, such as a psychologist or other trained observer, in which an outside person enters the situation that they are not normally a part of.

External observers, such as a school psychologist, are often chosen due to their objectivity and training in conducting behavioral observations. However, their presence in the new environment can cause reactivity, disruptions in the environment, and further affect the validity of the observational information obtained. Additionally, external observers can be costly in terms of time to conduct the observation, travel to and from the natural setting, and training needed.

The advantages of an internal observer include their knowledge of the context and the degree to which they can unobtrusively observe in their own natural environment (Winsor, 2003). Internal observers can remain in an environment for an extended period of time to collect frequency data on low-frequency behaviors, and they can plan to conduct a more structured observation at a suitable time. However, internal observers, such as teachers, often have limited time to conduct intensive observations without disrupting their other responsibilities; thus, teacher recordings are best accomplished when data can be recorded infrequently and through simple methods (Skinner et al., 2000).

## ***Observational Recording Procedures***

Following the specification of the target behavior, setting, and timing, observers must decide which data collection method is optimal. Towards this end, professionals should (a) ensure targeted behaviors align with the purpose of the instrument, (b) examine the reliability and validity of the system for adequacy, and (c) review the amount of time and training required to learn the system (Volpe, DiPerna, Hintze, & Shapiro, 2005). A variety of different methods of behavioral observation are available, including narrative and empirical recording techniques. Examples of recording procedures, along with a summary of general properties of these selected observation systems, are provided in Table 26.2.

### ***Narrative Recording Procedures***

Also called *anecdotal recordings*, narrative recordings simply describe what happens (Bloomquist & Schnell, 2002). This is generally accomplished by observing in a natural setting and recording a detailed narrative of the observed sequence of events. Following a referral, the school psychologist might observe in the classroom to record the sequence of events preceding and following behavioral outbursts. The school psychologist might note precipitating factors and resulting consequences, list classroom characteristics, and delineate what other students were doing at the time of the outburst.

Skinner and colleagues (2000) indicated five main purposes for recording behaviors through narrative means: to (a) confirm the presence of problems, (b) define target behaviors, (c) develop

**Table 26.2 General Properties of Selected Observation Systems**

Title	Author	Age	Behaviors Observed	Length of Observation	Recording Methods
Behavior Assessment System for Children–Student Observation System (BASC-2–SOS)	Reynolds & Kamphaus (2004)	Preschool to High School	<ul style="list-style-type: none"> <li>Classroom environment</li> <li>65 behaviors within 9 categories of problem behaviors</li> <li>4 categories of positive/adaptive behaviors</li> </ul>	15 minutes	Momentary time sample at 30-sec. intervals
Child Behavior Checklist–Direct Observation Form (DOF)	Achenbach (1986)	Ages 5 thru 14	<ul style="list-style-type: none"> <li>97 Problematic and on-task behaviors</li> </ul>	10 minutes	Likert scale
Behavior Observation of Students in Schools (BOSS)	Shapiro (2004)	Grades Pre-K thru 12	<ul style="list-style-type: none"> <li>Problematic Behaviors</li> <li>Positive behaviors</li> <li>On-task behaviors and engaged academic time</li> </ul>	15 minutes	Momentary time sample at 15-sec. intervals

empirical recording procedures, (d) develop procedures for future observations, and (e) identify the antecedents and consequences of behaviors. Describing what the behavioral outburst looks like (e.g., flailing one's arms and throwing oneself on the floor, versus screaming in a high-pitched voice) informs a more systematic and precise strategy for future observations. The psychologist might notice that the behavioral outbursts occur more frequently during physical education class or the psychologist might have been able to determine where to sit in the classroom to be able to observe the behaviors most easily (Skinner et al., 2000). Hypotheses regarding the function of the behavior and what might maintain the behavior can begin to take shape by analyzing the antecedents and consequences and recording what is taking place in the classroom. An "ABC" chart with three columns of notes describes in depth what happened immediately preceding the behavior (antecedents), a description of the target behavior (behavior), and what happened immediately following the behavior (consequences). Observing and recording the ABCs can help determine the function of a behavior or generate hypotheses about what might contribute to the frequency of the behavior. For example, a school psychologist might receive a referral to observe a child who tells inappropriate jokes during instructional time. During the observation, when the teacher turns around to write on the board (antecedent), the child tells an inappropriate joke (behavior), at which time the entire class may laugh (consequence). The ABC analysis leads to the conclusion that peer attention in the form of laughter is reinforcing the problem behavior. In an alternative scenario, classmates ignore the joke but the teacher punishes the offending student by taking away recess. Through repeated observations in multiple settings, the observer finds that the student wants to skip recess to avoid confrontations with a bully. The ABC analysis leads to the conclusion that taking away recess is reinforcing rather than deterring the student's inappropriate behavior. By recognizing the antecedents and consequences contributing to problematic behavior, an intervention that considers the function of problem behavior (teaches a replacement behavior or manipulates antecedents and/or consequences) is much more likely to succeed than if the problem behavior is simply punished.

Narrative recording procedures are advantageous, particularly with regard to the minimal amount of training required and the ease

with which descriptions of observations can be recorded. Conducting a general, global observation is often recommended prior to honing in on specific behaviors to observe, particularly when provided with a non-specific referral question (Sattler & Hoge, 2006); this type of general observation could be accomplished with a narrative recording. Specifically, Sattler & Hoge recommend that when a child is first referred for a behavior problem, the initial observation should be broad enough to allow for an observation of the child's overall behavior and the behavior of other children and adults in the setting. This allows for the observer to note specific behaviors that might need to be observed more closely, as well as make an assessment of the context in which the child's behaviors exist.

Disadvantages of narrative recordings include an end result of imprecise data subject to observers' biases. The descriptive record of behaviors and events and the sequence in which they occurred provides a limited amount of information leading to limited interpretations, particularly if quantitative data are desirable. Furthermore, anecdotal and descriptive accounts can be subject to over-interpretation (making inferences from an unstandardized and limited sample of behavior) and should not be used in high-stakes decisions (Hintze et al., 2008). Therefore, when narrative recording procedures are used it is important to consider limitations of the information gained and to build upon this information to collect additional empirical data when appropriate.

### ***Empirical Recording Procedures***

Although narrative recording procedures are often implemented and can provide meaningful descriptions, empirical recording procedures provide more precise data instead of simply recording the presence or absence of exceptional behavior (Skinner et al., 2000). Empirical procedures allow professionals to monitor goals that must be objective and measurable. The frequency (how often a hand is raised), latency (following a teacher request, how long it takes to initiate the desired behavior), and duration (how long a tantrum lasts) of behaviors can be recorded in a systematic fashion.

#### **EVENT OR FREQUENCY RECORDING**

Event or frequency recording provides information on the number of times a behavior occurs during a specified time period. The flexibility of the time period makes an event or frequency recording optimal for a variety of observers and is especially

conducive for behaviors that occur at a low frequency. The observer (e.g., parent, teacher, daycare worker, psychologist) can simply tally the number of times that the event occurs in the specified time period. The number of occurrences can be summed, and frequency data can be provided. If the frequency data are divided by the total time observed, an indicator of behavioral rate is provided. For example, frequency data might show that a child hit his sibling six times during a two-hour period, a behavioral rate of three times per hour. Intervention monitoring could include regular observations to check the frequency of behavior with the goal to reduce the frequency to a more desirable level.

Three criteria should be met to select an event or frequency recording: (1) the target behavior should have a clear and specified beginning and end; (2) the behavior should be relatively similar in length and intensity at each instance, and (3) the target behavior should occur in distinct instances (Merrell, 2003). The first criterion provides further reason for having a pre-specified operational definition of the target behavior. A behavior with a discrete beginning and end, such as raising one's hand, could easily be tallied in terms of the number of times that it occurs. However, a behavior such as tapping one's pencil might be ongoing and frequently varies in the length of occurrence and even perhaps its intensity. This inconsistency (criterion 2) leads to challenges such as whether the observer places a tally every time the pencil hits the desk or waits until the student stops tapping. If the behavior occurs too frequently, such as every second, recording the frequency of occurrence would be too burdensome (criterion 3). A different strategy, such as interval recording, would be more appropriate in this instance.

#### INTERVAL RECORDING AND TIME SAMPLING

Interval recording procedures measure whether a behavior occurs during a specified time period, and they have also been referred to as *time sampling procedures* since they only record a sample of the behavior (Sattler & Hoge, 2006). An observational period is divided into equal intervals, and the observer records if the predetermined behavior occurs at any time during the interval. For example, an observation period totaling fifteen minutes may be divided into 30-second intervals, providing for a total of 30 intervals. The observer would observe and note, during each interval, if the student displayed the target behavior.

Interval recording techniques are most useful with behaviors that occur at moderate to high or

steady rates, and/or if the observer is interested in observing multiple behaviors simultaneously. The observer can record the presence or absence of several behaviors (e.g., raising hand, out of seat, talking to neighbor, inappropriate movements) during each interval. The observer can also observe multiple students during a specified interval. Direct observation data can be collected on the target student, as well as on peers to facilitate comparisons. Data on one or several comparison students can be collected simultaneously (observe if the target student is on task while also observing if a peer is on task) or discontinuously (alternative intervals observing the target student and the peer) (Skinner et al., 2000). Simultaneous recording is easier if students are proximal, whereas discontinuous recording can allow for the rotation of comparison students across intervals, thereby including a wider sample of students.

Interval recording techniques require intensive attention by the observer and are facilitated by the use of a stopwatch or time-recording device. Earphones connected to a looped tape in which a beep denotes the beginning of the interval can be helpful to signal the observer that a new interval is starting. Alternatively, personal digital assistants (PDAs) or other hand-held computers can be programmed to provide a checklist of behaviors under observation and to alert the observer when to observe and when to record. Increasingly advanced technologies allow for user-friendly observations in which the observer is not responsible for juggling multiple forms, timepieces, and recording devices. Software is available for some observations systems (e.g., the Behavior Assessment System for Children-2 Student Observation System and Portable Observation Program; Reynolds & Kamphaus, 2004) that enables downloading to hand-held computers and charting and reporting of results from completed observations.

There are three main types of interval recording: partial-interval recording, whole-interval recording, and momentary time sampling. During a *partial-interval* recording, the observer records a behavior as occurring only once during that interval, whether or not it occurred multiple times, or lasted the entire duration of the interval. During a *whole-interval* recording, in order for the observer to record the behavior as occurring, the behavior must last throughout the interval. If the behavior was occurring at the beginning of the interval, but stopped in the middle of the interval, the behavior would be recorded as "not occurring." Similarly, if the behavior occurred for 25 seconds

out of the 30-second interval, it would be coded as a non-occurrence. A *momentary time sampling* involves paying particular attention to the exact moment in which the timed interval begins or ends and recording whether or not the behavior occurred during that brief instant. For example, given a 30-second interval, the only momentary time of interest is that first second. If the behavior is occurring at the beginning of the interval, it is recorded. However, if the behavior was not occurring during the first few seconds of the interval, but started during the fifth second of the interval and lasted the remainder of the interval, it would be recorded as a non-occurrence.

Each interval-recording technique yields an approximation rather than an entirely accurate estimate of the behavior. Whole-interval procedures may underestimate the true occurrence of the behavior, partial-interval procedures may overestimate the true occurrence of the behavior, and momentary time sampling techniques may miss behaviors that occur infrequently (Chafouleas et al., 2007). The choice of interval recording strategy depends on the characteristics of the behavior being observed and how frequently the behavior occurs. Whole-interval procedures are most useful if the behavior occurs continuously and the intervals are fairly short, while partial-interval procedures are best utilized with lower-frequency behaviors when the intervals are over a long period of time (Shapiro & Skinner, 1990).

#### DURATION AND LATENCY RECORDING

In comparison to event recording and time sampling procedures, duration and latency recording procedures are focused on the temporal aspects of the behaviors, rather than the frequency with which the behaviors occur (Merrell, 2003). Specifically, with duration recording, the observer measures the amount of time a behavior lasts, and with latency recording, the observer notes the amount of time between the onset of a stimulus and the behavior initiation. Behaviors that have discrete beginnings and endings are conducive to these types of recording procedures.

Duration recordings are helpful when the behavior is a problem, primarily due to its duration. For example, it might not be disruptive for a student to walk around the classroom on occasion; however, if the student is walking around for twenty minutes during a sixty-minute instructional period, it may disrupt classroom learning. Other examples of behaviors in which duration might be of interest

include temper tantrums (how long they last), time actively engaged in a subject, and arguing following being assigned a task or chore. Both total duration in which the behavior occurs and the average duration of the occurrence can be computed (Hintze et al., 2008) to inform intervention planning.

Latency recordings are helpful when the primary problem is the amount of time it takes to begin a behavior after a stimulus, such as a request. This type of recording can be employed to track a student's ability to comply with directions (Allessi, 1988) or to measure the amount of time between a response and an antagonistic stimulus in an aggression scenario (Stein & Karno, 1994). For example, consider a mother who asks her child to take out the trash. The latency recording records the amount of time following the directive ("Please take out the trash now") to the time in which the behavior is performed. The observer records how long it takes for the behavior to begin after the prompt, and this can be averaged across multiple events. The mother starts recording as soon as she gives the directive and stops recording as soon as the behavior is initiated. Over the course of five observations, it takes her child an average of thirty minutes to initiate the behavior of taking out the trash. A specific reinforcement system could be put into place to encourage her child to initiate the behavior within ten minutes. Ongoing observations will inform intervention success. For example, when the child is able to take out the trash within an average of 10 minutes of a request over three observations, the child can earn a reward.

#### ***Reliability and Validity of Observation Procedures***

The importance of reliable and valid data cannot be overstated, particularly when the data inform a diagnostic or placement evaluation. The reliability and validity of an observation can be affected by a variety of things, including the type of recording system and observation method selected, the setting, the observer, the target person or persons being observed, and the interaction between these sources (Sattler & Hoge, 2006). We provide a brief discussion of psychometric issues affecting observations as an introduction to some of the common issues when empirically evaluating the reliability and validity of observational data. See Table 26.3 for a summary of psychometric information for select published observational systems.

Reliability involves the extent to which the observations collected are consistent and replicable.

**Table 26.3 Psychometric Properties of Observation Coding Systems**

Observation Coding System	Setting	Norming Information	Reliability		Validity
			Inter-observer agreement	Convergent	Discriminate
BASC-2-SOS	• School	Authors recommend use of 2–3 randomly selected peers	• No published data	• No published data	• Discriminated ADHD from non-disabled children
CBCL-DOF	• School • Home	Authors recommend observing comparison peers 10 minutes before and 10 minutes after target child	• Average correlations across 4 studies inter-observer agreement $r = .90$ for total behavior problems and $r = .84$ for on-task scores	• TRF total behavior problems score ( $r = -.26$ to $-.53$ ) • TRF school performance ( $r = .14$ to $.66$ ) • TRF adaptive functioning composite ( $r = .48$ to $.72$ )	• Discriminated boys referred for problem behaviors from typically developing boys matched for age, grade, and race
BOSS	• School	Authors recommend use of classroom comparison child at every 5th interval	• Kappas between .93 and .98	• No published data	• Discriminated children with ADHD from their non-disabled peers

Information can be obtained to measure the degree to which behaviors are consistent across times and situations (test-retest reliability), although it is likely that the behaviors being observed might not be consistent across time points or settings. Regardless of behaviors changing across testing situations, the observers should be consistent in their recordings of observations (Skinner et al., 2000). The degree to which independent observers who are observing the same student at the same time are consistent with one another is referred to as “inter-observer reliability” or “agreement.”

Inter-observer agreement is important to establish the reliability of a behavioral observation technique. It is generally reported as the mean percentage of agreement amongst observers along with the range of agreement across sessions. Inter-observer agreement is calculated by dividing the number of agreements by the number of agreements plus the number of disagreements and then multiplying by 100 to yield a percentage (House, House, & Campbell, 1981). High inter-observer agreement confirms that data are due to actual behavior rather than biases or inaccuracies of the observer (Stein & Karno, 1994). Potential biases include expectancy effects, in which the observer’s expectations influence recordings, or

observer drift, in which the observer changes the criteria for judging the behavior due to fatigue or other variables (Sattler & Hoge, 2006). Additional threats include problems of omission or commission when the observer fails to record a behavior or miscodes a behavior (Sattler & Hoge).

Inter-observer agreement data are relatively easy to collect, although the procedure does require having at least two observers trained in a single method of observation collect data simultaneously. An inter-observer accordance of 80 percent is generally acceptable, and inter-observer agreement data are generally collected during a minimum of 20 percent of observation sessions (Skinner et al., 2000). Techniques to improve inter-observer agreement include: altering the recording system, providing improved operational definitions, reducing the number of behaviors recorded, increasing the amount of time training observers, and providing corrective feedback to observers during trainings (Skinner et al., 2000). Inter-observer agreement is not sufficient to demonstrate the validity of an observation system. There could be a high level of agreement between observers, but the observational system might still be flawed or the observations recorded might not be useful (Sattler & Hoge, 2006).

Whereas *reliability* generally refers to consistency, *validity* demonstrates if the test (or observation) measures what it is supposed to theoretically measure. When considering behavioral observations, validity can be affected by whether observations are representative of behavior in a particular situation and across situations (Sattler & Hoge, 2006). Clinicians conducting or overseeing behavioral observations should be aware of some of the potential threats to the validity of behavioral observations. For example, *reactivity* occurs when behaviors change as a result of being observed. In observer reactivity, the observer changes recording style when aware of being observed. For example, when observers are aware that their ratings will be compared to other observers or if their observation is being observed by a supervisor, they tend to be more attentive, careful, and accurate (Sattler & Hoge, 2006). In subject reactivity, the subject changes their behavior as a result of the presence of the observer. For example, consider the teacher who frequently yells at students but, when observed, maintains an even tone because yelling would be inappropriate. Similarly, children who frequently get out of their seat at inappropriate times might be more inclined to stay seated if they are aware of being observed. These changes in behavior affect the validity of the findings; thus, reactivity should be minimized to the degree possible by conducting observations in an unobtrusive and discreet manner (Merrell, 2003) or by allowing the client to get accustomed to the presence of the observer (Keller, 1986). Specifically, observers can practice techniques such as shifting attention away from the target child periodically, entering the setting in a non-disruptive way (during breaks or class changes), observing from a distance or through one-way mirrors, avoiding interactions with others during the observation, and finding an inconspicuous location from which to observe (Sattler & Hoge, 2006).

In addition to minimizing the effects of reactivity during an observation, clinicians should consider how to increase the likelihood that the behaviors sampled are representative of the child's behavior as a whole. This can be accomplished by conducting observations in multiple settings and at multiple time points and by not making broad generalizations from limited data (Merrell, 2003). It might also be useful to collect social comparison data, in which information on the behavior of peers is also collected. These comparison data can allow for more meaningful descriptions of the behaviors observed (e.g., how this student behaves in comparison to

his or her classmates) and can place the behaviors within a meaningful context (Sattler & Hoge, 2006). Comparison data should ideally be collected in the same setting and during the same time period as the observation. The variety of potential threats to validity and reliability is extensive; thus it is critical to consider the variety of ways to minimize these threats and to report data in light of these limitations to behavioral observations.

## **Behavioral Rating Scales**

Unlike behavioral observations, which provide data regarding behavior in a specific context during a limited time frame, behavior rating scales provide a summary of behavioral characteristics of a student that may occur in one or more settings as observed by a particular informant over a longer period of time (Merrell, 2000). Rating scales are different from personality tests in that they focus on patterns of overt behavior rather than underlying personality traits (Sattler & Hoge, 2006). Rating scales provide an efficient summary of a person's behavior by a specific rater. Possible raters include the person who is being assessed (self-report), teachers, parents, and other key informants who have specialized knowledge about an individual. A brief explanation of scale development is necessary to explain the complexity of behavior rating scales and highlight the importance of limiting their use to well-trained professionals.

## ***Development and Types of Behavioral Rating Scales***

Behavioral rating scales consist of statistically grouped behavioral and emotional problems or strengths that represent patterns of functioning. Scores indicate how different a person's behavioral and emotional functioning is compared to large normative samples that are most often separated by gender and age. The utility of a scale's published/stated purpose must be tested thoroughly with a normative sample prior to its use with true clients. Before implementing a rating scale, it is crucial that practitioners review its development and select one with empirically validated scales and large normative samples that are representative of the client being tested in terms of demographic characteristics such as gender, age, race, language status, and region of the country.

In the beginning stages of scale development, researchers generate a broad list of behavioral and emotional problems or skills related to the purpose of assessment. For example, to develop a depression

inventory, a scientist generates a list of behavioral and emotional symptoms or characteristics of depression such as being sad or tired. In order to generate items, the scientist might look at case files of clinically depressed clients, review the literature, include diagnostic criteria, or survey experts in the field. Once a comprehensive list is identified, the scale developer may or may not want to shorten the list of potential items prior to expensive norming procedures and statistical analyses. Thus, scale developers often use experts to rate the relevance of items to the construct under investigation. For example, the developer might send a list of potential depression items to 100 clinical psychologists with expertise in depression to rate each item for its relevance to the disorder. The highest-rated items are assigned response options so raters can identify the frequency with which a particular symptom or characteristic is present. Multiple responses such as “never, sometimes, often” or “never, rarely, sometimes, often, always” allow the rater to weigh the presence of a symptom more precisely than a yes or no option. Having multiple responses is one of the key characteristics of a behavior rating scale that differentiate it from a checklist, and this allows for more precise measurement of symptom frequency or intensity (Merrell, 1999).

Once a list of potential items has been identified, the developer must conduct a study to isolate and group a final list of items through statistical analyses. The developer recruits a large, diverse sample of participants who each provide responses to every item. Once data are collected, a statistician conducts various analyses, which may include item response theory, differential item functioning, or factor analysis, to evaluate the psychometric properties of the scale. For example, factor analysis is guided by decisions such as how many scales are desirable and which items fit together based on theory and expert knowledge. In creating a depression scale, if a single depression scale is predicted, any item that does not fit within a single factor might get eliminated. However, if statistics reveal unexpected results, such as two distinct factors, the scale developers would need to consider how the two scales fit within the existing knowledge and research regarding depression. Ultimately, psychometric analysis yields a final abbreviated scale that is ready to be tested. Scale developers assign labels to the *factors*, or *subscale*s, that describe their contents. For example, all items that describe symptoms of inattention might be labeled “inattention,” and all aggressive behaviors might be named “delinquency,” “aggression,” or

“conduct problems.” Note that scales with different names might measure similar behaviors and scales with similar names might measure quite different behaviors. It is up to the test user to review items and scales to understand what is being measured and how it compares to other tests and measures.

In the final stage, the scale developer must recruit a large sample of participants whose demographic characteristics (e.g., gender, age, race, geographical location) are representative of the types of clients who will complete the final version of the scale, yet who are drawn from the general population, so the developer can determine the full range of responses, including what are typical ratings for the average person. This sample is termed the *normative sample* and sets the standard for identifying average, at-risk, and clinical levels of symptoms. The data collected from the normative sample are examined to determine the distribution of scores. A number of reliability and validity analyses are crucial at this step; see Chapter 3 for a thorough discussion of related measurement issues. Behavior-rating scales all have somewhat different development procedures and psychometric properties. It is the responsibility of an assessment professional to carefully review the procedures and psychometric properties to ensure an assessment is valid for the purpose intended.

#### BROADBAND VERSUS NARROWBAND SCALES

In general, broadband scales assess multiple syndromes that may have overlapping symptoms and characteristics and allow for an assessment of multiple behaviors simultaneously. Using a broadband scale, an assessor can develop a better understanding of the pattern of behaviors displayed by a student. For example, a teacher might refer a student for having difficulty paying attention. Giving a broadband behavior rating scale with multiple informants, the assessor might determine that the student has inattentive behaviors from the teacher’s viewpoint; inattentive, emotional, and depressed behaviors from the parent perspective; and emotional ups and downs from the self-report. If a unidimensional attention rating scale had been administered, the practitioner might have concluded that the student has symptoms of attention-deficit hyperactivity disorder (ADHD). Using the broadband scale allowed the user to identify internalizing problems as the source of inattention, which requires a different course of treatment than ADHD.

In contrast to the omnibus measurement of a broadband rating scale, narrowband behavior

rating scales are disorder- or category-specific, assessing for subtypes or precise traits within a focused problem area. The implementation of more specific narrowband scales as a second step might help focus the assessment on the internalizing problems and further detail eligibility or treatment needs. As comorbidity (co-occurring disorders) tends to be the rule rather than the exception in these cases (Sroufe, 1997), it is important to assess broadly at first, and only narrow in once preliminary results are examined. See Table 26.4 for examples of broadband and narrowband rating

scales, including information on their general properties.

#### CHECKLISTS VERSUS RATING SCALES

Checklists are not rating scales; rather, they allow for simple ratings of the presence or absence of emotional or behavioral characteristics that represent a particular syndrome, diagnosis, or area of strength. The DSM-IV-TR and IDEA represent categorical classification systems that require a specific diagnosis for access to funding streams such as mental health or special education services. A categorical approach

assumes disorders are either present or not, and does not acknowledge subsyndromal levels of pathology (Kamphaus, VanDeventer, Brueggemann, & Barry, 2007). Although behavior rating scales can be used to complete a behavior checklist such as one used to make a diagnosis according to the DSM-IV-TR, behavior rating scales are much more complex and have many more uses than a behavior checklist. (See Chapter 9 for a more thorough description of classification systems and diagnosis.) Depending on the purpose of assessment, behavioral rating scales may be used in combination with observations, interviews, records reviews, and other types of direct and indirect measures of functioning. It is critical that behavior rating scales be validated for each specific purpose they are used for.

### **Purpose of Assessment**

Behavior-rating scales play an important role in the psychological assessment of children and adolescents. As previously mentioned, psychological assessment has historically focused on deficit-based, or “medical,” models for understanding behavioral functioning. The most accurate and legally defensible assessment takes into account ecological variables and includes a breadth of strengths and deficits. The main uses of behavior rating scales are screening, diagnosis, treatment planning, and progress monitoring.

### **SCREENING**

The purpose of screening is to efficiently identify those who are likely to be at-risk for problems and therefore need intervention. Schools are ideal settings for universal screening of children and adolescents, as they serve the entire youth population. Although few schools systematically screen for mental health problems (Romer & McIntosh, 2005), screening is a highly beneficial and cost-effective strategy that all schools should consider. This is particularly important as early identification and intervention of mental health problems attenuates the long-term consequences associated with mental illnesses, such as academic failure and healthcare costs (Campaign for Mental Health Reform, 2005). Schools routinely screen for other health challenges that may impede learning, such as vision, hearing, fitness, and language development; screening for mental health is the next step in allocating early intervention services to promote academic excellence.

For screening, a brief behavior rating scale is administered to a whole group. For instance, a school may wish to determine which students could most benefit from school-based counseling services.

A behavior rating scale is administered to the entire student population, and students whose scores fall a standard deviation above a preset cutoff point (e.g., one standard deviation above the mean) are selected for more intensive assessment. Through a multi-gating approach, students pass through increasingly more intensive assessments and interventions as needed to address problems. By assessing the entire population, screeners can identify challenges for students who may have been missed by less structured methods such as parent or teacher referral. For accuracy, the behavior rating scale needs to be validated for the purpose of screening.

One example of a systematic behavioral screening system is the Behavior Assessment System for Children, Second Edition–Behavior and Emotional Screening System (BESS; Kamphaus & Reynolds, 2007). The BESS consists of brief rating scales for students, parents, and teachers with 25 to 30 items. Elevated results provided by T scores and interpreted through cut-scores indicate which children demonstrate precursors for emotional and behavioral problems and can be used in the systematic identification of children in need for intervention. (For more information on screening, see Chapter 9.)

### **DIAGNOSIS**

Behavior-rating scales are important to help professionals categorize and diagnose behavior according to classification schemes such as the *Diagnostic and Statistical Manual of Mental Disorders–Fourth Edition, Text Revision* (DSM-IV-TR; American Psychiatric Association, 2000) or Individuals with Disabilities Education Act (IDEA; PL 101–476). The DSM-IV-TR is a comprehensive list of all recognized mental health disorders with their diagnostic criteria. If a certain number of behavioral criteria are met to a marked degree and over a sufficiently long period of time and causing significant disruptions to functioning, a person is assigned a mental health disorder. If criteria are not met, the individual is thought not to have a mental health disorder. The IDEA provides diagnostic criteria for children from birth to 21 years of age to access special-education services in the public schools setting. To receive services, children must meet criteria for one of 13 disabilities and be unable to access regular education without special-education supports and services. Although the DSM-IV-TR and IDEA overlap in terms of disabilities covered, the criteria are different, and it is possible, for example, to meet DSM-IV-TR criteria but not IDEA criteria.

Diagnoses are often tied to access to services and funding streams.

A sequence of steps is necessary to use behavioral rating scales as part of a diagnostic decision (Kamphaus et al., 2007). First, a broadband scale, which assesses several syndromes in one scale, can be used to assess multiple groupings of behavior (e.g., depression, anxiety, social skills; examples are provided in Tables 26.4 and 26.5). Level of functioning on the various scales/syndromes allows the assessor to determine the breadth and depth of difficulties. Score profiles indicate if a single disorder emerges as problematic or is accompanied by co-occurring problems, or if behavior that looks like one disorder is actually caused

by an alternative disorder (e.g., aggression masking depression). If scores on one or more syndromes falls in the at-risk or clinical range, the assessor must determine if the score is consistent with other sources of information including other informants and/or other assessment strategies (e.g., observations, interviews, records review). Narrowband scales, which assess a particular disorder, can be used as a second step in the assessment process to obtain more in-depth data regarding a particular problem, such as inattention, depression, or aggression (examples are provided in Tables 26.4 and 26.5). Prior to making a diagnosis based on rating scale results, alternative reasons for elevated scores should be considered and ruled out,

such as rater bias, environmental mismatch, or temporary stress.

### TREATMENT PLANNING AND PROGRESS MONITORING

Behavior-rating scales may be useful for treatment planning and progress monitoring. Ideally, scales that provide data useful for diagnosis could also inform the next step: deciding what evidence-based strategies can be implemented to help the individual being assessed. Unfortunately, not much empirical research has examined behavior-rating scales for this purpose (Merrell, 2000). A challenge with treatment identification is that there may be

several treatment options for a youth with a particular disorder depending on additional factors such as age, intelligence, and comorbidity. Thus, an expert may need to make a judgment based on a comprehensive set of data. A challenge with treatment monitoring is that ratings might not be sensitive to change, as behavior rating scales rely on rater memory of past behavior over a broad period of time (Chafouleas et al., 2007). With the recent focus on response-to-intervention strategies, however, some behavior rating scales are being developed for use with treatment planning and progress monitoring. Others have been revised and re-normed with more frequent assessment in mind.

When data gathered from behavior rating scales can be used to design interventions that improve behavior, the scale has *intervention validity* (Elliott, Gresham, Frank, & Beddow, 2008). When they are designed and validated for use in planning and monitoring intervention, behavior rating scales can add value and efficiency to the assessment-treatment process. For example, item wording can impact how valid a measure is for treatment planning. “Molar” items represent a series of behaviors (“Make friends easily”; Gresham & Elliott, 1990), whereas “molecular” items represent a specific skill set (“Raises hand to request a turn”). Although molar items are useful for classification and diagnosis, molecular items are more useful for treatment planning (Elliott et al., 2008). Strategies that encourage intervention validity are (a) basing scale development on theory for problem solution, (b) targeting behavior that is socially important, and (c) organizing results to facilitate treatment planning (Elliott et al., 2008). Further research is needed to validate the use of behavior rating scales for treatment planning and progress monitoring, but it is a promising approach to streamline the assessment to intervention process, which historically has been quite disconnected.

In response to the multitude of ways to identify children and the need for intervention, the authors of the Behavior Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2004) have also recently published the BASC-2 Progress Monitor (BASC-2 PM; Kamphaus & Reynolds, 2009) and the BASC-2 Intervention Guide (BASC-2 IG; Vannest, Reynolds, & Kamphaus, 2009). The BASC-2 PM has been developed as a means to collect additional behavioral information for a variety of purposes. It contains different form versions containing 15 to 20 items, gathering brief ratings completed by students, parents, and parents and teachers. These ratings provide scores in the following domains: externalizing behaviors and ADHD problems, internalizing problems, social withdrawal, and adaptive skills. Information is reported through raw scores, T scores, and percentile ranks. Results render mental health professionals with the information necessary to monitor the changes in an individual’s behavior over time. The BASC-2 IG provides recommendations on methods of intervention, prevention, and management of behavioral problems corresponding to BASC-2 TRS and PRS subcategories (see “Observation Systems and Rating Scales” section below for additional information on the BASC-2) and is grounded in empirically validated research.

Merrell (2003) proposes specific strategies for using behavior rating scales to inform treatment decisions. First, data gathered through behavior rating scales identify a set of problem behaviors that are interrelated. Subsequently, professionals could use a Keystone Behavior Strategy (Nelson & Hayes, 1986) to select interventions that target a subset of behaviors effective at reducing the entire set of problem behaviors. A Keystone Behavior Strategy includes reducing risk through identifying a behavior deficit and enhancing the missing skills to translate into improved outcomes broadly. For example, a psychologist could teach a child with aggressive tendencies anger-management and relaxation strategies. The increase in skills will reduce the problematic instances where aggression was once displayed, in exchange for more pro-social behaviors.

Alternatively, clinicians could use data from behavior rating scales to inform a Template-Matching Strategy (Hoier & Cone, 1987), which involves targeting skills to the level of those consistently displayed by behaviorally high-functioning children. A Template Matching procedure may include collecting baseline information on molecular behavior such as disruptively speaking out in class. After an assessment of how frequently a typical peer in the class engages in the same speaking out behavior, the goal for intervention could be to decrease the behavior and enhance skills of the targeted child to an acceptable level as established by matching the template of an average peer. Both strategies require monitoring to determine if interventions selected by using the rating scale lead to treatment improvement. Although treatments are often assessed for their “face value,” or apparent worthiness based on common sense, careful research is needed to validate the selection and implementation of a treatment and avoid potential iatrogenic effects.

### ***Measurement Issues with Behavioral Rating Scales***

Behavioral rating scales can provide rich information from multiple sources regarding a variety of student behaviors. However, the quality of rating scale development varies greatly from scale to scale. Numerous scales are marketed to clinicians, and it is tempting to purchase and implement measures based on the advertised benefits. However, not all published scales have psychometric properties adequate for making decisions about individual clients. Alternatively, there exist many unpublished scales that are thoroughly developed for multiple purposes. Thus, it is critical for any professional

who uses behavioral rating scales to understand how scales are developed and validated in general, and the psychometric properties of any particular scale selected for use. Assessment professionals must be able to discern whether an assessment tool has the reliability and validity adequate for the purpose intended. This section will review some of the measurement issues that need to be considered by test developers and understood by test consumers. (See Table 26.5 for a summary of the psychometric properties of selected published rating scales.)

Although the target of the measure is the subject being rated, behavioral rating scales may also provide information about the person providing the information on the rating scale. Results reflect a rater's perspective of another person's behavior, as the rating can be biased by inaccurate memory. Behavior-rating scales are susceptible to several types of effects that lead to bias and reduce the accuracy of results (Merrell, 1999). "Halo effects" occur when a rater's overall opinion of a student who is being rated as good or bad influences all the ratings. For example, if a teacher feels a student is particularly out of control, the teacher might rate the student poorly on all indices, due to his or her knowledge of the student's poor behavior. The same could be true of a teacher rating a popular or well-liked student; the teacher might rate all indices positively due to his or her overall good feeling about a student. Leniency or severity effects occur when a rater is consistently lenient or severe across ratings of various students. Central-tendency biases occur as well, because raters tend to avoid judgments at the far ends of the scale. Schwartz (1999) hypothesized that survey respondents also are most likely to choose response options near the middle of Likert scales because they may interpret them to convey "normative" behavior. Finally, a self-serving bias may occur if the rater responds in a manner designed to gain or avoid services (Furlong & Smith, 1994).

Behavior-rating scales are also susceptible to various types of error variance. *Source error* reflects the subjectivity of the rater, *setting variance* reflects the phenomenon that the environment has a unique interaction with behavior, and *temporal variance* notes that behaviors vary and are inconsistent over time and across settings. Instrument variance acknowledges that different scales measure related but slightly different constructs and represent distinct normative samples, and thus, should not be expected to completely align with each other (Merrell, 1999). Although threats to validity are a fact of behavior rating scales, serious errors can be

avoided by constructing scales that encourage accurate responding.

### **Format of Rating Scales**

Survey design and implementation has a critical impact on how accurately people respond to behavior rating scales. Long- and short-term memory limitations, emotional reactions to items, item wording, response wording, and time frames all might affect responses (Furlong & Smith, 1994). Instructions on the rating scale itself can influence accuracy (Merrell, 2003). Directions should be succinct yet clear, and provide decision rules when deciding between multiple response options. By understanding the research related to various development and administration procedures, clinicians can select the most accurate behavior rating scales possible for their purpose.

### **ADMINISTRATION**

When administered individually by a trained professional, behavior rating scales are most likely completed carefully and relatively accurately. Unfortunately, when administered in large group settings by untrained professionals, research has demonstrated that the accuracy of ratings may suffer. Cross and Newman-Gonchar (2004) compared rates of invalid responses to surveys administrated by trained versus untrained teachers. Results indicated that the trained administrators obtained far lower rates of highly suspect responses (3%) than did the untrained administrators (28%). Thus, it is important to train survey administrators regarding the importance of accurate ratings and procedures for how to obtain accurate results.

### **PRESENTATION FORMAT**

The presentations of information to be rated can significantly affect the ratings. In a study by Hilton, Harris, and Rice (1998), the authors examined the consistency of youth self-reports of violence victimization and perpetration and compared prevalence rates derived from traditional paper-and-pencil reports to those provoked by the same experience modeled in an audio vignette. They found that the same youths reported two to three times more violence perpetration and victimization using the self-report format. Perhaps hearing the information made it more salient than reading about the perpetration. Turner et al. (1998) provided one of few investigations regarding how traditional paper-and-pencil formats and computer-assisted presentation influence response rates. Turner and

colleagues found that the computer format produced statistically significantly higher prevalence rates than did the paper-and-pencil format for weapon-carrying, acts of violence, and threatened violence. It is possible that the computer format promotes more accurate and less socially desirable responses, as responses may seem more confidential to respondents; more research is needed to draw firm conclusions.

#### RATING SCALE TIME FRAME

Behavior scales sometimes include items that refer to past behavior using a particular time frame (e.g., 30 days, six months, one year). Presumably, respondents would report higher incidents of behaviors over a much longer period of time. However, research on the issue has found some counter-intuitive results. Hilton, Harris, and Rice (1998) examined differences in self-reports across one-month, six-month, and one-year time periods and found that rates of interpersonal violence were insensitive to time frame. Their participants reported the same number of violent acts over the past year as in the past month. Multiple factors affect student recollection of school experiences, and respondents may find it difficult to accurately remember past events (Cornell & Loper, 1998; Fowler, 1993). Raters tend to place priority on more recent events than on more distant events and remember unusual rather than ordinary behavior (Worthen, Borg, & White, 1993). It is also possible that respondents interpret response time frames as providing subtle cues about the types of events the researchers are interested in. Asking about the past month may convey to respondents that researchers want to know about less serious but common events. In contrast, students may interpret asking about the past year as seeking information about less frequent but more serious incidents (Schwartz, 1999).

#### RESPONSE OPTIONS

Response options on behavior rating scales are formatted so raters can provide their level of agreement on a scale with multiple options. With only two options, the scale acts more as a checklist than a rating scale. With too many options, it is difficult to establish inter-rater reliability. Thus, a three-point scale tends to be common (Elliott et al., 2008). More accurate ratings are obtained when each rating is well operationalized so it is easy for raters to distinguish between options and select the one that best fits the ratee (Merrell, 2003).

#### WORDING OF QUESTIONS

How the question is asked influences the response. For example, ratings of specific behaviors (e.g., the student says "please" when making a request) may be more accurate than ratings of global judgments (e.g., "the student is polite"; Sattler & Hoge, 2006). When test developers create items, they should have a rationale for the wording of items and carefully consider whether molecular or molar items are required for the purpose intended. Test consumers should review test manuals to determine the quality of item development and if the wording of questions was adequately considered for the intended goal of assessment.

#### DATA SCREENING

Data screening methods can be used to help professionals detect response inconsistencies or implausibly extreme patterns of responding. Some surveys ask raters directly if they are responding honestly. Survey methods should include strategies to detect if youths respond in a socially desirable way (under-reporting negative behavior) and recognize that youths involved with antisocial and aggressive peers may *exaggerate* their involvement in delinquent activities as an alternative form of social desirability (Furlong & Sharkey, 2006). Procedures can be built into scale analyses that detect patterns of responding or significant inconsistencies among similar items.

#### Informants

Behavior-rating scales are indirect measures of behavior, as they rely on a rater's memory of behavior over time rather than recording behavior as it occurs. Thus, ratings are only as accurate as the person or "informant" who does the rating. Research indicates that there is low agreement between parent, teacher, and self-respondents to the same rating system. For example, weak correlations of .27 between teacher and parent, .25 between parent and self-report, and .20 between teacher and self-report ratings have been found, while more modest correlations of .59 were found between two parents and .64 between two teachers (Achenbach et al., 1987). This phenomenon is based on several factors: (a) behaviors occur within specific environments, (b) the restricted number of response options might not fit the behavior of a particular child, and (c) there is error associated with measurement. Merrell (2000) identified six findings related to behavior ratings across informants: correlations are modest, agreement in ratings across raters in similar roles

(e.g., two parents) is more likely than across raters in different roles (e.g., parent and teacher), agreement is stronger for externalizing than internalizing problems, agreement between child self-report and adult raters is low, gender of rater or student does not impact ratings, and age of student may be important but the influence of age is not yet understood. All of these factors should be taken into consideration when selecting measures and informants for the purpose of assessment.

Given that consistent ratings across informants is the exception rather than the rule, when this does happen, results indicate areas of consistency across environments and expectations (McConaughy & Ritter, 2008). Differences should be examined for factors affecting a respondent's perceptions. Perhaps there are different behavioral expectations in different settings. A teacher sees dozens of children in the school context. When teacher ratings are in the normal range and parent scores are elevated, this result may be because teachers may have a more realistic sense of what a typical child feels and does. Parents may be comparing their child to a well-behaved or high-functioning sibling. On the other hand, teachers may have higher expectations for behavioral conformity given the structured setting, and rate students as more extreme than parents who provide their children lots of unstructured time to play freely where focus on required tasks is not necessary. Clinicians should look for explanations for different results across informants using observational data and interviews to corroborate hypotheses.

When considering who should complete ratings for a particular client, practitioners should consider who knows the person well enough to respond accurately to the questions. Some informants may not know the child well enough or for long enough to accurately report on the behaviors in question. Informants may not have the opportunity to know about the child's behavior outside the setting, so a rating scale developed for any adult to complete may be difficult for a teacher to complete if there are questions about free-time activities, or for a parent to complete if there are questions about classroom behaviors. Superior rating scales are developed and validated specifically for a particular user to a user class, such as teachers, parents, or self.

Self-reports are the most direct assessment of a person's behavioral and emotional functioning. Self-reports are particularly useful when trying to understand an individual's internal state of functioning, including thoughts and feelings that might otherwise not be visible. However, for information

gathered from self-report to be accurate, the developmental and cognitive ability of the respondent must be taken into consideration. In general, self-reports are not accurate for children under eight years of age (McConaughy & Ritter, 2008). Older children are more able to self-reflect, yet reading ability, self-awareness, meta-cognitive skills, interest and motivation may all impact the accuracy of their responses. Moreover, children often do not initiate the assessment process, but are referred by parents, teachers, or others close to them. Thus, children may be fearful or anxious about the testing situation, particularly since testing is generally a high-stakes process. That is, results may be used to make significant and life-altering placement and treatment decisions. Placed in a one-on-one testing situation, children may respond to please or get the "right" response rather than responding freely (Smith & Handler, 2007). Building rapport and establishing a relationship with the child can help offset some of these challenges. Additionally, children's report of their feelings may represent only the moment (Smith & Handler). For example, if a child recently was reprimanded by the teacher, the child might report that school is not fun. However, this could be a temporary response, and the child might normally enjoy school.

Overall, practitioners should take care to observe respondents for any signs that reports may not be accurate, and provide observational data regarding testing behavior as part of any comprehensive evaluation. Any data that may be compromised by lack of understanding or inattentive behavior should be interpreted with caution. In general, a multi-informant approach provides the most balanced view of an individual's behavior in multiple contexts with raters who have different priorities.

### ***Strengths of Behavioral Rating Scales***

In general, behavior rating scales possess a number of strengths that make them a popular and defensible choice for a variety of purposes. Behavioral rating scales provide quantifiable data regarding the frequency or intensity of a behavior or emotion. Thus, psychometric analyses can examine the reliability and validity of measurements to promote consistent findings (McConaughy & Ritter, 2008). The structured format increases objectivity and reliability (Furlong & Smith, 1994), and results are more reliable than unstructured types of data (Merrell, 1999). For practitioners, once the time-consuming rigorous development process is complete, rating scales can take just minutes to complete and can oftentimes be scored

by computer (McConaughy & Ritter). Saving additional time and resources, rating scales can be administered by paraprofessionals or in group settings.

By identifying syndromes, behavior rating scales represent what occurs in normative samples rather than clinician-derived or diagnostic code-derived checklists, which may be more realistic (McConaughy & Ritter, 2008). Results yield information about comorbidity, as scales acknowledge overlapping symptoms for various syndromes (McConaughy & Ritter). Using rating scales, professionals can judge the severity of a problem compared to a large normative group rather than a particular classroom or school where clusters of problems or a lack of problems might bias observations (McConaughy & Ritter). Moreover, rating scales can measure low-frequency behaviors that might not be seen in a series of observations in a particular setting, such as delinquent behavior in the school setting (Merrell, 1999). This ensures that potentially important behaviors are not missed or overlooked (Furlong & Smith, 1994). It is also possible for raters to provide data regarding the frequency or intensity of behaviors over a period of time in a natural environment that may not be accessible to a clinician (Merrell, 1999).

Behavior-rating scale systems may include related scales developed for multi-informants, allowing for a cross-informant approach with data that are comparable when scales are developed together (McConaughy & Ritter, 2008). This cross-informant approach allows for the input and perspective of important others in a person's life, such as parents or teachers (Merrell, 1999), leading to a more ecologically valid approach (Furlong & Smith, 1994). When differences are found, data can help provide an understanding of setting-specific behavior; these benefits are particularly important when the subject of assessment will not participate in self-report or does not exhibit typical behavior when under observation (Furlong & Smith).

### ***Limitations of Behavioral Rating Scales***

Despite numerous strengths to using behavior rating scales for a variety of purposes, professionals must be trained in their use and proceed with caution when interpreting results. Although the implementation of behavior rating scales seems simple, they are in fact quite complex and may be used inaccurately. Published scales do not always have the best reliability and validity, despite their potentially high costs, yet they are easy to access and use by anyone without the training truly needed for accurate interpretation

of results (McConaughy & Ritter, 2008). One considerable limitation of behavior rating scales is that scales are only valid for use with the population included in the norming sample. Unless extensive testing has been conducted with numerous individuals across demographic groups, a scale's use should be limited to the population represented by the norming sample. Otherwise, a threat to validity termed *measurement inequivalence* may occur. Measurement inequivalence occurs when a specific group, such as English-language-learners, responds differently to the latent constructs measured by an instrument than did the original norm group. This differential item functioning is expected when cultural values related to behavioral functioning are quite different across ethnic groups. Thus, it is important for test users to check the norms to make sure they are representative of any particular child being assessed.

Accurate interpretation of behavior rating scales rests on the reliability and validity of the measure and the objectivity of the rater. Behavior-rating scales measure the perception, not reality of a behavior (McConaughy & Ritter, 2008; Merrell, 1999) and are not very sensitive to change since responses are based on perception of behavior over time (Chafouleas et al., 2007). Measurement issues of response bias and error variance also impair accuracy, and clinicians must carefully review validation procedures to determine if scales have been developed for the purpose intended. For example, behavior rating scales do not identify the causes of behaviors (McConaughy & Ritter). Professionals must gather additional information about the antecedent and consequences for specific problems as well as environmental causes. Moreover, additional data are most often needed to determine and design effective intervention (McConaughy & Ritter).

### ***Observation Systems and Rating Scales***

Following a determination of the type of behavioral information of interest, a mental health professional might choose to use published observation systems and/or rating scales to facilitate data collection. In clinical and school practice, particular scales have become frequently selected for various reasons including superior psychometric properties; standardized norm samples on special populations of concern; low cost; easy administration; and the ability to obtain specific information that can aid in diagnosis, intervention, and treatment planning. Although using commercially available observation systems and rating scales may increase ease of use, mental health professionals are cautioned to

remember threats to reliability and validity remain, and each system warrants independent evaluation.

To provide the clinician and clinician-in-training with some information on available behavioral assessment systems, this chapter highlights two frequently utilized systems: the Behavior Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2004), and the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2001). The BASC-2 and the ASEBA have emerged as two of the more popular scales, in part due to their extensive research base (Hosp, Howell, & Hosp, 2003), psychometric properties, and ability to provide behavioral information from multiple informants across multiple environments. Tables 26.2–26.5 provide information regarding additional published behavioral observations systems and rating scales.

### ***Achenbach System of Empirically Based Assessment***

The Achenbach System of Empirically Based Assessment (ASEBA) is a multi-informant assessment that offers comprehensive, evidence-based assessment of adaptive and maladaptive functioning in children and adolescents. It is considered a comprehensive assessment system due to the multi-modal approach of information collected through rating scales, self-report forms, interview schedules, and observation forms (Achenbach & McConaughy, 2003). Multiple raters can provide information on a child's (ages 1½ to 18 years) functioning in a variety of applicable settings including the home (Child Behavior Checklist; CBCL), school (Teacher's Report Form; TRF), community, and any other setting where the child spends time (Achenbach & McConaughy). The ASEBA also includes self-report information on the Youth Self-Report (YSR) for youth ages 11 to 18. The ASEBA includes features such as computer scoring and a fifth-grade readability level on the rating forms, which increase ease of use and administration. The normative sample is nationally representative in terms of demographics including age, ethnicity, regional location, and gender. Extensive psychometric information is available in the manual (Achenbach & Rescorla, 2001).

Three overarching scores are provided for the CBCL, TRF, and YSR: an Internalizing behavior score, an Externalizing behavior score, and a composite Total Problems behavior score. These broader scores break down into eight subscales: the Externalizing scales include Aggressive Behavior, Attention Problems, and Delinquent Behavior and

the Internalizing Scales contain the Social Problems, Anxious/Depressed, Somatic Complaints, Thought Problems, and Withdrawn narrow subscales. The ASEBA also contains three scales for identifying adaptive and competency behaviors: Activities, Social, and School, which yield an overarching composite Total Competence score. Alternative methods of scoring allow for forms to be scored in terms of DSM-oriented scales targeted for diagnostic purposes. The following six DSM-oriented scales are based on the CBCL, YSR, and TRF for ages 6 to 18: Affective Problems, Anxiety Problems, Somatic Problems, Attention Deficit Hyperactivity Problems, Oppositional Defiant Problems, and Conduct Problems (Achenbach, 2007; Achenbach & Rescorla, 2001).

In addition to behavioral rating scales, the ASEBA includes the Direct Observation Form (DOF; Achenbach, 1986) to aid in the collection of behavioral observation data. The DOF employs narrative and time sampling recording procedures to observe on-task and 96 problem behaviors across 10-minute periods. The user conducts time sample recordings of on- and off-task behavior at the end of each minute for the duration of the observation and records narrative observations throughout the observation. Observers provide ratings on a 4-point Likert scale where 0 signifies the behavior is not observed, and 3 signifies a definite behavioral occurrence with severe intensity or for a behavior with greater than a 3-minute duration. The authors recommend conducting three to six 10-minute observations yielding an average score calculated across occasions. Also recommended is the use of comparison peers as "controls" for 10-minute observations before and after observing the targeted child. The sum of observation ratings provides raw scores corresponding with cutoff points for clinical levels of behavior across the problem behavior syndrome scales. These cutoff points were derived from both a referred and a non-referred control sample, and the DOF differentiates between referred and non-referred children (McConaughy, Achenbach, & Gent, 1988). Tables 26.2–26.5 summarize properties of the ASEBA.

### ***Behavior Assessment System for Children, Second Edition***

The Behavior Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2004) consists of multi-rater forms, a structured developmental history, and a systematic observation system that results in a multi-perspective report of problem and adaptive behaviors for youth ages

2 to 21 years spanning preschool through college. BASC-2 rating scales are available for multiple informants including teachers (Teacher Rating Scale; TRS), parents (Parent Rating Scales; PRS), and self-report (Self-Report of Personality; SRP) with different age-based forms for ages 8 to 25 years. Additional components of the BASC-2 include the Structured Developmental History (SDH), the Systematic Observation System (SOS), the Progress Monitor (PM), and the Intervention Guide (IG). See previous section on treatment planning and progress monitoring for information on the PM and IG.

The items of the BASC-2 TRS, PRS, and SRP are rated on a four-point response scale of frequency, ranging from "Never" to "Almost Always." The results from the parent and teacher rating scales yield T-scores across five composite scales: Externalizing Problems Composite, Internalizing Problems Composite, School Problems Composite, Behavioral Symptoms Index, and an Adaptive Skills Composite. The SRP provides the following composite scores: School Problems, Internalizing Problems, Inattention/Hyperactivity, Emotional Symptoms Index, and Personal Adjustment. In addition to problematic behavior identification, the BASC-2 assesses for positive characteristics and functional behaviors using the Adaptive Skills Composite score. Results from the BASC-2 ratings provide cut-scores utilized as thresholds to label levels of behavior as within the following ranges: Low (T scores 10 to 60 for problem behaviors;  $> 40$  for adaptive behaviors), At-Risk (T scores 61 to 69 for problem behavior; 30–39 for adaptive behaviors), or Clinically Significant (T scores  $> 69$ ;  $< 30$  for adaptive behaviors). By identifying severity of problematic behaviors in this way, the BASC-2 provides information regarding subsyndromal levels of behaviors not severe enough to meet DSM-IV-TR diagnostic criteria levels. Subscales and composites align with symptomology and characteristics of IDEA categorization for special education regulations and DSM-IV-TR diagnosis, aiding clinicians with categorization and diagnosis in both educational and clinical settings.

The BASC-2 forms are written at a fourth grade readability level and computer scoring is available. Internal validity indices, which detect internal threats such as "faking bad" (F-index), "faking good" (L-index), or responses that are nonsensical (V-index), are available. The BASC-2 manual provides extensive data on standardization, norms, reliability, and validity (Reynolds & Kamphaus, 2004).

The BASC-2-Systematic Observation System (BASC-SOS; Reynolds & Kamphaus, 2004) is a momentary time sample observation occurring at 30-second intervals requiring a 15-minute observation. BASC-SOS users can choose between the paper protocol and a computerized version called the BASC-Portable Observation Program (BASC-POP). At the end of a 15-minute observation, in addition to the time sampling data recorded, observers rate 65 adaptive and problem behaviors observed utilizing a 3-point scale from "never observed" (NO) to "sometimes observed" (SO), or "frequently observed" (FO). In addition to the behaviors delineated on the form for rating, users can also choose to observe and record information on additional behaviors that they specify. During the observation, observers can note directly onto the protocol specifics about teacher-student interactions and the classroom environment in addition to prioritizing which behavior is the most bothersome or is the focus of the observation. The BASC-SOS may also be utilized to measure changes in a child's behavior following an intervention. Normative data are not provided, but the manual recommends including two to three comparison peers for normative data. Although a paucity of reliability and validity data are available, the authors recommend repeated observations to increase reliability. Additionally, users should ensure threats to validity are minimized through inter-rater checks and checking for reactivity threats during an observation. Tables 26.2–26.5 provide information on the properties of the BASC-2. Information on additional observation systems and rating scales are also provided in Tables 26.2–26.5.

## Conclusions and Future Directions

It is likely that continual progress will be made in the development and use of behavioral observation systems and rating scales. More sophisticated tools will be developed to integrate future technologies that will make observation of behavior more efficient to collect and accurate to interpret. Behavioral rating scales of the future might be gathered solely through the use of PDAs, which would allow for immediate feedback, graphing, and progress monitoring. Or perhaps brief questionnaires will be sent via cell phone to gather information that is specific to the situation that the adolescent is currently in. Similarly, behavioral observation systems might implement software where video from the classroom is streaming live and advanced technology systematically codes how often students are out of their seats. Tracking devices might be attached to

shoes or desks to see how frequently hyperactive students move in comparison to their peers. Although advances seem limitless, the use of rating scales and observation systems will ultimately be decided by unsophisticated practicalities such as ease of use, ability to provide meaningful information, and cost in terms of time, materials, and personnel.

Realizing that new tools are frequently developed, it is imperative that clinicians and clinicians-in-training have the requisite tools and knowledge to be able to thoroughly evaluate new assessments. Throughout this chapter, a variety of issues were presented to highlight some of the critical concerns that should be attended to, such as the psychometric properties and limitations of assessments. Clinicians must guard against the adoption of a new tool prior to an extensive review of its psychometric properties, regardless of its popularity or face validity. Users will have to consider how to combine information gained from multiple sources and methods throughout the assessment process in a way that can be meaningfully digested and understood. Additionally, users will have to weigh actuarial data obtained with clinical judgments, recognizing that both can be biased and subjective. Above all else, great caution should be exercised when making diagnostic decisions that could potentially impact the delivery of future services.

Regardless of the assessment tool chosen, the actual behavioral assessment process should begin long before the observation period or the delivery of a rating scale and end long after the results are obtained. Prior to collecting information, a thorough evaluation of the selected tool, in light of the purpose for the assessment, is needed. Clinicians should engage in an iterative, problem-solving process until sufficient behavioral information is gained and results should be combined with other sources of information to provide a comprehensive assessment. Feedback from team members including parents should be solicited and incorporated into treatment planning and progress should be evaluated systematically. A psychologist is not simply a psychometrician gathering and reporting behavioral data. On the contrary, skilled clinicians utilize their full breadth of training and knowledge to conduct behavioral assessments as one part of a multifaceted assessment. We hope the concepts and recommendations discussed in this chapter will stimulate psychologists to critically evaluate and reflect upon how to improve current practices for behavioral assessment.

# Models and Methods of Assessing Adaptive Behavior

Jason Hangauer, Jonathan Worcester, and Kathleen Hague Armstrong

## Abstract

This chapter will summarize contemporary models and methods used for the assessment of adaptive behavior functioning in children and adolescents. This chapter will also emphasize how to best use such assessment information for diagnostic and eligibility purposes and in developing interventions and support plans. We will review the use of traditional, norm-referenced adaptive behavior assessment tools as well as what will be referred to as “supplemental methods,” including the direct observation of adaptive skill functioning. The assessment of adaptive behavior with respect to developmental expectations, cultural expectations, systems of care, and legislation will also be discussed. Lastly, case studies will be presented to illustrate the usefulness of these methods in assessing individuals and planning effective interventions and services.

**Key Words:** adaptive behavior, assessment, children, models, methods

## Definition of Adaptive Behavior

One of the most widely accepted definitions of adaptive behavior was first developed by the American Association on Mental Retardation (AAMR; 1992, 2002). As defined by the AAMR (2002), *adaptive behavior* is “the collection of conceptual, social, and practical skills that have been learned by people in order to function in their everyday lives” (p. 73). As such, adaptive behavior reflects one’s competence in dealing with social expectations and across environments. Limitations in adaptive behavior affect one’s daily life, one’s ability to respond to life changes and environmental demands, and the degree to which an individual can be independent. The AAMR defines *conceptual skills* as the ability to understand and communicate via spoken and non-verbal language, the ability to plan out one’s day-to-day activities, and performance of academic skills such as reading or writing. *Social skills* are defined as one’s ability to relate to others, hold a conversation, and initiate dialogue for the purpose of communicating one’s ideas or needs and wants. Additionally, social skills

include the ability to obey rules of an organization, such as family or school, as well as obey the laws of society. *Practical skills* include independence in performance of daily functions such as planning and preparing meals, putting on clothing, toileting, managing one’s own finances, using the telephone, and ability to take needed medications. Adaptive behavior emphasizes the developmental nature of skills, which become more complex as individuals mature and are faced with new demands from their environment. Ultimately, adaptive behavior assessment must take into account the culture and social standards of the community in which the individual lives and functions.

## Adaptive Behavior and Its Relationship with Intelligence

Adaptive behavior assessment evolved out of a concern voiced over 50 years ago, speaking to the need for nonbiased assessment beyond the IQ test for diagnosis, and linking to effective interventions for individuals with intellectual and developmental

disabilities (IDD). The first accepted definition of adaptive behavior from the AAMR was developed in 1961 (Heber, 1961), born out of the recognized bias of diagnosing individuals with IDD based upon the results of IQ tests alone, without examining their day-to-day functioning in society. With the advent of the Education for All Handicapped Children Act in 1975 (Public Law 94-142), concern for the over-identification and labeling of some minorities by the sole use of IQ testing lead to several court cases, and subsequently to the inclusion of adaptive behavior in assessing children for IDD (Reschley, Kicklighter & McKee, 1988). Over the years, adaptive behavior has become a required element in determining eligibility for other special education programs besides IDD, as well as in qualifying for federal assistance programs, such as Social Security benefits. Therefore, legislation and litigation came to establish the critical importance of assessment of adaptive behavior in diagnosis, program eligibility, and intervention for individuals with IDD, in that it not only identified limitations, but provided a basis for developing interventions and services towards developing competencies and strengths.

For the past 30 years, several researchers have examined the relationship between adaptive behavior assessment and IQ tests, particularly with respect to individuals with IDD. Across multiple studies, comparing several instruments, the correlations between IQ and adaptive behavior scores were found to be in the low to moderate range (Coulter, 1980; Harrison, 1990; Lambert, Nihira, & Leland, 1993). Some reasons for these findings may be a function of the differences between the construct for intelligence (innate abilities, maximal performance potential, and stability of scores) and the construct for adaptive behavior (daily living skills, typical performance, and developmental/modifiable). Individuals with similar IQ scores will often demonstrate very different skills related to their adaptive behavior functioning, as a result of their opportunities, expectations, or motivation (Harrison & Oakland, 2003). With proper intervention, individuals can be taught and will learn adaptive behavior skills aimed to help them to function more successfully in new environments and situations. (Bruininks, Thurlow, & Gilman, 1987; Kamphaus, 1987).

While the assessment of adaptive behavior has been primarily used in individuals with IDD, it has also been found useful in assessing the strengths and needs of other clinical groups, including autism spectrum disorders (ASD; Harrison & Boney, 2002; Holman & Bruininks, 1985), Attention-Deficit/

Hyperactivity Disorder (ADHD; Harrison & Oakland, 2003), as well as emotional and behavioral disorders (EBD; Armstrong, Dedrick & Greenbaum, 2003). For example, deficits in adaptive behavior functioning are apparent in the early childhood years, and as such have become an integral part of early childhood assessment, diagnosis, and intervention (Harrison & Raineri, 2007). Young children who do not receive intervention to assist in increasing their adaptive skills are at greater risk for later behavior problems (Grossman, 1983). Adolescents with poor adaptive skills are less successful in completing school and assuming adult roles, including independent living, employment, and achieving satisfactory relationships (Armstrong, Dedrick, & Greenbaum, 2003). Furthermore, Armstrong and colleagues found that improvement in adaptive skill functioning was a better predictor of successful adult outcomes than either reduction of behavior problems or IQ scores.

Thus, meeting the demands and expectations for one's environment is important at all ages, and is critical to consider in providing supports and services that promote adaptation. Everyone, regardless of their age or disability, must learn to take care of themselves and get along with others to the extent that is possible. Interventions specifically designed to address limitations in adaptive skills and build strengths become key to successful and independent functioning, and so become a critical function of special education supports and services (Eldevik et al., 2010; Gresham & Elliott, 1987).

### **Purpose of Adaptive Behavior Assessment**

The overarching purpose of adaptive behavior assessment is to develop supports and services to meet the needs of the individual. To accomplish this, it becomes essential to identify the individual's functional strengths and needs in relation to their family, culture, and community expectations. Often, adaptive behavior assessment is needed to help establish a diagnosis that may assist in explaining the reasons for the differences. Standard classification systems, including the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR; 2000), and the International Classification of Diseases, Ninth Revision (ICD-9; 1998) include the assessment of adaptive behavior for the diagnosis of IDD. Establishing a diagnosis can help link the individual and family to specific support groups, determine eligibility for supports and services, and supply a

deeper understanding of the nature of the individual's differences. The latest revision of the DSM has kept its current definition of mental retardation (now known as IDD) and requires documentation of deficits in adaptive functioning along with deficits in IQ for diagnosis. The DSM-5, which is expected to be released in 2013, is proposing only minor changes in the definition of IDD, and will likely increase its emphasis on adaptive functioning. The DSM-IV-TR stresses that effectiveness in adaptive functioning should be considered within the context of one's age and cultural expectations, in areas of communication, self-care, home living, social skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety.

A second emphasis of adaptive behavior assessment is to establish the level of an individual's functioning in order to determine their eligibility for special-education programs and to set goals and objectives. The Individuals with Disabilities Education Act (IDEA, 2004) is a federal law that mandates that all children aged birth to 21 receive free and appropriate services in the least restrictive environment. Part B of IDEA refers to regulations pertaining to children from three to 21 years of age, while Part C addresses regulations for infants and toddlers, from birth to age three. Lastly, there has been an increased focus on educational accountability extending from preschool to high school years, which requires assessment information that documents what children know and can do as part of the No Child Left Behind (NCLB) act of 2004 (NCLB, 2004). Given the developmental nature of adaptive behavior and presumed malleability, the emphasis on early identification and intervention with evidence-based strategies, adaptive behavior assessment becomes crucial. What children can and do perform in their everyday routines must be examined for the purposes of diagnosis and eligibility, as well as to establish interventions and supports needed to address specific functioning, and their response to the intervention (Harman, Smith-Bonahue, & Oakland, 2010).

Both the DSM-IV-TR, as well as the upcoming fifth revision, DSM-5, along with IDEA (2004) strongly emphasize the assessment of adaptive behavior for diagnostic purposes or when assessing an individual for special education services. This emphasis is not accidental. Adaptive behavior assessment initially was developed as a way to prevent misdiagnosing individuals, placing them in more restrictive settings, or giving them inappropriate

services. Adaptive behavior assessment provides information both about an individual's weaknesses and strengths, is useful in planning and evaluating interventions, and helps document progress towards goals.

## **Standardized and Supplemental Adaptive Behavior Assessment Tools and Techniques**

There are many well-standardized instruments that have been developed over the past two decades that are very useful in assessing adaptive behavior in individuals ranging in age from infants to senior citizens. As with other standardized assessment tools, adaptive behavior measures gather information about an individual's functioning to compare with those from national standardization samples and from certain clinical groups. Additionally, newer assessment techniques have been developed that allow for more in-depth assessment of key adaptive skills, which may be more useful for intervention planning and progress monitoring. Given the rapid changes in technology, and what is needed to interact with the environment and society, the construct of adaptive behavior is constantly changing and being modified (Oakland & Daley, 2010).

## **Standardized, Norm-based Assessment Methods**

Among the most contemporary, well-standardized, and widely used norm-based adaptive behavior assessment instruments are the Adaptive Behavior Assessment System–Second Edition (ABAS-II; Harrison & Oakland, 2003), and the Vineland Adaptive Behavior Scales–Second Edition (VABS-II; Sparrow, Cicchetti & Balla, 2005). In addition, the Battelle Developmental Inventory–Second Edition (BDI-2; Newborg, 2004), and the Behavior Assessment System for Children–Second Edition (BASC-2; Reynolds & Kamphaus, 2004), include measures of adaptive behavior as one of the domains within those assessments. These tools are similar in that they rely on gaining information from caregivers familiar with the individual, such as parents or teachers, obtained through survey and semi-structured interview methods. The strengths and weaknesses of each of these tools will be discussed in the following section, and are outlined in Tables 27.1 and 27.2.

The VABS-II measures adaptive behavior in four domains and eleven subdomains. Scores from the four domains (Communication, Daily Living Skills, Socialization Skills, and Motor Skills) are combined to form the Adaptive Behavior Composite,

**Table 27.1 Standardized Assessment Tools for Adaptive Behavior**

Instrument Name	Age Range, Areas Assessed, Strengths and Materials	Weaknesses	
Adaptive Behavior Assessment System (ABAS-II), 2nd Edition (Harrison & Oakland, 2003)	Age range: Birth–72 Years Areas Assessed: Domains: General Adaptive Composite: Adaptive Domains—Conceptual (Communication, Functional Academics, Self-Direction, Social (Leisure, Social,); Practical (Community Use, Home Living, Health & Safety, Self-care, Work,) Motor domain for children birth–5 Used in Bayley-3	Strong standardization sample Internal consistency and factor score coefficients were high across all subdomains Inter-scorer reliability is above .90 Number of clinical samples included Four-point Likert-type scale (is not able, never or almost never when needed, sometimes when needed, and always or almost always when needed) to assess each skill area rather than simply “yes/no”	
Vineland Adaptive Behavior Scales—Second Edition (VABS-II; Sparrow, Cicchetti, & Balla, 2005)	Age range: Birth–90 years of age Areas Assessed: Four main domains: communication, daily living skills, socialization, and motor skills (only used for individuals birth–6 years 11 months) Optional maladaptive behavior domain available	Number of clinical samples included Both clinical interview and parent/caregiver rating forms available Comprehensive, life span	Manual scoring is cumbersome and can lead to error Inter-rater reliability is relatively weak May be more accurate at measuring adaptive skill deficits versus high levels of performance

or overall measure of adaptive behavior. There are three forms: the Survey Form, the Expanded Form, and the Classroom Edition, which are selected by the evaluator based on the age of the individual. The Survey Form gathers information about adaptive functioning from caregivers, is normed for children birth through 18 years of age, and may be used for lower-functioning adults. The Expanded Form offers much more detailed information about adaptive behavior, and is normed for infants through adults up to age 77 years. The Classroom Edition is useful for children ages three to 12, and uses teacher report to assess adaptive functioning within the classroom. Both the Survey and the Expanded Forms include a maladaptive behavior domain for children age five and older, titled the Social-Emotional Early Childhood Scale (SEEC; Sparrow, Balla, Cicchetti, 1998).

The VABS-II used a representative, national sample of 3,000 individuals, selected by sex, race,

socioeconomic status, geographic region, and community size. Standard scores are used to express adaptive behavior functioning, with a mean of 100, and standard deviation of 15, percentile ranks, stanines, and age equivalents. Internal consistency, test-retest reliability and inter-rater reliability, and validity data are adequate, and provided in more detail in Table 27.1. The SEEC is available for children birth through age five, and provides standard scores, percentile ranks, stanines, and age equivalents similar to those of the VABS-II.

The ABAS-II measures adaptive behavior in three domains: Conceptual, Social, and Practical, consistent with the American Association of Intellectual and Developmental Disabilities (AAID; 2007) definition of adaptive behavior. Each of the domains is factored into 11 subdomains, including Communication, Functional Academics, Self-Direction, Leisure, Social, Community Use, Home Living, Health and Safety, Self-care, Motor,

**Table 27.2 Behavior and Developmental Assessment Tools Including Adaptive Behavior**

Instrument Name	Age Range, Areas Assessed, Strengths and Materials	Weaknesses	
Battelle Developmental Inventory—Second Edition (BDI-2; Newborg, 2004) Behavior Assessment System for Children, Second Edition (BASC-2; Reynolds & Kamphaus, 2004)	Age Range: Birth–7 years 11 months Areas Assessed: Adaptive, Social-Emotional, Language, Motor, and Cognitive Age Range: 2–25 years Areas Assessed: Adaptive skills and overall behavioral assessment of maladaptive behaviors.	Representative norm sample of 2,500 children in the U.S. 19% of children were identified as of Hispanic origin Adaptive domain assessed via multiple methods: Structured (child performs the behavior in front of you), Observation (observe the child performing the behavior as part of their daily activities), or Interview (caregiver provides the information) Internal consistency, test-retest reliability, high validity comparisons with other instruments and inter-rater reliability is medium–high Representative norm sample including a clinical sample of children and adolescents with a variety of behavioral, emotional, and physical disorders and/or disabilities Internal consistency, test-retest reliability, high validity comparisons with other instruments and inter-rater reliability is high Allows for direct observation of a child's behavior in addition to caregiver/teacher report	Norm sample did not include children at risk for developmental delays No test-retest reliability data provided for children under the age of 2. Item gradients for children 23 months old vs. 24 months can change substantially (e.g., earning significantly different scores between 23 and 24 months of age) Standard scores do not go below 55 thus limiting use with children who are very low-functioning Interpretation of results from multiple respondents can be difficult for professionals not experienced with the instrument Smaller sample size reported by authors for ages 2–5. However, authors note this had an insignificant effect on the norm sample overall

and Work (adults only). Scores from the three major domains are combined into a General Adaptive Composite score to represent overall adaptive behavior functioning.

There are five available forms, which are selected based upon the individual's age and the respondent. The Parent/Primary Caregiver Form is administered to parents or caregivers of children to age five. This form is used to assess adaptive behavior by the Bayley Scales of Infant and Toddler Development—Third Edition (Bayley-III; Bayley, 2006). The Parent

Form is given to parents of children ages five to 21, so there is some overlap with the younger ages. The Teacher/Daycare Provider is used by teachers of children ages two to 5. The Teacher Form is completed by teachers of children ages five to 21. Lastly, the Adult Form may be used for adults ages 16 to 89 years, and may be completed by the individual when able, or by someone familiar with them.

The ABAS-II was standardized with data gathered from national samples of parents and teachers, which were stratified based upon sex, race, education

level, and geographic region. Internal consistency, inter-rater and test-retest reliability, and validity studies are reported in the manual and are acceptable. Table 27.1 summarizes these estimates. In addition, several studies have compared differences between scores of individuals in clinical groups, including ADHD, autism and developmental delay.

In addition to broad-adaptive behavior measures that can be used with individuals from birth onward through geriatric populations, several behavioral and developmental assessment tools also include adaptive behavior as a component within the evaluation. Two of these tools, the BDI-2, and the BASC-2, may be used to provide supplemental information about children's adaptive behavior.

The BDI-2 measures adaptive behavior as a component of a comprehensive assessment of five domains of development (adaptive, personal-social, communication, motor, and cognitive skills). The adaptive component of the BDI-II assesses adaptive behavior in two sub-domains: Adaptive and Personal Responsibility. Scores derived from each subdomain creates a composite score that is expressed as a developmental quotient with a mean of 100 and standard deviation of 15. The BDI-II may be used with children ages birth through age 7 years 11 months. A single form is utilized with the BDI-II. However, with respect to adaptive behavior, the BDI-II assesses only adaptive behavior related to activities of daily living in children under two (e.g., feeding and helping with dressing) while children over two are assessed with the sub-domain Personal Responsibility (e.g., understanding common dangers). The BDI-2 uses caregiver interview, direct observation, or a structured format face-to-face with the child to determine whether or not children have attained a developmental skill. The BDI-II was standardized with a representative sample of the U.S. population of 2,500 children. Internal consistency, test-retest reliability and inter-rater reliability, and validity data are adequate and provided in more detail in Table 27.2.

The BASC-2 measures adaptive behavior as a component of an overall behavioral assessment in five domains: activities of daily living, adaptability, functional communication, leadership, social skills, and study skills. Scores derived from these subdomains create a composite of Adaptive Behavior. There are five available forms that the user selects based on the age of the respondent. The Teacher Rating Scale (TRS) is separated into three forms: Preschool (ages 2–5), Child (ages 6–11), and Adolescent (ages 12–21). All items are rated

on a four-point scale of behavioral frequency from "Never" to "Almost Always." The Parent Rating Scale (PRS) follows the same format as the TRS as well as using the same four-point scale. The Self-Report of Personality (SRP) consists of three separate forms: Child (ages 8–11), Adolescent (ages 12–21) and College (ages 18–25). An interview format (SRP-I) is used for the Child form in which a child is asked to answer simply "yes" or "no" to each item. A Parent Relationship Questionnaire (PRQ) is also available and is designed to gather information about the relationship between a child or adolescent and his or her parents.

The BASC-2 was standardized with two populations: (1) A representative general population of children, adolescents, and young adults in the U.S. from a variety of public/private schools, mental health clinics, and preschools; and (2) A additional clinical norm sample was also used in the standardization process consisting of children and adolescents diagnosed with a variety of behavioral, emotional, and physical disorders or disabilities. T-scores are used to express adaptive behavior functioning. Internal consistency, test-retest reliability and inter-rater reliability, and validity data are adequate and provided in more detail in Table 27.2.

### **Supplemental Methods Assessing Adaptive Behavior**

In addition to traditional norm-referenced methods that typically rely on caregiver reports to obtain information about an individual's functioning, it is possible to obtain meaningful and practical estimates of an individual's acquisition of adaptive skills through more objective methods. Specifically, two methods deserve consideration: (a) criterion-referenced assessments, as illustrated by The Assessment of Basic Language and Learning Skills-Revised (ABLLS-R; Partington, 2006); and (b) direct-observation data collected during probes teaching specific adaptive skills. Although these nontraditional methods have their own strengths and weaknesses, they offer clinicians a valid supplement to more traditional assessment methodologies of adaptive behavior assessment.

The ABLLS-R is a combined assessment, curriculum, and progress-monitoring system that was designed for children with language delays. Twenty-five different skill areas are grouped into four different assessments that are used to benchmark a child's acquisition of developmental skills. These include (1) the Basic Learner Skills Assessment; (2) the Academic Skills Assessment;

(3) the Self-Help Skills Assessment; and (4) the Motor Skills Assessment. The Basic Learner Skills Assessment comprises the following skill areas: cooperation and reinforcer effectiveness, visual performance, receptive language, motor imitation, vocal imitation, labeling, intraverbals, spontaneous vocalizations, syntax and grammar, play and leisure, social interaction, group interaction, following classroom routines, and generalized responding. The Academic Skills Assessment includes sections dedicated to reading, math, writing, and spelling, while the Self-Help Skills Assessment measures dressing, eating, grooming, and toileting skills. Finally, both gross motor and fine motor skills are assessed via the Motor Skills Assessment.

Skill areas on the ABLLS-R are composed of a series of discrete tasks. Each skill is defined operationally, has an interview question, an illustrative example, and a set of scoring criteria. Clinicians, educators, and parents are able to use three different sources of information to address scoring criteria, including interview, direct observation, and presentation of the task itself (i.e., an intervention probe). Data are then transferred into a skill-tracking grid for subsequent analysis.

The ABLLS-R has several distinct advantages. First, the ABLLS-R is versatile, serving several important functions, including as an assessment, instructional curriculum, and progress monitoring system. In this regard, the design of the ABLLS-R allows one to link assessment to intervention with relative ease (e.g., individualized educational plans, behavior intervention plans). Second, the ABLLS-R enhances its validity and utility through multi-method assessment, using a combination of interview, direct observation, and intervention probes. Third, its scoring criteria are highly observable and measurable, a feature that can be traced back to the behavior-analytic origins of the ABLLS-R's design. Fourth, the ABLLS-R allows for comprehensive analysis of a child's skill acquisition/progress. Data can be analyzed within the task itself, as well as both within and across skill areas across a maximum of four separate administrations using the same protocol. Not only does the ABLLS-R allow for fine-grained analysis of skill acquisition within a specific skill area, but its criterion-referenced design is also sensitive to changes in growth over time.

However, the ABLLS-R cannot be used to compare a child's performance to a normative sample, and consequently, it cannot be used to document a delay or an intellectual disability, as is the case with norm-referenced assessments of adaptive

behavior. In addition, the ABLLS-R only purports to offer approximations of the actual developmental sequence of a child's skill acquisition with a specific skill area (i.e., it is not necessarily an exhaustive list of tasks associated with the developmental progression of skill acquisition relative to a specific skill area). Another limitation pertains to the scope of the Self-Help Skills Assessment. The ABLLS-R addresses dressing, eating, grooming, and toileting skill areas, but does not include assessments of domestic and community-based skills. Finally, the ABLLS-R does not discriminate between performance and skill deficits. For example, if a child demonstrated challenging behavior when presented with demands to perform a specific task, it is not possible to use the ABLLS-R to determine whether or not a child's behavior may be predicted by the difficulty of the task, gaps in prerequisite skill acquisition, or other features of the child's environment. In such situations, a functional behavior assessment would be indicated either as an alternative or in conjunction with an ABLLS-R assessment.

Behavioral observations in the individual's natural environment offer another strategy to assess adaptive behavior functioning. In addition, one can administer specific probes across several periods of time, to assess skill mastery and response to intervention. Several steps are required in order to conduct adaptive skill probes, and are described by Table 27.3.

Using intervention probes of specific adaptive skills as a nontraditional method of assessing adaptive behavior presents both advantages and disadvantages. Given that the intervention itself is intended to take place within the person's natural environment, the most significant advantage involves generalization. Specifically, skills taught using this method are more likely to successfully generalize because they are trained within the natural environment during naturally occurring routines (e.g., mealtime, personal hygiene,

**Table 27.3 Steps to Generate Adaptive Skill Probes**

- Step 1. Identify and observe the specific skill to be targeted for acquisition.
- Step 2. Create operational definition.
- Step 3. Set criterion for mastery.
- Step 4. Select or generate training materials.
- Step 5. Teach the skill (modeling, role play, performance feedback).
- Step 6. Collect observation data.
- Step 7. Evaluate relative to mastery criterion.

shopping, completing chores); they can incorporate multiple caregivers and/or examples; and they can be trained via variations in stimuli, responses, and reinforcers. In addition, this method allows for efficient error analysis. Through direct observation during intervention probes, it is possible to pinpoint which specific steps or prerequisite skills that have yet to be mastered may be inhibiting a child from acquiring a more complex skill. These skills can then be taught directly within the context of naturally occurring routines (with increased levels of prompting) or in isolation through discrete trials.

The first step involves identifying the specific skill to be targeted for acquisition. Skills can be selected in several ways, including from norm-referenced assessments of adaptive behavior, direct observations of prerequisite and targeted skills, or interviews (e.g., with parents, teachers, or therapists). Selection of skills targeted for acquisition should consider patterns of prerequisite skill acquisition, the child's needs and preferences, linkage into more complex skills, and the overall utility of the skill for the child and family (i.e., whether or not the skill will contribute toward incremental improvements in the individual child or family's quality of life). The skill should be observed with baseline data collected (e.g., percent accuracy) in order to both document the need for skill acquisition and establish a baseline. Once the target skill is identified and baseline data are obtained, the next step is to create an operational definition and set a criterion for mastery. The operational definition should be observable and measurable in order to lend itself to direct observation and measurement. The criterion for mastery should be defined prior to instruction and reflect a minimum degree of accuracy that would indicate the child is able to independently demonstrate the skill.

The next step entails selecting or generating materials for use in training. Depending on the skill targeted for acquisition, materials may either be readily available (e.g., Mannix, 1992; Mannix, 1995; Stages Learning Materials, 2004) or require custom development. With regard to the latter, some materials may only require modification to meet the needs of the child (e.g., enlarged size, using digital pictures instead of drawings, adding text to a stimulus). In other situations, materials may need to be developed, such as creating a pictorial/text task analysis of steps to demonstrate a complex skill (e.g., steps to brush teeth, steps to tie shoes, steps to load/unload the dishwasher),

or arranging and modifying materials for instructional purposes (e.g., using color-coded laundry baskets to teach sorting dirty laundry). The goal of materials selection/generation is to use materials that are both cost-effective and typically used by the child/family during naturally occurring routines. Once materials are available, teaching should proceed, using a combination of modeling the skill and subsequently delivering prompts and performance feedback. Given that the new skill has not been mastered, most-to-least prompts should be used and systematically faded over time in order to promote both mastery and independence. Data collection resumes (using the same metric as collected during baseline), and data are compared to the baseline in order to document the evaluatee's response to intervention/skill acquisition.

Finally, treatment plans generated based on nontraditional assessments possess a greater degree of contextual fit than those developed using more traditional methods. Referring to the degree to which a treatment plan is congruent or compatible with variables related to an individual or environment (Albin et al., 1996), contextual fit takes three sets of variables into account: (1) characteristics related to the child and his or her patterns of behavior; (2) variables related to the people involved in the development and implementation of the intervention plan; and (3) features of the environments where the plan will be implemented and the systems in place within those environments. Treatment plans taking such variables into account may be more consistently implemented over time since they address potential barriers to treatment integrity on an *a priori* basis (e.g., considering the intervention strengths and weaknesses of natural intervention agents, considering how well the intervention could fit within the child's routines).

With regard to disadvantages of nontraditional assessments of adaptive behavior, the greatest barrier to their use is their greatest strength—they require that clinicians have access to a home- and community-based service delivery model. Clinicians who work in clinics, schools, and analogous settings would therefore have greater difficulties using a nontraditional method. Conversely, some community-based settings present with unique features that may limit or reduce the degree to which they are accessible or amenable to intervention (e.g., airports, hospitals). Aside from these disadvantages, concerns can be raised with potential risks of prompt dependence, dependence on

resources (both time and material), and the need to have a fluent knowledge of prerequisite skills (in order to effectively identify and account for gaps in individual skills encapsulated within complex skills).

In an effort to illustrate the differences between both traditional and nontraditional methods of assessing adaptive behavior, two cases studies are presented below. For the sake of illustration, both cases describe assessment of community-based adaptive skills.

### Case Study of a 12 Year-Old Boy with Autism and Seizure Disorder

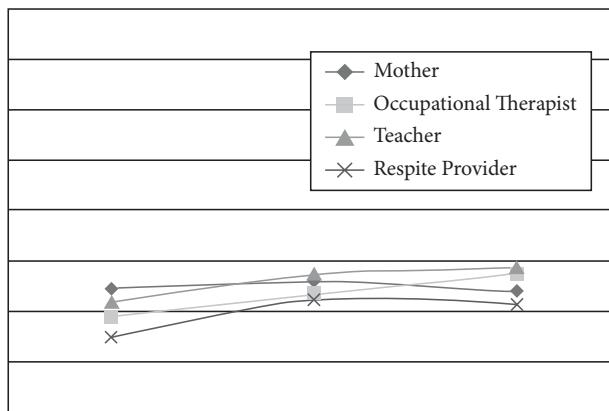

“GT,” a 12-year-old boy, presented with autism and seizure disorder, and challenging behaviors. These behaviors included a combination of aggression, self-injury, property destruction, tantrums, and non-compliance. Compounding the occurrences of these behaviors was the fact that GT did not have expressive language and relied on a combination of nonverbal functional communication training (e.g., picture exchange) and use of an augmentative communication device. These behaviors were exhibited across individuals, times of day, tasks/activities, and settings. In response to a parental request, a functional behavior assessment (FBA) and behavior intervention plan were developed in effort to both reduce occurrences of challenging behavior and to increase acquisition of age- and socially appropriate replacement behaviors.

With respect to medical and educational history, GT received medical care provided by a primary care pediatrician and pediatric neurologist. Relative to seizure history, the pediatric neurologist noted that seizures had not been reported in over two years and were considered well controlled with anticonvulsant medication. GT did not have any history of accidents, injuries, or surgical procedures. Hearing and vision were considered functional. In addition, a psychological evaluation conducted at age 14 revealed a non-verbal IQ score of 115 (which was indicative of average to above-average intellectual ability).

GT received a combination of speech language, occupational, and physical therapies, all of which were provided in a clinic. Inconsistent progress had been reported in all three therapies, particularly speech and occupational therapies. Therapists reported that GT’s receptive language was far better developed than his expressive language and fine-motor skills.

In addition, GT received special education services and supports. He was served in a full-day program, with additional support including speech language therapy, occupational therapy, daily living skills training, and social skills training.

Given reports from parents and caregivers that GT’s development appeared to have hit a plateau, a norm-referenced assessment of adaptive behavior was conducted and incorporated into his FBA (Vineland Adaptive Behavior Scales, 2nd ed.; Sparrow, Cicchetti, & Balla, 2005). Results of GT’s adaptive behavior assessment are reported below, in Figure 27.1.

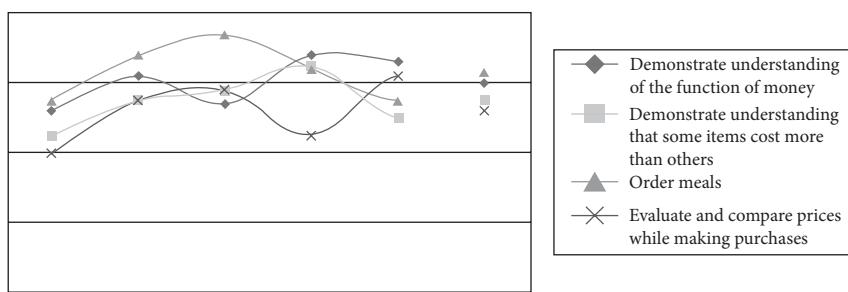

**Figure 27.1** Results of the Vineland Adaptive Behavior Scales, 2nd Edition (VABS-II)

On the VABS-II, data were obtained from multiple caregivers, including GT's mother, occupational therapist, teacher, and respite provider. Specifically, GT's communication skills ranged between 30 and 49, with strengths noted relative to receptive language and written language skills (in contrast to his expressive language skills). Daily living skill standard scores ranged between 45 and 55 across caregivers, with higher ratings obtained within the personal and school community domains (as compared to academic, domestic, and community skills). On the socialization domain, GT's skills ranged between 43 and 57, with strengths noted relative to coping skills (in comparison to interpersonal relations and play/leisure skills). Estimates of motor skill functioning (range = 48–64) revealed scores indicating that GT's gross motor skills are currently better developed than his fine motor skills. Finally, Adaptive Behavior Composite scores ranged between 37 and 50, which confirmed that GT's present level of adaptive functioning fell well below age-level expectations, not to mention his measured learning potential. These data supported the clinician's hypothesis that the presenting challenging behaviors were potentially triggered by demands that were difficult for GT due to his skill deficits with adaptive behavior.

Based on these results, four skills measured by the VABS-II were selected and targeted for intervention by the clinician and GT's parents: (1) understanding the function of money; (2) understanding that some items cost more than others; (3) ordering meals; and (4) evaluating prices while making purchases. A treatment plan was developed articulating interventions and goals specifically designed to teach each skill.

In effort to provide the parents with tools to use for intervention, the clinician chose reproducible lessons from published resources teaching life skills (Mannix, 1992; Mannix, 1995). Specific lessons and worksheets included recognizing the value of items, eating in restaurants, shopping for food, buying stamps, and using the public library. Lessons and worksheets were reviewed and practiced with role play and performance feedback at the clinic with the clinician over the course of five intervention sessions, and then at home with GT and his parents. Intervention data are presented below, in Figure 27.2.

The data in Figure 27.2 indicated that GT had acquired two of the skills (i.e., demonstrating an understanding of the function of money; ordering meals), while demonstrating progress toward the pre-established mastery criterion (i.e., demonstrating his understanding that some items cost more than others; evaluating and comparing prices while making purchases). Together, these data are suggestive of a positive response to intervention. Instruction continued at home with GT's parents until mastery of each worksheet was achieved (i.e., 80% accuracy or greater). Once GT reached mastery demonstrating these skills, intervention sessions were faded, and additional lessons and worksheets were provided for practice at home with his parents.

**Figure 27.2** Intervention Data Collected At Clinic

### Case Study of a 16-Year-Old Boy with Autism

“RV” is a happy, intelligent, and increasingly independent 16-year-old bilingual adolescent, with a diagnosis of autism and disruptive behavior problems. Behavior problems included a combination of noncompliance, inappropriate socializations, property destruction, and tantrums, which were reported by caregivers, across times of day, tasks/activities, and settings. RV’s parents requested help in both preventing challenging behavior and teaching him social, communicative, and adaptive replacement behaviors.

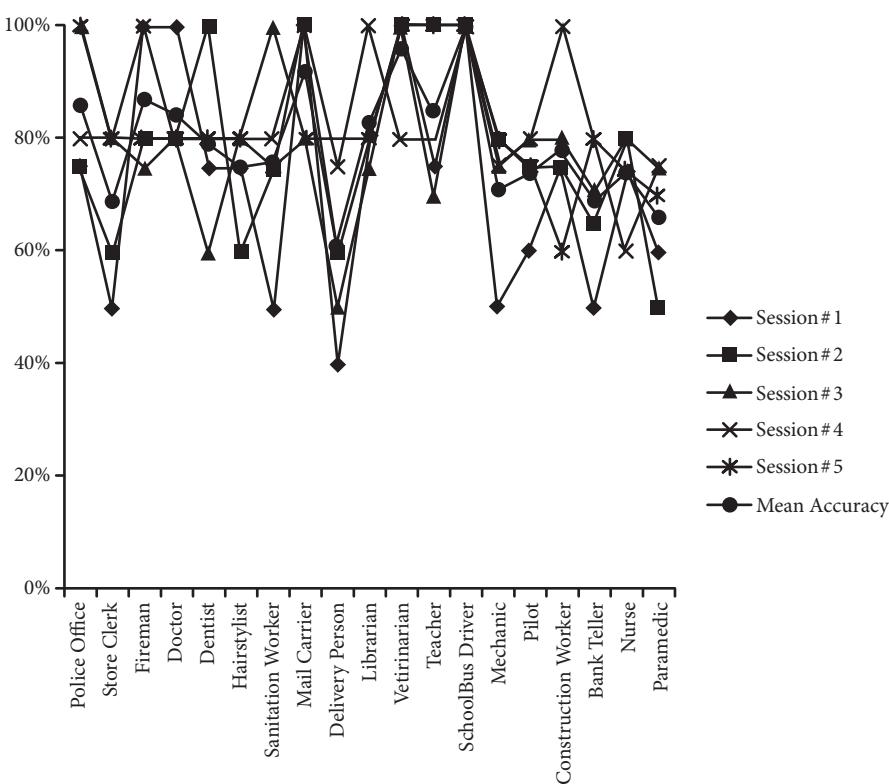

A review of medical and educational records indicated that RV was in good health overall, with no history of medication, accidents, injuries, surgeries, or seizures. Hearing and vision were both considered functional. RV had received both clinic-based speech language and occupational therapies in the past, and currently was provided care through applied behavior analysis services in his home and community. RV also received services and supports through the school district, and was placed in a full-time, self-contained program for students with autism. RV’s parents were interested in learning how to teach adaptive skills to their son. At the same time, they did not feel that previous standardized assessments were helpful in developing interventions. In response to this request, the clinician conducted direct observations during daily living skill routines in both the home and community. With these data, the RV’s parents and the clinician targeted the following skills for intervention: (1) discriminating function of community helpers; (2) discriminating function of community locations; (3) ordering and purchasing goods and services; and (4) determining whether items cost more or less than a given sum of money. A treatment plan was developed articulating interventions and goals specifically designed to teach each skill. Included within RV’s treatment plan were two operational definitions for community-based skills, which are presented in Table 27.4.

After setting a criterion for mastery (80% mean accuracy), the clinician selected published materials to teach identification and discrimination of community helpers (Freeman & Dake 1997; Stages Learning Materials, 2004). Training was then provided to RV at home using a combination of modeling, prompting, and performance feedback (e.g., praise, verbal prompts, nonverbal prompts, modeling, redirection). The clinician obtained accuracy data regarding community helpers and locations, which is shown in Figure 27.3.

As seen in Figure 27.3, RV was proficient in labeling common community helpers. Data for eight of 19 community helpers met the stated mastery criteria, while his identification of 11 of 19 community helpers fell below the target level. In general, RV had demonstrated a familiarity with community helpers whom he was most likely to come into direct contact with or to see regularly in his natural environment (e.g., police officers, firemen, doctor, mail carrier, librarian, teacher, school bus driver). It was also suspected that his skill acquisition was enhanced by the degree to which a specific community

**Table 27.4 Operational Definitions**

Community-Based Skill	Operational Definition
Community Helpers/Locations	Defined as any occurrence in which RV completes multi-step directions associated with functional community-based tasks using receptive, expressive, and written response formats (with fading prompts). Examples include: Identifying and/or discriminating basic community helpers by matching, sorting, and labeling; discriminating functions of community helpers and locations by matching, sorting, and labeling.
Purchasing/Ordering	Defined as any occurrence in which RV completes multi-step directions associated with functional community-based using both receptive and expressive response formats (with fading prompts). Examples include: Ordering goods/services, using setting-specific media to obtain information (e.g., ads, menus, coupons, catalogs, labels, and packages), and exchanging money in order to purchase and acquire products/services.

**Figure 27.3** Intervention Probe Data Collected At Home (Community Helpers)

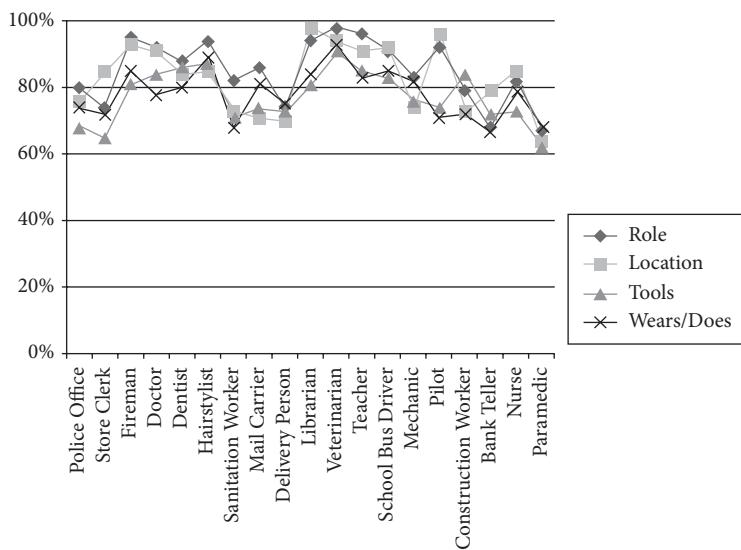

provider was associated with uniforms or any other visually identifiable characteristics that were easier for the child to identify (e.g., a police officer's uniform/badge/police car, a fireman's uniform/hat/fire engine, a mail carrier's uniform/mail truck, a doctor's white coat/stethoscope). If these types of concrete stimuli were not present, RV was less successful discriminating the type of community helper (e.g., bank teller, store clerk, delivery person).

In conjunction with the administration of intervention probes assessing mastery of community helpers, instruction was provided using written materials generated for the purpose of teaching RV to compare differences between community helpers relative to their role, location, tools associated with their role, and other relevant features (e.g., clothing, specific tasks). The clinician administered each of these probes, obtaining data are reported below in Figure 27.4.

Using these stimuli, probe data indicated that RV continued the same general trend as observed with community helper discrimination training, and appeared to have a better understanding of the general role/function that a specific community helper serves rather than the specific locations where they worked, the tools that they used, the uniforms/professional dress that they wore, or the more specific activities in which they are engaged.

Building on these results, intervention probes were custom-developed for RV for use within his natural environment. Probes consisted of multiple choice and open-ended questions that addressed a specific location (e.g., doctor's office; see Appendix of this chapter). In addition, specific activities were embedded within the probes so as to require RV to interact with and become more familiar with the setting itself. Data obtained through these individual probes are reported below in Figure 27.5.

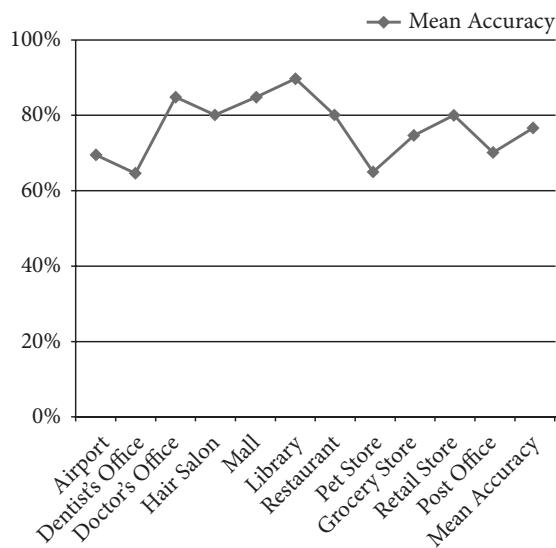

Data obtained from these probes indicated that RV was most successful at the retail store, a library, at a restaurant, at the mall, at a hair salon, and at the doctor's office. While these probe data are limited

**Figure 27.4** Intervention Probe Data Collected At Home (Community Locations/Community Helpers)

in that they represent performance during a single visit to each location, they provide an initial estimate of RV's familiarity and comfort with a specific community location, as well as the child's ability to navigate complex community environments in the presence of structured routines/activities (i.e., activities specified on the intervention probes).

Overall, data obtained through intervention probes administered in home and community environments indicated that RV was generally more proficient identifying or discriminating community helpers than he was at comparing community helpers, or engaging specific community helpers within complex community environments. These data also identified specific skill gaps; namely, mastery of the specific locations where a community helper works, the tools that are used, the uniforms/professional dress that are worn, or the more specific activities associated with their role. As a result of these

**Figure 27.5** Accuracy of Intervention Probe Data Collected In Community (Community Locations/Community Helpers)

data, the clinician was able to recommend both additional activities and continued opportunities for practice with the aforementioned stimuli in order to sufficiently train RV to acquire a greater understanding of each skill gap. It is equally important to note that the clinician was able to transfer training to RV's parents, since they were present for each intervention session and became familiar with the clinician's instructional methods. Most importantly, RV's parents were confident that they could replicate the instruction alone with their son, since they were coached by the clinician and were encouraged to participate in treatment sessions.

## Conclusion

In response to changes in social, legal, and educational conditions over the past 50 years, the significance of the assessment of adaptive behavior has intensified. No longer is adaptive behavior assessment limited to diagnosis and program eligibility, but it is increasingly recognized as critical to understanding development and needs of the individual. Furthermore, adaptive behavior assessment has gained notice outside the world of IDD, and is now recognized for its key role in identifying strengths and needs of all persons, with or without disabilities. As a result of this attention, adaptive behavior assessment approaches have become more sophisticated, comprehensive, and useful, and they may combine standardized and alternative assessment approaches. Whereas, in the past, psychometric concerns relative to the instruments were of primary concern for researchers, current and future interests are likely to focus on the utility of using adaptive behavior assessment information in understanding the needs of the individual, and in planning, monitoring, and evaluating interventions.

A central purpose of this chapter was to describe models and methods for assessing adaptive behavior. As compared to other domains of assessment, such as cognitive or personality, adaptive behavior assessments offer a natural link to intervention by targeting skills that are underdeveloped, and preventing further problems by addressing those needs within intervention plans. The links between assessment, intervention, and supports should be addressed within an ongoing, problem-solving process that improves outcomes.

Traditionally, clinicians have relied on information gathered from traditional, norm-referenced methods for diagnostic, intervention planning, and progress monitoring purposes. A second purpose of this chapter was to describe and illustrate nontraditional methods and tools that can also be used to pinpoint specific

skills or skill deficits within the context of naturally occurring routines and environments. Both traditional and nontraditional techniques have their tradeoffs as well; namely, limitations due to restrictions in scope of practice (traditional), and both available time and resources (nontraditional). However, a third option may be most efficacious—using a combination of both approaches. Using a combined approach enhances the traditional method's scope of assessment and access to feedback from multiple respondents, while also incorporating essential nontraditional elements that allow one to directly assess skills within the child's natural environment and facilitate generalization/transfer of training. Armed with these tools and techniques, clinicians will be able to customize assessment methods in order to obtain a more comprehensive understanding of the individual's strengths and needs, and ensure that interventions that are being provided are effective at improving outcomes.

# Chapter 27: Appendix

Name: \_\_\_\_\_

## Community Helpers Worksheet

**Location: Doctor's Office**

Which community helper works at this location?

- A. Dentists
- B. Postal Workers
- C. Veterinarians
- D. Doctors
- E. Librarians

Which other type of community helper works at this location?

- A. Dental Hygienists
- B. Postal Workers
- C. Veterinarians
- D. Construction workers
- E. Nurses

What are the Doctor Office's hours Monday through Friday?

---

What are the Doctor Office's hours Saturday and Sunday?

---

What is the first thing you should do when you walk into the office?

- a. Watch TV
- b. Sign in at the counter and tell the receptionist your name
- c. Read a book
- d. Sit down quietly

Look around the waiting room, what can you do while you are waiting for your turn to see the doctor? \_\_\_\_\_

---

Does this doctor's office accept insurance? \_\_\_\_\_ If so, what kinds of insurance do they take?

---

Look at your insurance card. Do they accept your insurance? \_\_\_\_\_

---

Give your insurance card to the receptionist.

How do you know when it's your turn to see the doctor?

- a. You wait for your mom to tell you it's your turn.
- b. Someone comes on the TV and tells you it's your turn.
- c. The nurse comes out to the waiting room and tells you it's your turn.
- d. You just walk back whenever you feel like it.

What is your doctor's name? \_\_\_\_\_

---

Are there other doctors who work in this office? \_\_\_\_\_

If so, what are their names?  
\_\_\_\_\_  
\_\_\_\_\_

What is your nurse's name? \_\_\_\_\_

What can you do if you need to take a break during your visit?  
\_\_\_\_\_

If you are not sick and are at the doctor's office for a simple check-up, which of the following can you expect the doctor to do? (HINT: There can be more than one correct answer)

- a. Check your weight
- b. Check your blood pressure
- c. Give you medicine
- d. Clean your teeth

Are you able to get your teeth cleaned at the Doctor's Office?

- a. Yes
- b. No

Are you able to get vaccines at the Doctor's Office?

- a. Yes
- b. No

Are you able to get X-rays at the Doctor's Office?

- a. Yes
- b. No

If you feel sick and have a fever but you do not have another doctor's appointment for 2 months, what should you do?

- a. Hope it gets better on its own.
- b. Call your dentist and schedule an appointment.
- c. Call your pediatrician (doctor) and schedule an appointment.
- d. Don't do anything.

How often should you go to the doctor's office for a check-up?

- a. Every 6 months
- b. Once a year
- c. Only when you need vaccinations
- d. I don't need to go to the doctor's office

Great work! You are all done!

## Special and Emergent Topics in Child and Adolescent Assessment

*This page intentionally left blank*

# The Authentic Alternative for Assessment in Early Childhood Intervention

Marisa Macy and Stephen J. Bagnato

## Abstract

Conventional tests and testing practices are at odds with professional “best practice” standards in early childhood intervention. Moreover, conventional tests have been neither developed for nor field-validated on young children with disabilities for early intervention purposes.

Dramatic changes are emerging in the assessment of young children, particularly those with developmental delays/disabilities. Interdisciplinary professionals must know and adhere to the professional practice standards for assessment in early childhood intervention. The National Association for the Education of Young Children (NAEYC) and the Division for Early Childhood (DEC) standards promote *authentic assessment* as the evidence-based alternative for young children to prevent the misrepresentation of young children with disabilities—the mismeasure of young children (Bagnato, Neisworth & Pretti-Frontczak, 2010).

**Key Words:** authentic assessment, alternative assessment, early childhood intervention, curriculum-based assessment

## Conventional Tests and Testing

Aziano, a 36-month-old boy born with cerebral palsy, was enrolled in his neighborhood early childhood program. His parents soon realized his special needs were not being adequately addressed. Staff recommended that he be referred to the lead agency for testing to determine his eligibility for special IDEA services. Soon Aziano was tested by professionals unfamiliar to him. A standardized, norm-referenced test was used. Aziano struggled to respond to the prompts, but his communicative attempts could not be interpreted by the assessors. He cried when asked to perform specific tasks from the test. The tabletop testing format restricted his movements, and the assessor eliminated items he could not perform. Since so few items were appropriate for Aziano, the psychologist prorated the test, and Aziano’s functioning was determined to be at about 11 months in most areas. His parents felt the test failed to reflect all of their son’s capabilities they had seen at home, school, and in community settings. Aziano and his parents were frustrated by the testing experience. Eventually, he was deemed eligible for services, and results from the conventional test were used by his teachers and related specialists to design an individualized education plan (IEP). When his team implemented interventions to address IEP goals and objectives, they discovered he had already mastered many of the skills. It was also discovered that there were other areas of learning and development that were not addressed in Aziano’s

IEP. The teachers and service delivery providers used some curriculum-based assessments, conducted another IEP meeting with Aziano's team, rewrote goals and objectives, and refocused their intervention efforts to address Aziano's "actual" capabilities and needs. The IEP team was mystified by results from the test, and disappointed that the test had failed to provide the information needed to develop program goals and inform intervention.

The scenario above illustrates a common practice wherein young children are assessed using rigid testing procedures and measures. Aziano was found eligible for services; however, the information collected during the eligibility assessment was not the functional information needed to develop a quality program for him and his family. Perhaps more important, the conventional test *misrepresented* Aziano's actual strong hidden capabilities, so that the teachers were expecting a child with severe disabilities. He was subsequently tested to determine: (a) specific supports needed in his inclusive classroom, (b) educational and developmental goals, (c) services for him and his family, and (d) where to enter the curriculum being used in his early childhood program.

Eligibility assessments should be linked to programmatic content in order to optimally serve children and their families. Early childhood is a unique and critical period when assessment efforts have the potential to make a positive difference for a child. We propose an alternative to the eligibility assessment process experienced by Aziano and his parents. In this chapter, we will describe salient features of early childhood assessment, research on conventional and authentic assessments, and conclude with recommendations for designing meaningful and authentic assessment practices.

## Early Childhood Assessment Features

Young children are assessed to examine their learning and development levels. The purpose of conducting early childhood assessment may be to determine: (a) if further assessment is warranted—*developmental screening*, (b) if a child is eligible for special services—*eligibility assessment*, and (c) program goals, intervention/treatment content, and evaluation of program performance—*programmatic assessment*. Although there are some points of similarity between assessment practices used for school-age students and young children, there are at least two salient features of early childhood assessment practices that are non-diagnostic and non-categorical approaches.

### ***Non-Diagnostic Feature***

A distinguishing feature of assessing infants, toddlers, and preschooler is the non-diagnostic approach used to determine a child's eligibility for services. The Individuals with Disabilities Education Improvement Act (IDEA) first introduced infants and toddlers in the 1986 amendment (P.L. 99-457), which was about ten years after the initial legislation was passed for individuals age three to 21. School-age individuals with disabilities, or at risk, are typically educated in school settings, making it easier to find eligible candidates for IDEA services, since students are educated in one location—schools. Conversely, children who are too young to attend formal school are more difficult to locate in order to serve the eligible population of IDEA candidates. Therefore, IDEA indicates that states serving children and families under Part C (early intervention; birth to age three) must implement a *child find* system. Developmental screenings are used to identify children in need of comprehensive eligibility assessment.

Finding young children who are eligible for special services is a priority for Part C and Part B, Section 619 (early childhood special education; ages 3–6) programs. Children are identified as eligible for services based on their performance on eligibility assessments. A specific diagnosis is not necessary in order for the child and family to receive early intervention. A child who meets their state criteria (e.g., 2 standard deviations below the mean in one or more developmental domains) could become eligible for IDEA special services. Early intervention is available to children who meet state criteria for identification of a disabling condition/delay, or are at risk for developing a disability (Losardo & Notari-Syverson, 2001; McLean, Wolery, & Bailey, 2004).

The three types of risk conditions are *biological*, *established*, and *environmental*. A child is at an increased likelihood for developmental delay if they have experienced problems during prenatal, perinatal, or postnatal development (e.g., prematurity, "small for gestational age" status). In contrast,

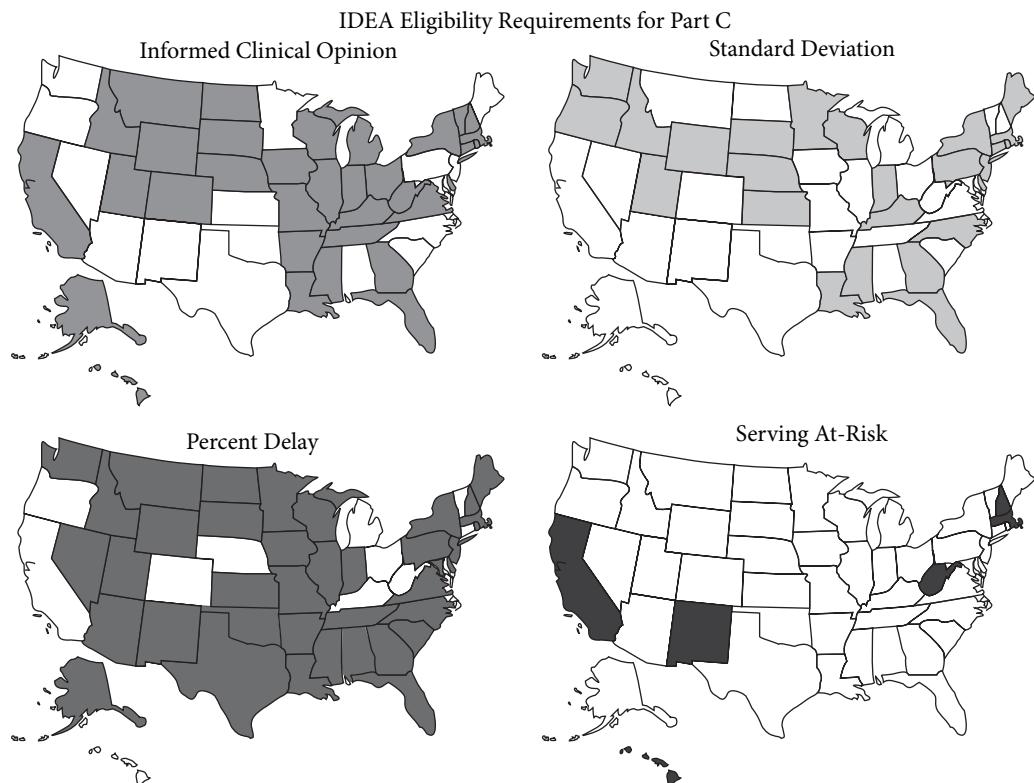

established risk is related to a known etiology with documented expectations for development. For example, a child born with Down syndrome may be at increased risk for developing atypical patterns of growth and learning. Environmental risk occurs when a healthy child has unhealthy living conditions (e.g., teratogens—radiation, pollution, illegal drug activity in household, etc.) and/or experiences (e.g., poverty). If left unaddressed, risk conditions could result in developmental delay. Part B of IDEA does not serve children with risk conditions, only those with identified disabilities. Part C of IDEA allows states to serve children at risk for developing a delay/disability. The majority of states/territories do not serve infants and toddlers with risk conditions; however, there are approximately eight that do serve children at risk, shown in Figure 28.1.

States and territories providing IDEA services have adopted guidelines and criteria for the eligible population of infants, toddlers, and preschoolers (Danaher, 2005; Danaher, Shakelford, & Harbin, 2004; Shakelford, 2006). The law allows three ways of deciding if a child qualifies for IDEA services: (1)

informed clinical opinion, (2) standard deviations, and (3) percent delay.

Informed clinical opinion involves an experienced practitioner making a judgment about a child's need for special services (Bagnato, Smith-Jones, Matesa, & McKeating-Esterle, 2006; Bagnato, McKeating-Esterle, Fevola, Bartolomasi, & Neisworth, 2008; Dunst & Hamby, 2004; Shakelford, 2002). It does not require direct testing of the child in order to render a decision. About 38 states and territories use informed clinical opinion for Part C eligibility determination process (Shakelford, 2006); and about 10 for Part B (Danaher, 2005).

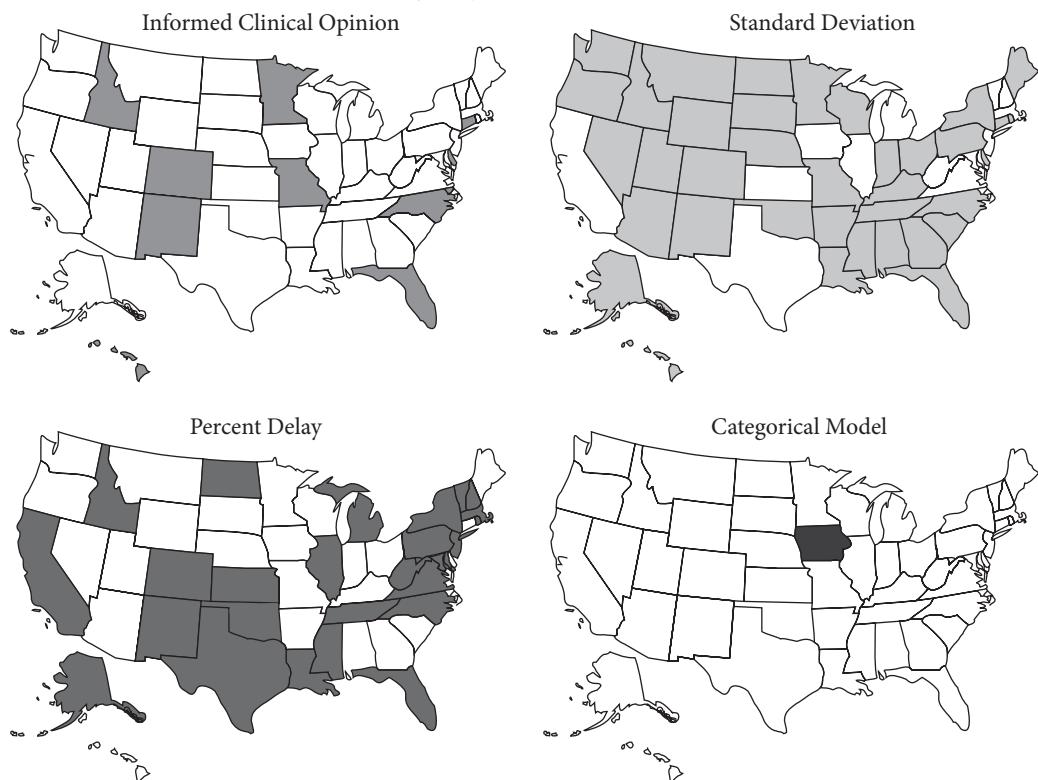

Determining standard deviation and percent delay require a process where a practitioner administers a comprehensive assessment to the child in order to gather information needed for making decisions about eligibility. States and territories commonly use percent delay for Part C (i.e.,  $n = 43$ ), and fewer use standard deviation (i.e.,  $n = 28$ ) (Danaher, 2005; Shakelford, 2006). A different trend is found with Part B, where both percent delay (i.e.,  $n = 27$ ) and standard deviation (i.e.,  $n = 38$ ) are used by

states and territories to establish the eligible population of children (Danaher, 2005; Shakelford, 2006). Some states and territories use all three options as part of their eligibility determination process. For example, Idaho uses all options for both parts of IDEA. Figures 28.1 and 28.2 show use of the three formats used for Parts C and B.

#### ***Non-Categorical Feature***

The second distinctive early childhood assessment feature is the absence of categorical labeling. Unlike the IDEA Part B requirement for school-age students to provide a disability category from a menu of 14 categories, it is unnecessary to provide a specific category of disability. States and territories have discretion in how they define the “developmental delay” (DD) category under Section 619 of Part B IDEA, and can choose to use the non-categorical option up to age nine.

There are several advantages of a non-categorical approach. First, the absence of defining a category at such a young age allows the child’s team to focus on functional aspects of development by building on the child’s strengths, rather than exerting efforts on

deficit-oriented labels that could tend to drive services. Categorical labels for defining an eligible population are potentially detrimental to young children (Haring, Lovett, Haney, Algozzine, Smith, & Clarke, 1992). Labels can create a stigma for families and have a lasting impact on a young child. It might be helpful to label hurricanes (e.g., Katrina) and earthquakes (e.g., 5.2 on the Richter scale), but not young children.

Second, early intervention programs can continue to serve children who may not meet specific categorical criteria. Therefore, children can be served earlier who would later be found eligible for special education. Children, like weather, are dynamic and constantly changing. They learn and develop at their own rate. It is important to give children time before rushing to categorize them with arbitrary social constructs that are meaningless to their overall development and learning.

Third, a non-categorical approach allows for smoother horizontal and vertical transitions. Parents who have a child in a Part C infant/toddler program

who move to another location will probably experience a seamless, non-categorical transition in service delivery. Vertical transitions from infant/toddler program to preschool, or preschool to kindergarten, or kindergarten to first grade are easier to navigate without categorical distinctions.

Finally, developmentally appropriate assessments are possible because instruments for determining some specific disability categories are limited or nonexistent for young children. The use of authentic assessment for determining eligibility for special services is preferred over using standardized, norm-referenced assessment, in part because authentic measures have an eye toward programmatic components (Bagnato et al., 2007; Neisworth & Bagnato, 2004; Macy & Hoyt-Gonzales, 2007; Pretti-Frontczak, 2002). Using standardized/norm-referenced (hereafter referred to as *conventional*) tests simply answers a yes/no question—"Is the child eligible for services?" Conventional tests do not necessarily lend themselves to creating learning or developmental goals for a young child, nor do they have accompanying curricula or interventions to facilitate learning and development. An alternative to conventional testing is authentic assessment.

### ***Authentic Assessment***

*Authentic assessment* refers to the "systematic recording of developmental observations over time about the naturally occurring behaviors of young children in daily routines by familiar and knowledgeable caregivers in the child's life" (Bagnato & Yeh-Ho, 2006, p. 16). Authentic assessment is commonly used for goal development, intervention, curriculum, and/or program evaluation (Bagnato, 2007; Grisham-Brown, Hallam, & Pretti-Frontczak, 2008). Authentic assessment links to a curriculum framework to promote positive developmental outcomes in young children (Bredekamp & Copple, 2009; DEC, 2008; Grisham-Brown, Hallam, & Brookshire, 2006; NAEYC & NASDE, 2003). Treatment validity is improved when authentic methods are used.

Authentic assessment can identify children eligible for early childhood services (Bricker, Clifford, Yovanoff, Pretti-Frontczak, Waddell, Allen, & Hoselton, 2008; Macy, Bricker, & Squires, 2005). Using authentic assessment at the time of eligibility determination obviates the need to assess the child again once s/he starts the early childhood program. This saves time, resources, and unnecessary stress on the child and family. The next section of this chapter will expand on the comparisons between conventional and authentic

assessment by presenting research related to eligibility assessment practices for young children.

### ***Research in Early Childhood Assessment: Growing Evidence for Authentic Practices***

Since the 1970s, a paradigm shift has occurred in relation to education and services for individuals with disabilities. People with disabilities did not consistently have access to appropriate and inclusive services prior to IDEA and other important legislation. Over time, special services have become more accessible. Now there is a trend toward ensuring that education and services for individuals with disabilities are of high quality. The early childhood field now has quality standards as well as accountability procedures in place (Greenwood, Walker, Hornbeck, Hebbeler, & Spiker, 2007; Harbin, Rous, & McLean, 2005; Head Start Bureau, 1992; Hebbeler, Barton, & Mallik, 2008; Meisels, 2007; National Early Childhood Accountability Task Force, 2007; Rous, Lobianco, Moffett, & Lund, 2005; Rous, McCormick, Gooden, & Townley, 2007). In addition, funding agencies, federal and state policy guidelines, and professional organizations (e.g., National Association for the Education of Young Children and Division for Early Childhood) advocate the use of research-based practices in early childhood programs.

There is a lack of research available on early childhood assessment practices used to determine if a young child is eligible for IDEA services. It has been a prevailing belief that the use of standardized, norm-referenced (hereafter referred to as *conventional*) measures is superior to other types of assessments designed to determine eligibility for services. Research does not substantiate the myth that conventional assessment has a more robust experimental base.

Bagnato and his colleagues conducted research syntheses on conventional (2007a) and authentic (2007b) assessments used to determine eligibility for IDEA early childhood services. The work was part of the Tracking, Referral, and Assessment Center for Excellence (Dunst, Trivette, & Cutspe, 2002). Research studies on conventional and authentic assessments were identified from the fields of child development, early intervention, psychology, special education, physical therapy, pediatrics, and behavioral development. A variety of widely used measures were chosen for each synthesis, displayed in Table 28.1. What follows are some highlights from both research syntheses.

**Table 28.1 Conventional and Authentic Measures**

Conventional Measures	Authentic Measures
1. Battelle Developmental Inventory (BDI) 2. Bayley Scales of Infant and Toddler Development (BSID) 3. Mullen Scales of Early Learning, AGS Edition (MSEL) 4. Stanford-Binet Intelligence Scales (SB) 5. Wechsler Preschool & Primary Scales of Intelligence (WPPSI)	1. Adaptive Behavior Assessment System (ABAS) 2. Assessment Evaluation and Programming System (AEPS) 3. Carolina Curriculum for Preschoolers with Special Needs (Carolina) 4. Child Observation Record (COR) 5. Developmental Observation Checklist System (DOCS) 6. Hawaii Early Learning Profile (HELP) 7. Pediatric Evaluation of Disability Inventory (PEDI) 8. Transdisciplinary Play-Based Assessment (TPBA) 9. Work Sampling System (WSS)/Ounce

**Research on Conventional Testing**

A total of 29 studies met search criteria for conventional assessment (Bagnato, Macy, Salaway, & Lehman, 2007a). Overall, there were 3,150 young children who participated in the conventional assessment research. Children's ages ranged from birth to 132 months. Twenty studies (69%) included children with identified disabilities or delays, and 12 studies (41%) included children at risk<sup>1</sup>. Table 28.2 shows the studies by each of the conventional tests examined in the research synthesis.

Each study reported in this synthesis examined some aspect of accuracy and/or effectiveness related to one or more of the conventional tests that were identified. Bagnato et al. (2007a) found ten studies (34.48%) that examined the *accuracy* of conventional measures; and 26 studies (89.65%) that looked at the *effectiveness* of conventional measures. The number of studies exceeds 29 because some studies examined both the accuracy and effectiveness

of conventional tests. The types of studies included five inter-item/inter-rater reliability, two test-retest reliability, two sensitivity/specificity, 14 concurrent validity, seven predictive validity, three construct and one criterion validity, and two utility studies.

**Research on Authentic Assessment**

A total of 27 studies met search criteria for authentic assessment (Bagnato, Macy, Salaway, & Lehman, 2007b; Macy & Bagnato, 2010). There were 10,272 young children who participated in the authentic assessment research. Children's ages ranged from birth to 224 months. Children were identified with various disabilities, and there were several studies that included children without disabilities and children who were at risk for developing a disability. Table 28.3 shows the studies by each of the authentic measures examined in the research synthesis.

There were 17 studies (59.26%) that examined the *accuracy* of authentic measures. Twenty

**Table 28.2 Conventional Testing Studies**

Measure	# of Studies	Publication Years	Children's Age Range (in months)	Sample Size (children)
BDI	16	1984–2000	birth to 95	1,637
BSID	11	1985–2004	2 weeks to 77	1,043
MSEL	2	1995–1999	0 to 48	237
SB	6	1992–2003	18 to 132	734
WPPSI	3	1992–2000	36 to 72	450

*Note:* BDI = Battelle Developmental Inventory; BSID = Bayley Scales of Infant Development; MSEL = Mullen Scales of Early Learning, AGS Edition; SB = Stanford-Binet–Fourth Edition; WPPSI = Wechsler Preschool and Primary Scale of Intelligence.

**Table 28.3 Authentic Assessment Studies**

Measure	# of Studies	Publication Years	Children's Age Range (in months)	Sample Size (children)
ABAS	2	2006–2007	33 to 216	151
AEPS	9	1986–2008	0 to 72	2,897
Carolina	1	2006	4.5	47
COR	3	1993–2005	48 to 68	4,902
DOCS	5	1997–2005	1 to 72	2,000+
HELP	2	1995–1996	22 to 34	29
PEDI	2	1993–1998	36 to 224	50
TPBA	4	1994–2003	6 to 46	74
WSS/Ounce	1	In progress	45 to 60	112

*Note:* ABAS = Adaptive Behavior Assessment System; AEPS = Assessment Evaluation & Programming System; Carolina Curriculum for Infants/Toddlers/Preschoolers with Special Needs; COR = Child Observation Record; DOCS = Developmental Observation Checklist System; HELP = Hawaii Early Learning Profile; PEDI = Pediatric Evaluation of Disability Inventory; TPBA = Transdisciplinary Play-Based Assessment; WSS = Work Sampling System/Ounce.

studies (74.07%) looked at the *effectiveness* of authentic measures. The number of studies exceeds 27 because some studies examined both accuracy and effectiveness. Researchers found the following types of studies: 13 inter-item/inter-rater reliability, five test-retest reliability, four sensitivity/specificity, 15 concurrent validity, three predictive validity, and six construct/criterion validity.

In general, the lack of research on assessments used for eligibility determination is troubling. More research is needed to examine the (1) extent to which assessments are used for Part B and Part C eligibility decisions; (2) ways in which

assessments are used; and (3) degree to which assessments facilitate eligibility, placement, and early programming decisions. Conventional intellectual measures are less reliable with infants and preschoolers and no more functional in providing data for interventions and progress monitoring than with older students. It is important to note there is building evidence in support of an authentic assessment approach.

### Early Childhood Authentic Assessment in Action

Evaluating a child to determine her or his eligibility using conventional testing practices presents

#### Authentic Assessment Approach

##### *Eligibility*

Aziano's familiar caregivers and professionals used an authentic assessment approach for eligibility determination. The current edition of the AEPS has cutoff scores used to decide if Aziano is eligible for IDEA services. The team selected the AEPS and used it over a two-week period to collect data across six developmental areas (i.e., adaptive, cognitive, social, social-communication, fine and gross motor). They found the authentic assessment more accurately represented Aziano's actual functioning and lead to a more useful program plan.

##### *Five-Step Programmatic Process*

Step 1—Develop IEP goals and objectives. Data obtained from the AEPS were directly used to create an IEP for Aziano to include: present levels of performance, goals, and objectives. Information from the

authentic assessment helped the team decide specific supports, modifications, accommodations, and intervention strategies to use. They also linked their state standards for learning to his IEP.

Step 2—Create an intervention plan. His team created an intervention plan that included routines during the day for intervention efforts. The AEPS curriculum was used for instruction whereby the team planned out a developmental scope and sequence based on Aziano's assessment information. Activity-based intervention strategies were identified for use across settings (e.g., school, home, community), people, materials, and events. A combination of routines and child-initiated, adult-directed, and planned activities were planned. There were also interventions planned to occur during individual, small group, and large group activities. The team discussed specific strategies and supports to address Aziano's mobility and communication needs, like physical prompts, a picture-exchange communication system, and voice-output devices. Target behaviors/skills were a priority for all members of Aziano's team, not likely to develop without intervention, addressed numerous areas, and matched his developmental level.

Step 3—Collect ongoing data. His parents and professionals decided on procedures for data collection. They identified who would be responsible for collecting data, where data collection would take place, which activities to target for data collection, how often to collect data (e.g., which days/times, daily/weekly/monthly/etc.), and methods for collecting data.

Step 4—Monitor the child's learning. The team decided to monitor Aziano's progress every three months using the AEPS. His parents also decided they would use the AEPS Family Report on the same schedule to capture his performance from their perspective and his behavior repertoire at home. The diverse and multiple data points would allow the team to see change over time.

Step 5—Make data-based decisions and recommendations. Decision rules would be considered if adequate progress did not occur within a specified timeframe. The team may make changes to the following when they review his program: (a) target goals/behaviors, (b) intervention strategies, (c) modifications/accommodations, (d) how frequently intervention opportunities occur, and (e) where intervention takes place. Table 28.4 shows a sample of how the authentic assessment approach could be used for Aziano across typical routines in his day.

the following problems not usually found with an authentic assessment approach:

- It takes the child away from meaningful learning activities and experiences,
- does not engage the child by building on their interests and motivations, and
- requires the child to attend to tasks that are adult-directed.

Authentic assessment is becoming a favored alternative to conventional testing. When authentic assessments are used, professionals can focus their efforts on program (i.e., IEP or IFSP) development and implementation without having to administer additional, unnecessary tests. Children will enter their program with relevant initial eligibility assessment information that will lead to the creation of tailored learning and developmental goals, objectives, and interventions. The scenario described at the beginning of the chapter under-represented Aziano's abilities in many areas of his learning and development. His team discovered the inaccuracies

of the conventional test based on Aziano's response to intervention. The assessment process described earlier in the chapter has been revamped to show how an authentic assessment approach can be used instead of the conventional eligibility assessment.

There are several advantages to authentic assessment. For instance, the assessment takes place during familiar activities, with familiar people and caregivers, and uses familiar materials with children. Naturalistic observations become the core method for gathering information. Monitoring the efficacy of the program should be frequent and ongoing. By using authentic assessment practices, assessment teams can gather meaningful information about children like Aziano. Here are five recommendations for creating authentic assessment practices.

### **1. Early Learning Standards**

Become familiar with federal, state, and local early learning standards for children. Knowing what expectations are for learning and development can help take eligibility assessment results and create individualized

goals for children. It is often necessary to refer to such standards when creating IEPs and IFSPs.

## **2. Become a “Programmer”**

Get to know the early childhood program. Become an expert on the program’s philosophy, mission, goals, and all things related to the organization. This will help when translating assessment results into relevant content. Some of the best assessment reports are developed by those who know the program inside-out.

## **3. Partner with Families and Team Members**

Involve parents and families in meaningful ways. Communicate with families and other professionals using common terms. Written and verbal communication related to authentic assessment should avoid the use of technical language or acronyms so that information is accessible to a wide audience. Jargon-free materials make it easier to communicate content as well as build positive relationships by facilitating clear communication.

## **4. Collaborate Effectively with Other Professionals and Team**

Interdisciplinary teams typically use curriculum-based assessments to guide the authentic assessment process (Keilty, LaRocco, & Casell, 2009). Curriculum-based instruments link assessment to programming and intervention planning. Curriculum-based assessments are also designed to gather information from various sources, including parents and teachers, and can be used for progress monitoring.

## **5. Use Sensitive and Universal Measures**

Gather information from several different situations (Bagnato & Macy, 2010). Before his team used authentic assessment, Aziano was observed only once. That event was only a snapshot of what he can do and the current skills he possessed at that point in time. Children need to be assessed across multiple events and time points to get a good understanding of what they can do and what they need to learn. It is also important to gain multiple perspectives from different people who know the child. A variety of views on the child’s development can help the team gather useful data that make sense to those using the information.

Selecting a measure is part of the authentic assessment process (Bagnato, Neisworth, & Pretti-Frontczak, 2010). When deciding on which tool to use it is important to consider six questions.

*First, does the measure include individuals with disabilities in the sample?* It is important that persons with disabilities were part of the standardization sample. Read the assessment manual to determine if young children with delays/disabilities were included in the normative group and any field-validation samples. Research indicates that it is critical that children with functional characteristics similar to those of the child being tested be included in the standardization/field-validation sample. The sample should have at least 100 people per each age interval.

*Does the measure have procedural flexibility?* Young children with special needs require flexible procedures. “Procedural flexibility” refers to the extent to which the administration procedures allow professionals to modify the method of assessment (i.e., tabletop vs. play), the stimulus attributes of items, and the response modes of the young child to accommodate their functional impairments leading to a more realistic and representative estimate of capabilities.

*Does the measure have comprehensive coverage?* The results of eligibility assessment must reflect the “whole child.” Choose an authentic assessment that contains assessment items from multiple domains of developmental functioning. Such broad coverage generates results that profile the young child’s capabilities across multiple and interrelated functional competencies (i.e., cognitive, motor, adaptive, communication, self-regulatory).

*Does the measure have functional content?* One way to find out if the content is functional is to try to write IEP and IFSP goals and objectives. Functional content from the measure allows meaningful goal development that can be incorporated into a child’s daily routines and family life. Avoid measures that focus on discrete and isolated tasks, like placing a peg in a pegboard. This is not a behavior that the intervention team would spend a lot of time teaching a child, since it does not help the child increase his/her independence. Rather, functional content might examine the child’s use of pincer grasp, which could be observed during snack time when raisins are presented on the high-chair tray and the child picks up to eat. The measurement item is functional and could be turned into a goal, as well as intervention/curricular content.

*Does the measure have item density?* It is necessary that assessments have enough items of varying complexity in each developmental domain. A dense bank of items allows even low functional levels to be profiled. The lowest range of standard scores can be obtained when a child does not pass

**Table 28.4 Authentic Assessment Approach During Selected Routine Activities for Aziano**

Typical Routines	Developmental Domain(s)	Early Learning Foundations	Goals & Objectives	Intervention Plan	Progress Monitoring
Indoor play	Social Communication	Initiate communicative exchange with peers	IEP	Daily	AEPS
Bathing	Cognitive	Anticipate familiar routines	IEP	Daily	AEPS Family Report
Mealtimes	Motor	Begin to feed finger foods to self	IEP	3x daily	AEPS
Nap	Social Emotional/ Attachment	Learn to comfort self	IEP	1x daily	AEPS & AEPS Family Report

assessment items, or only a few items were scored correctly on a measure or sub-domains. The assessment items should be low enough to discriminate age (i.e., very young children) and level of functioning. There should also be a comprehensive set of items in each age interval to describe a child's performance.

*Does the measure have a graduated scoring system?* A graduated scoring system provides more information about the child's skills. For example, a three-point scoring rubric (e.g., yes, emerging, and not yet) provides more information about a child's development when compared to a simple two-point scale (e.g., yes/no). It may also indicate

the conditions under which a young child can or cannot perform (i.e., with physical prompts, with verbal prompts, with general assistance, independently). These six practice characteristics are necessary to ensure accurate identification of eligible children. Table 28.5 shows these characteristics mapped onto various authentic early childhood measures.

Early childhood eligibility assessment is an essential component to creating quality programs for young children and their families. Non-diagnostic and non-categorical factors make assessment in early childhood distinctive from a school-age context. The use of an authentic approach to eligibility

**Table 28.5 Practice Characteristics of Authentic Measures**

and programmatic assessments is supported in the research literature. Practice characteristics are useful to practitioners who are implementing authentic assessment. Young children and families will have a better eligibility assessment experience given the authentic assessment framework.

## Note

1. Some studies included both children with *disabilities* and those *at risk* for developing a disability due to medical (e.g., low birthweight) or environmental (e.g., exposure to illegal drug use, teen parent) conditions. Therefore, the overall percentage of children included in sample exceeds 100%.

# Assessing Mild Intellectual Disability: Issues and Best Practices

Daniel J. Reschly

## Abstract

Broad consensus exists today regarding the conceptual definition of the diagnostic construct of intellectual disability (ID) as a disability with three prongs: intellectual functioning, adaptive behavior, and developmental origin (Luckasson et al., 2002; Reschly, Myers, & Hartel, 2002; Schalock et al., 2010). Less consensus and frequent controversy exist over the classification criteria used to operationalize the three prongs and how the prongs should be assessed in different contexts (education, law, social services). This chapter focuses on the ID diagnostic construct and classification criteria, with primary emphasis on the mild level of ID where the most controversy exists regarding classification criteria and assessment. Different approaches to the definition and assessment of the classification criteria are discussed, along with an evaluation of the implications of different options. Finally, persistent issues in ID are discussed as contributors to the decline in the identification of mild ID over the last 40 years.

**Key Words:** intellectual disability, mental retardation, death penalty, intellectual functioning, adaptive behavior

## Intellectual Disability Diagnostic Construct: Conceptual Definition

Kanner's (1964) history of the treatment of the mentally retarded describes the occasional reference to persons with significant mental disabilities prior to the eighteenth century, but few or no systematic attempts were made to understand the nature and characteristics of persons now understood as ID, and even less effort to treat the symptoms. The late eighteenth and most of the nineteenth century were marked by initial efforts at description and treatment, but these efforts were isolated events with little or no actual impact on most persons with ID. In the latter part of the nineteenth century in the United States and Europe, some persons with ID were put in institutions that were designed to provide protective care and humane living conditions, but the majority lived with their families in communities without formal recognition of ID, often

as subjects of derision, fear, and condemnation. Prior to the early twentieth century, nearly all of the concern was with what would later be described as more severe levels of ID.

The conceptual definition of a diagnostic construct specifies what it is, its key dimensions, and its boundaries. For example, the modern conceptions of ID specify that it must have a developmental origin, thereby excluding persons who function as ID due to, for example, a brain injury during the adult years. Moreover, a proper diagnosis of ID involves deficits in *both* intellectual functioning and adaptive behavior, not either one or the other. The modern ID conceptual definition was reasonably well established as early as the 1940s in Doll's (1941) famous six criteria for mental deficiency: (1) social incompetence due to (2) mental subnormality that is (3) developmentally arrested, (4) obtains at maturity, is of (5) constitutional origin,

and is (6) essentially incurable. Two of Doll's criteria were eliminated in subsequent formulations of ID; that is, constitutional origin and permanence were dropped beginning in the early 1960s (Heber, 1959, 1961). Both were inconsistent with the expanding literature that some persons with mild ID, properly diagnosed at one point in life (usually childhood), performed within broadly defined "normal" limits as adults. For some time in the 1940s and 1950s, these persons were designated as *pseudo-feebleminded*, a concept that was thoroughly discredited by Benton (1956). Since the 1959–1961 definitions of ID, all subsequent revisions have recognized that ID has diverse etiologies, refers to the current behavior of the individual, and is not necessarily permanent.

### ***American Association on Intellectual and Developmental Disabilities (AAIDD) Classification Manuals***

The primary organization in the United States that formulates the ID conceptual definition and classification criteria is the <sup>1</sup>American Association on Intellectual and Developmental Disabilities (AAIDD). The latest version is the eleventh edition of the classification manual (Schalock et al., 2010). The AAIDD classification manuals influence the Diagnostic and Statistical Manual of Mental Disorders (DSM; American Psychiatric Association [APA], 2000). Changes in the DSM ID criteria always follow rather than lead the AAIDD classification manual. For example, the current DSM mental retardation formulation is nearly identical to that in the Luckasson et al. (1992) classification manual, and it is expected that the DSM V, (anticipated publication in 2013) will closely reflect the eleventh edition of the AAIDD. Other formulations of ID criteria also are markedly influenced by the AAIDD, including state legal definitions (Duvall & Morris, 2006), Social Security disability criteria (Reschly et al., 2002), and education (Denning, Chamberlain, & Polloway, 2000).

### **THREE DIMENSIONS**

The current conceptual definition of ID reflects the influences of the earlier definition by Doll (1941) in its emphasis on social competence (adaptive behavior), intellectual functioning, and developmental origin. Significant limitations in both intellectual functioning and adaptive behavior are required and both appear to receive equal weight. "Intellectual disability is characterized by significant limitations both in intellectual functioning and in

adaptive behavior as expressed in conceptual, social, and practical adaptive skills. This disability originates before age 18" (Schalock et al., 2010, p. 3).

### **QUALIFICATIONS ON THE DEFINITION**

Although the definition appears to be straightforward, further significant qualifications appeared in Schalock et al. (2010) regarding the conceptual definition. At p. 1, these qualifications are stated (paraphrased here). First, contextual influences from the community, peers, and culture are to be considered. Second, assessment of the intellectual and adaptive behavior prongs must consider cultural and linguistic diversity as well as communication, sensory, motor, and behavioral factors. Third, it is recognized that significant limitations can appear with strengths. Fourth, the purpose of describing limitations is to develop a profile of needed supports; and fifth, provision of needed supports generally improves the functioning of persons with ID.

### **CURRENT BEHAVIOR**

The diagnosis of ID since the 1959–1961 formulation (Heber, 1959, 1961) and continuing today (Schalock et al., 2010) clearly refers to *current* behavior. The AAIDD clearly acknowledges that a person may be validly classified ID at one point and not at another across the life span. This provision overcomes the concern with the *pseudo-feebleminded* that puzzled the field in the 1940–1960 era.

### **LEVELS OF ID**

Levels are based on the degree of need for supports to attain improved functioning and to achieve mastery of the daily activities of living to as normal a degree as possible. Levels of ID have been part of research and practice in this area since the late nineteenth and early twentieth century when the levels of *idiot*, *imbecile*, and *moron* (from most to least severe) were used (Kanner, 1964). Later levels were defined by the degree of deviation from normal using intellectual functioning standard deviation criteria (Grossman, 1973, 1983; Heber, 1959, 1961). Since 1992, levels of ID are described by degrees of needed support (Luckasson et al., 1992, 2002; Schalock et al., 2010). The similarity in levels specified by intellectual functioning deviations and needed levels of support is unmistakable (see Table 29.1). The mild level with a traditional IQ range of about 55 to 70 (+/-5) is analogous to the intermittent level of needed supports, and so on.

**Table 29.1 Comparison of Pre- and Post-1992 AAIDD Levels of ID**

Pre-1992 AAIDD Levels	Description: Levels of Intellectual Functioning	Post-1992 AAIDD Levels	Description: Levels of Support
Mild	IQ of approximately 55 to 70–75	Intermittent	Episodic, short-term
Moderate	IQ of approximately 40–54	Limited	Consistent over time; daily
Severe	IQ approximately 25–39	Extensive	Consistent, daily, most social roles
Profound	IQ approximately <25	Pervasive	Intense, consistent, daily, all social roles

### MILD VS. MORE SEVERE ID

The current and 1992 and 2002 AAIDD classification manuals (Schalock et al., 2010) imply that all ID is on a continuum, differing only in degree. In fact the mild level of ID is significantly different from the more severe levels in more than quantity—qualitatively as well. From the lay perspective, the adjective “mild” is misleading, perhaps suggesting an insignificant degree of impairment. In fact, persons with mild ID have substantial and chronic problems with everyday coping due to limited thinking, conceptual understanding, and poor literacy skills, leading to adaptive behavior deficiencies. Most important, mild ID limits the person’s ability to reason abstractly and make sound judgments about everyday activities and responsibilities and, thereby, limits their capacity to consider the likely consequences of their behaviors and increases the vulnerability of the person to exploitation by others (Greenspan, 2006).

In addition, individuals with mild ID often have developed a keen ability to mask their significant limitations, making the proper recognition and diagnosis all the more challenging. The masking phenomenon is well known in the research on mild ID and was described extensively in a monograph by Robert Edgerton, “The Cloak of Competence: Stigma in the Lives of the Mentally Retarded” (Edgerton, 1967, 1993). Persons with mild ID and their parents typically would prefer a diagnosis of some other mental disorder, such as emotional disturbance, autism, or physical disability (Reschly et al., 2002).

Mild ID is different from *normal development* in the level and quality of intellectual functioning and adaptive behavior performance. Persons with significant limitations in intellectual functioning have a significantly reduced capacity to learn,

recall, and reason (Campione, Brown, & Ferrara, 1982; Campione, Brown, Ferrara, & Bryant, 1985; Reschly, 1987). Such persons are particularly limited in applying abstract reasoning (e.g., moral or ethical principles) to practical situations and in spontaneously recalling thinking strategies to solve problems. These fundamental intellectual deficits affect everyday activities and responsibilities. Other learning deficits reported frequently with persons with low intellectual ability include difficulty in applying basic learning to new situations, and chronic, severe limitations in literacy skills.

Mild ID is different from *severe levels of ID* both qualitatively and quantitatively. Severe levels of ID are more easily identified and, hence, more familiar to the general public. Persons with more severe levels of ID nearly always show:

- (a) Significant physical stigmata (i.e., their appearance usually shows anomalies associated with ID),
- (b) Identifiable underlying biological disorders that can be said to “cause” the ID,
- (c) Comprehensive deficits in all adaptive behavior domains, including very basic self-help skills,
- (d) Early identification, usually by age two, nearly always by health care professionals, and
- (e) Need for permanent, daily guidance and protection.

In contrast to the characteristics of persons at severe levels of ID, persons with mild ID typically:

- (a) Do not show physical stigmata (they look normal) and cannot be identified as likely cases of ID from physical appearance,
- (b) Do not have identifiable biological disorders that can be regarded as “causes” of the ID,

- (c) Often have areas of strength as well as weaknesses in adaptive behaviors; e.g., adequate self-care (grooming, eating, toileting),
- (d) Significant deficits in more complex reasoning and judgment that interfere significantly with personal independence and social responsibility,
- (e) Typically are identified by school psychologists (if at all) after age five, following entrance to public school, through referrals by teachers due to poor academic and social performance in the classroom,
- (f) Often are misplaced in school programs for specific learning disability (SLD) and receive the “SLD” diagnosis, and

(g) Typically need short-term, usually *intermittent*, guidance and protection in the community in order to avoid exploitation and to cope adequately. The person(s) providing this guidance were identified as “benefactors” in the literature over the last 50 years (Baller, Charles, & Miller, 1967; Charles, 1953; Edgerton 1967, 1984; Edgerton, Ballinger, & Herr, 1984; Koegel & Edgerton, 1984).

Diagnosis of ID at the severe levels is rarely difficult. Significant limitations that reflect functioning in adaptive behavior and intelligence of that severity typically are recognizable by lay persons and readily diagnosed by medical personnel when these children are preschool age. In contrast, diagnosis of mild ID is much more challenging, for the reasons that will be discussed shortly.

Mild ID was first formally recognized in the early 1900s and soon thereafter added to the classification scheme that existed at that time (Kanner, 1964; Reschly, 1992). Mild ID was controversial then and is now, particularly the presumed etiology and recommended diagnoses and treatments. During the first 80 years of the twentieth century, mild ID, or as it was known previously, mild or educable mental retardation, was the most prominent reason for the identification of disabilities in educational settings, leading to placement of most of these children in special education. This pattern began to change dramatically in the last 30 years, such that mild ID is identified in school today far less often. The evolution of the mild ID construct and the controversies associated with it are relevant to the large decline in educational settings and to contemporary assessment practices that will be discussed later.

## Assessment and Conceptual Criteria

Significant issues exist in the classification criteria and assessment of each of the three prongs of the

conceptual definition of ID. Issues with each and recommended best practices are discussed in the next section.

## Intellectual Functioning Assessment and Criteria

The current AAIDD classification manual requires a significant limitation in intellectual functioning to meet the intelligence prong of ID. Significant limitation is described as, “an IQ score that is approximately two standard deviations below the mean, considering the standard error of measurement for the specific instruments used and the instruments’ strengths and limitations” (Schalock et al., 2010, p. 27). This criterion is further described as not specifying a hard, immutable cutoff point for ID, but rather as an *approximate* score that needs to be considered in light of the inherent error in psychological tests and interpreted in relation to other factors such as cultural background, social environment, and overall health. The current classification manual further describes 10 factors that must be considered in interpreting IQ test results: measurement error, test fairness, the Flynn effect, comparability of scores from different tests, practice effect, extreme scores, determining a cutoff score, evaluating the role of tests in the diagnosis, assessor credentials, and test selection. Thorough discussion of all 10 challenges is beyond the scope of this chapter, but several of the most important are analyzed below.

### INTELLECTUAL CUTOFF SCORE

Clearly, there is considerable controversy around the interpretation of the  $-2$  SD criterion and the cutoff score. AAIDD unequivocally endorses clinical interpretation of the intellectual performance, not automatic application of a precise cutoff score. The question remains, how much flexibility should exist around the score of  $-2$  SD, or with modern tests, IQ = 70? The current DSM-IV-TR (APA, 2000) suggests a score of approximately 70 to 75, implying that scores above 75 should not be the basis for an ID diagnosis.

Consideration of context further complicates the problem. Precise, rigid cutoff scores are established in some contexts, including the educational criteria in some states for special-education eligibility under ID (Denning et al., 2000) and legal specifications of ID for the consideration of death penalty appeals (Duvall & Morris, 2006). These rigid specifications can lead to what most would consider as irrational decisions, such as determining one person as

ID-eligible with an IQ of 69 and another person ineligible with a score of 71. Virtually no psychologist would argue that the two-point IQ difference is meaningful in any practical sense, yet this trivial difference can have large consequences, even life or death in capital crime appeals.

Psychologists must explain the nature of ID to interested parties and decision makers, noting that human intellectual performance exists on a broad continuum with fine gradations in performance from very low to very high. Moreover, choosing any precise point on this continuum to define a disability or giftedness is arbitrary, meaning that large distinctions are being made at the margins of the cutoff score that have little meaning in terms of human performance.

Closely related to issues with the cutoff score is the interpretation of the results of different scales on the same test. For example, most modern tests are organized around two broad factors of intelligence: *crystallized* and *fluid general ability*, although the names given on specific tests may differ. The recent revisions of the Wechsler Scales use the names Perceptual Reasoning Index and Verbal Comprehension Index for what are essentially fluid and crystallized general abilities (Wechsler, 2003, 2008). First, scales in addition to crystallized and fluid are provided on several recent tests, typically Processing Speed/Accuracy and Working Memory. Both are important, but the processing speed measure on the Wechsler scales has a lower loading than the other scales with general intellectual ability. The AAIDD classification manual stresses reliance on a general factor of ability rather than more specific abilities like processing speed (Schalock et al., 2010, p 34). One option on the Wechsler adult scale is to use the General Ability Index, which is a composite of the Verbal and Perceptual Reasoning Scales. Procedures and norms for deriving this score appear in the *WAIS Technical and Interpretative Manual* (Wechsler, 2008).

Now consider this dilemma. What should be done regarding ID identification for a 35-year-old with, for example, a Verbal Reasoning Index of 61, the Perceptual Reasoning Index of 92, and a composite or General Ability Index of 76? Can the Verbal Reasoning scale be used to determine ID, or do the higher scores on Perceptual Reasoning and the composite score rule out ID? The answer depends on the examiner's clinical judgment and the context. In some contexts, the pattern of performance would not justify an ID diagnosis; while in others, especially those that allow scale scores from

broad-band measures of intellectual functioning, the person might be diagnosed legitimately as ID. There is no easy answer to this dilemma other than to emphasize using informed judgment involving the consideration of the consequences of different decisions and the context of the decision.

The National Research Council report *Mental Retardation: Determining Social Security Benefits* (Reschly et al., 2002) suggested a set of guidelines for making decisions when differing scores on broad ability scales from the same test were obtained. These guidelines may provide some useful information for psychologists making an ID diagnostic decision.

- *Composite score is 70 or below:* If the composite or total test score meets this criterion, then the individual has met the intellectual eligibility component of ID.

- *Composite score is between 71 and 75:* If the composite score is suspected to be an invalid indicator of the person's intellectual disability and falls in the range of 71–75, a part score of 70 or below can be used to satisfy the intellectual eligibility component.

- *Composite score is 76 or above:* No individual can be eligible on the intellectual criterion if the composite score is 76 or above, regardless of part scores.

- The committee recommends continuation of the presumptive eligibility for persons with IQs below 60.

## IMPLICATIONS OF VARYING CUTOFF SCORES

The recommended AAIDD classification manual cutoff scores for ID have varied significantly over the last 50 years. The most liberal cutoff was set as only one standard deviation below the mean ( $IQ \leq 85$ ) in the 1959–1961 classification manual (Heber 1959, 1961). This cutoff markedly influenced ID criteria in schools (Patrick & Reschly, 1982) and was the subject of much criticism in the courts (Diana, 1970; Guadalupe, 1972; Larry P., 1972, 1979) and by researchers (e. g., Mercer, 1973) as being too inclusive and stigmatizing excessive numbers of persons. In the 1973 and 1983 AAIDD classification manuals, the more traditional  $-2SD$  criterion was reestablished, with relatively little discussion of using flexibility and clinical judgment in applying that criterion (Grossman, 1973, 1983). In more recent versions, the intellectual criterion has been stated as *approximately  $-2$  SDs*, with discussion of flexibility and clinical judgment. The differences between an IQ cutoff score of 70, 75, 80,

**Table 29.2 Proportions of Population Eligible for ID at Different IQ Cutoff Scores**

Cutoff Score	Percent at or Below:
< 60	0.38% (38 per 10,000)
≤ 60	0.47%
60–69	1.90%
< 70	2.28%
≤ 70	2.68%
< 75	4.75%
≤ 75	5.48%

or 85 may seem trivial until the implications are specified. In Table 29.2, the proportions of persons eligible on the intellectual prong of the ID diagnostic construct at and below different cutoff scores are given. Surprising to most is the fact that a five-point change in the cutoff score doubles the number of persons potentially eligible on the intellectual prong of ID. The actual prevalence, of course, has always been far below the theoretical prevalence based on the IQ score distribution (Larson et al., 2001).

#### FLYNN EFFECT

The Flynn Effect was named after the New Zealand social scientist who described the phenomenon of norms for intellectual functioning tests' becoming less stringent over time at the rate of approximately 0.3 points per year (Flynn, 1984, 1985, 1987, 1999, 2009a, 2009b). Although most psychologists through their clinical experience knew that new norms for a test typically yielded lower scores for individual clients, no one prior to Flynn established systematically the breadth and historical persistence of this effect as well as its impact on decisions about ID eligibility.

It must be noted that the Flynn Effect is a group phenomenon, much like regression to the mean, which may or may not apply to a specific score for an individual. The Flynn Effect can be understood from two perspectives: the inflation of the mean score over time or the likely impact on individual scores. For example, the most widely used adult test, the Wechsler Adult Intelligence Test (WAIS) third and fourth editions were published in 1991 and 2008, respectively (Wechsler, 1991, 2008). The norms for the third edition (1991) were actually established in 1989. When the WAIS (1991) was administered to a client in 2007, the norms were

then 18 years old, and the population mean in 2007 on the test with norms from 1989 was not 100, but rather 105.4 ( $0.3 \times 18 \text{ years} = 5.4$ ). The point in the distribution that was  $-2$  standard deviations (SD) was no longer 70, but had changed to 75.4. The likely impact on an individual score can also be estimated by taking the original score, e. g., IQ = 74, subtracting 5.4 points for the Flynn Effect, yielding a score of 68.6.

The Flynn Effect can have dramatic effects on the interpretation of individual scores in contexts with serious consequences for using a rigid cutoff score.<sup>2</sup> In the Virginia death penalty appeal of Kevin Green, the court heard competing arguments about whether Mr. Green met the criterion for ID during the developmental period. Although ample evidence existed of significant adaptive behavior limitations during the developmental period—e. g., he was 14 years old in the fourth grade where a teacher described him as fitting in well socially with children four to five years younger than he—there was a dispute over the interpretation of a Wechsler Intelligence Scale for Children—Revised IQ score of 71. The prosecution argued that the score of 71 did not meet the Virginia death penalty appeal statutory definition of  $\text{IQ} \leq 70$ . Undisputed facts were that Mr. Green obtained an IQ of 71 in 1991 on the WISC-R, which was normed in 1972 (Wechsler, 1974). A sharp dispute ensued over whether the Flynn Effect should be considered in interpreting the score from a test whose norms were 19 years out of date. Adjusting the obtained WISC-R score for the Flynn Effect would have yielded a score of 65.3, clearly meeting the Virginia statutory standard. Recognition of an IQ score of 65 rather than 71 probably would have increased the likelihood of a successful appeal of Mr. Green's death sentence. In fact, the Flynn-adjusted score was rejected by the court, and Mr. Green was executed on May 27, 2008.

Although the Flynn Effect is a fact (Gresham, 2009) acknowledged by critics of test score corrections (Weiss, 2010), sharp disputes exist over whether it should be applied to individual cases in legal, social welfare, and educational settings (Hagan, Drogin, & Guilmette, 2008, 2010). One of the harshest critics of applying the Flynn Effect (Hagan), an expert witness in *Green* for the prosecution, argued that the Flynn Effect cannot be applied to any individual with certainty and that adjustments for the Flynn Effect do not meet the psychology standard-of-practice criterion. The standard-of-practice argument is advanced by

Hagan et al. based on a survey of the use of the Flynn correction method in psychological assessment textbooks (e.g., Sattler, 2001), journal articles, graduate courses for professional psychologists, and clinical practice. When the survey was completed in 2006 or 2007, the Flynn Effect was not mentioned in most of those sources, and none recommended correcting IQ scores. Standard of practice cannot, however, be based solely on what is done currently (Gresham & Reschly, 2011). Research findings also must inform psychological practice, including the fact of the Flynn Effect.

Consensus among psychologists exists. The Flynn Effect is a scientific fact (Gresham & Reschly, 2011). Test norms become obsolete with the passage of time. Although some disagreement exists about its origins and causes (Kaufman, 2010a; Zhou, Zhu, & Weiss, 2010), the guest editors of this special issue both endorsed Flynn corrections to scores on intellectual functioning measures in death penalty situations (Kaufman, 2010b; Weiss, 2010). It is important to note that Kaufman is an author of children and adult intelligence tests and Weiss has been intimately involved with the last two restandardizations of the Wechsler Adult Intelligence Scale. Psychological practice needs to reflect psychological science.

Other research documents the effects of outdated norms on the identification of ID in educational settings (Kanaya, Scullin, & Ceci, 2003; Scullin, 2006). In school settings, the WISC is used far more often than any other instrument as part of ID diagnosis for special education eligibility. These researchers documented the increase in ID with new norms on the WISC and gradual decline in ID identification as norms aged over time. Clearly, the Flynn Effect has significant influences on ID identification at both the individual and system levels.

Arguments about the application of the Flynn Effect therefore have real consequences in practical situations such as death penalty appeals, Social Security benefits, and special education eligibility. The AAIDD endorses consideration of the Flynn Effect, particularly as norms on current tests age (Schalock et al., 2007, 2010). "In cases where a test with aging norms is used, a correction for the age of the norms is warranted" (Schalock et al., 2007, p. 20). Schalock et al. concluded, "Thus the clinician needs to use the most current version of an individually administered test of intelligence and take into consideration the Flynn Effect as well as the standard error of measurement when estimating an individual's true IQ score" (p. 21). This appears to

be sound advice to persons making diagnostic decisions about persons with ID, particularly when the consequences are substantial and the application of a rigid cutoff score is required. Unanswered questions remain about the kinds of ability to which the Flynn Effect is most applicable (perhaps it has more impact on fluid than crystallized abilities) and the age of the norms when the Flynn Correction should be applied (3, 5, or 10 years out of date). Best practice certainly requires the use of recently normed tests and, I contend, applying the Flynn correction as soon as the norms are three or more years out of date, particularly when a rigid cutoff score is specified.

This discussion of assessing intellectual functioning for ID determination could be expanded significantly. Here, only the most controversial issues were addressed. Other important considerations described in Reschly et al. (2002) include:

- (a) Selection of reliable and valid *individually administered* intellectual assessment instruments that yield a composite IQ score composed of two or more group factors of intelligence, including crystallized and fluid general ability;
- (b) Administration and interpretation of tests in high-stakes ID determination by properly credentialed psychologists who have background and experience with ID;
- (c) Administration and interpretation of tests using standardized procedures;
- (d) Interpretation of results considering the client's motivation, effort, cultural background, health, and sensory status;
- (e) Consideration of test results in the context of other evidence of intellectual functioning;
- (f) Consideration of context factors that may or may not bias results; and
- (g) Application of the convergent validity principle in formulating conclusions about significant limitations in intellectual functioning; that is, determining the consistency or inconsistency of data from a variety of sources and methods of collecting information.

### ***Adaptive Behavior Assessment and Criteria***

Although the concept of *social competence* was well established as early as the 1940s, the term *adaptive behavior* was first used in the AAIDD classification in Heber (1961). Over the last 50 years, the conception and prominence of adaptive behavior in the conceptual definition and classification criteria for ID have evolved and strengthened. Today

adaptive behavior is equal in importance to intellectual functioning in both conception of and classification criteria for ID.

#### EVOLUTION OF CONCEPTIONS AND CRITERIA

Some prior conceptions of adaptive behavior and classification criteria inform this discussion of the current assessment of adaptive behavior in ID diagnoses. In the AAIDD classification manuals in 1973 and 1983 (Grossman, 1973, 1983), adaptive behavior was defined as “the effectiveness or degree with which individuals meet the standards of personal independence and social responsibility expected for age and cultural group” (Grossman, 1983, p. 1). Guidance was then provided in defining the major domains of adaptive behavior developmentally; that is:

*Infancy and Childhood:* Sensorimotor skills, communication skills, self-help skills, and socialization

*Childhood and Early Adolescence:* Application of basic academic skills, application of appropriate reasoning and judgment, and social skills.

*Late Adolescence and Adult Life:* Vocational and social responsibilities and performance.

The criteria were cumulative. At each developmental level, the criteria from prior levels were included, as well as more advanced expectations. The language connecting adaptive behavior to intelligence in the 1973 and 1983 classification manuals was the phrase “existing concurrently”; that is, “Mental retardation refers to significantly sub-average general intellectual functioning *existing concurrently* with deficits in adaptive behavior...” (emphasis added; Grossman, 1983, p. 1). Significantly sub-average intellectual functioning was defined as approximately  $-2SD$ , but no quantitative guidance was provided regarding what constituted an adaptive behavior deficit.

The role of adaptive behavior subtly changed in the classification manuals published over the last 20 years (Luckasson et al., 1992, 2002; Schalock et al., 2010). In 1992, adaptive behavior was defined by 10 skill areas (communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work). Limitations in two or more of the 10 areas were required for the diagnosis of ID, but no numerical guidance was provided regarding the degree of limitation. The Luckasson et al. (1992) definition of ID was criticized by several authors who pointed to the absence of a theoretical or psychometric rationale

for the 10 adaptive skills areas, varying importance of each to child and adult functioning, psychometric flaws in specifying so many skills areas, and the likely misapplication of the skills areas in decision-making about ID (Macmillan, Gresham, & Siperstein, 1993, 1995).

#### CURRENT ADAPTIVE BEHAVIOR DOMAINS

The conception of adaptive behavior changed again in the 2002 and 2010 classification manuals in at least two important ways (Luckasson et al., 2002; Schalock et al., 2010). The 1992 conception of 10 adaptive skills areas was abandoned, replaced by specification of three broad domains of adaptive behavior, applying in part a conceptual scheme by Greenspan (1981a, 1981b) that had been validated in a factor analysis of adaptive behavior measures (McGrew, Bruininks, & Johnson, 1996). The second change, subtle but potentially highly impactful, was to specify significant limitations in both intellectual functioning and adaptive behavior and to add for the first time a numerical cutoff for adaptive behavior at approximately  $-2SD$ , making it consistent with the traditional criterion for intellectual functioning and encouraging the use of the results from current adaptive behavior inventories in determining limitations in adaptive behavior. As will be explained later, the second change has vast potential implications for the existence of mild ID.

The three domains of adaptive behavior were described in Schalock et al. (2010, p. 44) as follows:

*Conceptual skills:* language; reading and writing; and money, time, and number concepts.

*Social skills:* interpersonal skills, social responsibility, self-esteem, gullibility, naiveté (i.e., wariness), follows rules/obeys laws, avoids being victimized, and social problem solving.

*Practical:* activities of daily living (personal care), occupational skills, use of money, safety, health care, travel/transportation, schedules/routines, and use of the telephone.

The same caveats regarding intellectual function were stated for adaptive behavior, including interpretation of specific scores as a range bounded by a confidence interval, consideration of culture and diversity in selection and interpretation of an instrument, flexibility around a cutoff score of 70, and so on.

#### MAXIMUM AND TYPICAL PERFORMANCE

Although the recent AAIDD classification manuals imply that assessments of intellectual functioning

and adaptive behavior are analogous, the two areas are markedly different in several important respects. First, and perhaps most important, intellectual assessment along with assessment of achievement and aptitude are part of a genre of *maximum performance* tests (Cronbach, 1990). Maximum performance tests are given directly to the client, who is encouraged to give her or his best effort to do well. Individually administered tests given by appropriately credentialed psychologists, as recommended by AAIDD, provide a context to observe the individual's effort and persistence in attempting to perform well. "Faking bad" or malingering is not completely prevented by the close observation, but it is much less likely, particularly when judicious use is made of effort measures and full developmental information is considered (Salekin & Doane, 2009). Although faking a bad performance on a maximum performance measure is possible, it is generally unlikely when tests are given according to standardized procedures with the further safeguards recommended by AAIDD.

In contrast, adaptive behavior inventories as they have been developed over the last 30 years are *typical performance* measures, meaning that there is an attempt to assess the individual's day-to-day, usual display of competencies. An example may clarify the distinction. A contemporary adaptive behavior item might be skill in using a cell phone. Persons without this skill are at a disadvantage in many situations. We could provide a cell phone and ask to the client to demonstrate its use. Alternatively, we could ask someone else about whether the client uses a cell phone. In the former version we are using a "can do" question similar to those on maximum performance measures. In the latter, the question is "does s/he do it?" The first could be observed, while the second requires a knowledgeable third-party respondent. Adaptive behavior measures nearly always ask the "does do" rather than the "can do" question, typically using third-party respondents such as a parent, teacher, relative, caretaker, neighbor, etc. Some instruments have an option of self-reporting, which is problematic with persons with mild ID due to reading level limitations and their tendency to deny adaptive behavior limitations (Edgerton, 1993; Tasse, 2009). Although current adaptive behavior measures represent significant advances in terms of reliability, validity, and norms (Bruininks, Woodcock, Weatherman, & Hill, 1996; Harrison & Oakland, 2003; Sparrow, Cicchetti, & Balla, 2005), none are adequate as the sole assessment of adaptive behavior as conceptualized by AAIDD (Schalock et al., 2010).

Assessment in the conceptual domain is particularly difficult with third-party respondents. Determining the client's skills in "language, reading and writing, money, time, and number concepts" (Schalock et al., 2010, p. 44) is much more accurate and enlightening through *direct* administration of tasks and use of maximum performance tests than asking a third-party respondent to report his or her perceptions of these literacy skills that may or may not be based on direct observation. Moreover, with many clients there are inconsistencies between third-party respondents and actual tests of competencies in the conceptual skills domains. It seems obvious that the actual behavior rather than a third party's perception of the behavior is more useful in making a decision about performance in the conceptual skills domain and for some aspects of skills in the social and practical domains, such as knowledge of and use of money.

#### LIMITATIONS OF ADAPTIVE BEHAVIOR MEASURES

Existing adaptive measures have significant limitations that were discussed thoroughly by Reschly et al. (2002). A brief description of these limitations follows. First, the item format frequently mixes "can do" and "does do" responses. For example, the following response format is used in the highly structured Scales of Independent Behavior-Revised (SIB-R) (Bruininks et al., 1996). How should this item be scored: "fills car with gas when needed," which the client does very well, but only about 50 percent of the time, given the following SIB-R response format? Similar formats are used on other structured adaptive behavior inventories.

Score = 1: does the task, but not well, or about 25 percent of the time (may need to be asked)

Score = 2: does the task fairly well, or about 75 percent of the time (may need to be asked)

Score = 3: does the task very well always or almost always (without being asked).

The appropriate response to this item is not clear. Moreover, a response to this kind of item requires deep and broad knowledge of the individual's everyday functioning in a variety of settings that frequently is not available in any third-party respondent. Often, the adaptive behavior inventory has to be administered to the most knowledgeable person available, who may have relevant knowledge about adaptive skills in one context, but not in others.

Third, some instruments urge respondents to make estimations or even guess about the client's

capabilities regarding specific items if they do not have direct knowledge of them. Such estimates or guesses undermine the validity of the inventory results. Fourth, response sets can subtly bias the results. For items and instruments with a three- or five-choice response format, there is a tendency to select the middle response when uncertain of the client's actual capabilities. Other well-known response sets include social desirability when items have negative or positive connotations, and halo effects that arise when the reporter has more positive or negative feelings about the client. Some response sets may be conscious. In assessment of adaptive behavior with relatives of individuals advancing death penalty appeals or claims for Social Security disability assistance, answering the questions in a particular direction has obvious advantages for the client and, frequently, for the family.

In addition to problems with third-party respondents, current adaptive behavior measures frequently have relative low ceilings, so that persons with mild ID pass easily, or a few items at the ceiling levels leading to superficial assessment and large changes in scores, depending on the success or failure on very few items (Reschly et al., 2002).

Although Schalock et al. (2010) recommend the use of currently available adaptive behavior measures, considerable caution is needed due to the limitations just discussed. No single score on an adaptive behavior measure should be the sole deciding factor in making a decision about limitations. All adaptive behavior measures must be supplemented with additional information from existing records, interviews with significant others, interviews with the client, and objective, maximum performance tests. It bears emphasizing that standardized achievement test results are highly relevant to assessing performance in the conceptual skills domain (literacy skills, language use). Determination of adaptive behavior limitations must be based on collecting a wide variety of relevant data, which are analyzed using the convergent validity principle.

#### **ADAPTIVE BEHAVIOR CUTOFF AND CLASSIFICATION EFFECTS**

The 2002 and 2010 AAIDD classification manuals require a significant limitation in only *one* of the three adaptive behavior domains: conceptual, social, and practical (Luckasson et al., 2002; Schalock et al., 2010). Using a standardized inventory and other information, an individual can be determined as displaying a significant adaptive behavior limitation if the result is a limitation in any of the three

domains or in the overall composite score. It is crucial to note that the AAIDD does *not* require significant limitations in all domains or in a composite score; significant limitation in one domain meets the AAIDD criterion.

These criteria seemed transparent and easily applied until the practical consequences of the  $-2SD$  standards on both the intellectual and adaptive behavior prongs were analyzed (Reschly et al., 2002). The 2002 and 2010 AIDD classification manual adaptive behavior requirement of the approximately  $-2SD$  (Luckasson et al., 2002; Schalock et al., 2010) on both intellectual functioning and adaptive behavior was not accompanied by any compelling justification or consideration of possible effects on the identification of mild ID. Persons with more severe ID, e.g., IQs below 55, nearly always show pervasive and significant adaptive behavior limitations, meaning that the  $-2SD$  criterion will have little or no influence on identifying persons at the severe levels of ID.

The largely unexplored issue is the likelihood of any client meeting simultaneously *both* the intellectual and adaptive functioning prongs required in AAIDD's recent ID classification criteria. An analysis in Reschly et al. (2002), led by panel member Keith Wildman, established that simultaneous application of both quantitative cutoffs would render ineligible most persons currently eligible for ID with IQs at 75, 70, 65, and even 60. It is highly unlikely that this result was intended by the AAIDD committees. Further consideration is needed to determine an appropriate cutoff with adaptive behavior, along with caution for the present in applying the current AAIDD criteria.

The appropriate assessment of adaptive behavior including the application of cutoff scores must go beyond the recommendations of the AAIDD (Schalock et al., 2010). Standardized adaptive behavior inventories are relevant when there are measures that match the age and functioning level of the client and knowledgeable third-party respondents are available. In most cases there are important limitations in the available inventories and third-party respondents, rendering highly tentative the interpretations of client's adaptive behavior status based on the results of an adaptive behavior inventory. Additional information about adaptive behavior must be gathered through other means, including standardized tests of conceptual skills, client interviews, client work products (e.g., letters actually written by the client), and observations in natural settings. The diverse information that results

must be interpreted through clinical judgment; that is, consideration of all the data in relation to whether significant limitations exist. Direct application of cutoff scores is not appropriate.

## **Determination of Developmental Origin of Mild ID**

The existence of a developmental origin has been an essential prong in the conceptual definition and classification criteria of ID for the last 50 years (Doll, 1941; Schalock et al., 2010). For some clients, particularly those at the more severe levels of ID, developmental origin is easily documented through a formal diagnosis of ID throughout the preschool and school-age years that appears in medical, school, and social service records. For many adult clients, however, determining developmental origin of *mild ID* is much more complicated, due to a variety of factors discussed below (Reschly, 2009a).

### **SCHOOL RECORDS**

Schools are more likely to diagnose mild ID than any other agency or service (Denning et al., 2000; Mercer, 1973; Reschly & Ward, 1991). Some public schools in the United States provided special classes for students we now would recognize as having mild ID in the late nineteenth and early twentieth century, even before intelligence tests were used as part of ID identification (Kode, 2002). Since enactment in the 1970s of mandatory special-education legislation in the states and by the federal government (Education of the Handicapped Act; 1975, 1977), reauthorized as the Individuals with Disabilities Education Act (IDEA; 1990, 1997, 2004), all schools have to identify students with disabilities and provide special education services. ID is included in every state plan for providing special education services, although the terminology may vary from state to state. School records reflecting education performance, special-education referral, psychological evaluation, and special education programming are, therefore, a potential treasure trove of information relevant to the developmental origin of mild ID. In many situations this is the case, but in many others there are significant problems in using school records.

The first limitation is that relevant school records for adults may no longer exist. The 2006 IDEA regulations at 34 C.F.R. 300.624, guided by the earlier Family Education Rights and Privacy Act (FERPA) (1994), permits the destruction of most school records pertaining to an individual in

accordance with state law. A permanent record *may* be retained by the school. Most states allow and some require destruction of individual records after three to five years have elapsed since the individual was enrolled. Most schools do retain a permanent record that contains only "the student's name, address, and phone number, his or her grades, attendance record, classes attended, grade level completed, and year completed." (34 C.F.R. 300.624). Important information such as referral, psychological and educational evaluations, test scores, and special-education participation frequently are not in the permanent school record. Some permanent school records (in the author's experience) may contain indications of special-education placement, special-education categorical diagnosis, grades in classes, grade retention information, and scores on standardized achievement tests. Although more information such as psychological and educational evaluations would be extremely helpful in determining the developmental origins of ID with adults, this information typically has been destroyed by the school. In some cases the school records may be preserved by another agency such as social services, private school, or state residential facility.

Interpretation of school records often is an art that draws on extensive prior experience in that setting. For example, teachers, administrators, and other school officials can interpret cryptic entries in the record that might not be understood by psychologists and others with little school experience. For example, some records may have a second letter by a grade indicating the student's placement, such as an S to indicate special-education placement or a B to denote that a course was at the basic level. Moreover, further information may exist about whether the student could pass the state high-stakes tests in designated areas, again through what may be ambiguous, cryptic designations. Assistance in interpreting school records clearly is useful in gathering information to establish the developmental origin of ID.

### **USE OF SCHOOL DIAGNOSES**

For a variety of reasons, schools over the past 40 years have been increasingly reluctant to identify students as mild ID (Donovan & Cross, 2002; Reschly, 2009b). Several influences are responsible, including litigation regarding overrepresentation of minority students in ID and, to a lesser extent, to emotional disturbance. Since special-education prevalence data were first collected nationally in 1977, the number of students identified in all levels

of ID has declined 50%, from about 950,000 to 425,000, while the prevalence of SLD has grown by 400%, from approximately 450,000 to 2.5 million. The prevalence trends are connected. Many students formerly diagnosed as ID now are determined to be SLD, even when the psychological and educational evaluation data are consistent with a mild ID diagnosis (MacMillan, Gresham, Siperstein, & Bocian, 1996). The discrepancy between school diagnoses of disabilities and AAIDD criteria for ID was the basis for the NRC Panel to recommend that objective school data be considered carefully in ID determination, but that school diagnoses should be treated more skeptically (Reschly et al., 2002).

#### **EDUCATIONAL TERMINOLOGY AND CLASSIFICATION CRITERIA**

Terminology for ID differs in the state special education statutes and rules. In some states, older terminology such as *mental retardation*, *mental handicap*, and *mental disability* are used to refer to ID (Denning et al., 2000). Moreover, many states have more lenient criteria for the intellectual functioning prong such as  $IQ \leq 80$  or  $IQ 1.5 SD$  below the mean. States also differ significantly in how adaptive behavior is conceptualized, assessed, and determined to reflect significant limitations. Knowledge of state rules and guidelines for each of the special education disability categories, including ID, is essential to understanding school records.

#### **RETROSPECTIVE ADAPTIVE BEHAVIOR ASSESSMENT AND INTERVIEWS**

Because adults who are functioning at the mild ID level may be misdiagnosed or not diagnosed prior to the age of 18, some kind of retrospective account of behavior from significant others is often sought. Retrospective accounts of behavior, whether using a formal standardized inventory or a more informal interview outline, are subject to several limitations and potential distortions (Olley, 2009; Tasse, 2009). Interviewing parents who often have had several children, sometimes in conditions of extreme poverty and social instability, will probably contain many guesses and unreliable information. Other retrospective reporters often are available such as general and special-education teachers who may recall the client vividly, but in a specific setting (school). These accounts may have greater credibility because they come from college-educated persons who have an informed perspective and ample experience with both normal and abnormal development. The general problems of retrospective

accounts still exist, including biases, faulty memory, and insufficient opportunity to observe relevant behaviors.

#### **SOCIAL SERVICES AND RECORDS**

Most persons with mild ID come from low socioeconomic circumstances, regardless of race or ethnicity (Donovan & Cross, 2002; Edgerton, 1984, 1993; Reschly et al., 2002; Richardson, 1981). Many of the families have other children performing at or close to the mild ID level, and some will have been involved with social services agencies. Records at these agencies, with proper consent of the client, may be available. Other adults with mild ID have been placed in juvenile correction facilities or other state facilities prior to age 18. Records from these sources may include psychological evaluations and educational records pertaining to the existence of mild ID in the developmental period.

#### **SUMMARY**

Determination of the existence of mild ID during the developmental period from birth to age 18 is complicated by a number of factors, including the destruction of much of the school record, inadequate retrospective reporters, and the use of other diagnoses when mild ID would be more appropriate. The challenge to psychologists again is complex, requiring deep knowledge of ID and intimate knowledge of educational, social service, and legal agencies. In some cases, the records from these agencies provide unequivocal evidence; however, in many others, the evidence of ID will be incomplete and ambiguous. Consideration of a broad variety of information using the previously described convergent validity principle is essential to making sound judgments about the existence of ID during the developmental period.

#### **Conclusion**

The mild ID diagnostic construct has been recognized for slightly over 100 years. The essential features of the conceptual definition are well established by authoritative sources, particularly the AAIDD. ID is a status marked by significant limitations in intellectual functioning and adaptive behavior that appears during the developmental period. The classification criteria are broadly in line with the conceptual definition; however, significant disagreement and controversy exist over specific classification criteria. These disagreements have vast implications for individual clients who

may or may not be diagnosed as having mild ID by psychologists, with accompanying high-stakes consequences for the client. High-stakes consequences include application of the death penalty, income assistance and health system support, and placement in appropriate educational services.

No easy answers exist to complex determinations of mild ID eligibility in diverse settings with inconsistent classification criteria. Direct application of test results, even with well-developed intelligence tests, using rigid cutoff scores is undesirable and inappropriate for many reasons. Rigid application of scores from less accurate and less well-developed adaptive behavior inventories is even less justified by the existing research.

Use of a wide range of information gathered through the methods of testing, observing, interviewing, and reviewing records, drawing on diverse sources, including the client and significant others, is required for sound diagnosis of mild ID. Appropriate interpretation of this diverse information requires clinical judgment informed by research on and experience with ID. Application of the convergent validity principle in weighing the information is the best approach to making sound ID diagnostic decisions that are justifiable to the general public and acceptable in educational, legal, and social service settings.

## Notes

1. The organization that now is AAIDD had at least two prior titles in the twentieth century—American Association on Mental Retardation until 2008, and American Association on Mental Deficiency, previously.
2. The author was an expert witness for the defense in the *Green v. Johnson* 2006 death penalty appeal.

# Toward a Synthesis of Cognitive-Psychological, Medical/Neurobiological, and Educational Models for the Diagnosis and Management of Dyslexia

Nancy Mather, Bennett A. Shaywitz, and Sally E. Shaywitz

## Abstract

The most common and best understood specific learning disability is dyslexia, or specific reading disability, a disorder that affects the development of word-level reading, reading rate, spelling, and certain aspects of oral language, particularly phonological awareness and word retrieval, but with verbal reasoning and listening comprehension intact. Both the assessment and the treatment of dyslexia have interested researchers for over a century, not only in education, but also in the fields of psychology and neurology. This chapter reviews this disorder from three varying theoretical, scientific, and practical perspectives or models: cognitive-psychological, which emphasizes exploration of a learner's strengths and weaknesses in an attempt to understand the reasons for the reading failure; medical/neurobiological, which addresses the etiology, basis and mechanisms, explaining and predicting the symptoms; and educational, which is driven by legal mandates, as well as services provided by school systems. Each model offers insights into and contributes to the fullest understanding of the nature of this disability, as well as the conceptual and methodological frameworks that can contribute to the formulation of a diagnosis.

**Key Words:** dyslexia, specific reading disability, response-to-intervention, ability-achievement discrepancies, intra-individual variations, neural organization in reading and dyslexia, learning disability

Specific learning disability (SLD) is a diagnostic category that encompasses a group of heterogeneous cognitive and linguistic disorders that typically affect some aspect of academic performance (e.g., reading, written language, mathematics). Although different types of SLD exist, the most common and well researched is a word-level reading problem often referred to as *dyslexia* (developmental dyslexia) or *specific reading disability* (SRD). The word "specific" is critical, as it indicates that individuals with dyslexia have specific cognitive assets but also specific deficits that lead to poor reading; this differentiates individuals with SLD from those

who have lower global intelligence (Hale, Kaufman, Naglieri, & Kavale, 2006). Because it is the most common learning disability (Lerner, 1989) and considerable evidence has accumulated regarding how children learn to read and why some experience difficulties (Bradley & Bryant, 1983; Hooper, 1996; Torgesen et al., 1999), the focus of this chapter is on dyslexia.

The definition of dyslexia as an *unexpected* difficulty in reading (Critchley 1970; Lyon 1995; Lyon, Shaywitz, & Shaywitz, 2003; Monroe, 1932; Peterson & Pennington, 2012) has remained invariant over the century since its first description

(Morgan, 1896). Dyslexia is found in readers of all languages, including both alphabetic and logographic scripts. Dyslexia is defined as a specific reading disability that is neurobiological in origin and characterized by difficulties with accurate and/or fluent word-recognition and spelling. The addition of the adjective *specific* implies that the poor reading performance emanates from a limited number of underlying deficits (Kavale & Forness, 2000), most typically from a deficit in the phonological component of language that is “unexpected” in relation to the person’s other cognitive abilities.

## Historical Perspective

One of the first descriptions of dyslexia is credited to an English general practitioner, W. Pringle Morgan (Morgan, 1896). Shortly thereafter, James Hinshelwood, a Scottish ophthalmologist at the Glasgow Eye Infirmary, presented additional cases of children and adults with dyslexia (termed *congenital word blindness* in that era). Hinshelwood not only described the cases but made recommendations regarding treatment. For example, in a monograph describing two cases of children with “word blindness,” Hinshelwood (1902) concluded that:

- (a) particular areas of the brain appear to be involved;
- (b) the children often have average or above-average intelligence and good memory in other respects;
- (c) the problem with reading is localized, not generalized to all areas of academic performance;
- (d) the children do not learn to read with the same rapidity as other children;
- (e) the earlier the problem is identified, the better, so as not to waste valuable instructional time;
- (f) the children must be taught by special methods adapted to help them overcome their difficulties;
- (g) the sense of touch can help children retain visual impressions; and
- (h) persistent and persevering attempts will often help children improve their reading.

By 1917, Hinshelwood concluded that, “With the possession of a knowledge of the symptoms, there is little difficulty in the diagnosis of congenital word-blindness when the cases are met with, since the general picture of the condition stands out as clear-cut and distinct as that of any pathological condition in the whole range of medicine” (p. 88). This same sentiment was expressed over 85 years later:

“The diagnosis of dyslexia is as precise and scientifically informed as almost any diagnosis in medicine” (Shaywitz, 2003, p. 165).

These early case studies described individuals who often had normal intelligence and even excelled in other areas, but their poor reading and spelling performance were in sharp contrast to their other abilities. Through the analyses of case studies of individuals over several decades, two basic concepts emerged: (1) the concept of unexpected under-achievement (that reading performance was unexpected or unpredicted based upon the person’s higher cognitive abilities); and (2) the notion of variations among learning abilities (intra-individual variations).

## Prevalence and Course of Dyslexia

As with other disabilities, the specific prevalence rate for dyslexia will reflect the particular definition and cut-points established as criteria for identification. Data emanating from multiple sources indicate that, for large segments of the population, reading remains effortful, and skilled reading elusive. For example, results of the 2005 National Assessment of Educational Progress (NAEP) indicated that 27% of high school seniors are reading below the most basic levels (i.e., the minimum level at which a student can demonstrate an understanding of what has been read (Grigg, Donahue, & Dion, 2007), and 36% of fourth-grade children are reading below basic levels (Perie, Grigg, & Donahue, 2005). In the Connecticut Longitudinal Study sample survey in which each participant was individually assessed, 17.5% of students were reading below age or ability levels (S. Shaywitz, Fletcher, & Shaywitz, 1994). This population has been followed continuously since 1983 with yearly individual assessments of their cognitive, academic, behavioral, social, and more recently, neurobiological characteristics. Accordingly, these longitudinal data permit examination of issues relating to the developmental course of reading difficulties and indicate the persistence and chronicity of reading problems, refuting the notion, long and tightly held, that reading difficulties can be “outgrown” or merely reflect a developmental lag (Francis, Shaywitz, Stuebing, Shaywitz, & Fletcher, 1996; B. Shaywitz, Fletcher, & Shaywitz, 1995). While the problems are persistent, it is important to keep in mind that the expression of the reading difficulty may change with time, so that difficulties with reading accuracy, especially in very bright children, often evolve into relatively accurate, but dysfluent, reading (S. Shaywitz,

Morris, & Shaywitz, 2008). Spelling difficulties also persist. In fact, poor spelling is often described as a hallmark of dyslexia (Gregg, 2009). Difficulties with word retrieval, fluent reading, and spelling persist throughout adulthood.

These explanatory and causative factors of dyslexia have interested researchers in the fields of psychology, neurology, and education for over a century (Hinshelwood, 1917; Monroe, 1935; Morgan, 1896; Orton, 1925). Thus, the assessment and diagnosis of dyslexia can be viewed from varying perspectives. Each perspective offers insights into the multifaceted perceptions and nature of this disability, as well as the conceptual, philosophical, and methodological frameworks that may be incorporated into the diagnostic process.

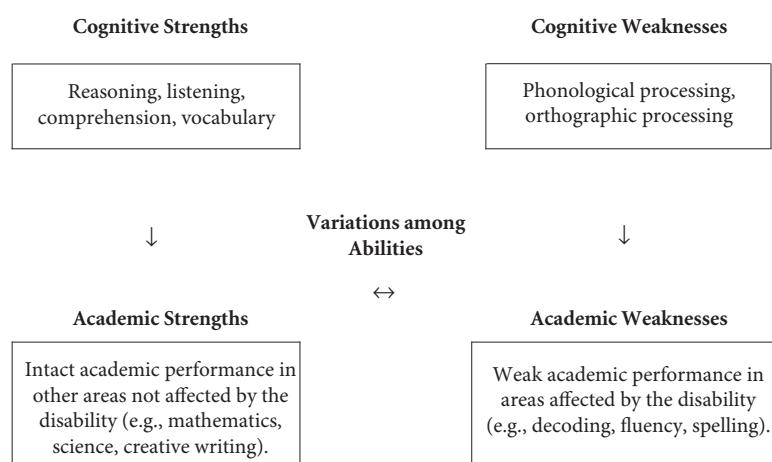

### Cognitive-Psychological Models

Cognitive-psychological models of dyslexia attempt to explain human variability in terms of both the consistencies and inconsistencies within performance. From this perspective, researchers and practitioners have attempted to answer the central question of *why* some people struggle to learn to read. Typically, the basic information for psychological study is gathered through a comprehensive evaluation that addresses both the intrinsic and extrinsic factors related to reading, considering areas of strength as well as areas of weakness. In fact, from a cognitive-psychological perspective, the primary goal of a cognitive assessment is to acquire data specific to understanding the core cognitive constructs and traits that underlie reading development and achievement (Feifer, 2008; Semrud-Clikeman, 2005; Witsken, Stoeckel, & D'Amato, 2008). The results from a

comprehensive evaluation can help determine the nature of the individual's difficulties, whether or not special education is necessary, and the type of individualized instruction that will be most beneficial.

The basic defining component of nearly all cognitive-psychological definitions of SLD in general and dyslexia specifically has been that one or more specific disorders exist in the basic psychological processes involved in learning. Because development is uneven, with some abilities being far more advanced than others, a *discrepancy*, then, often exists between a set of intact cognitive processes and one or more disordered processes (Hale, Kaufman, Naglieri, & Kavale, 2006; Hale, Naglieri, Kaufman, & Kavale, 2004). These weaknesses in basic psychological processes, compared to strengths in other processes, often referred to as intra-cognitive or intra-individual discrepancies or variations (unexpected differences), are considered to be the hallmark of SLD (A. S. Kaufman & Kaufman, 2001; Kavale, Kaufman, Naglieri, & Hale, 2005). Thus, in the case of dyslexia, the central purpose of a comprehensive cognitive-psychological assessment is to document cognitive integrities and unexpected deficits within the basic cognitive-psychological processes that are linked to the reading difficulties (Hale et al., 2004; Kaufman, 2004). This type of evaluation documents the learning abilities, as well as the learning disabilities (Kaufman, 2008).

Figure 30.1 represents the major goal of a cognitive-psychological dyslexia assessment, the basis for a pattern of strengths and weaknesses (PSW) approach. The purpose is to examine patterns of cognitive strengths and weaknesses and determine how these patterns relate to and affect

**Figure 30.1** Relationships among cognitive abilities and the diagnosis of a specific reading disability.

reading development. A PSW approach involves several steps: (a) identifying an academic need; (b) determining if areas of cognitive weakness exist that have a research-based link to academic performance; (c) establishing cognitive and linguistic strengths; and (d) analyzing the results to see if the pattern is consistent with a profile of SLD (Schultz, Simpson, & Lynch, 2012). Essentially, the evaluator is attempting to explain the interrelationships among and between the individual's stronger and weaker cognitive and academic abilities.

In fact, the regulations of the Individuals with Disabilities Education Act (IDEA) §300.309(a)(2) (ii) also permit identification of a specific learning disability from consideration of whether or not the child exhibits a pattern of strengths and weaknesses in performance, achievement, or both, relative to her or his intellectual development. This provision is in line with the concept of intra-individual variations. This type of approach aligns the definition of SLD, as a deficit in basic psychological processing, with a possible way to operationalize identification. Kavale, Kauffman, Bachmeier, and Lefever (2008) noted: "Cognitive processing assessment aligns diagnostic procedures with a clearly articulated SLD definitional component: a disorder in one or more of the basic psychological processes" (p. 144). Children with SLD and dyslexia have *specific* cognitive deficits that lead to poorer academic performance than would be expected given their *specific* cognitive assets. This differentiates children with SLD from those with intellectual impairments (Hale et al., 2006, 2008).

In some aspects, the diagnosis of dyslexia falls within the framework of a PSW approach; however, the evaluator must have knowledge of the specific strengths and weaknesses that typify dyslexia. In the evaluation of children for dyslexia, the goal is to determine whether or not the particular PSW is symptomatic of dyslexia, such as a child with weaknesses in phonological processing, but strengths in listening comprehension and reasoning, a pattern consistent with an unexpected difficulty in reading. Proper use and interpretation of a PSW approach, incorporating the unexpected difficulty that characterizes dyslexia, could result in a true synthesis of the cognitive-psychological, the medical, and the educational models.

In the case of dyslexia, the central academic problems are difficulties with accurate and/or fluent word recognition and poor decoding and spelling abilities, as well as difficulties in word retrieval (Hanly & Vandenberg, 2010). This weakness

in word reading is often surrounded by a "sea of strengths," wherein the individual's reasoning, general knowledge, and critical thinking abilities are intact, or even advanced (Shaywitz, 2003). For example, in many cases, often what distinguishes individuals with dyslexia from other poor readers is that their listening comprehension ability is significantly higher than their ability to decode nonsense words (Rack, Snowling, & Olson, 1992).

Though difficulties in phonological processing are most common in dyslexia, other factors may be associated with the poor reading. For example, one student may have poor phonological awareness, but strengths in listening comprehension and vocabulary, which may serve as partial compensation for the weakness in phonological processing. In another case, a student may have advanced reasoning and linguistic abilities, but poor orthographic awareness that may be exacerbated by overall slow processing speed (Konold, Juel, McKinnon, & Deffes, 2003). Variations, then, often exist between and among the person's intact and deficient cognitive and academic abilities. Konold et al. explained that learning to read is a multivariate phenomenon that is best understood by joint consideration of these processes and their influences on reading outcomes. Although much is known, questions still remain about the exact nature of the interrelationships among these variables (Bell, McCallum, & Cox, 2003).

### ***Intra-Individual Variations***

Intra-individual variations are determined through an analysis of a profile of cognitive-psychological abilities. In order to identify the unique abilities of an individual, the first line of analysis is the individual case study (Fawcett & Nicolson, 2007). An essential element of this diagnostic study is an exploration of the individual's cognitive and linguistic abilities to determine not only the unexpected nature of the reading difficulties but also how these other cognitive-psychological abilities may be related to the reading difficulties. Within the cognitive-psychological model, Ferrer, Shaywitz, Holahan, Marchione, and Shaywitz (2010) used dynamic modeling within a longitudinal framework to examine the relationship between cognitive and academic (reading) ability in different groups of readers. The findings confirmed the uncoupling of cognitive ability and reading ability in subjects with dyslexia. Specifically, using data from the Connecticut Longitudinal Study, Ferrer and associates provided empirical evidence demonstrating differences in the dynamics of reading and cognition

between typical readers and those with dyslexia. Typical readers manifest mutual dynamics between reading and intelligence (IQ) with positive interrelations between both over time. For readers with dyslexia, however, such interrelationships are not perceptible, suggesting that reading and cognition develop more independently. These new data, based on dynamic models, provide an explanation for the “unexpected” nature of developmental dyslexia and provide the long-sought empirical evidence for the seeming paradox involving cognition and reading in individuals with developmental dyslexia.

Thus, valid dyslexia diagnosis uses data including both cognitive and achievement information. The assessment often reveals discrepancies among intact processes and those that are disordered (Hale et al., 2004); for example, the evaluator may find difficulties in phonological processing and reading fluency in comparison to strengths in other cognitive abilities. Some factors, such as working memory (Baddeley, 2007; Baddeley, 2012; Baddeley, Eysenck, & Anderson, 2009), have been associated with poor reading. Poor working memory may be particularly characteristic of students who have both dyslexia and attention deficit/hyperactivity disorder (ADHD) (Bental & Tirosh, 2007). Cognitive factors, such as phonological awareness, verbal short-term memory, orthographic awareness, rapid naming, and processing speed, have been shown to be correlates of reading failure, or in essence, factors contributing to specific reading impairments. In addition, problems with attention can also play a critical role. We briefly review each of these examples of cognitive correlates below.

## PHONOLOGICAL PROCESSING

As noted above, difficulties with phonological processing represent the most commonly reported problem in dyslexia (Morris et al., 1998). “*Phonological processing*” includes phonological awareness, a component of oral language ability that encompasses the abilities to attend to, discriminate, and manipulate individual speech sounds. This metacognitive understanding involves the realization that spoken language is composed of a series of discrete speech sounds (phonemes) that are arranged in a particular sequence (Clark & Uhry, 1995). *Phonemic awareness* refers to the ability to discern and identify the smallest individual speech sounds or phonemes, whereas *phonological awareness* is a broader term that includes phonemes, as well as all types of larger elements of speech that can be assessed by asking the child to rhyme words or

count the number of syllables in a word. Both types of awareness involve the understanding that speech can be divided into sounds and these sounds can then be sequenced into a series to form syllables and words. In addition, working-memory abilities may influence some phonemic awareness tasks, such as phoneme-deletion tasks in which the person says a word while omitting a sound (e.g., say the word “nice,” without the /n/ sound) or phoneme-reversal tasks in which the person reorders the sounds in a word to make a new word (e.g., Say the word “tip.” Now say the sounds in the word “tip” backwards), since these tasks involve both storing and manipulating phonemes (Gathercole & Alloway, 2008; Savage, Lavers, & Pillay, 2007; Tunmer & Hoover, 1992).

Weaknesses in phonological processing play a critical role in dyslexia (Shaywitz, 2003; Willcutt, Pennington, Olson, Chhabildas, & Hulslander, 2005). While spoken language is natural and instinctive, print or written language is artificial and must be learned (Shaywitz, 2003). Brain mechanisms are in place to process the sounds of language automatically, but not the letters and words that make up print. Accordingly, these printed elements must link to something that is accepted by the neural machinery and has inherent meaning—the sounds of spoken language. To read, a child first must pull apart the spoken words into their individual sounds, link the letters to their appropriate sound (phonics), and then blend the sounds together. Thus, the awareness that spoken words come apart and the ability to notice and identify phonemes, these smallest elements of sound, allow the child to link letters to sound. In order to read, a child first must master what is referred to as “the alphabetic principle”; i.e., develop the awareness that the printed word has the same number and sequence of sounds as the spoken word. Phonemic awareness abilities have their primary impact on the development of phonics skills, or knowledge of the ways that letters represent the sounds in printed words (Torgesen & Mathes, 2000), as well as on encoding or spelling development (Bailet, 2001).

Reflecting the core phonological deficit, a range of downstream effects is observed in spoken as well as in written language (S. Shaywitz et al., 2008). Phonological processing is critical to both spoken and written language. While most attention has centered on print difficulties, the ability to notice, manipulate, and retrieve phonological elements also has an important function in speaking. For example, uttering a spoken word requires a two-step mechanism involving, first, semantic and then, phonological components (Levelt, Roelofs, & Meyer, 1999).

In dyslexia, it is the second step involving phonology that is affected (Hanly & Vandenberg, 2010). First, one must generate the concept of what one wants to communicate; this in turn triggers activation of the semantic or meaning-based representation of the word in the speaker's lexicon. However, in order to speak the word, once the concept and associated semantic form are activated, the lexical representations must be transformed into their phonological codes. To accomplish this, in the second step, the speaker accesses and retrieves the phonological representations (phonological codes) that link to the semantic structures, a necessary step in order to generate the articulatory (motor) patterns that are ultimately put into action by the articulatory muscles, resulting in the production of the spoken word.

In dyslexia, activation of the concept and its semantic representation proceeds smoothly; however, it is the second step, the transformation of the semantic (meaning) into the phonological (sound) code that is disrupted. A feedback mechanism enables the speaker to monitor his or her own speech and exercise some output control to correct errors. However, if the individual is anxious, as often is the case in dyslexia, word retrieval is further negatively affected. In fact, a considerable body of research indicates that anxiety disorders are frequently observed in individuals with dyslexia. Thus, higher levels of anxiety have been found in college students with dyslexia as compared to control college students, particularly in social situations and during interviews (Carroll & Iles, 2006). In adolescents, anxiety disorders were three times more prevalent in readers with dyslexia; in particular, social phobia and generalized anxiety disorder were both five times more prevalent among readers with dyslexia than among typical readers. In this study, many of the students with social phobia indicated that rather than have to talk in front of the class or make presentations, they would often skip classes or even accept lower grades (Goldston et al., 2007). More recently, the association between SLD and anxiety was further buttressed using meta-analysis, concluding that students with SLD had statistically significant increased scores on measures of anxiety (Nelson & Harwood, 2011).

As a consequence of this sound-based difficulty in accessing and retrieving the phonological codes, an individual with dyslexia, no matter how intelligent or well educated, may exhibit difficulties in word retrieval, so that his/her verbal output does not represent his/her abilities and knowledge. Thus,

it should not be surprising that problems with spoken language are often observed. These include late speaking, mispronunciations, difficulties with word retrieval, needing time to summon an oral response, and confusing words that sound alike, such as saying "recession" when the individual means to say "reception" (Faust, Dimitrovsky, & Shacht, 2003; Faust & Sharfstein-Friedman, 2003). Dyslexia is conceptualized as a "sea of strengths" in higher cognitive functions surrounding weaknesses in phonological awareness and fluent reading (Shaywitz, 2003). Thus, the same individual who struggles to retrieve words and reads slowly with effort may have great strengths in conceptual abilities, problem solving, verbal reasoning, the ability to grasp the big picture, and what has been referred to as creative or out-of-the-box thinking. Indeed, it is just these higher-level strengths that make it imperative for individuals who have dyslexia to receive the accommodations (e.g., extra time) they require in order to demonstrate their abilities (S. Shaywitz et al., 2008). When individuals have weaknesses in phonological awareness, interventions often focus on improving phonological awareness, accompanied by specific instruction in phoneme-grapheme relationships (phonics).

#### **VERBAL SHORT-TERM MEMORY**

In addition to phonologically related processes, memory-related processes also appear to contribute to dyslexia (Crews & D'Amato, 2009; Swanson, Zheng, & Jerman, 2009). Children with dyslexia have weaknesses in verbal short-term memory or the immediate serial recall of unrelated words (Kibby & Cohen, 2008; Steinbrink & Klatte, 2008). In a meta-analysis that included 43 studies between 1963 and 2006, Swanson et al. (2009) found that children with reading disabilities performed poorly on tasks that required non-word repetition as well as the immediate recall of letter, number, and word strings. A weakness in repeating nonsense words may indicate a problem in the overall quality of the phonological storage system, which would then relate to both phonological processing and word learning (Gathercole, 2006).

#### **ORTHOGRAPHIC AWARENESS**

Although difficulties in phonological processing are often described as the most common cause of reading disability, other cognitive and linguistic domains can also be involved (Friedmann & Lukov, 2008). For example, word recognition skill begins with phonological awareness, but then in skilled reading,

orthographic representations take on an increasingly important role (Perfetti, 2011). Some have suggested that, in addition to phonological awareness, orthographic awareness should be viewed as a unique factor in the assessment and diagnosis of developmental dyslexia (Badian, 2005; Mano & Osmon, 2008; Roberts & Mather, 1997). High-functioning college students with dyslexia make some use of phonological skills to spell familiar words, but they still have difficulty memorizing orthographic patterns and recalling spelling rules, which results in inconsistent spellings of irregular and less familiar words (Kemp, Parrila, & Kirby, 2009).

Whereas phonological processing addresses acquisition of the sound system, orthographic processing reflects one's knowledge of the spelling system and the relationships between the speech sounds and print. Orthographic processing permits a reader to access from memory a whole word unit, a letter cluster unit, or a component letter (Berninger, 1996). Because orthographic knowledge enables instant recognition of letter chunks or whole words, it is more related to measures of reading speed than to measures of reading accuracy (Georgiou, Parrila, Kirby, & Stephenson, 2008). Students with weaknesses in orthography have particular difficulties remembering letter sequences and reading and spelling words that contain irregular spelling patterns (e.g., "once"), some believe because they do not have mental images of words stored in memory or word-specific memory (Ehri, 2000). This ability to store the orthographic forms of words in memory may play a role in attaining fluency in reading (Reitsma, 1989), as it helps readers establish detailed visual or mental representations of words that then allow rapid access to these representations. Individuals who fail to develop appropriate representations in the phonological and semantic regions of the brain may struggle to read because the brain lacks the hierarchical connections required to make predictions based on visual stimuli and contextual cues (Price & Devlin, 2011). Later in the chapter, we discuss the neurobiological correlate of this process in a specific neural system—the word-form area.

Successful spelling involves the abilities to remember the position of each letter in the word and to recall the letters in the correct sequence. Knowledge of orthographic structure (the constraints of permissible letter sequences) is evidenced by the ability to place common letter strings in the correct order (e.g., the letters "ck" would be used to end a word, but not to begin a word). Although unexpected letters and irregular spelling patterns may be stored in these

representations, securing these images is more difficult than securing words that conform to common spelling patterns (Ehri, 2000). Even when accuracy improves for students with dyslexia, their reading remains effortful and slow even into late adolescence, and difficulties persist throughout adulthood (S. Shaywitz & Shaywitz, 2008).

In addition, students with weaknesses in orthography tend to regularize the element of the word that does not conform to a language's spelling rules. Their attempted spellings often violate the underlying rules of English spelling. Thus, they spell words the way they sound, rather than the way they look (e.g., spelling "houses" as "howssis"). Common methods for assessing orthographic awareness involve reading and spelling exception words and homophone choice tasks (e.g., Which is a flower?—*rows* or *rose*) (Barker, Torgesen, & Wagner, 1992; Stanovich, West, & Cunningham, 1991). Because the pronunciation leads to the same sounds, phonological mediation does not help one identify the correct spelling; the reader must consult the orthographic input lexicon to know which spelling is correct (Friedmann & Lukov, 2008). In addition, the speed of perception of letter, word, and word-like stimuli is an important component of visual word recognition (Mano & Osmon, 2008). In individuals with poor orthographic awareness, interventions often focus on mastering common spelling patterns, as well as increasing the rate of word perception.

#### RAPID AUTOMATIZED NAMING (RAN)

Naming speed, also known as rapid automatized naming (RAN), is another cognitive variable that appears to be related to reading difficulties (Denckla & Cutting, 1999). RAN is often measured by asking an individual to name a series of repeating randomly ordered colors, objects, letters, or digits, as quickly as possible. As with poor orthographic awareness, slow RAN performance seems to be more related to reading speed than reading accuracy (Georgiou et al., 2008). RAN is a good predictor of orthographic skills, but not untimed non-word reading (Abu-Hamour, 2009; Abu-Hamour, Urso, & Mather, 2012). Early on in reading development, RAN reflects both phonological and orthographic processing, but later on RAN primarily relates to orthographic processing and reading speed (Georgiou et al., 2008).

Bowers and Wolf (1993) hypothesized that slow RAN signifies disruption of the automatic processes that result in quick word recognition. Morris et al. (1998) described these individuals as having a "rate

deficit" because they were impaired on tasks requiring rapid serial naming but not on measures of phonological awareness. Bowers, Sunseth, and Golden (1999) concluded that their results give some support to the notion that (a) students with RAN impairments have less knowledge of orthographic patterns and are slower readers than students with poor phonemic awareness, and (b) orthographic pattern knowledge may depend, in part, on the processes tapped by naming speed. Further research has suggested that the significance of the relationship between RAN and word reading may be attributable to the fact that both require fast cross-modal matching of visual symbols and phonological codes, a process that is not measured by phonological awareness tasks (Vaessen, Gerretsen, & Blomert, 2009).

### **PROCESSING SPEED**

Processing speed is another important cognitive mediator and a correlate of reading failure in children and adults (Evans, Floyd, McGrew, & LeForge, 2002; Gregg, Coleman, Davis, Lindstrom, & Hartwig, 2006; Kail, 1991; Kail, Hall, & Caskey, 1999; Konold et al., 2003; Shanahan et al., 2006; Trainin & Swanson, 2005; Urso, 2008; Willcutt et al., 2005). In analyzing processing speed performance in a group of poor readers, Urso (2008) found that processing speed was a significant weakness in over one-third of the sample. Although less research has addressed processing speed, the impact of slow processing speed on reading performance appears to be most related to reading speed. Based on a cross-sectional study using structural equation modeling, processing speed has been suggested to have a direct effect on reading fluency that increases with each grade (Benson, 2007). However, given that this was a cross-sectional study, this finding needs to be replicated using longitudinal data.

Children with dyslexia have problems making reading-related skills automatic through practice. Their difficulty lies not just in decoding the words, but also in the rate and ease of decoding; their basic reading skills do not become effortless and automatic over time (Semrud-Clikeman, 2005; S. Shaywitz & Shaywitz, 2008). Processing speed may be related to the reading of words with irregular spelling patterns (e.g., "once"), but not to the reading of nonsense words that conform to English spelling patterns (e.g., "flib") (Abu-Hamour, 2009; Abu-Hamour et al., 2012). Poor performance on processing speed tasks could be attributable to several different factors, including slow motor speed, inefficiency of visual scanning, or weaknesses in attention.

Slow processing speed has also been described as a common characteristic of students with ADHD (Shanahan et al., 2006; Willcutt et al., 2005). In a large sample of 395 children with dyslexia and/or ADHD, Shanahan et al. found that slow processing speed was a shared cognitive risk factor for both disorders, but that children with dyslexia had greater impairments than did children with ADHD. Good evidence relates automaticity of reading to the development of the word-form area in the left occipito-temporal brain region; however, while processing speed may relate to automaticity of reading, the neurobiological evidence for this relationship is yet to be demonstrated. As described later in the chapter, readers with dyslexia exhibit an inefficiency of functioning in this region, suggesting that the inefficient functioning of the left occipito-temporal word-form area is the neural correlate of the lack of automaticity of reading in dyslexia.

### **ATTENTION**

Disruption of attentional mechanisms may also play an important role in reading and dyslexia (S. Shaywitz & Shaywitz, 2008). Although ADHD and dyslexia are distinct disorders, 15% to 40% of students with dyslexia also meet the criteria for ADHD (Bental & Tirosh, 2007; B. A. Shaywitz, Fletcher, & Shaywitz, 1995; Willcutt & Pennington, 2000). Although progress has been made, the neuropsychological profile for ADHD is not as well understood as the correlates of dyslexia (Willcutt et al., 2005). Results from preliminary studies suggest that pharmacotherapeutic agents used for the treatment of ADHD may also prove to be valuable for potentially new adjunct treatment options for dyslexia (S. Shaywitz & Shaywitz, 2008).

### ***Academic and Classroom Functioning***

Within the classroom, a teacher will note a range of difficulties in reading (e.g., misreading especially small function words and unfamiliar words, slow reading); spelling; the ability to master a foreign language; oral language (retrieving spoken words, lack of glibness); handwriting; and attention (Shaywitz 2003). The lack of reading fluency brings with it a need to read "manually" (a process consuming great effort), rather than automatically; the cost of such reading is a tremendous drain on the student's attentional resources. This is often observed in the classroom when struggling readers are asked to read quietly; they deplete their attentional resources as they struggle to decipher the print, and,

as a consequence, appear to be daydreaming or not attending to the assigned reading.

In contrast to these difficulties, and consistent with the unexpected nature of dyslexia, other cognitive abilities, including thinking, reasoning, vocabulary, and listening comprehension are intact, and in fact may even be superior. Intact higher-level abilities offer an explanation of why reading comprehension is often appreciably better than single-word reading accuracy and fluency in individuals with dyslexia (reviewed in Shaywitz, 2003). As children mature, compensation often occurs, resulting in relatively accurate, but not fluent, reading. Awareness of this developmental pattern is critically important for the diagnosis of dyslexia in older children, young adults, and beyond. The consequence is that older children with dyslexia may appear to perform reasonably well on an untimed test of word reading or decoding because these tests give credit for a response regardless of how long it takes the individual to pronounce the word or whether the person corrects his or her initial word reading errors. Accordingly, tests of reading fluency that measure how quickly and accurately individual words and passages are read and tests assessing reading rate are essential assessment components

for an accurate diagnosis of dyslexia (Mather & Wendling, 2012; S. Shaywitz et al., 2008).

In summary, the essence of the cognitive-psychological perspective is the development of a thorough case study that explores an individual's unique learning profile. The elements of the cognitive and psychological strengths and weaknesses forming the individual's learning profile coalesce to explain that individual's reading difficulties, as well as his or her academic functioning in classroom settings. Together, the results of the cognitive-psychological assessment and the clinical history provide the elements for the diagnosis of dyslexia. Dyslexia is a clinical diagnosis, best made by an experienced clinician who has taken a careful history, observed the individual speaking and reading, and administered a battery of tests that assess cognitive abilities; academic skills including reading accuracy, fluency, and comprehension, spelling, mathematics (which is often average or high); and language skills, particularly phonological processing (Marzola & Shepherd, 2005; Shaywitz, 2003). The uneven peaks and valleys of cognitive and academic functioning contribute to the clinical picture of dyslexia: a weakness in phonologically based or orthographically based skills in the

**Table 30.1 Assessment for Dyslexia\***

**The School-Age Child: Grade 2 and beyond**

**1. History:\*\* Ask about weaknesses in:**

*Spoken language:*

History of delayed speech

Mispronunciations of words

Lack of verbal fluency, hesitations before responding, lack of glibness

Word retrieval difficulties

Needing time to summon an oral response when questioned

*Reading:*

Difficulty learning letters and learning to associate letters with their sounds

Slow progress in acquiring reading skills

Trouble reading (pronouncing) new or unfamiliar words that must be sounded out

Omitting parts of words when reading

Confusing words of similar appearance (e.g. *who* and *how*)

Needing substantial repetition and review to develop a sight-reading vocabulary

Relying on use of context to discern the meaning of what is read

*(continued)*

**Table 30.1 (Continued)**

Disproportionately poor performance on multiple-choice tests
Reading slowly with much effort—even with improvement in reading accuracy
Having good knowledge of the material but nevertheless unable to finish tests on time
Fear of reading out loud
Avoiding reading
Messy and illegible handwriting
Spelling difficulties
Difficulty learning foreign languages
Increasing anxiety related to testing situations and to speaking on demand, reading and spelling
<b><i>History: Ask about strengths in higher-level conceptualization and abstract, out-of-the box thinking</i></b>
Strong ability to conceptualize, excellent reasoning skills
Strong ability to grasp the “big picture”
Listening comprehension that is much higher than reading comprehension
Excellence in areas not dependent on reading—visual arts, conceptual (versus fact-driven) subjects such as biology, philosophy, social studies, neuroscience, and creative writing (ignoring spelling errors and focusing on content)
<b><i>2. Observation of individual speaking and reading aloud</i></b>
Spoken language not fluent, hesitations, mispronunciations, not glib
Reading aloud—mispronunciations, omission and insertion of words, pauses, labored and choppy, poor prosody (phrasing and expression)
<b><i>3. Cognitive and academic testing</i></b>
Intelligence and linguistic abilities—pattern of peaks and valleys: strengths in abstract thinking; reasoning, vocabulary; information. Indications of ability to think and reason above ability to read accurately or fluently, reflecting the unexpected nature of dyslexia.
Weaknesses in oral language (e.g., phonological processing) and written language (orthographic processing, e.g., spelling)
<b><i>Weaknesses in:</i></b>
Basic reading skills: word identification; word attack (nonsense words)
Reading fluency: real and nonsense words
Reading passages out loud
Reading rate in connected text
Reading comprehension with and without time constraints
Spelling: real and nonsense words
Assessment for potential strengths (e.g., math problem-solving; reasoning; listening comprehension).

\*The testing and interpretation will vary according to the age and education of the person. The approach above is relevant to school-age children in Grade 2 and higher. (Symptoms of spoken-language difficulties may be present in preschool children, and reading accuracy may significantly improve in young adults and adults while substantial problems in reading fluency persist.)

\*\*Adapted with permission from © S. Shaywitz, “Overcoming Dyslexia” (Knopf, 2003)

context of stronger cognitive and academic skills in non-reading-related areas. Dyslexia is more than simply a score on a reading test. Accordingly, the focus of a cognitive-psychological approach is not solely on test scores, but rather on understanding the unique learning profile, history, characteristics, and circumstances of an individual so that instruction can be tailored to meet his or her individual needs. Table 30.1 provides an overview of questions and characteristics to consider in the assessment of dyslexia.

Exceptionally bright and capable students with dyslexia, who are sometimes referred to as being “twice exceptional,” may fail to meet current school-based criteria if a rigid psychometric approach is taken that ignores that individual’s functioning in a full range of psychometric and clinical areas. In order to make an accurate diagnosis, an evaluator must, when comparing higher-level cognitive functions to reading related difficulties such as phonological processing and reading fluency, keep in mind that dyslexia reflects an *unexpected* difficulty within the individual. As such, the evaluator must consider the person’s special circumstances, unique abilities, educational history, and outstanding areas of competence (Mather & Gerner, 2009; S. Shaywitz & Shaywitz, 2012). Psychological and cognitive tests are diagnostic tools that help people understand and explain the reasons for an individual’s reading difficulties, the types of reading difficulties present, as well as the severity of the disability. These measures can help us understand the reasons why a student is struggling (Mather & Kaufman, 2006). At the same time, such measures are only proxies, attempts to reflect cognitive processes; they take second place to the reality of life experiences.

A variety of cognitive skills can be implicated in the acquisition of reading skills (Bell et al., 2003). An analysis of the assessment results of an individual often leads to an increased understanding of the cause or causes of the reading disability, as well as providing pertinent information related to treatment and the need for accommodations. Over seventy years ago, Stanger and Donohue (1937) made the following observation: “If these tests will give us a basis from which we can start to understand a child’s difficulties, they will have justified the time spent on them. Anything which helps educators or parents to *understand* any phase of development or lack of development is of immeasurable value” (p. 189).

Additionally, after careful consideration of all factors, the evaluator attempts to select the most appropriate accommodations and interventions for the individual. (See Mather & Wendling, 2012; and

Shaywitz, 2003, for descriptions of effective interventions for the treatment of dyslexia.) Clearly, the primary goal of an assessment is to enhance intervention (Shaywitz, 2003). Over seven decades ago, Monroe (1935) observed: “After proper diagnosis of the child’s difficulty, remedial work, if carried out consistently, is usually highly successful. The foundation of remedial success is careful observation of the pupil, with thorough diagnostic analysis, careful tabulation and study of his errors, and ingenuity in applying specific treatment” (p. 228). Identifying cognitive integrities, as well as specific needs, is a prerequisite of intervention efficacy, as is having a deep understanding of the condition, such as dyslexia, that is impacting reading development (Hale et al., 2004). In the case of adults who have a long-standing diagnosis of dyslexia and who have a good understanding of their learning profile, as well as their need for accommodations, a new or re-evaluation should not be necessary or required. Dyslexia is established as a persistent chronic condition characterized by a lack of fluency and slow reading, poor spelling, and word retrieval difficulties that persist throughout the lifespan.

## Medical/Neurobiological Models

The term *medical model* is often mentioned in reference to education. Unfortunately, the term is sometimes used pejoratively, suggesting that somehow use of this model is trying to “medicalize” what is primarily an educational concern. In our view, “medical model” refers to an approach that considers the many facets of an entity in a systematic, organized manner, including its definition, prevalence, course, etiology, symptoms, signs, diagnosis, intervention, and management. Importantly, the medical model is a diagnostic one that synthesizes all available information—neurobiological, clinical, and assessment—to arrive at a cohesive, integrated, big-picture understanding of an individual’s symptoms. A diagnosis provides much more than a listing of psychological processes; a diagnosis provides critical information about “the whole.” Awareness of the diagnosis provides both the individual and treaters, including educators, a link to the large body of knowledge relating to that diagnosis, including its underlying neurobiological mechanisms, prevalence, developmental course, outcome, and effective treatments. Some of these issues were examined above within the cognitive-psychological model. Here we will focus on one very vital and specific component of the medical model, the rapidly accumulating and converging evidence demonstrating the neural systems implicated in dyslexia. Perhaps most importantly, the

information emerging from functional brain imaging has the unique power to provide the critical glue allowing synthesis of the cognitive-psychological and the medical model into a unified whole.

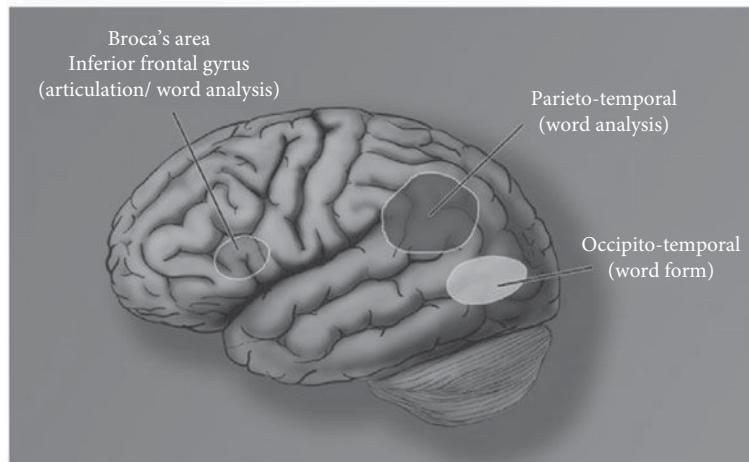

### Neural Systems for Reading

Neural systems for reading were demonstrated more than a century ago, with descriptions of adults who (usually due to a stroke) suddenly lost their ability to read, a condition termed *acquired alexia* (Dejerine, 1891, 1892). Within the last two decades, the development of functional brain imaging, particularly functional magnetic resonance imaging (fMRI), has provided the most consistent and replicable data on the localization of the neural systems for reading and how they differ in readers with dyslexia. fMRI is non-invasive and safe and can be used repeatedly, properties that make it ideal for studying people, especially children. The signal used to construct MRI images derives from the determination of the blood-oxygen-level-dependent (BOLD) response; the increase in BOLD signal in brain regions that are activated by a stimulus or task results from the combined effects of increases in the tissue blood flow, volume, and oxygenation. On cognitive tasks, BOLD changes are typically in the order of 1%–5%. Details of fMRI are reviewed in several sources (e.g., Anderson & Gore, 1997; Frackowiak et al., 2004; Jezzard, Matthews, & Smith, 2001).

Reflecting the language basis for reading and dyslexia, three critical neural systems are localized in the left hemisphere: two left-hemisphere posterior systems, one around the parieto-temporal region and another in the left occipito-temporal region; and an anterior system around the inferior frontal gyrus (Broca's area) (Brambati et al., 2006; Kornbichler et al., 2006; Nakamura, Dehaene, Jobert, Le Bihan, & Kouider, 2007; Nakamura et al., 2006; Paulesu et al., 2001; Rumsey et al., 1992; Seki et al., 2001; B. Shaywitz et al., 2002; S. Shaywitz et al., 1998; S. Shaywitz et al., 2003). (See Figure 30.2.)

Many brain imaging studies in patients with developmental dyslexia (see below) have documented the importance of the parieto-temporal system in reading, properties involving word analysis, operating on individual units of words (e.g., phonemes). The parieto-temporal system encompasses portions of the supramarginal gyrus in the inferior parietal lobule, portions of the posterior aspect of the superior temporal gyrus, and the angular gyrus in the parietal lobe. The second posterior reading system is localized in the occipito-temporal area, which Cohen and Dehaene have termed the *visual word-form area* (VWFA; Cohen et al., 2000; Dehaene, Cohen, Sigman, & Vinckier, 2005; Dehaene et al., 2001; Gaillard et al., 2006; Vinckier et al., 2007) and their colleagues refer to as the *ventral occipito-temporal cortex* [(reviewed in Price & Devlin, 2011)]. Still another reading-related neural circuit involves an anterior

### Neural Systems for Reading

**Figure 30.2 Neural systems for reading.** This figure illustrates three neural systems for reading on the surface of the left hemisphere: an anterior system in the region of the inferior frontal gyrus (Broca's area) believed to serve articulation and word analysis; and two posterior systems, one in the parieto-temporal region believed to serve word analysis, and a second in the occipito-temporal region (termed the “word-form area”) believed to serve for the rapid, automatic, fluent identification of words. (Reprinted from S. Shaywitz, 2003, with permission.)

system in the inferior frontal gyrus (Broca's area), a system that has long been associated with articulation and also serves an important function in word analysis (Fiez & Peterson, 1998; Frackowiak et al., 2004). In recent studies inspired by Levelt's two-step model of language (Levelt et al., 1999), Heim and his colleagues (Heim et al., 2008) have further examined the function of two architectonic regions of the inferior frontal gyrus, BA 44 and BA 45.

### ***The Reading Systems in Dyslexia***

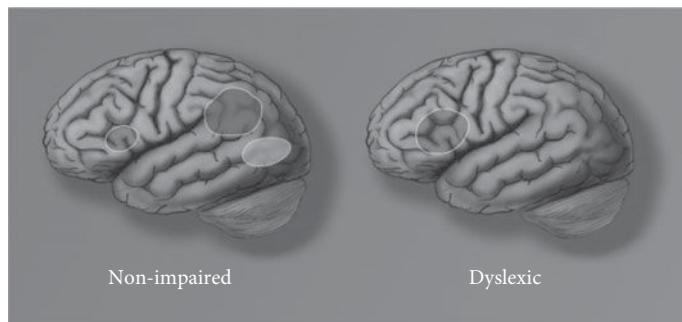

Converging evidence from many laboratories around the world has demonstrated what has been termed "a neural signature for dyslexia"; that is, a disruption of posterior reading systems during reading real words and pseudowords, and often what has been considered a compensatory over-activation in other parts of the reading system (see Figure 30.3). This evidence from fMRI has for the first time made visible what previously was a hidden disability. In a study from our own research group, we (B. Shaywitz et al., 2002) used fMRI to study 144 children, approximately half of whom had dyslexia and half of whom were typical readers. The children were asked to read pseudowords and real words. Our results indicated significantly greater activation in typical readers than in readers with dyslexia during phonological analysis in the posterior reading systems.

Other studies report similar findings in German and Italian readers with dyslexia. For example, Kronbichler et al. (2006) used sentences to study dysfluent compared to fluent German readers. Individuals with dyslexia demonstrated reduced activation in the

left supramarginal gyrus (parieto-temporal system) and left occipito-temporal system with compensatory activation in left inferior frontal area. Brambati et al. (2006), studying Italian adults with dyslexia as well as a family history of dyslexia, found reduced activation in posterior reading systems, paralleling results in English-speaking and German-speaking readers with dyslexia. Studies in Chinese readers with dyslexia show some differences, though the systems are generally the same. For example, in both typical Chinese readers and Chinese readers with dyslexia, there is more involvement of the left-middle frontal, superior parietal, and bilateral posterior visual regions and less for the inferior frontal and superior parietal regions (Perfetti, 2011). Thus, these data from fMRI studies in children with dyslexia reported by our group converge with reports from many investigators using fMRI that show a failure of left-hemisphere posterior brain systems to function properly during reading, particularly the systems in the left-hemisphere occipito-temporal region. (See Peterson & Pennington, 2012; Price & Mechelli, 2005; Richlan, Kronbichler, & Wimmer, 2009; 2011; S. Shaywitz & Shaywitz, 2005, for reviews.)

Recent findings indicate differences between readers with dyslexia and typical readers in connectivity of the visual word-form area (VWFA) and other components of the reading system. In typical readers, the VWFA was connected to distant and as well as adjacent reading systems in the left and right hemispheres. In contrast, functional connectivity in readers with dyslexia was significantly reduced to primarily adjacent areas in the left VWFA (van der Mark et al., 2011).

### **Neural Signature for Dyslexia: Disruption of Posterior Reading Systems**

**Figure 30.3 Neural signature for dyslexia.** This schematic view depicts the left-hemisphere brain systems in both non-impaired readers (left) and readers with dyslexia (right). In non-impaired readers, the three systems are shown in Figure 30.2. In readers with dyslexia, the anterior system is slightly over-activated compared with systems of non-impaired readers; in contrast, the two posterior systems are under-activated. This pattern of under-activation in left-posterior reading systems is referred to as the "neural signature for dyslexia." (Reprinted from S. Shaywitz, 2003, with permission.)

Although readers with dyslexia exhibit an inefficiency of functioning in the left occipito-temporal word-form area, they appear to develop ancillary systems in other brain regions (B. Shaywitz et al., 2002). While these ancillary systems allow the reader to read accurately, readers with dyslexia continue to read dysfluently. Inefficient functioning in this essential system for skilled reading has very important practical implications for individuals with dyslexia—it provides the neurobiological evidence for the biological necessity for the accommodation of additional time on high-stakes tests (see Figure 30.4).

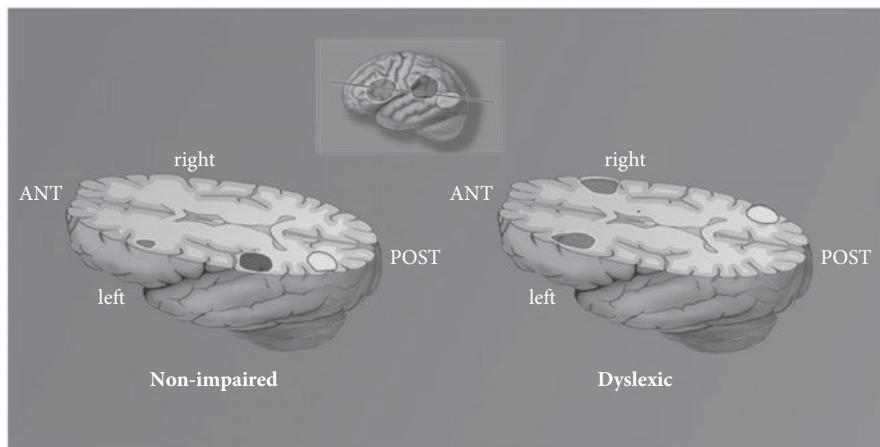

#### DEVELOPMENT OF READING SYSTEMS AND THE OCCIPITO-TEMPORAL READING SYSTEM

We examined just how the neural systems for reading develop in typical readers compared to those with dyslexia. We used fMRI to study age-related changes in reading in a cross-sectional study of 232 children (B. Shaywitz et al., 2007), comprising a group with dyslexia and a group of typical readers as they read pseudowords. Findings indicated that the neural systems for reading that develop with age in non-impaired readers differ from those that develop in readers with dyslexia. These findings noted below now permit a more fine-grained analysis of the word-form area by identifying two systems within the greater word-form area. Specifically, a system for reading that develops with age in readers with dyslexia differs from that in non-impaired readers,

primarily to being a more *posterior and medial system*, rather than a more *anterior and lateral system* within the left occipito-temporal area.

Interestingly, this difference in activation patterns between the two groups of readers has parallels to reported brain activation differences observed during reading of two Japanese writing systems: *Kana* and *Kanji*. Consideration of the mechanisms used for reading *Kanji* compared to *Kana* provides insights into potentially different mechanisms that develop with age in children with dyslexia as contrasted to non-impaired readers. Left anterior lateral occipito-temporal activation, similar to that seen in non-impaired readers, occurred during reading *Kana* (Nakamura, Dehaene, Jobert, Le Bihan, & Kouider, 2005). *Kana* script employs symbols that are linked to the sound or phonological element (comparable to English and other alphabetic scripts). In *Kana* and in alphabetic scripts, children initially learn to read words by learning how letters or symbols and sounds are linked, and then, over time, these linkages are integrated and permanently instantiated as a word form. In contrast, posterior medial occipito-temporal activation, comparable to that observed in readers with dyslexia, was noted during reading of *Kanji* script (Nakamura et al., 2005). *Kanji* script uses ideographs where each character must be memorized, suggesting that the posterior medial occipito-temporal system functions as a memory-based system.

#### Neural Basis for Extended Time

**Figure 30.4 Neural basis for the requirement for extended time for students with dyslexia on high-stakes testing.** This image shows a cutaway view of the brain so that both left and right hemispheres are visible. Non-impaired readers (*left panel*) activate three left-hemisphere neural systems for reading, an anterior system and two posterior systems. Readers with dyslexia (*right panel*) have inefficient functioning in the left-hemisphere posterior neural systems for reading but compensate by developing anterior systems in left and right hemispheres and the posterior homologue of the visual word-form area in the right hemisphere. This compensates for accuracy, but fluent reading remains impaired. (Reprinted from S. Shaywitz, 2003, with permission.)

Perhaps as children with dyslexia mature, this posterior medial system supports memorization rather than the progressive sound-symbol linkages observed in non-impaired readers. These findings are consonant with other evidence that readers with dyslexia are unable to make good use of sound-symbol linkages as they mature and instead come to rely on memorized words as they enter adolescence and adult life (Bruck, 1992; S. Shaywitz et al., 1999). Thus, persistently poor adult readers read words by memorization so that they are able to read familiar words but have difficulty reading unfamiliar words (S. Shaywitz et al., 2003). Furthermore, these data may help explain and confirm what many clinicians have observed; that is, the reliance by readers with dyslexia on memorization rather than phonological analysis in reading. This represents an example of neurobiological, cognitive-psychological, and educational findings and observations coalescing.

These results support and now extend previous findings to indicate that the system responsible for the fluent, automatic integration of letters and sounds, the word-form area in the anterior lateral occipito-temporal system, is the neural circuit that develops with age in typical readers. Just how the VWFA functions is the subject of intense investigation. Price and Devlin (2011), in what they term “the Interactive Account,” suggest that this region acts to integrate phonological, orthographic, and semantic information, though some have suggested that visual familiarity, phonological processing, and semantic processing all make significant but different contributions to activation of the word-form region (Cohen et al., 2003; Cohen & Dehaene, 2004; Henry et al., 2005; Johnson & Rayner, 2007; Xue, Chen, Jin, & Dong, 2006). Readers with dyslexia who struggle to read new or unfamiliar words come to rely on an alternate system, the posterior medial occipito-temporal system that functions via memory networks.

#### IMPLICATIONS OF BRAIN IMAGING STUDIES

The brain imaging studies reviewed above provide neurobiological evidence that illuminates and clarifies our current understanding of the nature of dyslexia and its treatment. For example, brain imaging has taken dyslexia from what had previously been considered a hidden disability to one that is visible—as noted, these findings of a disruption in left-hemisphere posterior reading systems are often referred to as a “neural signature for dyslexia.” These results should eliminate any speculation of whether or not dyslexia is a real or a “valid” diagnosis; even more so, these cutting-edge

converging data from imaging laboratories worldwide should encourage the use of the word *dyslexia*, as it has meaning and relevance at all levels, including the basic neural architecture essential for fluent reading and its disruption in struggling readers. As noted above, these findings, too, are universal, having been demonstrated in not only readers of English, but in readers of Italian, French, and German (Brambati et al., 2006; Kronbichler et al., 2006; Paulesu et al., 2001) and with similar findings in readers of logographic languages as well. In addition, the disruption of the neural systems for reading is found in younger and older readers; providing strong evidence for the persistence of reading difficulties, particularly the lack of fluency and with it, slow reading, throughout life. Here, an added implication is that past high school or the early years of post-secondary schooling, further assessment should not be needed to confirm the diagnosis or the need for accommodations.

#### Educational Models

Since the early descriptions of dyslexia (Morgan, 1896), a large body of research has shed much light on the nature, expression, and ontogeny of dyslexia, as well as on evidence-based approaches to treatment. The challenge is to reconcile this scientific knowledge with the constraints of educational settings. The goal is to honor the science and to translate it into a framework that will be practical and applicable in an educational setting with the primary objective of ensuring that struggling readers who require and would benefit from intervention are not overlooked. How can this be accomplished? Consistent with research and based on the fundamental concept of an unexpected difficulty in reading characterizing dyslexia, the discrepancy model—a discrepancy between cognitive ability and reading achievement—was applied to help determine if students had dyslexia and required educational intervention. Under IDEA 2004, in addition to an ability-achievement discrepancy, two alternative approaches have been proposed as potential methodologies for dyslexia identification: response to intervention (RTI) and alternative research-based methodologies (typically defined as a pattern of strengths and weaknesses [PSW] approach, described earlier).

#### *Unexpected Nature of Dyslexia: Ability-Achievement Discrepancy*

The purpose of the ability-achievement discrepancy in dyslexia diagnosis is to demonstrate whether

a person's poor reading performance is unexpected in relationship to an estimate of cognitive ability. Although the concept is fundamental to SLD, the challenge becomes how to operationalize this discrepancy (S. Shaywitz et al., 2008). Ever since its incorporation in 1975 in PL 94-142, concern and dissatisfaction have been expressed regarding the use of a mathematical formula as the sole diagnostic criterion for SLD (e.g., Aaron, 1997; Bateman, 1992; Lyon, 1995; Mather & Healey, 1990; Stanovich, 1991). For the last three decades, the field seemingly has been focused more on developing specific mathematical formulae for SLD identification, by comparing intelligence and achievement test scores, rather than on the underlying concept of an unexpected difficulty in reading which was what the discrepancy was intended to represent. This rigid emphasis on global test scores and formulae often resulted in decreased attention to a careful analysis of both qualitative and quantitative information. Some have argued that focusing assessment on this type of discrepancy alone is too narrow, does not necessarily lead to instructional recommendations, and ignores the cognitive and linguistic abilities underlying academic achievement (Mather & Gregg, 2006; Semrud-Clikeman, 2005). In addition, the size of the required discrepancy has varied among states, as well as among school districts within states. Thus, a child might be identified as having an SRD in one school district, but not in another, depending upon the state or local guidelines or the personal philosophy of an independent evaluator (Berninger, 1996). These criticisms, however, are directed to *how* the discrepancy has been operationalized but *not* to the construct of unexpected underachievement or the use of an ability-achievement discrepancy as one component of an overall assessment that considers a person's history, observes the person speaking and reading aloud, and reviews his or her unique cognitive-psychological profile. This, once again, reinforces the diagnosis of dyslexia as a clinical diagnosis. While tests are helpful, they are only proxies for the real-life experiences and abilities and weaknesses of the person. Because this point is so often overlooked and lost sight of, we emphasize that we are talking about individuals and not isolated numbers. Thus, we reiterate, dyslexia is a clinical diagnosis, based on clinical judgement, made by an experienced clinician who considers both the individual's history and symptoms and his/her learning profile, including cognitive and achievement abilities that may point to an unexpected difficulty in reading, as well as the reasons for this difficulty.

Thus, a major criticism associated with use of the ability-achievement discrepancy has been the focus on various formulae as the key to eligibility for special services, and not the construct itself. As noted by Willis and Dumont (2002), the determination of a disability should be far more than "...an exercise in arithmetic" (p. 173), nor should students who truly have SRD be denied services "...simply because of the results of a statistical exercise" (Dumont, Willis, & McBride, 2001, p. 13).

In addition, the use of an ability-achievement discrepancy may reduce the chances of early reading intervention because the child had to fall behind his or her expected reading achievement before he or she would be eligible for services. As a result, identification was often delayed and services were denied until the requisite discrepancy had developed, resulting in what has been described as a "wait-to-fail" approach. By the time a child was identified, he or she was often far behind peers in reading skill. So, for the most part, concerns focused on the mechanics—that is, how the discrepancy or unexpected condition was to be operationalized—as well as on the delay of identification of children in the first years of school. On the other hand, accumulating empirical evidence supports the fundamental concept of dyslexia as an unexpected difficulty in reading, and the use of a discrepancy as one key diagnostic element to demonstrate unexpected reading difficulty.

As noted above, for the first time, strong empirical evidence demonstrates that differential relationships exist between IQ and reading in groups of typical readers versus readers with dyslexia. Moreover, these differences go directly to the definition of dyslexia as an unexpected difficulty in reading as typically operationalized as an ability-achievement discrepancy. Whereas cognition and reading are dynamically linked in good readers, they are uncoupled in readers with dyslexia, so that individuals with high intelligence, for example, may demonstrate poor reading, which in turn, in assessment, is operationalized as an ability-achievement discrepancy (Ferrer et al., 2010). These new data provide a strong scientific basis and validation for use of an ability-achievement discrepancy to help identify children who have dyslexia and argue strongly for its importance and maintenance as a component of the assessment of a child for the presence of a dyslexia. Particularly for bright or gifted children, the ability-achievement discrepancy signals the unexpected underachievement of children who appear to be reading on par with their classmates but are underachieving in

relation to their academic potential and intellect. For younger children, in kindergarten through the second grade, a discrepancy may not be present, because many children have not fallen behind sufficiently to reveal a disparity between their ability and achievement (S. Shaywitz et al., 2008). Here, as elsewhere, it is important to note that, for the initial identification of such children, it is critical to consider the whole child, which requires a synthesis of the child's history, observation of the child speaking and reading out loud, and the results of a cognitive-psychological assessment administered by an individual who has a contemporary understanding of dyslexia. Given that an ability-achievement discrepancy may not be present in some young children who have dyslexia, it should not be used as the sole diagnostic criterion. In addition, cases exist where the lack of reading lowers performance on measures of knowledge and vocabulary, and/or where the processing or attentional problems (e.g., slow processing speed) lower the overall ability score, so that a discrepancy does not exist. In contrast, longitudinal data indicate that those students who have dyslexia and have higher ability may actually maintain and even increase their ability scores, including their scores on subtests measuring, for example, vocabulary. Such students may catch up in their reading comprehension scores, but they continue to be slow, dysfluent readers (Shaywitz, 2003; S. Shaywitz et al., 2003).

Thus, if present, an ability-achievement discrepancy is helpful in demonstrating an unexpected difficulty in reading and should continue to be used as one component of the assessment for the determination and diagnosis of dyslexia. These new results of an uncoupling of IQ and reading in children with dyslexia are in addition to other empirical evidence demonstrating that IQ is important in the consideration of the existence of a SLD. For example, after reviewing major syntheses of the literature, Swanson (2008) noted: "My point in reviewing these major syntheses of the literature is to suggest that removing IQ as an aptitude measure in classifying children as LD, especially, Verbal IQ, from assessment procedures is not uniformly supported by the literature" (p. 36). This statement counters the critics who argue for the removal of IQ from such diagnostic procedures and to indicate that "...intelligence mediates responsiveness to intervention in reading instruction" (Reynolds & Shaywitz, 2009). Continuing, Swanson (2008) notes: "The obvious implication is that IQ does have relevance to any policy definitions of LD" (p. 37).

With the reauthorization of IDEA 2004, the mandate of an ability-achievement discrepancy was removed (while still permitting it as an option), potentially providing more flexibility in identification procedures, but at the same time creating a new set of issues and concerns regarding SLD identification procedures. Although the use of a discrepancy procedure is still permitted under federal law, some states have passed guidelines that do not allow a discrepancy model to be used at all (Berkeley, Bender, Peaster, & Saunders, 2009). This is unfortunate because it ignores the science and, even more important, ignores the bright student with dyslexia. As discussed, the concept of ability-achievement discrepancy is related to a major criterion that is a marker for SLD identification—that is, the concept of "unexpected" underachievement. In many cases, measures of cognitive ability can help evaluators determine students' "potential" for academic success and identify those with unexpectedly low achievement levels relative to their abilities. Such discrepancies strongly suggest the existence of SLD, particularly, as children progress in school (Kavale & Spaulding, 2008).

A suggested potential replacement is what has been referred to as response-to-intervention, an approach many consider to be a premature adoption of a large-scale change without the requisite scientific data and evidence of effectiveness. We note especially the lack of large-scale studies supporting its procedures or efficacy, and its inherent structural flaws that may only result in significant groups of struggling readers' failing to be identified.

### **Response-to-Intervention**

As one possible alternative to the ability-achievement discrepancy, IDEA 2004 allows states to permit a process that theoretically examines whether or not a student responds to scientific, research-based interventions as *part* of the SLD evaluation procedure. This process is most often referred to as response-to-intervention (RTI). In principle, RTI involves the systematic use of data-based decision-making to identify struggling readers within a school and then provide a series of more intensive interventions for those in need (Burns & Van Der Heyden, 2007). Many questions, issues, and concerns, however, have been raised regarding the use and implementation of RTI (Barth et al., 2008; Berninger, O'Donnell, & Holdnack, 2008; Feifer, 2008; Franzen, 2008; Johns & Kauffmann, 2009; Kavale, 2005; Kavale, Holdnack, & Mostert, 2005; Kavale, Kauffman, Bachmeier, & Lefever, 2008;

McKenzie, 2009; Pass & Dean, 2008; Reynolds, 2008; Reynolds & Shaywitz, 2009; Schatschneider, Wagner, & Crawford, 2008; Speece & Walker, 2007; Suhr, 2008; Vaughn & Fuchs, 2003).

When viewed in the context of dyslexia evaluations, RTI has serious shortcomings as a means of diagnosis or determination of a disability. If followed to its ultimate conclusion, the approach and definition embedded in RTI have the strong probability of eliminating the basic concept of SLD as it was intended, as it is empirically supported, and as it is currently understood. This would be extraordinarily unfortunate, particularly since so much progress has been made in neuroscience in understanding and validating dyslexia.

The RTI approach fosters the dangerous concept of relativity of a disability in the context of the individual classroom as opposed to the long-accepted concept of a disability as a neuro-psychological condition residing *within* the individual. This fundamentally alters the concept of disability at its very roots. The RTI model focuses on the failure of a child–school interaction that is complex and modified by the overall achievement level of an individual classroom that will vary within schools and across schools. Consequently, a child may be identified by RTI in one classroom but not be found to require intervention in the classroom next door, depending on the make-up of each class. This approach represents a fundamental alteration and cuts out the very roots basic to the concept of dyslexia as an unexpected difficulty in learning to read that is intrinsic to the child. As an approach to diagnosis, RTI does not have proven value as either a rule-out or a rule-in process for a disability. Simply stated, a student who is not identified as having dyslexia through the RTI procedure, especially if he or she is above the classmates in ability or achievement, may have a reading disability. Conversely, one who fails in RTI may or may not have a reading disability, and the nature of the disability, when one is present, is unknown, following a failed RTI. A failed RTI is neither a necessary nor a sufficient condition for determination of the presence or absence of dyslexia. Whereas it is intuitively appealing to argue that RTI is a strong process for ruling out a disability, RTI, in its relativistic form for comparisons, cannot be applied accurately even in this manner. More unfortunately, it is becoming the sole or major criterion for the identification of an SLD. In fact, the regulations appear more concerned with the provision of adequate instruction, rather than accurate SLD diagnosis leading to effective instruction (Kavale & Spaulding, 2008). IDEA

2004 does not provide diagnostic criteria for SLD, but instead focuses on the issue of special education eligibility (Berninger & Wolf, 2009). RTI should not be viewed as a method for diagnosing dyslexia, but rather as a potential school-wide prevention model designed to provide early intervention and potentially reduce the number of children who are struggling to learn to read—a notion that awaits empirical support. An added concern is that RTI is a very large non-empirically supported experiment to apply on a national scale to tens of thousands of students.

One more serious concern is that RTI ignores bright struggling readers in the identification process. In the RTI process itself, consider the impact of so-called peer comparison to classmates if a specific child is highly intelligent or even gifted. What if such a child is in a class of “peers” who are functioning at lower cognitive levels? Such a bright student might be struggling and functioning well below his or her own capabilities, but at an absolute level that is comparable to the class average of his or her less-able peers. That struggling reader would be entirely invisible and overlooked in an RTI process. Within the RTI process, such students would never be detected, much less referred for a full evaluation of their cognitive and psychological processing abilities. Most critically, such struggling readers would not receive helpful interventions or accommodations, “despite the fact that their relative deficit in a particular domain could cause severe psychological distress as well as unexpected underachievement” (Boada, Riddle, & Pennington, 2008, p. 185) which could be ameliorated through interventions and accommodations. In fact, often the only way such struggling readers are identified is through a complete, comprehensive assessment in which their history, cognitive abilities, and psychological processes are evaluated. The data clearly show these bright students, although reading at higher levels, still are performing below their ability and share many qualities (e.g., phonological deficits) with lower-functioning struggling readers (Hoskyn & Swanson, 2000; Stuebing et al., 2002). It would be no fairer to leave out these bright struggling readers than it would be to leave out their lower-functioning classmates.

## Conclusion

Time is of the essence. It is critical to identify dyslexia early and accurately. This means getting a careful synthesis of the individual’s history, observing the individual’s speaking and reading, and analyzing the

results of an assessment of cognitive and academic abilities. To accurately diagnose dyslexia requires first and foremost the awareness that dyslexia represents an unexpected difficulty within the individual, together with the knowledge of the basic underlying difficulties of getting to the sounds of spoken words, and the resultant symptoms. Identification of that individual's cognitive abilities along with his or her strengths and weaknesses, together with associated difficulties such as anxiety, will help ensure accurate diagnosis followed by effective interventions and accommodations. To accomplish this goal, the assessment of a dyslexia requires an individualized approach, not just the use of group-based assessments. If we forego individualization in assessment, the essence of special education is lost and "the SLD category becomes the convenient home for those who otherwise might be left behind, something that perverts the category and is consistent only with the fantasy world of NCLB" (Kavale et al., 2008, p. 141). Students with disabilities will not disappear, but if they are not identified, their rights certainly will (Johns & Kauffman, 2009).

The ultimate goal of an assessment is to provide better services to children in need (Hooper, 1996). To accomplish this goal, we need competent evaluators who understand and can identify individuals who have dyslexia. An accurate diagnosis requires a deep understanding of the cognitive-psychological, neurobiological-medical, and educational factors underlying dyslexia. We want to emphasize that dyslexia is real—it exists, and thus, it not only makes sense but is imperative for evaluators to diagnose this disability. Without specific diagnoses, we have no way of talking about problems or solutions (Johns & Kauffman, 2009). Dyslexia needs to be accurately diagnosed. To not do so would be an injustice to the affected individuals. In discussing his own realization that he had dyslexia, Schultz (2011), a Pulitzer prize-winning poet, reflected: "My ignorance of my dyslexia only intensified my sense of isolation and hopelessness. Ignorance is perhaps the most painful aspect of a learning disability" (p. 64). Most scientists and educators would agree that the first step in solving a problem is to define it and understand its nature (Boada et al., 2008).

The concept of dyslexia is valid and supported by strong converging evidence. Dyslexia conveys specific meaning emerging from its definition, cognitive-psychological profile, and now neurobiological imprint. We now have knowledge of its epidemiology, including its prevalence and developmental course, the educational impact, and the

importance of providing early evidence-based treatments, as well as the provision of accommodations. Dyslexia provides a common language with which a range of relevant individuals—educators, parents, psychologists, physicians, affected children, and others—can converse and collaborate. Many of these students with dyslexia will lose their identity as individuals with an SLD if they are not accurately identified; moreover, they will continue to struggle needlessly. By combining knowledge from the cognitive-psychological and neurobiological-medical models and recognizing that interventions will be applied within school settings, practitioners will be better prepared to make accurate diagnoses that identify the problem and propose the most efficacious solutions based upon a careful examination of all of the influences and variables.

## Acknowledgements

We would like to acknowledge the support of the National Institutes of Health (RO1 HD 057655), Eli Lilly Ltd., and the Yale Center for Dyslexia and Creativity to Sally E. Shaywitz and Bennett A. Shaywitz. In addition, Michael E. Gerner and Deborah Schneider provided valuable editorial suggestions on the penultimate draft of this chapter.

# Testing Accommodations for Children with Disabilities

Brian C. McEvitt, Stephen N. Elliott, and Ryan J. Kettler

## Abstract

Educators have a responsibility for including all students, including those in special education, in assessment programs designed to hold states, school districts, and schools accountable for student learning. Testing accommodations often are used to facilitate the participation of students with disabilities in these testing programs. Testing accommodations are changes to the conditions under which a test is administered or responded to by a student. This chapter discusses the use of testing accommodations with students with disabilities, including information about types of accommodations, research about accommodations, and psychometric issues associated with using accommodations on standardized tests. The chapter demonstrates how the use of testing accommodations can be a valid and fair method for including students with disabilities in testing.

**Key Words:** accommodations, accountability, assessment, disabilities, special education, standardized, students, testing

## Introduction

Now more than ever, educators are required to document student learning outcomes. Recent federal education legislation in the United States, including the No Child Left Behind Act of 2002 (NCLB) and the Individuals with Disabilities Education Improvement Act (IDEA 2004), emphasizes the importance of regular testing of all students. Such large-scale standardized testing is intended to demonstrate students' educational progress so that schools and school districts may be held accountable for the academic performance of their students. If schools and school districts fail to meet annual goals for student achievement and participation in the testing, then corrective procedures must be undertaken.

One hallmark of NCLB and IDEA 2004 is that, in order for a school or district to meet annual achievement and participation goals, *all* students, including those with disabilities, must take the

required tests. Before these laws, it was common practice to exclude children with disabilities from large-scale testing, perhaps because of parents' not wanting their children to experience failure or because a school did not want its test scores to be negatively impacted by lower-achieving students (Kettler & Elliott, 2010; Pitoniak & Royer, 2001). However, excluding students with disabilities violated the spirit of inclusion and participation in the general education curriculum that IDEA espoused for these students. In addition, if students with disabilities did not participate in the testing, little was known about their academic outcomes, making it virtually impossible to hold schools accountable for academic achievement and to compare performance of students with disabilities across schools and school districts. As a result, educators must now enable students with disabilities to participate meaningfully in large-scale standardized testing programs.

Unfortunately, students with disabilities may have characteristics that interfere with their ability to successfully show what they know on a test. For example, a student with a learning disability in reading may have difficulty reading items that test math knowledge, thus potentially affecting his performance. A student with a behavior disability might not be able to sit quietly for a full hour to complete a long standardized test. Thus, testing accommodations may be used to facilitate the participation of students with disabilities in a school's testing program. Testing accommodations are changes in the way a test is administered, or the way that a student responds to the test, with the intent of offsetting any distortions in performance caused by the student's disability (Elliott, Kratochwill, & Schulte, 1999). The changes are *not* intended to change what the test is measuring or invalidate resulting scores, but rather to "level the playing field" for students with disabilities so they may show their true abilities on a test without the characteristics of their disabilities interfering with their performance (Elliott, Braden, & White, 2001).

Inherent in the use of testing accommodations are questions about their validity and fairness (Elliott, McEvitt, & Kettler, 2002). Obviously, standardized tests are supposed to be given in a uniform way to all students to allow for comparability of students' scores across classrooms, schools, districts, and states. If some students take the tests with accommodations and others do not, are those resulting scores truly compatible? In other words, does a score from an accommodated test have the same meaning as a score from a non-accommodated test? Can the same inferences be made about the scores? Is it fair for some students to receive accommodations while others do not?

The purpose of this chapter is to explore the use of testing accommodations on large-scale standardized tests and address the aforementioned questions. First, types of accommodations used and how educators select those accommodations will be discussed. Next, research concerning the effect that accommodations have on students' test performance and on students' and teachers' perceptions of testing will be reviewed. Finally, psychometric issues associated with testing accommodations will be presented, and in particular, issues surrounding their reliability, validity, and fairness of use. Suggestions for future directions in research and practice in the use of testing accommodations will be offered.

## The Use of Testing Accommodations

### *Types of Accommodations*

As stated earlier, a testing accommodation is a change to a test or testing situation that is intended to allow the test taker to demonstrate her or his knowledge and skills pertaining to the construct being measured. Testing accommodations can include alterations to the presentation and response format, timing and scheduling, setting, and assistive technology, but such alterations are not intended to change the construct reflected by the test score.

An important distinction between *accommodations* and *modifications* must be made. A test *modification* commonly refers to alteration of the test *content*. Because the content is changed, a modification usually changes to a certain degree the construct that is measured, thereby potentially impacting the validity of the resulting score and inferences that can be made about a student relative to that construct (Elliott et al., 1999). Appropriate accommodations, on the other hand, are not intended to alter item content. For example, reading a test of decoding skills aloud to students with reading disabilities is a *modification* to the test that changes the skill measured by the items; the test items become listening-comprehension items rather than reading-decoding items, thereby changing the construct of the test (McEvitt & Elliott, 2003). Reading aloud a math test to students with reading disabilities, however, is an appropriate *accommodation* because the test is intended to measure math skills, not reading skills. The read-aloud accommodation simply removes the barrier created by a students' reading disability when demonstrating math skills.

Testing accommodations are commonly grouped into four categories: (a) time accommodations; (b) environmental accommodations; (c) presentation format accommodations; and (d) response format accommodations (Elliott, 2007; Kettler & Elliott, 2010). Accommodations that address time typically extend the time allowed to complete a test, eliminate the time requirement altogether, or allow for more frequent breaks during testing. Environmental accommodations change aspects of the test-taking environment, such as providing a quiet, distraction-free space to complete a test, or having students take the test in a small-group setting. Accommodations that change the presentation format address how the test is administered or presented, such as reading directions aloud to a student or enlarging the text for those with a visual impairment. Finally, accommodations that address how

students respond to a test include using an adult to record answers on a bubble sheet or dictating responses orally.

The Assessment Accommodations Checklist (AAC; Elliott et al., 1999) is a tool that lists 67 common testing accommodations to help educators and parents make decisions about choosing accommodations for individual students. Accommodations are selected based on student need, the accommodations that are used during regular classroom instruction, and the nature of the test that is being considered for accommodations. The AAC groups accommodations into the following categories: (a) assistance prior to test administration; (b) motivation; (c) scheduling; (d) setting; (e) assessment directions; (f) assistance during assessment; (g) equipment or assistive technology; and (h) changes in test format. Examples of accommodations listed on the AAC are provided in Table 31.1.

While not intended to affect the validity of resulting test score interpretations, accommodations may still impact the comparability of scores (and thus the validity), depending on their nature and how they are used. Testing experts at CTB/McGraw-Hill

(2000) developed a useful taxonomy for categorizing accommodations relative to the likelihood that they would change the interpretation of the resulting test score if they were used. A Category 1 accommodation under this taxonomy should not impact the score's validity and interpretation. An example of a Category 1 accommodation is moving a student to a distraction-free space to complete a test; it is unlikely a distraction-free space will change the nature of the resulting score. A Category 2 accommodation *may* influence score interpretation, depending on how it is used. Providing extra time on a test is an example of a Category 2 accommodation; it may influence score interpretation depending on how much of a departure from standardized administration the extra time was. A Category 3 accommodation almost always affects score interpretation and probably alters the construct itself. Paraphrasing directions for a student is an example of a Category 3 accommodation; by restating the directions in a way other than stated in the test manual, the test-giver may provide unintended clues or significantly change standardization, thus making the resulting score incomparable to other scores from the same test.

**Table 31.1 Examples of Testing Accommodations Listed on the Assessment Accommodations Checklist**

Accommodation Category	Example of Accommodations
Assistance Prior to Administering the Test	Teach test-taking skills
Motivational Accommodations	Provide verbal encouragement of effort
	Provide treats, snacks, or prizes
Scheduling Accommodations	Provide extra time
	Schedule testing over several days
Setting Accommodations	Provide a distraction-free space
	Provide special lighting
Assistance with Test Directions	Read directions to the student
	Circle or highlight the task in the directions
Assistance During the Assessment	Read questions and content to the student
	Turn pages for the student
Equipment or Assistive Technology	Tape recorder
	Calculator
Test Format Accommodations	Use large-print answer document
	Mark responses in test book rather than on a separate answer sheet

### **Frequency of the Use of Accommodations**

Testing accommodations typically are provided as packages to students (Elliott, Kratochwill, & McKevitt, 2001). Rarely does a student receive just one accommodation (e.g., extra time); it is a more common practice for a student to receive multiple accommodations for a single test (e.g., extra time, distraction-free space, reading directions aloud to the student). In a 2005 study, Gibson, Hauberli, Glover, and Witter examined the frequency with which various accommodations were selected by students' individualized education program (IEP) teams. The IEP team has the primary responsibility for determining the participation of a student with disability in large-scale standardized testing and the accommodations required for that participation. The researchers used the AAC to track accommodations selected and categorized them according to the CTB/McGraw-Hill model described above.

Gibson et al. (2005) found that the five most-recommended accommodations were (a) providing extra testing time; (b) reading directions to students; (c) providing a distraction-free space or alternative location for the student; (d) reading questions and content to student; and (e) simplifying language in directions (paraphrasing). Each of these accommodations, except providing a distraction-free space, is considered a Category 2 or 3 accommodation, thus potentially affecting the validity of the resulting score and its interpretation. The authors caution that educators must consider the validity of accommodations when selecting them and question whether a particular accommodation is truly necessary for a given student.

### **Decision-Making about Using Accommodations**

As stated above, IEP team members are charged with choosing testing accommodations for students. Keeping in mind that accommodations are intended to *enhance* the validity of score interpretations, educators must be careful to avoid accommodations that *decrease* the validity of score interpretations. As indicated by Gibson et al. (2005), the latter choices can be quite common. To assist with decision making, Elliott (2007) suggested six areas of knowledge that educators should have when choosing accommodations:

- (a) knowledge about the student and the characteristics of the student's disability;
- (b) knowledge about accommodations the student typically uses during classroom instruction;

- (c) knowledge about state or district regulations;
- (d) knowledge about the test items and format;
- (e) an understanding about the concept of validity in score interpretation; and
- (f) knowledge about previously used accommodations and their effectiveness for the student.

State and district regulations are important considerations for IEP teams when choosing accommodations. All 50 U.S. states have policies or guidelines in place about the use of testing accommodations for large-scale standardized tests (Crawford, 2007). However, state policies are quite variable. Christensen, Lazarus, Crone, and Thurlow (2008) summarized the most recent state policies on testing accommodations. They found that state policies are paying closer attention to validity issues than in the past. However, certain controversial accommodations (i.e., those that are Category 2 or 3 and may impact score interpretation) are still allowed by several states with or without restrictions. For example, reading aloud questions and content is allowed with no restrictions in three states, while 24 states allow it under certain circumstances (e.g., on math tests). Simplifying or paraphrasing directions is allowed without restrictions in 13 states, yet prohibited in one state. Using a calculator is allowed by 10 states without restrictions and 19 states with restrictions. Finally, the use of a spell checker on a test is allowed without restrictions by seven states and prohibited completely by one state.

Also according to Christensen et al. (2008), state policies are increasingly providing recommendations for scribes, readers, and sign-language interpreters to enhance the validity of scores when these accommodations are used. These changes are indicators that state policies are evolving to carefully consider issues of validity when deciding which accommodations are allowable and which are not. Such variability among states, however, may have consequences (Crawford, 2007). Scores from tests given with allowable accommodations may be reported for a school or school district's NCLB accountability requirements. Variability among states in allowable accommodations may degrade the comparability of scores between states and may inflate scores in states where certain controversial accommodations are allowed. Next, if a student moves from one state to another, he or she may not be allowed an accommodation that was once allowable, causing potential frustration and disappointment. Finally, teachers may avoid using non-allowed testing

accommodations during classroom instruction, a time during which such accommodations could be beneficial for a student, thus affecting the quality of his or her education.

IEP teams must select accommodations within the parameters of state guidelines and policies, as well as their own knowledge about the student and the test. Empirical research on the effect of testing accommodations should also play a role in the selection of accommodations for individual students. Over the past 15 years, research has been conducted using a variety of designs to test the effect that various accommodations, used in isolation or in packages, have on the scores of students with and without disabilities. Research has also informed educators about students' and teachers' perceptions of testing accommodations and their validity and fairness of use.

### **The Effects of Testing Accommodations**

In 2000, Thurlow, McGrew, Tindal, Thompson, Ysseldyke, and J. Elliott wrote a monograph for the National Center on Educational Outcomes (NCEO) to address the state of assessment accommodations research. The researchers indicated that future research should (a) focus on accommodations of most interest, (b) focus on students who compose a large part of the population needing accommodations, (c) use students without disabilities as a group in any comparison designs, and (d) collect other measures to help clarify findings. Thurlow et al. (2000) identified four group-research designs, all including participants taking tests under both accommodated and non-accommodated conditions, to address the matter of whether assessment accommodations work. Since the Thurlow et al. report, research on the effects of such accommodations has become more abundant. A review of the relevant literature reveals numerous studies examining the use of testing accommodations and the validity of score interpretations on tests given with accommodations (e.g., Elliott, McKevitt, & Kettler, 2002; Fletcher et al., 2006; Kosciolek & Ysseldyke, 2000; Lang, Elliott, Bolt, & Kratochwill, 2007; McKevitt & Elliott, 2003; Mehrens, 2002; Pitoniak & Royer, 2001). Another suggestion by Thurlow et al. was that work on assessment accommodations needs to be done as part of a program: "Even with the best research designs, we will not get nice answers unless we have a program of research to follow up with additional questions" (p. 28). Two of the most active and systematic programs of research have been conducted by Fuchs, Fuchs,

and colleagues and S. Elliott and colleagues. These investigators' research is featured next, along with a few other key studies.

Fuchs, Fuchs, and colleagues have done a number of research studies on assessment accommodations, in addition to their development of *Dynamic Assessment Tool for Accommodations* (DATA; a decision-making framework about using accommodations). In a meta-analytic study, Tindal and Fuchs (2000) found that the most effective accommodations included providing large-print or Braille tests for the visually impaired, as well as reading problems aloud for students with disabilities in math. Rather than examining accommodations in packages, Fuchs, Fuchs, and Capizzi (2006) indicated that research should be done on one accommodation at a time, with work on packages only commencing after individual accommodations have been validated. Findings from their studies include that:

- (a) extended time does not provide a differential boost (i.e., it does not improve the scores of students with disabilities more than students without disabilities),
- (b) reading a test orally helps students with disabilities more than it does students without disabilities,
- (c) heterogeneity among students with disabilities reduces the likelihood of one set of accommodations' being appropriate for the entire group,
- (d) student demographic characteristics may influence teachers' accommodation recommendations, and
- (e) students with severe disabilities and severe reading deficits may benefit from reading a test aloud.

Based on a review of assessment accommodations literature, Fuchs, Fuchs, and Capizzi (2006) concluded that decisions about testing accommodations must be individualized, that the meaningfulness of test scores must be of primary importance when selecting accommodations; also that the mandated inclusion of students with disabilities in educational outcomes testing makes this area of research critical.

Elliott and colleagues have examined the effects of testing accommodations on the performance of students with and without disabilities in more than eight studies. In an early study, Elliott, Kratochwill, and McKevitt (2001) showed that the majority of students both with and without disabilities

performed better on an achievement test when they were provided accommodations. Notably however, the average effect size of accommodations provided to students with disabilities (SWDs) was 0.88, while the effect size for students without disabilities (SWODs) was only 0.45.

In a second study, Schulte, Elliott, and Kratochwill (2001) had students with and without disabilities complete two equivalent forms of math achievement tests, one with accommodations and one without accommodations. The results of this study showed that on the constructed response tasks, most students performed better under the accommodated condition than under the non-accommodated condition. The largest interaction effect was found when responses to multiple-choice questions were compared across the two disability groups. For this type of question, accommodations produced an effect size of 0.41 for SWDs and an effect size of 0.00 for SWODs.

In a related study, McEvitt and Elliott (2003) examined the effect of testing accommodations on students' performance on the reading portion of the same achievement test. In this study, students with and without disabilities were administered the reading test either with or without accommodations. The group that received the test with accommodations was further divided into two groups—one that received a teacher-recommended accommodations package, and one that received a teacher-recommended accommodations package plus a read-aloud accommodation. Findings from this study revealed that (a) the teacher-recommended accommodations did not significantly improve scores for either disability status group, (b) the read-aloud accommodation significantly improved scores for both disability status groups, and (c) there was no significant interaction effect between disability status and the accommodation package with the read-aloud accommodation.

Expanding on the McEvitt and Elliott study, Elliott and Marquart (2004) examined the effects of a specific accommodation—extended time—on students' test performance and also on their perceptions of testing and testing accommodations. Results from this study showed that when students were grouped according to disability status, there was no significant effect of the accommodations on test performance for either group. When SWODs were grouped as at-risk and at-grade-level groups, however, the effect size of testing accommodations for the at-risk group was 0.48, whereas the effect size for the grade-level group was 0.20. Overall,

students in this study reported they felt more motivated and less frustrated, thought they performed better, thought the test was easier, and preferred taking the test when accommodations were provided.

Fletcher and colleagues (2006) examined the effects of accommodations on the high-stakes test results of Texas students with reading disabilities. Specifically, they examined the effects of accommodations on the reading performance of third-grade students, half of whom had word-decoding difficulties with dyslexia and half of whom were considered average decoders. Only students with decoding problems were found to benefit from the accommodation package, showing a significant increase in average performance and a sevenfold increase in the odds of passing the test. The authors suggested that these results demonstrated that "accommodations designed for a clearly defined academic disability can enhance performance on a high-stakes assessment" (p. 136).

A study conducted by Kosciolek and Ysseldyke (2000) added an important variable to testing accommodation research. These investigators examined students' attitudes towards the provision of testing accommodations and the alignment between the students' perceptions of accommodations and their test performance. Results based on a small sample of students indicated that most students preferred taking an accommodated test, but that SWDs showed a stronger preference for the accommodated condition. There was also a difference between the two student groups in the reason they gave for their preferences. While SWDs claimed that the accommodations made the test easier, SWODs said that the accommodations enabled them to take the test at their own pace. Overall, previous research on testing accommodations has produced mixed outcomes, and a great deal is yet to be determined about their effects and the means by which those effects are produced.

One hypothesis regarding the means by which accommodations may affect students' test performance is that accommodations affect specific thoughts and attitudes that students have about the tests and about their own test-taking abilities. Specifically, this hypothesis draws on social cognitive theory, in which self-efficacy plays a key role in task performance (Bandura, 1997). With achievement testing, a student who has low test-related self-efficacy may be less motivated to work hard on the tests, may lack persistence to work steadily on the more challenging problems, may have insufficient perseverance to continue working when the

test gets hard, may have little interest in the test, may be likely to put forth only minimal effort, and may be extremely anxious about the test. As a result, this student's score on the test might not accurately reflect the student's true ability in the targeted skill area, but would be influenced by many other extraneous factors that can affect the construct being measured, particularly in comparison with the score obtained by a student with high test-related self-efficacy who was not hindered in a similar manner. Recently, Elliott and several colleagues have focused on the potential consequences of large-scale achievement testing on the self-efficacy of students who take the tests.

Lang et al. (2008) provided one of the first experimental examinations of the effects of testing accommodations on a number of student characteristics, as well as on performance outcomes. Most notably, Lang and her colleagues examined responses to questionnaire items completed by both fourth- and eighth-grade students following a test administration. Results demonstrated that testing accommodations improved most students' performance on the tests and showed that the effects of testing accommodations on student performance were larger for SWDs than for SWODs (i.e., a differential boost). Lang and colleagues also found that students both with and without disabilities preferred the accommodated testing condition, but that this preference was stronger among SWDs. Lang et al. also reported no significant correlation between disability status and the effect of testing accommodations on students' self-reported motivation.

In a follow-up experimental study to Lang et al. and using similar tests, Feldman, Kim, and Elliott (2008) examined the effects of testing accommodations on eighth-grade students' performance on large-scale achievement tests and also on the students' attitudes and reactions related to taking such tests. Their findings revealed significant differences in the ways in which students with and without disabilities experienced the testing, and in the ways that testing accommodations affected students' attitudes toward and beliefs about the tests. Specifically, results suggested that (a) students with disabilities had significantly lower test-related self-efficacy than students without disabilities; (b) self-efficacy was positively correlated with test performance for all students; and (c) the provision of accommodations improved the test performance of all students and exerted a differential boost for students with disabilities on constructs such as test-related self-efficacy and motivation. Collectively, these findings suggested

that testing accommodations may have a positive effect on students' test performance by improving their attitudinal constructs such as test-related self-efficacy and motivation, especially for students with learning disabilities.

## Psychometric Issues Associated with Testing Accommodations

Testing accommodations are used to improve the measurement of abilities for students for whom tests administered without accommodations may not yield scores from which inferences are as reliable, valid, or fair. Testing accommodations are not intended to provide an advantage for SWDs, but are intended to make inferences yielded by test scores for SWDs comparable to those yielded by scores that SWODs obtain without accommodations. This section of the chapter addresses the issues of reliability and validity, as well as fairness, which must be considered with testing accommodations. To illustrate these issues, we revisit the example of students with reading disabilities taking a math test with a read-aloud accommodation.

### *The Impact of Testing Accommodations on Reliability and Validity*

The variance in a set of scores can be subdivided into variance based on the construct being measured, or *true-score* variance, and variance based on other factors, or *error-score* variance. In our example, true-score variance corresponds to variance in students' abilities in mathematics. Error-score variance can be further subdivided into that which is from systematic sources (e.g., reading ability), and that which is from random sources (e.g., inconsistency in accommodation administration). One danger in using testing accommodations is that if they are applied inconsistently, the accommodations may increase the amount of error from random sources, therefore decreasing the reliability or consistency of test scores. Suppose that the administrators of the read-aloud accommodation in the example were not explicitly trained, but were only told that the students are allowed to have the test read aloud. To one person, this might mean that the directions, item stems, and answer choices can be read aloud, but not text in the item stimulus. A second person might think that everything can be read aloud, including the item stimulus, unless it contains key mathematics vocabulary words that are grade-appropriate for the students. A third person might interpret the accommodation to mean that absolutely everything can be read aloud. Other

sources of confusion might be distinctions between whether the item must be read aloud or should only be read aloud upon student request, whether the item can be reread upon request, and whether the meaning of the text can be clarified by the administrator. Without explicit rules and training, the application of this accommodation would probably vary from person to person, as well as when administered by the same person at different points in time. The impact of this inconsistency of administration on the students taking the test is unpredictable, and the reliability of the resulting scores would almost certainly be reduced.

The most direct, intended psychometric impact of testing accommodations is to reduce error-score variance that is from systematic sources. Appropriate accommodations should be designed to match these sources, in order to help the student get around these barriers to good measurement, so that a higher proportion of the variance in scores is true-score variance. In our example of students with reading disabilities, a math test with a moderate to high reading load would be likely to yield scores that are indicative partially of mathematics ability and partially of reading ability (along with error from random sources). Some form of read-aloud accommodation could reduce the amount of variance that is connected to variance in reading ability, so that a larger proportion of the variance in the scores would be due to variance in mathematics ability, the target construct.

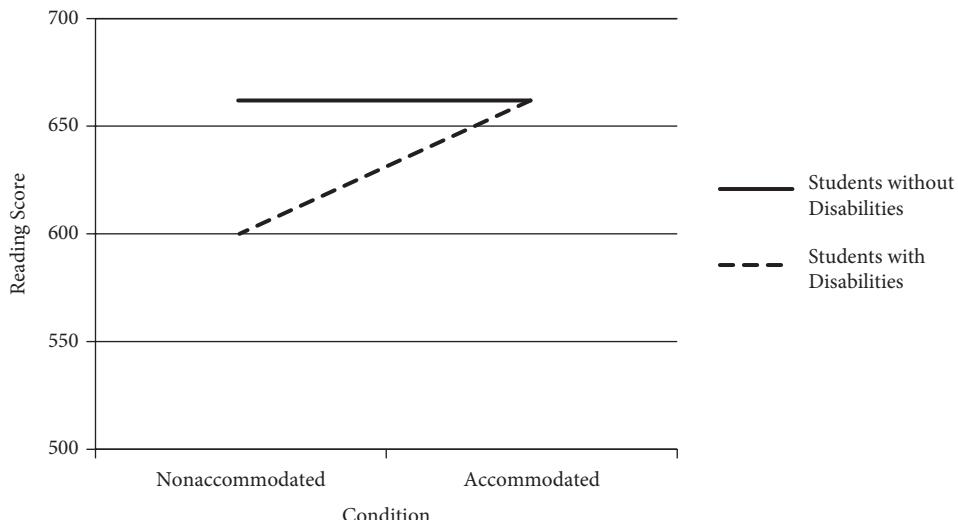

A few notes are important to consider when interpreting this example. The first is that this read-aloud accommodation would only be effective when applied to students who have reading problems. While the read-aloud accommodation may be appropriate for this group, it would probably not lead to more valid inferences if used with students who have a different disability. For example, students who are good readers but who have fine-motor deficits that cause difficulty holding a pencil are not likely to be helped. Another group who would probably not be helped are students with mathematics disabilities who are good readers. The variance in these students' scores would be largely composed of variance in mathematics abilities, as is appropriate for good measurement. Accommodations are not intended to distort students' abilities on the construct the test score is intended to reflect. Finally, it is important to note that although SWODs would not be helped by the read-aloud accommodation, they are not likely to be hurt by it, either. These students' scores on the non-accommodated test would be highly dependent on their mathematics abilities,

because reading would not be a barrier to them. The effect of the read-aloud accommodation for students with reading problems would be to make their scores more dependent on their mathematics ability, and thus more comparable to the scores of SWODs.

Once a model has been established for how testing accommodations should affect the reliability and validity of inferences drawn from test scores, the next logical question is how to evaluate whether testing accommodations are actually working in this fashion. The Standards for Educational and Psychological Testing (the Standards; American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME], 1999) prescribe an evidence evaluation orientation toward establishing validity, including the collection of evidence based on relationships with other variables. "Evidence based on relationships with other variables" is the degree to which scores from the newly developed or accommodated test converge with scores for measures of similar constructs (e.g., other tests, known groups), but diverge with scores from dissimilar constructs. A special case of validity evidence based on relationships with other variables, the *interaction paradigm* (i.e., differential boost), has been used as a framework for evaluating improved access based on accommodations or modifications (Kettler & Elliott, 2010; Phillips, 1994), and is the focus of the next section.

### ***The Interaction Paradigm***

The interaction paradigm indicates that the gap between scores from SWDs and scores from SWODs should be reduced through the use of appropriate accommodations, because these accommodations would directly address sources of systematic error-score variance. An example from an authentic research study can illustrate the interaction paradigm: Kettler et al. (2005) administered research versions of standardized reading and mathematics tests to SWDs and SWODs, in a condition that included a package of accommodations identified by Individualized Education Programs and the students' teachers, as well as in a non-accommodated condition. In the non-accommodated condition of the fourth-grade reading test, SWDs ( $n = 49$ ) had a mean score of 600 ( $SD = 45$ ) and SWODs ( $n = 69$ ) had a mean score of 662 ( $SD = 37$ ). An ideal result from an interaction paradigm perspective, indicating that the packages of accommodations worked perfectly, would be for both groups of students to

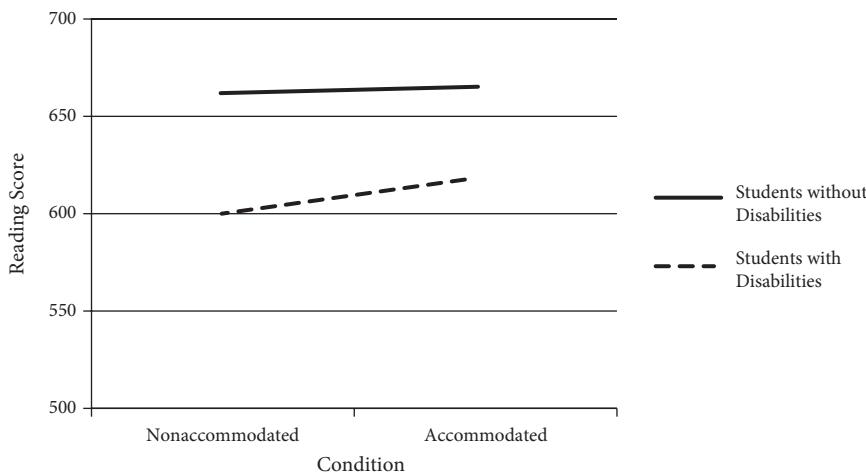

**Figure 31.1** Ideal interaction between accommodation condition and group status in Kettler et al. (2005).

have a mean score of 662 in the accommodated condition. The effect size in that case would have been 1.38 for SWDs and 0.00 for SWODs. Figure 31.1 depicts this hypothetical, ideal finding.

While the aforementioned results would have been ideal evidence that the package of accommodations in Kettler et al. (2005) was appropriate, there are many reasons why consistently finding large effects for SWDs and no effects for SWODs is unlikely. The first of these reasons is the assumption that the SWDs and SWODs compose two completely non-overlapping groups, such that the accommodations used are helpful for SWDs, but do not make any difference to SWODs. In reality, it is very likely that the SWOD group will be composed of students with a continuum of abilities on skills that are related to the target construct, and that lower-performing or at-risk SWODs may very well benefit from some of the accommodations designed for SWDs. A second reason that finding the ideal interaction paradigm is unlikely is that it assumes that SWDs as a group have equal ability to that of the SWODs on the construct being measured. Such a scenario is unlikely, because SWDs often face more barriers in accessing classroom material, and to the degree that access to learning the material is limited, SWDs are likely to have lower achievement than SWODs, even if measurement is nearly perfect. A final complication is that many content areas (e.g., reading, mathematics) and sub-areas (e.g. fluency, comprehension) are closely related, so that students with one type of learning problem often struggle in other areas. All three of these complications make it

unlikely that SWODs and SWDs would have the same scores, even in the accommodated condition.

In Kettler et al. (2005), a significant interaction was found between accommodation condition and disability group on the fourth-grade reading test (significant interactions were not found on the other tests), indicating that the accommodations helped SWDs more than they helped SWODs. In the accommodated condition, SWDs had a mean score of 619 ( $SD = 25$ ), and SWODs had a mean score of 666 ( $SD = 34$ ). Cohen's  $d$  for SWDs (.42) was larger than Cohen's  $d$  for SWODs (0.13). Figure 31.2 depicts the observed interaction between accommodation and disability group, with the slope of the line for the SWD group being greater than the slope of the line for the SWOD group. The SWOD group probably improved on average because some students were relatively low performing and at-risk for academic problems. The SWD group likely did not reach mean score of SWODs in the non-accommodated condition (662) because the same barriers that make testing difficult have affected their access to instruction over the years, and because accommodations cannot change the reality that students who have difficulty with vocabulary are at a disadvantage for showing how well they comprehend, and vice versa. It is difficult to imagine accommodations that could overcome this discrepancy and have SWDs performing at the same level as SWODs, while improving the validity of inferences that can be drawn from the test scores. How to select fair accommodations, given these limitations, is the subject of the next section.

**Figure 31.2** Actual interaction between accommodation condition and group status in Kettler et al. (2005).

### ***Fairness of Testing Accommodation Use***

The issue of which testing accommodations are fair is more subjective than are issues of reliability and validity, but determination of fairness should begin with the intention of measuring each construct as accurately as possible. For all tests, this means minimizing sources of error-score variance, both random and systematic. Maximizing measurement accuracy also means that, for some groups of students, testing accommodations need to be used for a test score to reflect the same construct that it reflects for most students in the non-accommodated condition. While SWODs reading and responding to a hypothetical math test may provide interpretable scores, SWDs may need to take the test under different conditions in order to obtain comparable scores. This is fair in the sense that the conditions under which a test is taken are not as important as the interpretability of the resulting scores. It is by this logic that using the interaction paradigm is a sensible method for evaluating testing accommodation fairness.

Researchers have used a couple of techniques to address the issue of fairness and testing accommodations. Lang et al. (2007) surveyed students ( $n = 170$ ) who had taken a test with and without accommodations about whether testing accommodations are fair. On a five-point scale from 1 (*strongly disagree*) to 5 (*strongly agree*), the mean rating for the statement that “accommodations are fair for students who need them” ranged from 3.69 to 3.98 across grades and disability groups. Ratings were slightly higher for the statement that “accommodations are fair for students with disabilities,” ranging from 4.19 to 4.41. These findings indicate that students

believe accommodations are fair, and perhaps even fairer for SWDs.

Lang et al. (2007) did not address the fairness of any isolated accommodations used outside of a package. One almost universally accepted, if not empirically proven, method for considering the fairness of isolated accommodations is to only use testing accommodations that have been used as instructional accommodations prior to testing. A National Center on Educational Outcomes (NCEO) report on the peer review of progress in meeting NCLB requirements indicated that 39 states had acceptable language in their policies, indicating that testing accommodations should match instructional accommodations (Thurlow, Christensen, & Lail, 2008). For example, the State of Florida included a table linking student behavior with possible instructional and testing accommodations. The theory is that error-score variance could emerge if students see an accommodation for the first time in a testing situation. While the vast majority of states have language in their policies addressing this issue, it is debatable whether the match between instructional and assessment accommodations is very close. Based on an analysis of the Special Education Elementary Longitudinal Study (SEELS), Bottsford-Miller, Thurlow, Stout, and Quenemoen (2006) reported that the percentage of students with accommodations on IEPs was very close to the percentage of students who received instructional accommodations, but in most cases exceeded the percentage of students who received assessment accommodations. These data imply that many students are receiving instructional accommodations that they do not receive on assessments. It is less likely, based

on these data, that students are often seeing accommodations for the first time in a testing situation. However, no direct analysis of which students were receiving which accommodations was done.

## Conclusion

Research on the use and effects of testing accommodations has come a long way since the educational accountability movement began. As long as there is a requirement to include all students in large-scale assessment, educators will rely on testing accommodations to facilitate the participation of students with disabilities in those assessments. Research on testing accommodations has demonstrated that they can have a measurable impact on test scores for students with disabilities, and in some cases, for students without disabilities. Examining the impact of testing accommodations on the performance of students without disabilities is a useful way to assess the validity of accommodations, given that accommodations generally should not impact the scores of these students. When they do, questions about validity and fairness of accommodations may be raised. As educators continue to grapple with using accommodations appropriately, researchers and policy makers will continue to add new knowledge to our understanding of this complex assessment tool. Ultimately, however, knowledge about the student being tested, the test being used, local policies, and validity and fairness in measurement must be used in the provision of testing accommodations.

## Future Directions

Research on the use and effects of testing accommodations still needs to be conducted. Such research should focus on students with and without disabilities, using single-subject and large-group designs. Ultimately, the research needs to help educators decide which accommodations to use for which students, and when to use them. State policies also may inform educators about using accommodations based on continuing research. As Christensen et al. (2008) reported, state policies are improving in the attention they pay to issues of validity and fairness with the use of accommodations. Still, more states need to develop specific accommodation policies that account for validity issues identified in the research.

There is also a need to examine the use of accommodations with other student groups, such as English language learners or students with more severe disabilities. Like students with disabilities, English language learners must be included in state and district accountability assessments.

Accommodations may be used in some cases to facilitate their participation as well. Research is needed to test the impact of accommodations with this group of students. Furthermore, the law allows a small percentage of students with disabilities to participate in an alternate assessment because of the severity of their disabilities. Research and policy are needed to help inform educators about how to design these alternate assessments and what role, if any, testing accommodations may play in their use.

The use of testing accommodations may seem, at first, a simple and effective way to help students with disabilities demonstrate their true knowledge on a test. However, the use of accommodations is anything but simple. Educators have a legal responsibility to include all students in testing and an ethical responsibility to attend to the validity and fairness of testing. Research on the use and effects of testing accommodations has shown that these two responsibilities may be difficult to reconcile in harmony with one another. Only with the continued efforts of researchers, policy makers, and educators will our understanding of the use and effects of testing accommodations continue to evolve in a positive direction.

## Glossary and Abbreviations

**Accommodation.** A change in the way a test is administered or a student responds to it with the intent of offsetting any construct-irrelevant distortion on test performance caused by a student's disability.

**Alternate assessment.** A method of assessment for students with severe disabilities that is an alternative to a traditional large-scale standardized test. Alternate assessments can take many forms and vary between and within states.

**Assistive technology.** Any device that can be used to help students respond to test items (e.g., a pointer).

**Construct.** The characteristic that is being measured by a test.

**Differential boost.** See *interaction paradigm*.

**Fairness.** A judgement about whether the use of accommodations is equal for all those using them.

**IDEA.** The Individuals with Disabilities Education Act.

**IEP.** Individualized Education Program.

**Interaction paradigm.** An expected phenomenon in the use of testing accommodations wherein students with disabilities should experience greater gain in test scores when using accommodations

than do students without disabilities who receive the same accommodations.

*Modification.* An alteration to the content of a test, thus changing the construct being measured.

*NCLB.* No Child Left Behind Act.

*Standardized test.* A test given and scored with uniform directions and procedures to all those taking it.

*Student with a disability.* A student who has undergone a school-based evaluation and has been determined to have one or more of 13 possible disabilities identified by IDEA.

*Validity.* The degree to which a test score reflects the construct that it is intended to measure, and allows accurate inferences to be made.

# Special Issues in the Forensic Assessment of Children and Adolescents

Kathryn Kuehnle, Steven N. Sparta, H. D. Kirkpatrick, and Monica Epstein

## Abstract

This chapter describes the forensic mental health assessment of children and adolescents related to psycholegal questions in three areas of civil law and one area of criminal judicial proceedings. The authors describe general principles of forensic assessment, including considerations of tests and methods, as well as special assessment issues applied to each of four common areas of assessment. In the forensic assessment for child custody, evaluation procedures are described for how best to assess the relationship between a child and each parent, where a broad consideration exists for the child's best interests. Child abuse and neglect cases, a second type of case calling for a forensic assessment, are usually heard in child dependency departments of the legal system. This chapter describes the assessment of the child's and/or the parents' psychological functioning, with particular reference to the child's safety and well-being. Forensic assessment also is described regarding certain types of civil matters, usually involving personal injury cases and how the psychological functioning of individuals may be affected by legally relevant events in the person's life. Finally, the authors describe the forensic assessment for determining the competency to stand trial of children or adolescents in criminal proceedings, including the individual's capacity to understand and meaningfully participate in the legal proceedings.

**Key Words:** forensic assessment of children and adolescents, civil judicial proceedings involving children, criminal judicial proceedings involving children, child abuse

The purpose of forensic evaluations conducted by mental health professionals is to be helpful to the legal decision-maker (i.e., judge, jury, or other hearing officer) or helpful to the retaining authority (e.g., attorney). In contrast, the purpose of the clinical evaluation is to be helpful to the patient. It has sometimes been said that the forensic evaluator "advocates for the data," striving for an objective and informed opinion, utilizing, when available, empirical data to form opinions. Forensic mental health evaluators may perform evaluations in many different psycholegal contexts.

To avoid confusing the reader with terms that may be inconsistent across various jurisdictions, we offer a brief description of the terminology we have

used in this chapter to identify various judicial proceedings. In the adjudicative process, there are four major types of judicial proceedings: *criminal*, *civil*, *administrative*, and *quasi-criminal* (e.g., therapeutic courts) (Melton, Petrilà, Poythress, & Slobogin, 2007). States vary in how they organize court divisions of civil judicial proceedings. Various states may hold cases for child custody (i.e., parent responsibility and timesharing), adoption, and potentially other family matters in "Family Courts," child protection matters in "Dependency Courts," juvenile delinquency cases in "Juvenile Courts," and personal injury or tort proceedings in "General Civil Courts." Other states may combine child custody and child protection cases in "Unified Family

Courts" and handle juvenile delinquency cases in a different court. In this article, we will refer to child custody cases (parenting plan and child-access cases) as *family law matters*, child protection cases as *dependency law matters*, and personal injury cases as *tort law matters*.

The following areas of forensic assessment are the focus of this chapter:

- Family law—Family dissolution and parenting plans
- Dependency law—Child abuse and neglect
- Tort law—Psychological injury: intentional and negligent
- Criminal law—Juvenile competency

## General Principles of Forensic Assessment

In all forensic contexts when the legal proceedings involve children, there are two essential and necessary components: (1) skilled and developmentally appropriate interviewing of children and (2) the acquisition of sufficient information from the evaluation—including collateral sources—combined with an appropriate analysis adequate to support the opinions proffered regarding the child. Generally speaking, the following methods and procedures are applied in the forensic assessment of children and adolescents in a forensic context:

1. A competent forensic assessment usually involves the utilization of multiple methods to consider diverse sources of independent data. The utilization of collateral sources is often the *sine qua non* of forensic methodology—i.e., without collateral data, the forensic assessment fails the test of adequacy (Heilbrun, Warren, & Picarello, 2003).

2. To guard against confirmatory bias, a forensic evaluator considers multiple hypotheses when collecting and analyzing the data, including consideration of the limitations of existing data.

3. Collateral data are obtained from two general sources—*collateral persons* who may have relevant information pertaining to the child/adolescent, and *collateral information* that may provide useful data about the child. Relevant collateral persons may include parents, step-parents, extended-family members, babysitters, day-care providers, teachers, neighbors, other families who have had contact with the child or the child's family, or law enforcement personnel having contact with one or more family members. Relevant collateral information could include information from school, mental health treatment, medical, legal, child protection or other sources.

4. A forensic mental health evaluator of children and adolescents must always consider the evaluation context of the psycholegal question, and therefore guard against accepting at face value any information from a single source, e.g., one parent involved in a parenting dispute.

5. A forensic expert who engages in the assessment of children and adolescents in a psycholegal context recognizes that an adequate informed consent requires greater consideration that the relevant parties understand and agree upon matters such as the scope of the evaluation, the methods, fees and costs and how they are to be paid, the limits of confidentiality for all involved, and other relevant information. Because of the serious issues and associated emotional tension which accompany such matters, a careful execution of informed consent will help protect the forensic expert from risk derived from misunderstandings, distortion or unfounded accusations.

6. Forensic evaluators should adequately document the evaluation methods and results, and in cases involving investigations of child maltreatment, electronic recording of child interviews is essential. Empirical evidence is robust in showing that note-taking is not a reliable means of capturing the important data from children's interviews regarding alleged maltreatment (Berliner & Lieb, 2001; Lamb, Orbach, Sternberg, Hershkowitz, & Horowitz, 2000).

7. Psychological testing can contribute valuable norm-referenced data regarding a child's or parent's functioning. When considering such testing, forensic evaluators recognize many potential instruments may not have been developed for a specific forensic purpose, or that tests that do have some relevance may not answer ultimate psychological or psycholegal questions, but only limited elements of the questions.

8. Quasi-assessment tools, such as children's doll play, drawings, and sand play, should not be misrepresented as "tests," implying measurement validity beyond their value. To the extent such methods are ever used in a forensic assessment, the evaluator must recognize the reliability and validity limitations of quasi-assessment methods, and not communicate an unfounded or misleading justification for an opinion based on their limited use. Sometimes a forensic evaluator uses such techniques for rapport building, especially with young or psychologically defended children. Quasi-assessment tools should not be used to

answer ultimate psycholegal issues, e.g., the child was or was not abused.

9. The forensic evaluator recognizes that psychological testing should not be interpreted in isolation of other data, especially in a forensic context. In a forensic evaluation, the same test results can have different relevance or meaning, depending upon the case context and the nature and extent of other information associated with the forensic questions.

### **Assessment Instruments**

Tests and measures should strive to meet *Daubert* (1993)<sup>1</sup> and *Kumho* (1999)<sup>2</sup> criteria of relevance and reliability for the context in which they are used—they should add valid and reliable information to the psycholegal question under consideration—even if the local jurisdiction does not adopt the federal rules. Appropriate, valid test data may add *incremental* validity to other data obtained in the evaluation, e.g., observations and interviewing of the child, collateral interviews, collateral records review, and application of relevant social sciences research. First and foremost, the forensic assessment of children and adolescents requires valid methods and procedures that demand consideration in case specific contexts. Consideration of the instruments' validity for the particular psycholegal question must be considered (Grisso, 2005, cited in Sparta & Koocher, 2006).

Melton, Petrila, Poythress, and Slobogin (2007, p. 48) identified 12 factors evaluators should consider before selecting a psychological test or assessment technique as part of a forensic evaluation:

1. What is the construct to be assessed?
2. How directly does the instrument assess the construct of interest?
3. Are there alternative methods that assess the construct of interest in more direct ways?
4. Does the use of this instrument require an unacceptable degree of inference between the construct it assesses and the relevant psycholegal issue(s)?
5. Is the instrument commercially published?
6. Is a comprehensive user's manual available?
7. Have adequate levels of reliability been established?
8. Have adequate levels of validity been demonstrated?
9. Is the instrument valid for the purpose for which it will be used?
10. What are the qualifications necessary to use the instrument?

11. Has the instrument been subject to peer review?

12. Does the instrument include measures of response style?

Examples of techniques sometimes relied upon by mental health providers in clinical settings that would fail in meeting the above criteria include play therapy and its derivatives. Play therapy (e.g., sand play/sand tray therapy, doll play), when employed as a projective assessment technique, meets few, if any, of these guidelines for forensic assessment tools (see Kuehnle, 1996, 2002). These techniques are not objective and reliable measures of concepts that are of relevance to the court, nor are they reliable indicators of external events. There are no established psychometric properties, manuals for use, or measures of response style for these techniques (Murray, Martindale, & Epstein, 2009). Children's drawings also meet few, if any, of the criteria set forth by Melton and his colleagues (2007). Despite this absence of empirical support, it is not uncommon for quasi-assessment projective techniques to play a role in forensic evaluations in the context of child maltreatment and parenting plan evaluations. Bow and colleagues found that, among experienced doctoral-level forensic specialists, approximately one in five reported they used projective drawings such as the House-Tree-Person Drawing or Human Figure Drawing (21%) or the Family Drawing (19%) (Bow, Quinnell, Zaroff, & Assemany, 2002; see also Murray, et al, 2009, and Weiner & Kuehnle, 1998, for psychometric information on these instruments).

There is an absence of standardized instruments to assess toddlers or preschool-age children other than checklists typically completed by respondent caretakers. With elementary school-age children, standardized testing appropriate for use in forensic cases also is limited to checklists with parents and teachers as the respondents and self-report checklists with the child as the respondent. Although the authors of several projective instruments for children have attempted to develop a quantifiable scoring system with sound psychometric properties, none of the currently published projective instruments (e.g., Roberts Apperception Test for Children, 2nd Edition; Children's Apperception Test; Thematic Apperception Test) show acceptable psychometric properties (e.g., norms, reliability, and validity) for evaluating children in forensic settings and in answering psycholegal questions. (for reviews, see Buros Institute of Mental Measurements, <http://buros.unl.edu/buros/jsp/search.jsp>). The use of these projective instruments should be avoided.

Similarly, there are insufficient standardized assessment instruments for use with adolescents in forensic matters. Although there are some widely used personality tests that, depending on the adolescent's response style, may provide the evaluator with some useful data about the teen's emotional status, normative data on adolescents involved in legal proceedings are limited. The evaluator who contemplates using standardized personality measures for adolescents in legal contexts is encouraged to be knowledgeable about considerations and controversies in the professional community; for example, it might be useful to consider reviews included in Sparta and Koocher's volume on forensic assessment of children wherein two specific adolescent measures—the Minnesota Multiphasic Personality Inventory—Adolescent (MMPI-A) and the Millon Adolescent Clinical Inventory (MACI)—are discussed (2006; see Chapters 24 and 26) or review the evolving literature contained in forensic psychological journals and reviews in Buros Institute of Mental Measurements. (<http://buros.unl.edu/buros/jsp/search.jsp>).

### ***Interviewing Children and Adolescents***

The child's interviews may produce some of the most crucial data in the forensic evaluation. Forensic mental health evaluators must approach the task of interviewing children with a solid knowledge of forensic child interview techniques in order to avoid contamination of a valuable source of information. (For further information, refer to Kuehnle and Connell, (2009; see Chapters 12, 13, and 14). Furthermore, knowledge of empirically based interview techniques is important when reviewing the quality of other interviewers' methods. The ability of adults to elicit accurate information from children depends, in large part, on the degree to which children's limitations and abilities are understood. The quality of children's reports is a co-mingled product of their cognitive and social maturity, their experiences outside formal interviews, and the interview context (Lamb, Sternberg, & Esplin, 1998). When the interview goal is to gather precise information, young children may not possess the cognitive and language skills to answer accurately many specific content-type questions (e.g., "when" or "how often"). When interviewing does not match the developmental capabilities of the child, inaccurate responses are more likely to be given by the child (Friedman & Lyon, 2005; Quas & Schaaf, 2002; also refer to Malloy and Quas, 2009, for a discussion of children's suggestibility). This is an

extremely important consideration, because a child not only might fail to report important information, but also inadequate interviewing may produce misleading or inaccurate information.

### ***Parent Responsibility and Time Sharing—Best Interests of the Child***

In assessing the best interests of children and adolescents, forensically, in a family law context, there are numerous variables that should be considered, including but not limited to the following:

1. The child's *best interests* (a legal construct);
2. The child's *psychological best interests* (CPBI) (a psychological construct);
3. The child's *expressed interests* (both a legal and subjective construct);
4. The context of the assessment (an environmental construct);
5. What methods of assessment to utilize?

Two obvious elements that should be considered in a best interests analysis are the functional capabilities of each parent and how his/her abilities do or do not match with the child's best interests (sometimes referred to as "goodness of fit"). An examination of these two elements is beyond the scope of this chapter. The APA Guidelines for Child Custody in Family Law Proceedings (2010) recommend that the evaluation focus on parenting qualities, the child's psychological needs, and the resulting fit between them.

### ***Definitions of Legal and Psychological Constructs***

The reader is referred to primary professional documents that address mental health professions' approaches to the assessment of the CPBI in custody and visitation matters, including the American Psychological Association's child custody "guidelines" (APA, 2010), the American Academy of Child and Adolescent Psychiatry's "parameters" (AACAP, 1997); and the American Association of Family and Conciliation Courts "standards" (AFCC, 2006). Forensic mental health practitioners would do well to be mindful of what standards do exist in constructing an assessment within a family law context. Some states—for example, California—have adopted Superior Court Rules that specify the minimum criteria that must be addressed in all child custody evaluation reports to the court. There are other models available to courts for obtaining a child custody and visitation evaluation. For a discussion

of these alternatives, see Kirkpatrick, 2004; see also Rohrbaugh (2008).

### ***The Child's Best Interests (CBI)***

Despite the fact the CBI is the basis for deciding child custody or parenting schedules in disputed proceedings, the best interests of the child (BIC) is a well known and well established legal construct that ironically remains without a consensus definition within the practice of family law in the United States and other countries. In an initial definition of the BIC, the Uniform Marriage and Divorce Act (1973; 1979) stated that the court shall consider:

- The wishes of the child's parent or parents as to the child's custody
- The wishes of the child as to his custodian
- The interaction and interrelationship of the child with his parent, his siblings, and any other person who may significantly affect the child's best interest
- The child's adjustment to his home, school, and community
- The mental and physical health of all individuals involved

The American Law Institute (ALI) referred to the BIC standard as "elastic" and "too subjective to produce predictable results," advocating for its refinement (ALI, 2002). Nevertheless, the BIC standard is the "polar star" by which family courts are guided to make decisions about the custody, well-being, and welfare of children whose parents are divorcing, or who are engaging in post-divorce litigation. There are circumstances, too, wherein the child's parents are not married and the BIC may not involve a "divorce," but may pertain to custody and child access. The BIC might be viewed as a large umbrella held by the court under which all other constructs and factors pertaining to the child's welfare are contained. Courts are encouraged "to consider 'all relevant factors' that they view as important in any given case, and to weight those factors in any manner they choose" (Rohrbaugh, 2008, p. 44).

Its definition notwithstanding, the clear consensus about the BIC is the presiding judge may exercise considerable discretion about what it means. The forensic evaluator should be aware of his/her local and state jurisdictional definitions and relevant case law pertaining to the BIC standard.

### ***The Child's Psychological Best Interests (CPBI)***

The American Psychological Association Guidelines for Child Custody Evaluations in

Family Law Proceedings (2010) encourages psychologists to weigh and incorporate a variety of factors, including the following: family dynamics and interactions; cultural and environmental variables; relevant aptitudes for all examined parties; and the child's educational, physical and psychological needs. Psychologists focus on an array of conditions and capacities related to the child's psychological best interests, recognizing that the court will ultimately decide which factors will be considered and to what degree.

### ***The Child's Expressed Interests (CEI)***

A court may consider and give considerable weight to the interests and wishes of a child of sufficient age in choosing a custodian. However, in the totality of the case, the child's wishes are rarely, if ever, controlling. While the expressed preferences of older children in many states must be given greater weight, there is no absolute recognition for such preference, nor are there uniform ages when such preferences should be given priority (Sparta, 1998).

The forensic mental health evaluator may be asked to aid the court in addressing the child's wishes. The court may ask for help in determining whether or not the child should be allowed to make a statement to the court as to his or her wishes or thoughts about custody and visitation. There is no consensus about an age at which a child is of sufficient age to exercise discretion in giving an opinion about custody. The "test" on this matter is not the child's chronological age. In considering a child's expressed interest, the evaluator considers the child's mental capacity and comprehension to make a reasoned opinion, and whether the wishes are a product of the child's independent considerations or parent/caretaker manipulation.

The above factors are a subset of competency, and a court may require proof of a child's competency. While some states provide a presumption of lack of competency below a specific age, a child of any age may demonstrate competence if he or she understands the difference between truth and lies, understands the requirement of the oath to tell the truth, and is able to testify reasonably accurately (Haralambie, 1999, 2005; for a more general discussion of children's competency, see Myers, 1997).

In considering the child's expressed wishes, courts may want to know what is the level of conflict between the parents in relation to the child's wishes, what factors may be influencing the child's wishes, and what is the child's vulnerability to suggestibility?

## ***The Context of the Assessment***

There are many potential contextual factors that define a thorough assessment of a child's best interests in family law matters. As used here, the *context* is defined as the cultural, legal, and environmental factors within which and about which the child is being assessed forensically. The following is a partial list of some of the more salient contextual factors that may be relevant to a particular case:

1. The history, duration, and tone of the litigation;
2. The level, degree and history of the parental conflict;
3. The nature of the child's psychological attachment with each parent at different times in the child's life;
4. Domestic violence allegations and issues;
5. Abuse and neglect allegations and issues;
6. Estrangement, alienation, or resistance issues;
7. Normal developmental stages and dynamics of the child;
8. Relocation, interstate, and international custody disputes;
9. Effects of parents' personalities on child;
10. Remarriage and blended family relationships;
11. Child abduction/kidnapping;
12. Alcohol/substance abuse history or allegations;
13. The child's stability within different schools and neighborhoods, as well as community bonds.

## ***Assessment Procedures***

Almost without exception, the forensic evaluator in a family law case should seek to be agreed upon by the parties through a consent order, or be appointed by court order. Some jurisdictions require advanced court appointment either by stipulated agreement of the parties, which is subsequently made into the court's order, or the order is made directly by motion of the court. While there are instances where an evaluator may be retained by one party—e.g., as a consulting expert whose role and identity is under the aegis of the attorney work product privilege—most forensic assessments of children and adolescents in family law will involve an expert who is court-appointed, impartial, and whose “client” is the court, the child's guardian, the child's attorney, or a child protection agency.

Generally speaking, the following methods and procedures are typically applied in the forensic

assessment of children and adolescents in a family law context:

1. A forensic expert who engages in the assessment of children and adolescents in a family law context has established a comprehensive and clearly written policy statement that delineates the scope, methods, associated fees and costs, limits of confidentiality, and other relevant information that, in effect, become the “contract” between the evaluator and the parties in the specific case. Many evaluators have found it prudent to have their protocol attached to or referenced within the court order appointing the evaluator.
2. Collateral data are obtained from two general sources—*collateral persons* and *collateral information* (refer to definitions above).
3. Absent a compelling reason, the evaluator must conduct interviews with each parent and or caretaker and conduct/administer similar interviews, observations, and testing. To this end, the evaluator should obtain and be familiar with the relevant pleadings—especially the controlling custody and visitation order.
4. In a post-divorce, high-conflict case in which there are allegations of alienation, abuse, domestic violence, and/or estrangement, as in other forensic evaluations, the forensic evaluator must guard against accepting at face value information provided by the child or adolescent, because the child or adolescent's account may be influenced by one parent over or against the other, or the child or adolescent may have her/his own agenda.
5. Absent a compelling reason, the forensic evaluator, when asked to evaluate a parent-child relationship, should conduct an interview/observation of each parent-child dyad, even in instances where the evaluator has been asked to address child sexual abuse allegations. To be sure, this situation is extremely complex. On one hand, the professional should not participate in a harmful action against the child, such as, for example, coercing a child beyond their current coping capacity to engage in an experience that the child is incapable of dealing with. On the other hand, the evaluation is ordered by a court when there are not yet adjudicated findings of abuse, and it is the allegation that is pending before the court, not the conclusion. When a parent in family law litigation is the object of abuse allegations that have not been substantiated or adjudicated, forensic mental health evaluators should not prematurely avoid conducting a

standardized evaluation, which includes individual and joint sessions with both parents, including the accused. To avoid or omit a parent-child observation under such circumstances runs the risk of omitting essential data. 6. The forensic evaluator recognizes that psychological testing should not be used in isolation, should be considered as but one source of data, and should not solely be used to make custody, access, or visitation recommendations. Evaluators use assessment techniques or tests within the appropriate boundaries of what each method can contribute, neither over-interpreting data nor ignoring information contrary to conclusions.

## **Child Maltreatment—the Best Interests of the Child**

In assessing the best interests of children and adolescents in a dependency case, there are numerous variables, similar to variables that should be considered in family law cases, including (but not limited to) the following:

1. The child's *best interests* (a legal construct);
2. The child's *physical safety and welfare* (a legal construct);
3. The child's *physical, psychological and emotional functions* (legal and psychological constructs);
4. The child's *expressed interests* (both a legal and subjective construct);
5. The context of the assessment (an environmental construct);
6. What methods of assessment to utilize?

Families found in the Dependency Court system are more often at the lower end of the socio-economic spectrum and receiving services from other community agencies (Sedlak & Broadhurst, 1996). This may make these impoverished families more visible to outside authorities, compared to families at the middle and upper end of the socioeconomic spectrum. The reader is referred to primary professional associations which have addressed mental health professions' approaches to the assessment of the CPBI in child protection and dependency matters, including: (a) the American Psychological Association (APA, 1998), (b) the American Academy of Child and Adolescent Psychiatry (AACAP, 1997), (c) the American Professional Society on the Abuse of Children (APSAC, 1995, 1997, 2002, 2008) and (d) the National Association of Counsel for Children (Duquette & Haralambie, 2010). Forensic examiners would do well to be mindful of what standards

do exist in constructing an assessment within a child protection context.

In child custody cases, the primary goal of the mental health evaluator is to assess the best fit between the child's needs and each parent's abilities to meet the child's needs toward developing the child to his or her fullest potential. In child dependency cases, the goal is to assess the child's needs and the parents' abilities, and to make recommendations that assist the court and participants in determining the child's "best interest" specifically related to the child's psychological functioning, attachment relationships, and "safety" from future harm (Kuehnle, Coulter, & Firestone, 2000). As identified by Budd, Connell, and Clarke (2011), generally the concept of "best interest" in child dependency proceedings is invoked in consideration of disposition, visitation, and permanency planning, and the termination of parental rights. Elements in state statutes typically include the child's:

- (a) age and developmental needs;
- (b) physical safety and welfare;
- (c) emotional, physical, and mental status or condition;
- (d) background and ties, including family, culture, and religion;
- (e) sense of attachments;
- (f) wishes and long-term goals;
- (g) need for permanence, stability, and continuity of relationships, including with siblings.

For "definitions of legal and psychological concepts, refer to this subsection within the above section, "Parent Responsibility and Time Sharing—Best Interests of the Child."

## **Assessment Procedures**

In assessing the best interests of children and adolescents forensically in a child dependency context, there are several variables that should be considered:

1. Focus on minimally adequate parenting.
2. Identify clinical and forensic issues of short- and long-term planning.
3. Assess the child's psychological functioning, interpersonal attachments, and safety.

## **Focus on Minimally Adequate Parenting**

Although the standard for deciding cases of child maltreatment is to determine what is in the "best interest of the child," the focus of the forensic evaluation in these matters is often on the parents and whether they are likely to be able to remedy deficits

in their parenting capacity in order to achieve a minimally adequate level of parenting (Budd, Connell, & Clark, 2011). Within child maltreatment cases, the assessment of children and adolescents is typically conducted for purposes of initial treatment, annual evaluations of children in out-of-home placements, and, when parental deficits are not remedied, long-term placement.

### ***Clinical and Forensic Issues of Short- and Long-Term Planning***

The forensic evaluator may address treatment needs, placement needs, and the potential impact of visitation with parents or the absence of visitation, when the child has been temporarily removed from the parents. The forensic assessment of the child may shift to a focus on long-term planning. If the parental deficits that led to intervention cannot be remedied, long-term foster care, residential placement, or adoption may be under consideration, and the determination of a successful placement may be assisted by the forensic evaluation. The evaluator may be asked to focus on the potential impact on the child of permanent severance of the child's relationship with a parent, for example, or the child's long-term placement needs.

### ***Assessment of the Child's Psychological Functioning, Interpersonal Attachments, and Safety***

Forensic evaluations of children during out-of-home placement may occur annually or at other intervals in order to comply with statutorily defined reviews or because of facility licensing requirements. Evaluations are required in order to insure that the child's needs are being addressed, including educational, psychosocial, and behavioral needs. The evaluator may need to gather records of earlier evaluations from other providers. In contrast to a parenting plan evaluation conducted during divorce litigation, evaluations conducted for dependency proceedings may focus on whether the child's intellectual and academic development are delayed due to neglect or whether the history of the child's parenting has created psychopathology interfering in the child's adequate adjustment to living in a normal family environment, or co-existing well with society in general.

Evaluators conducting dependency evaluations also may be asked to address, specifically, the child's attachment to the parent whose parenting is considered to be deficient, to the foster parent, or to a relative with whom the child has lived or may be placed. Specialized understanding of manifestations

of healthy attachment and of techniques for assessment of parent-child relationships should be sought by evaluators undertaking such evaluations. There is a rich literature on attachment, and evaluators bear an obligation to undertake these evaluations, like all other psychological services, only when they have the necessary knowledge, training, and experience to competently provide the service. Courts often order individual evaluations of only the child or parent, and, whenever there is not an opportunity to observe the parent-child interaction, the evaluator should recognize and identify the potential limitations in a dependency evaluation. Similar to family court parenting-plan evaluations, evaluators use collateral information, assessment techniques, or tests within the appropriate boundaries of what each method can contribute.

### ***Psychological Injury—Tort Law***

In assessing psychological injury of children and adolescents in a civil law context, there are certain variables that should be considered:

1. Psychological or emotional injury (a legal and psychological construct)
2. Negligence (a legal construct—a part of the law of torts)
3. Intentional tort (a legal construct)

*Personal injury* law is also known as *tort* law. Forensic evaluators may be involved in personal injury lawsuits related to psychological injury. Psychological injuries consist of stress-related emotional conditions, damaged self-esteem, or self-damaging behaviors as a result of imagined or real threats or injuries having the potential to become the subjects of legal attention, such as personal injury litigation. In the legal system, it is not required to prove an event is the sole cause of psychological injury. In personal injury litigation, the concept of *proximate cause* is important, reflecting an understanding that a contested event in the litigation was the cause for the claimed psychological injury, as opposed to alternative explanations, such as preexisting or coexisting causes (Sparta, 2003). These concepts are further explained in the next section (and for a further review, see Greenberg, 2003).

### ***Definitions of Legal and Psychological Constructs***

The legal claim or complaint, in the form of a lawsuit, is technically known as a *tort* (a "wrong"). A tort is an area of law in which the victims seek compensation for civil "wrongs" allegedly imposed on them. The viability of the claim usually requires

a showing that the defendant has breached a legal duty that was owed to the plaintiff by the defendant (Greenberg & Brodsky, 2001). Personal injury claims fall into two stages—liability and compensation (Sawaya, 2010–2011).

#### **TORT LAW**

“Personal injury” is a legal term for an injury to the body, mind, or emotions, as distinct from an injury to property. A tort is an area of law in which the victim seeks compensation for civil “wrongs” imposed on him or her. There is a distinction between wrongs and wrongdoings—a difference between committing a wrong and acting wrongfully. To “act wrongfully” is to act without justification or excuse. To commit a *legal* wrong is to breach a duty, to invade another’s right. One can breach a duty for good reason, with adequate justification, or under excusing conditions. Rights, in other words, can be invaded innocently (or justifiably) on one hand, or wrongfully (or unjustifiably) on the other (Sawaya, 2010–2011).

The person who sustains injury as the result of tortious conduct is known as the *plaintiff*, and the person who is responsible for inflicting the injury and incurs liability for the damage is known as the *defendant* or *tortfeasor* (Black et al., 1979; Trawick, 2010; Sawaya, 2010–2011). Torts or legal wrongs are legally defined. There are two kinds of torts: intentional and negligence.

#### *Tort—Intentional*

An intentional tort is a wrong perpetrated by a person who intends to do an act that the law has declared wrong, as contrasted with negligence, in which the person fails to exercise that degree of care in doing what is otherwise permissible (Black et al., 1979). Intentional “wrongs” may include physical or sexual abuse of a child or adolescent; intentional neglect such as confinement of a child from social interactions—e.g., confining a child 24 hours a day to a cage, room or house—or keeping a child from receiving an education or adequate food, which may result in mental handicaps.

#### *Tort—Negligence*

In tort law, *negligence* may be defined as the failure to act reasonably (Black et al., 1979; Sawaya, 2010–2011; Florida Standard Jury Instructions in Civil Cases, 2007). Depending on the individual facts of a case, failure by a mental health professional to intervene on a patient’s threat during therapy to commit suicide may be an act of negligence, if the patient acted on his or her threat.

Negligence has three requirements, and a person claiming negligence must prove all three to hold the alleged wrongdoer (i.e., the defendant or tortfeasor) accountable (Sawaya, 2010–2011; Trawick, 2010). The elements of negligence are (a) duty, (b) breach of duty, and (c) causation (Myers, 1998; Trawick, 2010; Sawaya, 2010–2011). Negligence is a type of tort in which most children seek compensation in personal injury claims.

#### **Context of the Assessment**

The majority of torts have five legal requirements in order to prove liability (Trawick, 2010). These requirements differ greatly from other forensic cases. For example, in child custody cases, the sole legal criterion is typically based upon “the best interest of the child(ren).” The five requirements for torts are listed below (Goldberg, 2006):

1. Legal duty
2. Breach or dereliction of that duty
3. Proximate cause
4. Actual damage
5. Compensability

#### **LEGAL DUTY**

This criterion refers to an obligation that requires one individual to conform to a standard with respect to another person.

#### **BREACH OR DERELICTION OF DUTY**

After determining that the defendant owed a legal duty to the plaintiff, the plaintiff is required to prove that the defendant failed to complete his duty or acted in omission.

#### *Proximate Cause*

Forensic psychological evaluators are often asked for their expert opinion when it comes to the issue of causation. Under tort law, “proximate cause” requires a determination of cause and linking that cause as “proximate” to the psychological injury. To determine causation, experts often use the “but for” test. This test requires determination that the injury/damage would not have happened “but for” the defendant’s actions (Black et al., 1979; Sawaya, 2010–2011).

#### **ACTUAL DAMAGE**

The law does not compensate for negligent behavior unless the plaintiff has truly suffered an injury. According to the law, no liability for damage exists if no harm occurred (Black et al., 1979; Trawick, 2010; Sawaya, 2010–2011).

## COMPENSABILITY

In order to prove liability, one must determine that the complaint constitutes a type that the legal system sees as compensable. Once it is determined that the defendant did, in fact, have liability, the compensation process begins. Compensatory losses focus on the actual losses suffered by the plaintiff. There are two types of general compensatory damages in the context of psychological injury (Florida Standard Jury Instructions in Civil Cases, 2007). These include:

1. Loss of consortium: compensation for losing the companionship and love of a close relative.
2. Hedonic damage: how the injury will impact the individual's ability to enjoy life.

## Assessment Methods

A systematic approach to the forensic assessment of emotional injuries includes viewing the claimant's life through three windows of time:

1. Who the child was and how he/she was functioning prior to the alleged tort;
2. Reconstruction of the events that surrounded and possibly created the alleged "tort";
3. The likely impact of experiencing such an event and the child's current level of functioning post-event.

Psychological evaluations in personal injury litigation primarily focus on whether or not an injury has occurred, the defendant's role in the injury, and the prognosis for rehabilitation and functioning in the future. Three primary types of data used in assessment of personal injury include: interviews and observations (discussed above), collateral data, and psychological testing.

## COLLATERAL DATA

The collateral data collected for personal injury evaluations will, at times, have a different focus than the collateral data collected for child custody and dependency cases. In personal injury cases, the forensic evaluator will need to obtain information related to the developmental and clinical background of the child in order to contrast the child's assessed emotional, behavioral, cognitive, learning, social, or psychosomatic functioning against the child's normal expected functioning. Information from a variety of sources would document the child's actual functioning at different times, including any information related to the child's family environment, educational history, diagnosis of mental disorder

and/or substance abuse, history of prior involvement with the legal system, and medical/health issues. This information can be obtained from collateral interviews with current or past caregivers, teachers, mental health providers, or other parties familiar with the child or adolescent plaintiff. Past and current academic records, previous psychological reports, medical records, videotaped interviews or depositions of the plaintiff or other persons related to the case, and legal documents relevant to the case are essential to review. It is important to ask for such records, as sometimes an attorney would not necessarily identify the relevance of such data. Greenberg (2003, p. 241) provides the following data-organizational system related to five conceptual parts of the examination:

### *Pre-Allegation History*

- Strengths and competencies
- Preexisting vulnerabilities
- Preexisting impairments in functioning

### *Trauma and Distress*

- What the child (plaintiff) was exposed to

### *Sequelae*

- Substantial impairments in functioning that the child (plaintiff) suffered
- Ways in which the child (plaintiff) was resilient

### *Proximate Cause*

- Impairments that would not have occurred but for the alleged events
- Impairments that would have occurred otherwise

### *Prognosis*

- Degree of future impairments (partial or complete, temporary or permanent)
- Interventions or accommodations indicated

### *TESTING*

There is no universally accepted set of assessment tools to be used in personal injury examinations. Furthermore, there are no tests that directly answer the legally relevant questions regarding preexisting conditions, proximately caused damage, or the severity or the distress caused by the defendant's behavior (Greenberg, 2003). Personal injury forensic examiners tend to use the same core battery of tests for adults that are used in adult clinical assessments. The most commonly used instruments for adult assessments

are the MMPI-2, the WAIS-R or III, MCMI-II or III, Rorschach, Beck Depression Inventory, Trauma Stress Inventory, and the Symptom Checklist 90-Revised (Boccaccini & Brodsky, 1999). The Minnesota Multiphasic Personality Inventory-2nd Edition-Restructured Form (MMPI-2-RF) (Ben-Porath & Tellegen, 2008) is emerging as a useful measure in adult personal injury assessments. Similar surveys have not been conducted on identifying the test battery most commonly used with children and adolescents in personal injury cases.

Several instruments have been developed in an attempt to measure traumatic experiences in children and identify the presence of post-traumatic stress disorder (PTSD). These include: Trauma Symptom Checklist for Children, with both child respondent and parent respondent forms (there is also a preschool-age version); the Clinician-Administered PTSD Scale for Children; the Child Dissociative Checklist; the Child Post-Traumatic Stress Reaction Scale; Child Rating Scales of Exposure to Interpersonal Abuse; and the Child's Reaction to Traumatic Events Scale. Shuman (2003) identifies a heightened criticism of PTSD claims in personal injury lawsuits, given the perception of the increased frequency of PTSD claims, as well as increased challenges to the expert testimony presented in support of PTSD claims.

As identified in reviews published by Buros Institute of Mental Measurements (<http://buros.unl.edu/buros/jsp/search.jsp>), the above-listed checklists and scales all have psychometric weaknesses, about which the forensic evaluator should be knowledgeable. Furthermore, any test result should be used to formulate hypotheses and not be used as a diagnostic tool in isolation from the myriad other data collected.

### ***Juvenile Competency—Criminal Law***

In *Dusky v. United States* (1960), the Supreme Court of the United States ruled that a defendant must have “sufficient present ability to consult with his attorney with a reasonable degree of rational understanding,” and have a “rational as well as factual understanding of the proceedings against him” (p. 402). The Supreme Court further decided in *In re Gault* (1967) that juveniles are afforded the same rights as adults, which enabled the courts to consider competency to proceed for juveniles. In the forensic assessment of the competency of children and adolescents in a criminal law context, there are certain variables that should be considered:

1. Defendant’s capacity to meet the *Dusky* standard (a legal construct)

2. Developmental and functional capacities: i.e., mental illness, mental retardation, or cognitive immaturity (legal and psychological constructs)

3. Interpersonal: i.e., to what degree can a juvenile interact and communicate with his/her counsel (legal and psychological construct)

### **DEFINITIONS OF LEGAL AND PSYCHOLOGICAL CONCEPTS**

Grisso (2005) identified the following characteristics of competency:

- Functional—specific knowledge or understanding
- Causal—cause(s) of functional inabilities
- Contextual—the specific environment in which functional abilities are necessary
- Conclusive—based on information provided by a forensic evaluator, the court will determine the competency issue

#### *Functional Capacities*

Significant to issues of immaturity, Grisso and colleagues (2003) reported that juveniles between the ages of 16 and 17 typically had an understanding of the legal process comparable to that of adults; however, juveniles under the age of 15 demonstrated significant difficulty with understanding and participating in the legal process (Melton et al, 2007).

#### *Causal capacities: Causes of Functional Inabilities*

While statutes governing the legal construct of competency vary from state to state, whether a defendant has the capacity to meet the *Dusky* standard is typically associated with cognitive ability; i.e., the impact of mental illness or mental retardation (McGaha, Otto, McClaren, & Petrila, 2001), as well as developmental limitations and physical disabilities (Geraghty, Kraus, & Fink, 2007). Some courts are beginning to recognize cognitive or developmental immaturity as factors in juvenile incompetency, with relevant factors varying from case to case (Grisso, et al., 2003; Poythress, Lexcen, Grisso, & Steinberg, 2006).

#### *Contextual*

Given the adversarial nature of criminal courts, the ability of younger juveniles and juveniles with cognitive or developmental disabilities to recall information and testify relevantly may be significantly challenging. Juveniles also show greater brain activity in the limbic system compared to adults, which can have a significant influence on courtroom behavior, including emotionally charged behavior, emotional rather than

logical thinking, and difficulty weighing decisions (Mayzer, Bradley, Rusinko, & Ertelt, 2009).

### THE CONTEXT OF THE ASSESSMENT

All fifty U.S. states have a statute that delineates the procedures to be followed when the question of competency is raised in criminal court (Geraghty et al., 2007). The objective of the competency evaluation is to determine the defendant's *current* level of functioning, not to evaluate retrospective capacity (e.g., when the alleged crime was committed) or to predict future behavior. Forensic examiners are called upon to determine whether the juvenile defendant has a mental illness or is mentally handicapped and to determine whether the defendant lacks developmental maturity to the degree that this would interfere with the juvenile defendant's ability to meet criteria for "competence to proceed" in his or her criminal trial. The forensic evaluator must be familiar with the relevant state statutes and definitions of legal terms as they relate to the evaluation.

### **Conclusive**

It is up to the judge or jury, not the evaluator, to answer the ultimate question: is the defendant competent?

### ASSESSMENT METHODS

When addressing issues of competency, the forensic examiner considers and reports upon the defendant's capacity to:

1. Appreciate the charges or allegations
2. Appreciate the range and nature of possible penalties
3. Understand the adversarial nature of the legal process and the roles of the various participants
4. Disclose to counsel facts pertinent to the proceedings at issue
5. Manifest appropriate courtroom behavior
6. Testify relevantly if necessary

The following methods and procedures are typically used to address the competency criteria listed above when conducting a juvenile competency evaluation:

#### *Interviews*

Structured and semi-structured interviews have been developed for assessing competency. A semi-structured interview developed by Grisso (2005), the Juvenile Adjudicative Competency Interview (JACI), is structured to obtain information about the juvenile's abilities in twelve (12)

areas relevant to competence to stand trial, and includes the assessment of developmental immaturity (e.g., perceived autonomy, perceptions of risk, time perspective, and abstract/concrete thinking), mental disorder, and intelligence.

Forensic evaluators who interview juveniles facing legal charges should be aware of the difficulties they might encounter when trying to communicate with the defendant—e.g., inaccurate understanding of the legal system, which might cause suspicion of the evaluation process; refusal to talk; threats to self-esteem for being suspected of having a mental disorder; or a lack of motivation to cooperate with the evaluator (Melton et al, 2007). Furthermore, it is essential to assess a juvenile's response style, i.e., how the juvenile approaches being evaluated in a criminal context and to determine if the defendant is responding in an honest and forthright manner (Melton, et al, 2007). Reasonably accurate hypotheses about an individual's response style can be developed by a confluence of data from validity scales from standardized assessment measures, collateral information, and clinical observation.

#### *Observation*

The forensic evaluator may reasonably infer that a juvenile can or cannot be cooperative when interacting with legal counsel or during court proceedings, or that the juvenile can or cannot understand and retain information based on demonstrated behavior during the evaluation (Otto, 2006). Observation of physical or developmental disabilities that may interfere with the defendant's capacity should be duly noted, as well as the juvenile's ability to accurately recall and communicate information. Behaviors suggestive of responses to stress, depression, delusions, or unusual behaviors should also be specifically noted as they relate to the defendant's ability to interact during the criminal process.

#### *Testing*

A greater proportion of juveniles of below-average intelligence are found in the juvenile justice system, and they are more likely to demonstrate impaired abilities relevant to competency, compared to juveniles of average intelligence (Grisso, et al. 2003; Melton et al., 2007). Therefore, tests of intelligence (e.g., Wechsler Intelligence Scale for Children) are useful in establishing intellectual and cognitive functioning. Tests of achievement and cognition may also be useful in identifying specific deficits significant to the juvenile's capacity; e.g., verbal abilities, comprehension,

reasoning. Personality testing or neuropsychological testing may be warranted. When using psychological tests, the findings must be integrated with other assessment data (Gudas & Sattler, 2006).

### *Historical Information*

Information regarding the family environment, educational history, psychosocial, cognitive, and emotional functioning, history of delinquency, mental disorders, and/or substance abuse, and physical health are factors that may contribute to the present capacity of the defendant. This information can be obtained from collateral interviews with past and/or current caregivers, teachers, healthcare providers, or other parties familiar with the defendant. Additionally, information can be gleaned from a review of records, e.g., police records, academic (including discipline) records, previous psychological reports or medical records, after obtaining the necessary consent from the parent or legal guardian.

### **Summary**

The purpose of forensic evaluations conducted by mental health professionals is to be helpful to the legal decision-maker (i.e., judge, jury, other hearing officer) or retaining authority. In contrast, the purpose of the clinical evaluation is to be helpful to the patient. Forensic mental health evaluators may perform evaluations of children and adolescents in many different psycholegal contexts. This chapter described the forensic assessment of children and adolescents related to psycholegal questions in three areas of civil judicial proceedings and one area of criminal judicial proceedings. Forensic mental health evaluators of children and adolescents attempting to answer psycholegal questions must be familiar with the relevant state statutes and definitions of legal terms as they relate to the evaluation. They must also utilize multiple methods to consider diverse sources of independent data, multiple hypotheses when collecting and analyzing the data, and an awareness of the evaluation context of the psycholegal question—guarding against accepting at face value any information from a single source. A competent forensic evaluator utilizes a healthy dollop of skepticism as part of the assessment. Assessment of children in forensic contexts requires clarity of focus and adherence to general forensic guidelines and standards for objectivity. Instruments should be chosen with consideration for their relevance to the psycholegal construct and reliability for the purpose for which they are used. Whether the assessment procedures and instruments are also used in

clinical assessments or are designed specifically for use in forensic contexts, their use in the forensic context must be undertaken thoughtfully and with good foundation. Ultimately, the evaluator should be able to draw a clear connection between the data collected and the resulting findings and opinions.

### **Notes**

1. In 1993, in *Daubert v. Merrell Dow Pharmaceuticals*, the U.S. Supreme Court determined that the Federal Rules of Evidence (FRE) focus on *reliability* was the proper standard for determining admissibility of expert testimony (Flens, 2005).
2. In 1999, in *Kumho Tire Co. v. Carmichael*, the U.S. Supreme Court clarified that the court's "gatekeeping" role should encompass all expert testimony, not just "scientific" testimony (Flens, 2005).

# Assessing Non-Cognitive Constructs in Education: A Review of Traditional and Innovative Approaches

Anastasiya A. Lipnevich, Carolyn MacCann, and Richard D. Roberts

## Abstract

This chapter provides a broad overview of both conventional and novel approaches for assessing non-cognitive skills, specifically focusing on their application in educational contexts. Conventional approaches include self-assessments, other-ratings, letters of recommendation, biodata, and interviews. We outline the current uses and validity evidence for these methods, and discuss the theory of planned behavior as a useful heuristic for assessment development. Novel approaches to non-cognitive assessment include the situational judgement test, day-reconstruction method, and use of writing samples. After reviewing these new approaches, we discuss the issue of response distortion in non-cognitive assessment, outlining some assessment techniques thought to be less susceptible to faking. Suggested fake-resistant assessments include the implicit association test and conditional reasoning test, as well as forced-choice tests and the Bayesian truth serum. We conclude with a series of summary statements concerning uses of non-cognitive testing in education.

**Key Words:** non-cognitive assessment, self-report, other-reports, situational judgement test, biodata

## Introduction

It is increasingly obvious that succeeding in education requires much more than just “book smarts.” To succeed, students need to be not just intelligent, they need to work hard, believe in themselves, cope with the stress of academic evaluations, develop and maintain networks of social and academic support, and organize their homework, projects, and study. That is, students’ non-cognitive qualities can be as influential as their cognitive skills in influencing their academic achievement and educational aspirations (e.g., Burrus, MacCann, Kyllonen, & Roberts, 2011). Moreover, these non-cognitive qualities do not just predict the grades awarded by teachers or schools, but the hard data collected by large-scale testing programs. For example, research demonstrates that children and adolescent’s levels of self-efficacy, self-concept, and self-confidence predict their mathematics, science, and reading scores

(Campbell, Voelkl, & Donahue, 1997; Connell, Spencer, & Aber, 1994). Non-cognitive constructs are important predictors of academic achievement and behavioral adjustment from early childhood, with Abe’s (2005) research demonstrating that personality at age three predicted academic achievement in later schooling.

Perhaps even more importantly, these non-cognitive constructs are not simply proxies for a privileged background or for student ability variables. Duckworth and Seligman (2005) demonstrate that non-cognitive variables still predict academic achievement even after controlling for key socioeconomic variables such as demographics, school attendance, and home educational materials. Meta-analyses testify that non-cognitive constructs such as conscientiousness, self-efficacy, achievement motivation, and test anxiety predict academic achievement and attrition rates over and above the

effects of cognitive ability and socioeconomic status (Poropat, 2009; Robbins, Lauver, Le, Davis, Langley, & Carlstrom, 2004; Seipp, 1991). It seems that students' non-cognitive qualities are important in their own right, and play a vital role in whether students are able to profit from their experience of school.

Given the importance of non-cognitive factors for school success, the goal of the current chapter is to provide a broad overview of the different ways that these non-cognitive constructs can be conceptualized and measured. We begin with a brief explanation of the different types of non-cognitive qualities that have been examined in the literature, focusing primarily on an education context. We then discuss both traditional and innovative measurement methods for indexing these kinds of constructs, and evaluate the strengths and weaknesses of each psychometric approach. Traditional approaches include self- and other-report rating scales and interviews. Novel approaches include situational judgement tests (SJT), day reconstruction, implicit association tests (IATs), and conditional reasoning tests (CRTs). One commonly stated disadvantage of non-cognitive compared to cognitive assessment is the concern that test-takers are able to distort their responses to create an erroneous impression. We therefore discuss faking in non-cognitive assessment, devoting special attention to whether innovative assessment methodologies can mitigate the effects of faking. In a concluding section, we discuss the existing and potential applications of non-cognitive measurement in educational research, policy, and practice.

## What Are Non-cognitive Factors?

“Non-cognitive constructs” is a broad umbrella term in the education literature that refers to a range of student characteristics thought to be distinct from students’ intellectual competence and their capacity for mastering the “three Rs” of schoolwork. The extensive research on non-cognitive constructs crosses many different disciplines, including education, educational psychology, social psychology, developmental psychology, personnel psychology, and individual differences (to name just a few). This breadth of research can sometimes result in inconsistent use of construct labels across studies from different disciplines, thus leading to both the “jingle fallacy” (assuming that two constructs are the same because they share the same label) and the “jangle fallacy” (assuming that two constructs differ because they have different labels; e.g., Block, 1995). For

example, the meta-cognition literature uses the term *confidence* to refer to an evaluation of correctness (e.g., “I am confident my answer is right”) whereas the positive psychology literature uses the term *confidence* to refer to a positive emotional state (e.g., “I am feeling happy and confident today”). Conversely, the term *integrity* may vary widely in meaning from *intellectual integrity* to through to *absenteeism*. While we acknowledge that terminology is currently not set in stone and may vary slightly from discipline to discipline, we provide a rough taxonomy of some of the most commonly researched non-cognitive constructs, grouped into four domains: (1) attitudes and beliefs, (2) social and emotional qualities, (3) habits and processes, and (4) personality traits.

## Attitudes and Beliefs

The first broad group of non-cognitive constructs includes the beliefs that students hold about themselves as learners, the nature of learning, the fairness or supportiveness of the school environment, and their attitudes towards different disciplinary areas and towards school in general. One prominent self-belief system is Dweck and Leggett’s (1988) “implicit theories of intelligence.” This model proposes that students may hold different types of beliefs about the malleability of intelligence. Entity theorists believe that ability is preset, and cannot be changed through training or practice. In contrast, incremental theorists believe that ability is malleable. As might be expected, entity theorists tend to perform worse at school (Blackwell, Trzesniewski, & Dweck, 2007). This beliefs-and-attitudes grouping of non-cognitive constructs also includes the conscious or unconscious attitudes that students may hold about particular disciplines (e.g., beliefs that mathematics is difficult or that science is fun). Such attitudes may strongly influence students’ subsequent behavior and thus their academic success (e.g., Lipnevich, MacCann, Krumm, Burrus, & Roberts, 2011). Students may also hold particular beliefs relating to their self-concept, self-confidence, or self-efficacy, which predict their achievement in various academic and life domains (e.g., Marsh, Byrne, & Shavelson, 1988).

## Social and Emotional Qualities

There is a range of non-cognitive constructs that relate to students dealing with their emotions and the emotions of others. Perhaps the most salient and most frequently studied of these constructs is test anxiety (e.g., Sarason, 1984; Zeidner, 1998).

Students who suffer from test anxiety become overwhelmed by the thoughts and physiological sensations of anxiety during assessment situations and thus will be distracted from the task at hand, impairing their performance (e.g., Wine, 1971). Other non-cognitive constructs relating to students' emotions include self-regulation, emotion management, emotional control, coping with stress, and students' emotional states (e.g., MacCann, Fogarty, & Roberts, 2012; MacCann, Wang, Matthews, & Roberts, 2010; Pekrun, Elliot, & Maier, 2006). Research has demonstrated plausible causal pathways that relate greater emotional skills to higher levels of achievement. For example, students with better emotion management tend to use more effective coping strategies in response to academic stressors, which relates to higher levels of academic achievement (MacCann et al., 2011). Social and interpersonal constructs such as teamwork and leadership might also be considered under this broad banner (e.g., Wang, MacCann, Zhuang, Liu, & Roberts, 2009).

### ***Habits and Processes***

A further category of non-cognitive constructs relates to particular classes of habits or processes that students engage in when completing academic tasks. For example, students differ in the extent to which they engage in time management practices such as list-making, using time management aids (e.g., a planner or a system of electronic reminders), allocating time to particular tasks, or carefully noting deadlines for assignment due dates. Liu, Rijmen, MacCann and Roberts (2009) demonstrate that time management predicts academic achievement at middle school, and that girls at this age tend to have better time management habits than boys. Similarly, some students may routinely set particular kinds of learning goals, whereas others may not set goals at all, or may set goals that relate to publicly proving their ability rather than learning new things (Grant & Dweck, 2003). Other constructs in this category include organizational skills, study habits, learning strategies, and test-taking strategies (e.g., Crede, & Kuncel, 2008; Liu, 2009). Students' meta-cognitive skills such as self-monitoring and self-evaluation might also be considered part of this broad group of constructs (e.g., Flavell, 1979; Stankov & Lee, 2008).

### ***Personality Traits***

Finally, the broad personality domains and narrow personality facets have a long research history

within psychology and education (e.g., Fiske, 1949; Norman, 1963). Personality traits are thought to be relatively stable and long-lasting, and describe an individual's consistent patterns of thoughts, behaviors, and emotions across different situations. Although there are several competing personality models, there is a rough consensus that five broad domains are the best starting points for describing differences between individuals' personalities (e.g., Digman & Inouye, 1986; Tupes & Christal, 1992). These five factors are:

- (1) Extraversion (the tendency to be social, positive, and energetic);
- (2) Agreeableness (the tendency to be kind, truthful and trusting);
- (3) Conscientiousness (the tendency to be detail-oriented, achievement striving, and work-focused);
- (4) Neuroticism (the tendency to experience negative emotions easily, often, and strongly) and
- (5) Openness to Experience (the tendency to be open to new feelings, thoughts, and experiences).

Both conscientiousness and openness to experience show a robust relationship with academic achievement, although only conscientiousness predicts achievement independently of cognitive ability (Poropat, 2009; Trapmann, Hell, Hirn, & Schuler, 2007). In addition to the five broad personality domains, most contemporary models of personality also acknowledge more specific facets of personality that underlie each domain (e.g., Costa & McCrae, 1995; MacCann, Duckworth, & Roberts, 2009). For instance, Costa and McCrae propose six relatively distinct facets of conscientiousness: competence, order, dutifulness, achievement striving, self-discipline, and deliberation. Some research indicates that the narrow facets of personality may be more predictive than the broad domains (e.g., Paunonen & Ashton, 2001).

Each of these different types of non-cognitive factors can be assessed in a variety of ways, and each method of assessment has different strengths and weaknesses. The method of assessment can affect a large variety of test characteristics. These include (but are not limited to):

- (a) the nature of what is measured,
- (b) the potential for response distortion,
- (c) the accuracy of measurement in different groups (e.g., some methods may be more appropriate for young children or test-takers with developing English-language literacy);

- (d) the type and variety of feedback that can be given;
- (e) the feasibility of large-scale testing and group assessment, compared to individual assessment;
- (f) the cost of testing in terms of time, money, required equipment, assessor-training, and assessment development expenses;
- (g) the reliability of the tests;
- (h) the ease of building interventions or development plans targeting the measured construct;
- (i) the sensitivity of the measure to changes over time;
- (j) the potential for adverse impact, particularly if the assessment is used for high-stakes purposes such as selection; and
- (k) test-taker reactions and engagement with the testing process.

In the paragraphs below, we describe and evaluate some of the most commonly used assessment methodologies, as well as some of the innovative and emerging methods that may be used in future assessments.

## Traditional Non-cognitive Assessment Techniques

### *Self-Assessments*

Self-assessments are undoubtedly the most widely used approach for gauging students' non-cognitive characteristics. These uses include: evaluating the effects of training; program evaluation; outcomes assessment; research; and large-scale, group-level national and international comparisons, to name a few. Indeed, most insights concerning the relationship between non-cognitive qualities and educational (or for that matter, work-related) outcomes come from research, practice, and policy conducted with self-report questionnaires.

### GENERAL APPROACH

Self-assessments usually ask individuals to describe themselves by answering a series of standardized questions. The answer format is generally a Likert-type rating scale, but other formats may also be used (such as Yes/No or constructed response). Typically, questions assessing the same construct are aggregated; this aggregate score serves as an indicator of the relevant non-cognitive domain. The variety of constructs that can plausibly be assessed with self-reports are myriad. At a broad or abstract level these include personality, values, beliefs, and affect. Examples of specific

constructs that may be assessed with self-reports include communication skills, time management, teamwork, leadership, self-regulation, self-efficacy, and altruism. (Table 33.1 in this chapter includes a selection of sample items indicative of this approach.)

Self-assessments are a relatively pragmatic, cost-effective, and efficient way of gathering information about the individual. However, many issues must be taken into account when one is developing a psychometrically sound questionnaire, and there is a large literature on a wide variety of such topics. The optimal number of points on a scale, scale point labels, the inclusion of a neutral point, alternative ordering, and other test characteristics have been widely analyzed and examined in the literature (e.g., Krosnick, Judd, & Wittenbrink, 2005). For instance, studies reveal that response scale format influences individuals' responses (Rammstedt & Krebs, 2007), while the inclusion of negatively keyed questions (to avoid acquiescence) is considered controversial, especially with younger children (e.g. Barnette, 2000; DiStefano & Motl, 2006). Respondents vary in their use of the scale—for example, young males tend to use extreme answer categories (Austin, Deary, & Egan, 2006), as do Hispanics (Marin, Gamba, & Marin, 1992); and in general, there are large cultural effects in response style (Harzing, 2006; Lipnevich et al., 2011).

Respondents can fake their responses on self-assessments to appear more attractive to a prospective educational institution or employer, or to avoid remedial programs (e.g., Griffith, Chmielowski & Yoshita, 2007; Viswesvaran & Ones, 1999; Zickar, Gibby & Robie, 2004). Researchers have identified several promising methods for collecting data through self-reports while reducing fakeability. These include giving real-time warnings (Sackett, 2006), using a forced-choice format (Stark, Chernyshenko, & Drasgow, 2005), and using one's estimates of how others will respond to help control for faking (Prelec, 2004; Prelec & Weaver, 2006). However, evidence for the effectiveness of these procedures in controlling for faking remains to be demonstrated unequivocally (Converse, Oswald, Imus, Hedricks, Roy, & Butera, 2008; Heggestad, Morrison, Reeve, & McCloy, 2006). We consider the issue of fakeability in greater detail in a later section of this chapter.

### THEORY OF PLANNED BEHAVIOR (TPB) AS A FRAMEWORK FOR DEVELOPING SELF-ASSESSMENTS

Self-assessments are based on a number of different conceptual frameworks, including those based

**Table 33.1 Self-Report: Examples of Constructs, Items, and Response Scales**

Construct	Sample Items	Response Scale
1 Achievement Striving	1. I detect mistakes. 2. I do just enough work to get by (R).	Five-point Likert scale: "Not At All Like Me" (1) to "Very Much Like Me" (5).
2 Conscientiousness	1. I am always prepared. 2. I work hard.	Five-point Likert Scale: "Very Inaccurate of Me" (1) to "Accurate" (5).
3 Goals	1. I focus on the happy ending. 2. I fully focus on the obstacles (R).	Seven-point Likert scale: "Never" (1) to "Always" (7).
4 Grit	1. I am diligent 2. Failures double my motivation to succeed.	Five-point Likert scale: "Not at all like me" (1) to "Very much like me" (5).
5 Learning Strategies	1. When I study, I try to figure out which parts of the material I need to study most. 2. When I do my homework, I check to see whether I understand the material.	A four-point Likert-type scale: Never or Hardly Ever (1), Sometimes (2), Often (3), Always or Almost Always (4).
6 Self-Efficacy	1. I am certain that I can accomplish my goals. 2. I can handle whatever comes my way.	A four-point Likert-type scale: Hardly Ever (1), Sometimes (2), Often (3), or Almost Always (4).
7 Academic Motivation	1. I do only as much work as I have to for the grade I want. 2. I put little effort into my classes (R).	A four-point Likert-type scale: Strongly Agree (4), Agree (3), Disagree (2), Strongly Disagree (1).
8 Feelings About School Life	1. When doing after-school activities, I have felt nervous (R). 2. When doing homework, I have felt confident.	A four-point Likert-type scale: Never or Rarely (1), Sometimes (2), Often (3), Usually or Always (4).
9 Anxiety	1. I worry about things. 2. Fear for the worst.	Yes/No
10 Leadership	1. Can talk others into doing things. 2. Wait for others to lead the way.	Five-point Likert scale: "Not at all like me" (1) to "Very much like me" (5).

Notes: (R) refers to items that are reverse-keyed for respective scales of the instruments.

on clinical criteria, lexical analysis, and psychological theory. TpB has been particularly effective in serving as a framework for the development of assessments of individuals' attitudes (see Table 33.2 in this chapter for examples of items measuring TpB components). Only recently has the theory of planned behavior been applied in educational contexts (see Davis, Ajzen, Saunders, & Williams, 2002; Lipnevich et al., 2011). The initial findings appear promising. Hence, a brief overview follows.

The TpB is based on the psychological theory of reasoned behavior (Ajzen, 1991, 2002). The TpB posits that the central determinant of volitional behavior is one's intention to engage in that behavior. The theoretical model of the TpB is shown in Figure 33.1. Ajzen (1991) further proposes three independent determinants of behavior that exert

their effects through intentions. These are: (1) attitudes, (2) subjective norms, and (3) perceived behavioral control. *Attitudes* are defined as the overall positive or negative evaluation of the behavior. In general, the more favorable the attitude towards the behavior, the stronger the individual's intention is to perform it. Subjective norms assess the social pressures on the individual to perform or not to perform a particular behavior. Finally, perceived behavioral control provides information about the potential constraints on action as perceived by the individual (Armitage & Conner, 2001).

Several meta-analyses and literature reviews show support for the general principles underlying the TpB model (see Ajzen, 1991; Armitage & Conner, 2001). Studies reveal that the TpB accounts for 27 percent and 39 percent of the variance in behavior

**Table 33.2 Self-Report: Theory of Planned Behavior-Based Assessment of Attitudes Toward Mathematics (after Lipnevich et al., 2011).**

TpB Component	Sample Item	Response Scale
1. Attitudes	I enjoy studying math.	(1) Strongly Disagree (2) Disagree (3) Neither Agree nor Disagree (4) Agree (5) Strongly Agree
2. Subjective Norm	My friends think that math is an important subject.	
3. Perceived Behavioral Control	If I invest enough effort, I can succeed in math.	
4. Intentions	I will try to work hard to make sure I learn math.	

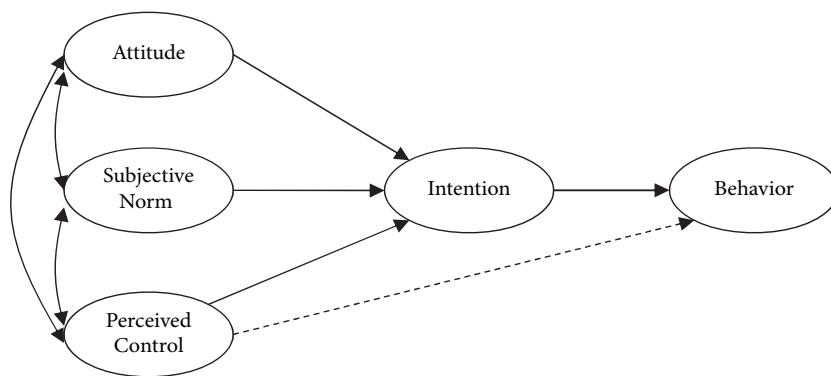

and intention, respectively (Armitage & Conner, 2001; Sheeran, 2002). Davis et al. (2002) used the TpB to successfully predict high school completion (Davis, Ajzen, Saunders, & Williams, 2002). Results revealed that the TpB questionnaire significantly predicted high school completion. The model was a good fit to the data, and attitudes, subjective norms, and perceived control accounted for 51 percent of the variance in the intention to complete the present school year. Furthermore, attitudes, subjective norms, and perceived control all significantly predicted intention.

Another study that applied TpB to an educational context was conducted by Lipnevich et al. (2011). The researchers examined the effectiveness of the TpB in predicting students' mathematics performance. They found that between 25 percent and 32 percent of the variance in mathematics grades could be explained by TpB components. Moreover, 17 percent of the variation in test grades can be

explained by the TpB over and above the effects of mathematics ability test scores. So, development and implementation of TpB-based self-assessments may be instrumental in predicting a number of meaningful educational outcomes. Additionally, researchers suggest that the TpB has tremendous potential to inform the development of behavior-change interventions (see e.g. Armitage & Conner, 2001; Hardeman, Johnston, Johnston, Bonetti, Wareham, & Kinmonth, 2002; Rutter, 2000).

### Other-Ratings

Other-ratings are assessments in which others (e.g., supervisors, trainers, colleagues, friends, faculty advisors, coaches, etc.) rate individuals on various non-cognitive skills. This method has a long history, and numerous studies have been conducted that employed this methodology to gather information (e.g., Tupes & Christal, 1961/1992). Other-ratings have an advantage over self-assessments in that they

**Figure 33.1** Representation of the Components of the TpB model.

**Key:** *Attitudes*—the overall evaluation of whether a behavior is positive or negative (based on prior behavioral contingencies). *Subjective Norms*—the perceived social pressure to perform the behavior. *Perceived Control*—the person's estimate of his or her capacity to perform the behavior. *Intentions*—the readiness or willingness to perform the behavior.

preclude socially desirable responding, although they are prone to rating biases. Self- and other-ratings do not always converge (Oltmanns & Terkheimer, 2006), but other-ratings have been demonstrated to often be more effective in predicting a range of educational outcomes, compared to self-ratings (Kenny, 1994; Wagerman & Funder, 2006).

#### TEACHER- AND PARENT-RATINGS

Teacher- or parent-ratings of personality have been widely used for gauging younger students' non-cognitive characteristics due to concerns that children lack the cognitive ability and/or psychology-mindedness to self-rate on personality instruments (e.g., Hendriks, Kuyper, Offringa, & VanderWerf, 2008). Other-ratings are also most appropriate when used to evaluate individuals with low verbal ability. For instance, the Child Behavior Check List (CBCL; Achenbach, 1991)—completed by teachers and/or parents—has been successfully employed to assess behavioral and emotional competencies (e.g., Anxious/Depressed, Rule-breaking Behavior) of children aged 6 to 18 years. Similarly, the Parent Rating Scale of the Behavioral Assessment System for Children (currently in its second edition—BASC-2) has been widely used to gauge adaptive and behavior problems of children between the ages of two and 21 (Reynolds & Kamphaus, 2004). Both CBCL and BASC-2 has been shown to capture a range of problems and competencies that would be difficult—if not impossible—to capture through self-reports.

MacCann, Lipnevich, and Roberts (2013) conducted a series of studies to compare parent judgments of personality with sixth to eighth-grade students' self-assessments. The results from three studies suggested that parent-ratings were both more reliable and more useful in predicting academic achievement than students' self-reports. This large difference in utility between self- and parent-reports of personality is noteworthy: Parent-reported Conscientiousness explained over twice as much variation in grades as students' self-reported Conscientiousness. Although such results might be used to justify the idea that younger children (in their preteens and early teens) might lack the psychology-mindedness or cognitive ability to accurately self-rate on personality questionnaires, it is worth comparing current results to studies of self- versus other-reports in older teenagers and adults. Thus, research studies demonstrate that peer-, co-worker-, supervisor-, and customer-ratings may be more reliable and more predictive of

valued outcomes than self-ratings, particularly for Conscientiousness (e.g., Mount, Barrick, & Strauss, 1994; Small & Diefendorff, 2006).

There are several possible reasons that parent-reports might differ from self-reports. John and Robins (1993) speculate that self-reporting differs from other-reporting in three main ways: (1) ego involvement is implicated in self-reports but not other-reports; (2) perspectives are different (the other-report is from an external observer, whereas the self is actively involved in the phenomena that personality items ask about); and (3) the self has access to privileged information such as previous experiences, internal thoughts, values, and intentions that are not available to others. If point (1) is responsible for the greater prediction by parent-reports, response bias in self-reports might attenuate correlations with grades. However, large-scale results from personnel psychology demonstrate that response bias does not actually affect the predictive power of personality tests (Barrick, & Mount, 1996; Ones, Viswesvaran, & Reiss, 1996). Moreover, when comparing mean differences in self- versus parent-reports, MacCann et al. (2013) demonstrated the opposite effect—parent-ratings resulted in higher means (i.e., were more flattering) than self-ratings. MacCann et al.'s study showed that score inflation in parent-versus child-reports might relate to different processes, with parent-reports prone to self-deceptive denial, whereas inflation of self-reports appears due to self-deceptive enhancement. Newspapers are full of illustrative examples of parents who deny that their children could possibly have behaved in such an immoral or unrestrained fashion as to commit crimes, for example, despite all the evidence to the contrary. When the other-rater shares a close emotional bond with the individual being assessed, the general rule that score inflation will be greater for self- than other-reports appears controversial.

Point (3) might also account for differences in parent and self-report prediction. Given that parents do not have access to privileged internal information, they may need to use cues from the child's academic outcomes (which they know) to answer questions about the child's personality. That is, parents may make estimates on available information (which may be drawn from other constructs) when answering questionnaire items that refer to this privileged or internalized information. The implication of this finding for test development is that parent-reports (and other-reports more generally) should refer to observable information or facts to avoid the risk of criterion contamination.

However, parent-reports do have the advantage over self-reports in terms of point (2). A more external perspective might be viewed as a more objective reporting of the facts and so might result in more accurate measurement of the construct. Overall, parent- and teacher-reports are indispensable when assessing non-cognitive characteristics of younger students or students with limited verbal abilities.

#### LETTERS OF RECOMMENDATION

Letters of recommendation represent a specific form of other-rating and have been extensively used in a broad range of educational (e.g., Vannelli, Kuncel, & Ones, 2007) and workplace contexts (e.g., Arvey, 1979). Letters of recommendation provide stakeholders with detailed information about applicants' past performance, with the writers' opinion about the applicant being presented in the form of an essay. One major drawback of letters of recommendation is that they are not in a standardized format: different letter-writers may include or exclude qualitatively different types of information, so it is difficult to judge one letter against another. Walters, Kyllonen, and Plante (2003, 2006) developed a standardized format for such letters to counter this perceived problem (see Table 33.3 in this chapter for sample items). Initially termed the Standardized Letter of Recommendation, and now the Educational Testing Service (ETS)<sup>®</sup> Personal Potential Index (ETS, 2009), this assessment system prompts faculty members to respond to specific items using a Likert scale, in addition to eliciting their open-ended comments. It has been used operationally at ETS for selecting summer interns and fellows (Kyllonen & Kim, 2004; Kim & Kyllonen, 2008), through Project 1000 for the selection of graduate student applicants (Liu, Minsky, Ling, & Kyllonen, 2007), and since 2009, it has supplemented the Graduate Record Examination (GRE; see ETS, 2009; Kyllonen, 2008). Several research teams are currently collecting and analyzing data to address questions of validity and predictive power of letters of recommendation, but preliminary results provide some evidence for the reliability and validity of this method of measurement.

#### Biodata

Biographical data (biodata) have been explored for college admissions in the United States (Oswald, Schmitt, Kim, Ramsay, & Gillespie, 2004), Chile (Delgalarrondo, 2008), and other countries. Biodata has also been a standard methodology for assessing constructs such as opportunity to learn

**Table 33.3 The ETS<sup>®</sup> Personal Potential Index: Sample Items**

	Construct and Sample Items	Response Scale
1	Knowledge and Creativity Has a broad perspective on the field Produces novel ideas	(1) Below average (2) Average (3) Above average
2	Ethics and Integrity Is among the most honest persons I know Maintains high ethical standards	(4) Outstanding (5) Truly exceptional (7) Insufficient opportunity to evaluate
3	Planning and Organization Sets realistic goals Meets deadlines	
4	Resilience Accepts feedback without getting defensive Works well under stress	
5	Teamwork Supports the efforts of others Works well in group settings	
6	Communication Skills Speaks in a clear, organized, and logical manner Writes with precision and style	

and socioeconomic status in large-scale national and international group-level comparative studies (e.g., the National Assessment of Educational Progress, Programme for International Student Assessment, and Trends in International Mathematics and Science Study) (Chapter 6, this volume). Biodata are typically obtained by asking standardized questions about individuals' past behaviors, activities, or experiences. Respondents are typically offered multiple-choice answer options or are requested to answer questions in an open format (e.g., "state frequency of behavior"). Baird and Knapp (1981; see also Stricker, Rock, & Bennett, 2001) developed a biodata (documented accomplishments) measure that produced scores for six scales: Academic Achievement, Leadership, Practical Language, Aesthetic Expression, Science, and Mechanical.

Jackson, Wood, Bogg, Walton, Harms, & Roberts (2010) demonstrated that biodata approach can be effective when assessing individuals' personality. The researchers attempted to identify the behavioral component of conscientiousness and to specify a

relatively large pool of behaviors that represent this personality facet. They developed and validated the Behavioral Indicators of Conscientiousness (BIC) and showed that the lower-order structure of conscientious behaviors (as assessed by BIC) is nearly identical to the lower-order structure obtained from extant self-report measures. Furthermore, the researchers used a daily-diary method to validate the BIC against frequency counts of conscientious behavior and found that behaviors assessed with BIC were strongly related to behaviors assessed daily through a diary method. The findings of Jackson et al. (2010) allow for a conclusion that may be extended to the biodata method in general: “Reports of past behavior are at least partially valid, mitigating a criticism often applied to self-reports of behavior” (p. 7).

Measures of biodata show incremental validity beyond SAT scores and the Big Five personality scores in predicting students’ performance in college (Oswald, et al., 2004). Biodata may offer a less fakeable method of assessment than standard self-report scales, as there are several test characteristics that can be implemented to minimize faking (e.g., Dwight & Donovan, 2003; Schmitt, Oswald, Kim, Gillespie, & Ramsay, 2003). These include asking students to elaborate on the biodata details (e.g., “What was the name of the last foreign movie you saw?”) or triangulating results obtained with alternative measurement approaches (e.g., other-reports). A sample biodata item is presented in Table 33.4 in this chapter.

### Interviews

Interviews are the most frequently used method of personnel-selection in industry (Ryan, McFarland, Baron, & Page, 1999) and in clinical practice (Meyer et al., 2001), but they are also used for admissions, promotions, scholarships, and other awards in educational contexts (Goho & Blackman, 2006; Hell, Trapmann, Weigand, & Schuler, 2007). Interviews vary in their content and structure. In a

**Table 33.4 Sample Biodata Item (from the Leadership scale of Oswald et al., 2004, p. 204).**

Item	Response
How many times in the past year have you tried to get someone to join an activity in which you were involved or leading?	(A) never (B) once (C) twice (D) three or four times (E) five times or more

structured interview, questions are prepared before the interview starts. An unstructured interview simply is a free conversation between an interviewer and interviewee giving the interviewer the freedom to adaptively or intuitively switch topics. Research has shown that unstructured interviews lack predictive validity (Arvey & Campion, 1982) or show lower predictive validity than structured interviews (Schmidt & Hunter, 1998).

Structured interviews can be divided into three types: the behavioral description interview (BDI; Janz, Hellervik, & Gilmore, 1986), situational interview (SI; Latham, Saari, Pursell & Campion, 1980), and multi-modal interview (MMI; Schuler, 2002). The behavioral description interview involves questions that refer to the candidate’s past behavior in real situations. The situational interview uses questions that require that interviewees imagine hypothetical situations (derived from critical incidents) and state how they would act in such situations. The multi-modal interview combines the two approaches and adds unstructured parts to ensure high respondent acceptance.

Meta-analyses of the predictive validity of interviews for job performance (Huffcutt, Conway, Roth, & Klehe, 2004; Marchese & Muchinski, 1993; McDaniel, Whetzel, Schmidt, & Maurer, 1994; Schmidt & Hunter, 1998) show that structured interviews: (a) are good predictors of job performance (corrected correlation coefficients range from 0.45 to 0.55); (b) they add incremental validity above and beyond general mental ability; and that (c) behavior description interviews show a higher validity than situational interviews.

Similarly, in educational contexts, interviews have been deemed moderately effective for the prediction of meaningful outcomes. For example, Goho and Blackman (2006) investigated the effectiveness of using selection interviews for admissions into medical schools, conducting meta-analyses to predict academic achievement and clinical performance. The mean effect size for studies examining the predictive power of interviews for academic success was 0.06 (95% confidence intervals 0.03–0.08), indicating a very small effect, whereas the sample of studies for predicting clinical success had a mean effect size of 0.17 (95% confidence intervals 0.11–0.22), indicating modest positive predictive power.

Wilkinson et al. (2008) report similar findings. Their study examined how well prior academic performance, admission tests, and interviews predicted academic performance in a graduate medical school. The researchers found that medical school grade

point average (GPA) was most strongly correlated with prior academic performance (e.g., for overall score, partial  $r = 0.47$ ;  $p < 0.001$ ), followed by interviews (partial  $r = 0.12$ ). Interestingly, whereas the relationship between GPA and performance weakened from Year 1 to Year 4, the association between interview score and performance increased from Year 1 to Year 4. Considering that the admissions interviews mostly focus on assessing candidates' non-cognitive characteristics (i.e., their motivation to become doctors, interest, drive, etc.), these findings attest to the effectiveness of interviews as methods for gauging students' non-cognitive skills. Thus, interviews were found to be better predictors of both medical school GPA and clinical practice than the Graduate Australian Medical School Admissions Test (Wilkinson et al., 2008), a finding reminiscent of the Swedish enlistment study conducted by Lindqvist and Vestman (2011).

## Innovative Non-cognitive Assessment Techniques

### *Situational Judgement Tests (SJT<sub>s</sub>)*

SJT<sub>s</sub> are a type of test where individuals are presented with a situation and then select either the most appropriate response or their typical response out of a list of possible choices (see Table 33.5, this chapter, for sample items). SJT<sub>s</sub> can be text-based or presented through multimedia, and responses can be multiple-choice (i.e., pick the best response), constructed response (i.e., provide a response to this situation), or ratings (i.e., rate each response for its effectiveness, on a Likert-type scale) (see, e.g., McDaniel, Morgesen, Finnegan, Campion, & Braverman, 2001). SJT<sub>s</sub> represent fairly simple, economical simulations of relevant academic- (or job-) related tasks (Kyllonen & Lee, 2005).

#### SELF-RATED SJT<sub>s</sub>

SJT<sub>s</sub> have several advantages over traditional self-assessment instruments. First, SJT<sub>s</sub> may be developed to reflect more subtle and complex judgement processes than are possible with conventional tests. Carefully constructed, the methodology of the SJT enables the measurement of many relevant attributes of applicants, including social competence, communication skills, critical thinking, and leadership, to name a few (e.g., Oswald et al., 2004; Waugh & Russell, 2003). By getting at these hard-to-measure constructs, SJT<sub>s</sub> carry the possibility of overcoming the validity ceiling found for conventional cognitive assessments in personnel selection and college admissions. Second, SJT<sub>s</sub> appear to be associated

**Table 33.5 Situational Judgement Test Item: Teamwork Assessment**

<b>Item stem</b>	You are part of a study group that has been assigned a large presentation for class. As you are all dividing up the workload, it becomes clear that both you and another member of the group are interested in researching the same aspect of the topic. Your colleague already has a great deal of experience in this area, but you have been extremely excited about working on this part of the project for several months. Which of the following is the best approach to dealing with this situation?
<b>Responses</b>	<p>(A) Flip a coin to determine who gets to work on that particular aspect of the project.</p> <p>(B) Insist that, for the good of the group, you should work on that aspect of the project because your interest in the area means you will do a particularly good job.</p> <p>(C) Compromise your preferences for the good of the group and allow the other person to work on that aspect of the project.*</p> <p>(D) Choose a different group member to work on that aspect of the project so that no one person is privileged over another.</p>

with less adverse impact on (ethnic) minorities. Of relevance in this context, reduced subgroup differences have indeed been found with SJT<sub>s</sub> (e.g., McDaniel et al., 2001). Third, SJT<sub>s</sub> can be used in training sessions to provide a student or prospective employee with feedback on his or her competencies in the domain of interest. Finally, SJT<sub>s</sub> appear to be less susceptible to faking than are self-assessments, where the improvement due to incentives can be up to a full standard deviation.

SJT<sub>s</sub> have been shown to predict a range of important outcomes such as college success (Lievens & Coetsier, 2002; Oswald et al., 2004) and leadership (Krokos, Meade, Cantwell, Pond, & Wilson, 2004). Although applications in education have been relatively limited, using SJT<sub>s</sub> in educational domains is certainly on the rise (Lievens, Buyse, & Sackett, 2005; MacCann et al., 2010; Oswald et al., 2004; Wang et al., 2009). This trend is partly due to the fact that there is more and more evidence that SJT<sub>s</sub> have high construct validity, both of predictive and consequential

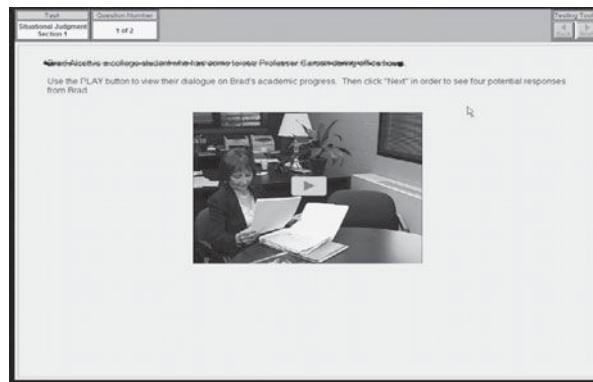

nature (e.g., Etienne & Julian, 2005; Sternberg et al., 2000). A recent study of high school students compared showed that an SJT of teamwork showed a higher correlation with GPA than a self-report rating scale of teamwork (Wang et al., 2009).

Depending on the information delivery mode, SJTs are typically dichotomized into text-based and multimedia-based types. Text-based SJTs fall into the category of traditional SJTs in the sense that they are presented in a paper-and-pencil format where scenarios and response options are in written form. Quite differently, multimedia SJTs use multimedia

technology to present scenarios and sometimes also response options in video format (Lievens et al., 2005; McHenry & Schmitt, 1994; Olson-Buchanan & Drasgow, 2006; Weekley & Jones, 1997). Recent meta-analytic results demonstrate that multimedia SJTs show stronger criterion-related validity than written SJTs for predicting interpersonal skills (Christian, Edwards, & Bradley, 2010), and appear most effective when used to assess students' affective characteristics. A figural representation of a multimedia SJT item is presented in Table 33.6 in this chapter.

**Table 33.6 Figural Representation of a Typical Multimedia SJTEA Item**

Scenario

Response scale

Response justification

There are several reasons for the above-mentioned finding. First, multimedia SJTs enable the assessment of certain emotional abilities that cannot easily be assessed with other methodologies that are limited by the delivery medium. For instance, written SJTs can only provide verbal content, but multimedia SJTs represent a richer medium because they can present many more social cues, including verbal, nonverbal, and paralinguistic information.

Secondly, the use of multimedia technology enhances the degree to which the test mirrors the real environment, also referred to as *stimulus fidelity* (i.e., the extent to which the assessment task and context mirror those actually present in real life, Callinan & Robertson, 2000). Higher stimulus fidelity of multimedia SJTs is related to (a) enhanced ecological validity of the test (Chan & Schmitt, 1997), (b) more favorable test-taker reactions (Richman-Hirsch, Olson-Buchanan, & Drasgow, 2000), and (c) better prediction of meaningful outcome variables (Christian et al., 2010; Lievens & Sackett, 2006).

Thirdly, the use of multimedia technology does not rely excessively on verbal ability, a problem that has characterized the field to date. For example, written SJTs require the understanding and interpretation of text, making them dependent on text comprehension. The fact that text-based SJTs assume fairly advanced levels of reading comprehension may constitute a source of construct-irrelevant variance and may lead to higher correlations with cognitive ability. Contrary to text-based SJTs, multimedia SJTs do not require as much reading comprehension, instead more clearly targeting focal processes such as perceiving emotions and understanding the causes of these emotions. Indeed, recent studies confirm that multimedia SJTs have lower correlations with cognitive ability than do text-based SJTs (Lievens & Sackett, 2006).

In sum, SJTs represent a promising method for assessment of students' non-cognitive characteristics, with multimedia SJTs offering something that text-based assessments do not. Despite relatively high cost associated with their production (e.g., hiring actors and videotaping) and special requirements for administration (e.g., computers), we predict that multimedia SJTs will become an increasingly popular tool for measuring students' affective characteristics in a range of educational contexts (e.g., as supplements to college or graduate school admission interviews). An example of an SJT item is presented in Table 33.5.

#### OTHER-RATED SJTS

It is possible to administer SJTs in other-report format. That is, an observer such as a parent or teacher would be presented with a particular situation, and would judge what the target student would do in that situation. An example of the other-rated SJT item is presented in Table 33.7. MacCann, Wang, Matthews, and Roberts (2010) demonstrated that SJTs can be reliably administered in other-report format. This study used both self-report and parent-report SJTs to assess middle schools students' emotion-management skills. They found that although self- and parent-judgements were only weakly related, they both independently predicted valued criteria such as school grades, life satisfaction, and emotional reactions (both positive and negative) to the school environment. These findings support the idea that the non-shared variation between self- and parent-judgements is not random error, but represents different aspects of the phenomenon under investigation (in this case, emotion management). The researchers suggest that self- and parent-evaluations may index the frequency of different types of emotion management strategies. Parent-evaluations might relate to strategies involving interaction with others (e.g., seeking social support, talking through the issues), whereas self-evaluations might relate to strategies involving kind and sympathetic feelings towards others (e.g., expressing sympathy to diffuse tension, complimenting others). Other-rated SJTs represent a very promising approach for assessing non-cognitive characteristics, as they combine the benefits of SJTs

**Table 33.7 Situational Judgement Test Item: Parent-Report of Teamwork Assessment (after MacCann et al., 2010).**

<b>Item stem</b>	Your child and a classmate, James, sometimes help each other with homework. After your child helps James on a difficult project, the teacher is very critical of this work. James blames your child for his bad grade. Your child responds that James should be grateful, because helping him was a favor. What would your child do in this situation?
<b>Responses</b>	(A) Tell James that from now on he has to do his own homework. (B) Apologize to James. (C) Tell James "I am happy to help, but you are responsible for what you turn in." (D) Don't talk to James.

(e.g., high ecological validity of situations) and other-reports (e.g., suitable for younger kids and those with limited verbal abilities).

### ***Time Use: Day-Reconstruction Method***

A relatively new behavioral science domain concerns how people use their time. An assessment technique is the Day-Reconstruction Method (DRM; Kahneman, Krueger, Schkade, Schwarz, & Stone, 2004). The DRM assesses how people spend their time and how they experience the various activities and settings of their lives. It combines features of two other time-use techniques, time-budget measurement (the respondent estimates how much time is spent on various categories of activities) and experience sampling (the respondent records his or her current activities when prompted to do so at random intervals throughout the day). The DRM requires that participants systematically reconstruct their activities and experiences of the preceding day with procedures designed to reduce recall biases.

When using the DRM, a respondent first recreates the previous day by producing a confidential diary of events. Confidentiality encourages respondents to include details they may not want to share through any other assessment approach (such as an interview). Next, respondents receive a standardized response form and use their confidential diary to answer a series of questions about each event, including (1) when the event began and ended, (2) what they were doing, (3) where they were, (4) whom they were interacting with, and (5) how they felt on multiple affect dimensions. The response form is returned to the researcher for analysis. In addition, respondents answer a number of demographic questions.

Respondents complete the diary before they are informed about the content of the standardized response form, so as to minimize biases. A study of 909 employed women showed that the DRM closely corresponds with experience sampling methods (Kahneman et al., 2004). The DRM is a time-consuming and intrusive form of assessment that requires a significant effort from respondents. More research is needed to capture psychometric qualities of the method. However, initial evidence suggests that this method is effective in assessing characteristics otherwise difficult to capture (Belli, 1998; Kahneman et al., 2004). Moreover, the method appears generalizable to high school and college populations. For example, Roberts et al. (2011) report similar findings with the DRM for 131 college freshman as found for employee

samples. In particular, participants reported significantly greater positive affect while engaging in hobbies or socializing than attending class or completing homework. In this study, the DRM was also substantially correlated (i.e.,  $r$ 's exceeding 0.40 for each activity) with a self-assessment of psychological well-being and a situational judgement test of emotional management.

### ***Writing Samples***

Chung and Pennebaker's (2007) analysis of writing samples as a gateway to personality is based on the idea that what we write and say, as well as how we write and say it, reflects our personality. This stream of research involves correlating words and word types from open-ended writing (e.g., emails) with personality and behavioral measures. Research suggests that the use of particular function words (e.g., pronouns, adjectives, articles) is related to individuals' affective states, reactions to stressful life events, social stressors, demographic factors, and biological conditions (Chung & Pennebaker, 2007; Mehl & Pennebaker, 2003). For example, the use of "I" is associated with depression, and speaking to a superior, based on email correspondence. Moreover, word choices can be used to detect deception (Hancock, Curry, Goorha, & Woodworth, 2004; Newman, Pennebaker, Berry, & Richards, 2003).

Vast volumes of materials are available to explore this research program further (especially given the preponderance of social networks and the archival capabilities that are part of the Internet), while the availability of inexpensive automated classification tools provides noteworthy research opportunities to continue to identify relationships between written communication and non-cognitive skills. The magnitude of correlations found tends to be quite low, but the method's low cost and unobtrusiveness suggests that it may lead to future applications in psychological testing. Although most of this research has focused on adult behaviors, the amount of writing that needs to be completed in secondary and tertiary education poses some intriguing possibilities for the assessment of non-cognitive skills during childhood and adolescence.

### ***The Thorny Issue of Response Distortion***

A potential problem with using non-cognitive assessments for high-stakes purposes such as educational selection is that test-takers may try to "fake" high scores in order to get into the course. Even an exceptionally lazy person is unlikely to agree with the statement "I am lazy" if they are answering

this item as part of a college admissions process. Meta-analytic research from personnel psychology supports this intuitive idea with hard empirical data. Viswesvaran and Ones' (1999) meta-analysis demonstrates that people can fake personality tests when asked to do so, raising their personality test scores by the equivalent of 7 to 14 IQ points. Furthermore, research suggests that between 20 percent and 40 percent of people actually do fake when taking personality tests for selection purposes (Birkeland, Manson, Kisamore, Brannick, & Smith, 2006).

Psychologists have long realized that people are prone to exaggerate on rating-scale tests in order to get a better score and so get into the school of their choice or procure a better job. The predominant approach to dealing with faking has been to detect fakers with lie scales, also known as *response distortion scales* (e.g., Crowne & Marlowe, 1960; Paulhus, 1998). Lie scales intermix items such as "I never swear," or "I always pick up my litter" with focal personality items. Fakers are identified by their high scores on lie scales. Although lie scales are immensely popular and commonly used, there is a growing consensus that they do not work (Dilchert, Ones, Viswesvaran, & Deller, 2006; Ellingson, Sackett, & Hough, 1999; MacCann, Ziegler, & Roberts, 2011). Both logic and empirical evidence suggest that people scoring high on lie scales might actually be exemplary individuals who always pick up their litter and never swear. Correlations of lie scores with substantive personality traits like conscientiousness and agreeableness suggest that it is not liars, but nice, kind, hard-working people who are caught out by lie scales (e.g., Li & Bagger, 2006).

Given that lie scales do not seem to catch the liars, there are two broad strategies for dealing with response distortion when assessing non-cognitive constructs. First, non-cognitive constructs, particularly as measured with self-reported rating scales, simply cannot be used as selection criteria for high-stakes purposes. For example, it may be reasonable for medical schools to exclude applicants with very low scores on empathy, given that these applicants might make poor healthcare professionals. However, it would be unreasonable to select only the top applicants based on empathy, as the very top scores on a rating-scale measure of empathy might be fakers who displace genuinely empathetic applicants. That is, using non-cognitive scores to screen out wildly inappropriate applicants is still a useful exercise, even if some people fake.

The second strategy to combat faking in non-cognitive assessments is to use a range of

innovative assessment methods that show greater resistance to faking than standard rating scales. Implicit measurement techniques are chief among these new methods. In implicit measurement, the measurement objective is not obvious to the participants, such that these measures may be less susceptible to faking (e.g. Ziegler, Schmidt-Atzert, Buehner, & Krumm, 2008). Implicit measurement techniques include the implicit association test (IAT) paradigm, as well as the conditional reasoning test (CRT) paradigm, which we describe below. Other testing methods that may reduce faking include forced-choice assessment and the Bayesian truth serum. Many of these measurement techniques are still in their infancy, with limited empirical data to provide evidence of their validity and their non-fakeability. In the paragraphs below, we describe each of these techniques in turn and outline the empirical evidence for these techniques as viable methods to measure non-cognitive constructs.

### ***Implicit Assessments: Implicit Association Tests (IATs)***

The implicit association test (Greenwald, McGhee, & Schwartz, 1998) has become an incredibly popular method for researching non-cognitive factors, particularly attitudes, having been examined in many hundreds of empirical studies (see Greenwald, Nosek, & Sriram, 2006). IATs record the reaction time it takes to classify stimulus pairs (e.g., word, picture), which is then treated as an indirect measure of whether a participant sees the stimuli as naturally associated. IATs thus measure the strength of implicit associations to gauge attitudes, stereotypes, self-concepts, and self-esteem (Greenwald, Banaji, Rudman, Farnham, Nosek, & Mellot, 2002; Greenwald & Farnham, 2000).

IATs generally exhibit reasonably good psychometric properties. Meta-analyses have revealed high internal consistencies (0.80 to 0.90) (Hofmann et al., 2005), although somewhat lower test-retest reliabilities (0.50 and 0.70), which is a common finding in reaction time research. IATs predict a wide variety of criteria, particularly spontaneous (as opposed to controlled) behavior (Bosson, Swann, & Pennebaker, 2000; Gawronski & Bodenhausen, 2006; McConnel & Leibold, 2001). However, to our knowledge, they have not been used in studies of educational outcomes, although there is an emerging literature using this method to explore the attitudes of children and adolescents to health-related behaviors (e.g., smoking; see Andrews, Hampson, Greenwald, Gordon, &

Widdop, 2010). The Hofmann et al. meta-analysis estimated the correlation between implicit (IATs) and explicit (self-reports) measures of personality to be 0.24, with about half of variability being due to moderating variables.

The promise of the IAT is that it should be less susceptible to faking. However, preliminary findings demonstrate the IAT is to a certain extent fakeable (Fiedler, Messner, & Bluemke, 2006). Given that there is still controversy about what the IAT measures (Rothermund & Wentura, 2004), and that there is a lot of method-specific (construct-irrelevant) variance associated with IATs (Mierke & Klauer, 2003), it is clear that more research is needed before IATs (and the related Go–No Go Association Test, Nosek & Banaji, 2001) can be regarded as viable tools in various applied educational contexts.

### ***Implicit Assessments: Conditional Reasoning Tests (CRTs)***

Conditional reasoning tests are multiple-choice tests consisting of items that look like reading comprehension or logical reasoning items, but are used to measure world-view, personality, biases, and motives (James, 1998; LeBreton, Barksdale, & Robin, 2007). Following a passage and a question, the CRT presents two or three logically incorrect alternatives, and two logically correct alternatives, which reflect different (often opposing) worldviews. Participants are asked to state which of the alternatives seems to be most reasonable, based on the information given in the text. Thus, respondents assume that they can solve a problem by reasoning about it, not realizing that there are two correct answers, and that their selection is guided by implicit assumptions underlying answer alternatives.

Participants are prompted to select one of the logically correct alternatives, presumably according to his or her underlying beliefs, rationalizing the selection through the use of justification mechanisms. For example, the examinee might select an

aggressive response to a situation, justifying it as an act of self-defense or as retaliation (LeBreton et al., 2007). These justification mechanisms serve to reveal hidden or implicit elements of the personality. To see an illustration of this idea, consider the example from LeBreton et al. (2007) presented in Tables 33.1–33.4.

The CRT for aggression has been shown to be unrelated to cognitive ability, yet reliable and valid for predicting different behavioral manifestations of aggression in the workplace (average  $r$  over 10 studies = 0.44) (James, McIntyre, & Glisson, 2004). Most of the research on CRTs has been in measuring aggression or achievement motivation (James, 1998). However, the method has proven difficult to replicate (Gustafson, 2004), and so far there is a paucity of research with children and adolescents (indeed, the cognitive difficulty of the items is currently such that applications would need to be restricted to high school populations and above). Also, as with IATs, the promise of resistance to faking has not been established (LeBreton et al., 2007). Thus, it seems that CRTs may need further work before being used in high-stakes academic situations. A sample CRT item is presented in Table 33.8.

### ***Forced Choice***

Peabody's (1967) early musings on personality assessments proposed a distinction between descriptive and evaluative judgements of personality. In any personality item, there is both a descriptive element and an evaluative element. For example, the descriptive element of the item "I am lazy" is that it measures conscientiousness (reverse-coded). The evaluative element is that "I am lazy" sounds like a bad thing. The basis for forced-choice testing is that test-takers are forced to choose between two or more statements that are equal in evaluative content (i.e., are equally socially desirable) but differ in terms of their descriptive content (i.e., measure different personality traits). Test-takers cannot then

**Table 33.8 Conditional Reasoning Item (after James et al., 2004)**

Item	Response
Half of all marriages end in divorce. One reason for the large number of divorces is that getting a divorce is quick and easy. If a couple can agree on how to split their property fairly, then they can get a divorce simply by filling out forms and taking them to court. They do not need lawyers. Which of the following is the most reasonable conclusion, based on the above?	(A) People are getting older when they get married. (B) If one's spouse hires a lawyer, then he or she is not planning to play fair. (C) Couples might get back together if getting a divorce took longer. (D) More men than women get divorced.

grade themselves highly on all positive statements, but must choose between them. Thus, faking-related variation in scores should be minimized.

There are several methods for forced-choice measurement, including pair comparisons, rank-ordering, and multidimensional forced-choice. In pair comparisons, the test-taker must choose between two equally desirable statements (e.g., “Which is more like you: ‘I work hard’ or ‘I think up new ideas?’”). In rank-ordering, test-takers must rank a series of equally desirable statements in order from “most like me” to “least like me.” Both these methods require that statements included in any one item be carefully matched for social desirability so that test-takers cannot use the evaluative aspects of the statements in their responses. In multidimensional forced-choice assessments, test-takers are presented with a dichotomous quartet of four different traits in which two socially desirable statements are paired with two socially undesirable statements (Jackson, Wroblewski, & Ashton, 2000). For example, a test-taker would be asked to select which is “most like you” and which is “least like you” from the following four statements: (1) “I work hard,” (2) “I lose my temper,” (3) “I love to help others,” and (4) “I cannot deal with change.” The statement selected as “most like you” would be scored +1; the statement selected as “least like you” would be scored -1, and the statements that were not endorsed at all would be scored zero.

There is some evidence to suggest that forced-choice tests are less fakeable than standard rating scales, and show stronger relationships with performance (e.g., Jackson et al., 2000; Martin, Bowen, & Hunt, 2002). However, forced-choice measures may have ipsative or partly ipsative properties. That is, scores on forced-choice measures may be appropriate for comparing the relative level of different traits within an individual, but inappropriate for comparing the relative levels of a trait across different people. Essentially, personality dimensions are not independent: one cannot be high on them all. This poses a problem for test-takers who really are high on multiple personality dimensions, or for test users who want to select individuals based on high scores on more than one personality dimension.

However, Stark, Chernyshenko, and Drasgow (2011) propose a number of IRT-based processes for constructing forced-choice items that ameliorate these issues of ipsativity. For example, in the sequential approach to developing a multi-dimensional pair-wise preference (MDPP) measure, one first determines both social desirability and item

parameters of a large number of items presented in conventional format. Social desirability ratings and item parameters may then be used to develop pairs of statements that act as a pair-comparison judgement (e.g., “I work hard” versus “I think up new ideas”). An important feature is that within most pair comparisons, items are drawn from two different personality domains (e.g., a Conscientiousness item is compared to an Agreeableness item). However, at least for some pairs, the items belong to the same domain. That way, it is possible to compute scores that also have a normative value; that is, can be used to differentiate between people. Empirical evidence to date suggests that tests constructed and scored using the MDPP method appear resistant to faking, and that normative rather than ipsative information can be recovered from this process. In this way, an empirically based procedure for item selection and test development combined with new statistical modeling techniques seems to produce the best of both worlds: fake-proof tests that also lack the ipsativity that plagued earlier operationalizations of forced-choice measurement. For this reason, we contend the approach will be explored much more in educational contexts in the years ahead. For example, an upcoming Program for International Student Assessment (PISA) field trial uses several variants of this approach to assess learning strategies. Table 33.9 contains a sample multidimensional forced-choice item.

### ***Bayesian Truth Serum***

The Bayesian Truth Serum (BTS) calculates how often people endorse item content they perceive as unusual and therefore possibly undesirable (Prelec, 2004). A person who rarely agrees with unpopular attitudes or behaviors is assumed to be adjusting their answers based on conformity to group opinion or expectations, rather than giving an honest appraisal of the item content. The extent of agreement with self-perceived “unpopular” items can be taken as an index of truth-telling. The method requires the test-taker to provide two pieces of

**Table 33.9 Multi-dimensional Forced-Choice Item**

Item	Response
Consider the four statements at right.	I work hard. I lose my temper.
Which is most like you, and which is least like you?	I love to help others. I cannot deal with change.

information for every item: their own response, and the proportion of people they estimate would respond the same way on that item. For example, a test-taker might have to choose which statement described them better: “I think up new ideas” or “I work hard.” The test-taker would also have to estimate the preference of the wider population (e.g., guessing that perhaps 75% of the overall population would choose “I think up new ideas” over “I work hard” to describe themselves). Prelec argues that respondents who answer questions honestly will tend to overestimate the percentage of other people who agree with them. In this way, an index of truth telling can be calculated.

However, estimating the beliefs of other people is both meta-cognitively complex, and may be subject to frame-of-reference effects as to who these “others” are considered to be (other college applicants, other people the test-taker personally knows, other people of similar SES and demographics to the test-taker, or all other people in the world). For these reasons, the BTS may not function accurately for test-takers with poor meta-cognitive skills or test-takers using an unusual frame of reference. In addition, collecting additional information doubles the test-taking time, since twice as many questions are asked. Like the conditional reasoning test, the complexity of the Bayesian truth serum suggests that the method might only be accurately applied after the mid-teens, and then only among cognitively normal populations. Young children may not have the meta-cognitive skill to answer such questions, nor the concentration to sit through tests of double the normal length.

### **Future Directions: Potential Uses of Non-cognitive Assessments**

In the final section of this chapter, we consider the findings from the literature analysis, and synthesize them in a way to suggest several ways in which comprehensive non-cognitive assessments might be used (or are currently used) in education.

#### ***High-Stakes Assessment***

High-stakes applications of non-cognitive tests in education include diagnosis and selection. For diagnosis, non-cognitive assessments have an important role to play in augmenting traditional cognitive assessments aimed at diagnosing learning disorders and difficulties. For example, test anxiety shows frequent comorbidity with learning difficulties, as students who struggle with scholastic material develop an aversion to and fear of evaluative

situations (e.g., Bryan, Sonnefeld, & Grabowski, 1983; Sena, Lowe, & Lee, 2007). Test anxiety can function as both a symptom of learning difficulties and an exacerbation of learning difficulties, and may even affect scores on cognitive assessments designed to diagnose learning difficulties. Thus, this particular non-cognitive factor may be a pertinent factor to consider when diagnosing a student with a particular learning disorder.

The second major high-stakes application of non-cognitive assessments is selection for college, graduate school, preparatory school, gifted classes, or the honors or advanced placement track. Large-scale, high-stakes non-cognitive assessment, based on faculty ratings, has been implemented recently for graduate school admissions (Kyllonen, 2008). If this is successful, it is reasonable to expect that a similar application for undergraduate admissions could follow. Recent meta-analytic evidence shows that non-cognitive assessments are just as predictive of academic achievement as traditional intelligence testing (Poropat, 2009). Moreover, this prediction is separate from intelligence, that such non-cognitive assessments retain their strong relationship to achievement even after controlling for ability. Such results imply that accuracy in selection decisions could be improved drastically with the addition of non-cognitive assessments. For example, two students of equal intelligence might have very different chances of success in advanced placement classes if one of them is willing to work hard, seek help, and extend effort to maintain a supportive social network, whereas the other believes that success is due to lucky breaks and chance factors. Using appropriate non-cognitive tests to augment selection decision could feasibly result in better outcomes. Moreover, there is some evidence to suggest that including non-cognitive factors in selection decisions would result in less adverse impact on ethnic minorities and women (e.g., McDaniel et al., 2001).

A diagnosis or selection decision may be vastly influential for children and adolescents, with long-term consequences. Therefore, the potential for motivated individuals to try to gain a particular outcome should be not ignored: it is quite possible that even young children will give a socially correct answer rather than one that describes their actual tendencies. For this reason, several safeguards against response distortion should be considered when tests are used for high-stakes purposes. First, a non-cognitive assessment should never be the sole basis for a high-stakes decision, but should be

considered in conjunction with other key factors (e.g., cognitive test scores, teacher and parent interviews, and record of achievement relative to ability for learning disorder diagnosis). Second, in most selection scenarios, it may be more beneficial to exclude those with unacceptably low non-cognitive skills, rather than select the top few with exceptionally high non-cognitive skills. Third, an aggregate of multiple other-reports should be preferred over self-reports, as in the case of the Personal Potentiality Index assessment for post-graduate admissions (Kyllonen, 2008). With these appropriate safeguards in mind, non-cognitive assessments have the potential to drastically improve selection and diagnosis decisions.

### ***Developmental Scales***

Another possible application of non-cognitive assessments is to track students' development over time (Roberts, 2009; Roberts & Wood, 2006). At the individual level, a "report card" each year could show the students' development of non-cognitive skills such as impulse control, social skills, coping strategies, and attitudes towards school and school-work. Particularly in the early grades, this sort of feedback could feasibly be used for early identification of individuals or cohorts at risk for learning disorders, conduct disorders, or other academic or social problems. At the institutional level, schools that provide programs for social and emotional learning, peer support, or the development of academic skills such as time management or learning strategies could monitor the progress of their student body in developing and maintaining these skills. Schools would also be able to track trends at specific levels (e.g., the adjustment to a new environment by students beginning kindergarten or high school; or the stress experienced by students undertaking college preparations in the last two years of secondary school). At the wider level, district, state or national comparisons of students' non-cognitive tests scores would allow a strong evidence base for policy development in education.

### ***Interventions***

One of the strengths of using non-cognitive tests as developmental scales is the potential for interventions or training. There are several ways that assessments can form the backbone of intervention and training development. First, as mentioned above, large-scale developmental assessments can be used to guide policy change, as well as to evaluate the effectiveness of policy implementation. Second, scores

on specific assessments may serve as the basis for particular suggestions in the form of tailored feedback and action plans. For example, a high-school student might complete a three-component measure of time management, and score much lower on the *planning* component than the other two parts. Such a student would receive the information that they are (for example) good at coping with change, and tend to refrain from procrastination, but that planning is their weak point. Such information should increase their self-knowledge (and potentially their meta-cognitive skills). The student could also receive a series of suggestions about how to improve their planning skills, some helpful tools such as a weekly or monthly time-and-task calculator, or a referral to existing school- or district-based programs for assisting with academic-readiness skills. As we mentioned in earlier sections of this chapter, the TpB is a particularly powerful technique for linking assessments with interventions, as its theoretical basis focuses on behavior and behavior change (Ajzen, 2011).

Educational applications of non-cognitive testing might also borrow from personnel psychology, applying ideas such as the development assessment center, which directly links assessment with development activities (e.g., Thornton & Rupp, 2005). In developmental assessment centers, the test-taker:

- (a) learns about the non-cognitive dimensions the test measures (e.g., learns about the underlying components of time management);
- (b) learns their own strengths and weaknesses;
- (c) learns how to set goals to improve;
- (d) learns how to monitor their progress in improvement;
- (e) is provided with exercises, feedback, and experiential learning activities.

These programs are currently being implemented by several research teams, and the initial results are promising (Elias & Clubby, 1992). This paradigm holds great promise for improving non-cognitive skills for education.

### ***Concluding Comments***

In this chapter we presented an overview of a rather wide variety of both conventional and novel methods for assessing non-cognitive skills in an educational context. Self-assessments are the most common and are likely to be useful in any kind of non-cognitive assessment system, particularly when the stakes are not high. Other-ratings, such as teacher ratings, parent reports, letters of recommendation, and interviews, are also quite useful, and as

discussed in corresponding sections of this chapter, they are currently the most viable for high-stakes selection applications. A range of non-traditional assessments hereby reviewed—such as the implicit association test, day reconstruction method, and conditional reasoning tests—are intriguing and may potentially be quite useful for assessing students' non-cognitive characteristics. Situational judgement tests are an increasingly popular way to measure non-cognitive characteristics. They have been used in so many studies over the past 10 years that the methodology for developing them is now fairly affordable, and the measures are becoming increasingly reliable and valid. All of these methods are constantly evolving, so more information attesting to their validity and applicability for educational contexts will be accrued in the upcoming years.

Overall, our understanding of non-cognitive factors influencing academic achievement and possible approaches toward the measurement and assessment of these factors allows us to identify students who are more or less likely to do well in a specific academic program. Additionally, our knowledge of the relationships among a range of non-cognitive constructs and educational outcomes can be used to develop effective interventions. These interventions can be successful in enhancing students' non-cognitive characteristics, and, consequently, their achievement. In sum, these constructs can be successfully assessed and modified, and it is our hope that more and more researchers will start designing studies investigating the quality of such assessments and the effectiveness of such interventions.

## Authors' Note

We thank Anthony Betancourt, Jeremy Burrus, Daniel Howard, Teresa Jackson, Stefan Krumm, Mary Lucas, Bobby Naomi, Jen Minsky, and Patrick Kyllonen for supporting the preparation of this manuscript. All statements expressed in this chapter are the authors' and do not reflect the official opinions or policies of the authors' host affiliations. Correspondence concerning this article should be directed to Anastasiya A. Lipnevich via email: a.lipnevich@gmail.com.

# Assessment of Subjective Well-Being in Children and Adolescents

E. Scott Huebner and Kimberly J. Hills

## Abstract

Research has suggested that measures of positive subjective well-being add incremental validity in relation to traditional measures of psychopathological symptoms in predicting child and adolescent psychosocial adaptation. Measures of subjective well-being, including measures of life satisfaction and positive affect, have been constructed that are appropriate for children and/or adolescents. Several measures are reviewed and recommendations for future research are provided. A case study is employed to illustrate the usefulness of subjective well-being instruments in school-based psychological assessments.

**Key Words:** subjective well-being, life satisfaction, positive affect, assessment, children

Research on the subjective well-being or happiness of adults and children has increased significantly in the last decade. Prominent scholars (e.g., Seligman & Csikszentmihalyi, 2000) have proposed that psychologists study positive constructs of well-being to provide a more comprehensive understanding of human development, including optimal development. In doing so, measures of subjective well-being and other positive psychology constructs have been developed to advance a science and practice of “positive psychology” to complement the field’s traditional emphasis on psychopathology (Frisch, 2000; Lopez & Snyder, 2003).

Although numerous alternative conceptual models of positive mental health or well-being have been put forth, most models include subjective well-being (SWB) as a central component. The most widely accepted definition of SWB has been offered by Diener (1984, 2000). In his tripartite model, SWB comprises the three major components of *positive affect*, *negative affect*, and *life satisfaction*. Positive affect involves the experience of frequent positive

emotions (e.g., joy, enthusiasm, interest) over time, whereas negative affect involves the experience of frequent negative emotions (e.g., sadness, anxiety, anger) over time. Life satisfaction is conceptualized as a cognitive judgment of the degree of positivity of one’s life as a whole or with specific domains (e.g., family, school, work). Taken together, an individual is thought to have high SWB if s/he reports relatively frequent positive emotions, infrequent negative emotions, and a high degree of satisfaction with her or his life (Diener, 2000).

Research has supported the differentiability of the three domains of SWB among adults and children, as early as third grade (Huebner, 1991a). Research has also supported the differentiability of the SWB constructs from related constructs. For example, global life satisfaction has been shown to be distinct from such constructs as self-esteem (Huebner, Gilman & Laughlin, 1999; Lucas, Diener, & Suh, 1996), depression (Lewinsohn, Redner & Seeley, 1991), and optimism (Lucas, Diener, & Suh, 1996). Furthermore, it is important

to note that when measured across relatively lengthy periods of time (e.g., several months), respondents' reports of positive and negative emotions are not strongly inversely related as might be expected, but rather are somewhat independent. Although the reasons for this relative independence are complex, they involve the particular emotions sampled, the time period sampled, and distinctions and interrelationships between affect intensity and frequency of affect (Diener, Larsen, Levine, & Emmons, 1985; Pavot, 2008). The general conclusions emerging from the body of research support the need to measure positive affect and negative affect separately to adequately understand persons' SWB.

Fredrickson's Broaden-and-Build Theory of positive emotions and the associated research provide further distinctions between positive affect and negative affect (see Cohen & Fredrickson, 2009; and Fredrickson, 2001, for reviews). The Broaden-and-Build Theory hypothesizes that negative and positive emotions serve different purposes, resulting in different long-term outcomes. On the one hand, negative emotions, such as fear or anger, elicit narrowed perceptions and cognitions and specific action tendencies, such as "fight or flight" responses. On the other hand, positive emotions, such as joy or interest, are thought to elicit broadened perceptions and an associated wider range of behavioral response options. Both positive and negative emotions are crucial for survival. Fredrickson and colleagues have produced considerable evidence that in the long run, the experience of frequent positive emotions is associated with broader thought-action repertoires, resulting in greater resilience and physical and intellectual resources, and increased positive affect in the future (Fredrickson, 2001).

The benefits of frequent positive affect have been further supported by a large meta-analysis of cross-sectional, longitudinal, and experimental studies of positive affect (Lyubomirsky, King, & Diener, 2005). The findings of the meta-analysis revealed that frequent positive emotions precede a wide variety of indicators of individuals' success, including a higher likelihood of satisfying interpersonal relationships, high incomes, high productivity at work, good health, and a long life. Thus, frequent positive emotions are more than a simple byproduct of positive life circumstances. Rather, frequent positive emotions appear to facilitate more positive life experiences in many important arenas of life.

Such research findings are not inconsistent with evolutionary theory, which postulates that the mechanisms and processes associated with SWB

maintenance have been shaped by evolution through natural selection to address fundamental problems of survival and reproduction. According to Hill and Buss (2008), SWB reflects "an internal signaling device that tells an organism that an adaptive problem has been solved successfully or is in the process of being solved successfully" (p. 71). In other words, SWB can be construed as a process as well as an outcome. As a process associated with evolutionary fitness, SWB serves as both an internal reward and motivator, increasing the probability that an individual will continue to approach and move toward attaining important goals related to universal needs, such as personal safety, financial resources, professional success, intimate relationships, and physical health (Hill & Buss, 2008). Thus, again, the monitoring and maintenance of relatively high levels of SWB over the long term is crucial to the adaptation of humans.

The tripartite model of SWB implies that positive mental health and psychopathology are distinguishable psychological constructs, not simply opposite ends of a single continuum of mental health. Thus, positive mental health is not equivalent to the absence of psychopathology. That is, a child who is not depressed or anxious does not necessarily demonstrate an optimal level of mental health functioning. Thus, comprehensive assessments of children's well-being are thought to require measures of positive functioning as well as psychopathological functioning to capture the full range of children's developmental possibilities.

The notion that students who are not depressed or anxious may not have high SWB has been investigated through variable-centered and person-centered research approaches. Using variable-centered approaches, Wilkinson and Walford (1998) administered measures of subjective well-being (e.g., life satisfaction, positive affect) and distress (e.g., anxiety, depression) to 345 adolescents. Although correlated, two distinguishable factors emerged. In a study of the differentiability of adolescents' reports of positive and negative affect, Lewis, Huebner, Reschly, and Valois (2009) evaluated the independent contribution of positive affect data (e.g., frequency of joy, interest) relative to negative affect data (e.g., anxiety, sadness) in predicting adaptive school functioning with a sample of middle and high school students. Their results indicated that measures of positive affect demonstrated significant incremental validity in explaining individual differences in school satisfaction, adaptive coping, and student engagement. Taken together, such studies

support the differentiability of SWB and psychopathological symptoms.

Person-centered approaches have also been used to investigate the distinction between positive psychological health, such as SWB and psychopathology. Such a distinction is manifested in the Dual-Factor Model of Mental Health (Greenspoon & Saklofske, 2001), in which positive indicators of SWB are included with traditional negative indicators of psychopathology (i.e., internalizing and externalizing behavior problems) in a comprehensive assessment of child well-being. Results indicated that among the students with low psychopathology, those who had higher SWB showed significantly higher global self-esteem, academic self-efficacy, internal locus of control, and overall social support. Among students with significant psychopathological symptoms, children with higher SWB also showed higher global self-esteem, locus of control, sociability, and social support from fathers. The group of students with high psychopathology and low SWB demonstrated the lowest psychological functioning. Greenspoon and Saklofske underscored the fact that if only the presence of psychopathological symptoms had been investigated, then important group differences could not have been identified, indicating that both SWB and psychopathology need to be assessed to develop the most comprehensive portrait of a child's mental health.

In another critical demonstration of the importance of differentiating SWB and pathology, Suldo and Shaffer (2008) demonstrated the existence of four distinct groups of middle school students: 57% of the sample who had "positive mental health" (i.e., high SWB and low pathology), 13% who were "vulnerable" (low SWB and low pathology), 13% who were "symptomatic but content" (high SWB and high pathology), and 17% who were "troubled" (low SWB and high psychopathology). Although the means of all four groups differed significantly on a variety of variables, most importantly, the "vulnerable" group had lower standardized test scores, academic self-concepts, valuing of school, and social support from classmates and parents, as well as more school absences, self-perceived physical health problems, and social problems, compared to the students with positive mental health. The identification of a group of students who were non-symptomatic, but relatively low in SWB, and who were clearly distinctive in terms of academic, physical, and interpersonal functioning, provides strong support for the additional utility of the inclusion of positive psychology measures (e.g., SWB) in comprehensive child and youth assessments.

Antaramian, Huebner, Hills, and Valois (2010) also identified four groups of adolescents based on the Dual-Factor Model. Their findings extended beyond those of Suldo and Shaffer by showing significant differences on behavioral, cognitive, and emotional engagement as well as academic achievement measures (i.e., GPA). The results of their analyses showed that the positive mental health youth had behavioral, cognitive, and emotional engagement scores significantly greater than all other groups. Additionally, Antaramian and colleagues reported that the symptomatic, but content, youth had significantly higher engagement scores than did troubled youth. In terms of academic achievement, the authors found the positive mental health youth had significantly higher GPA scores compared to the other three groups, including vulnerable youth.

Taken together, the variable- and person-centered studies support the assumption that measures of positive SWB provide important, incremental information in comprehensive assessments of child and youth functioning. Greenspoon and Saklofske (2001) note that the Dual-Factor Model of Mental Health is "surely a crude representation of reality," but they further note that it represents a "doubling of the current taxonomy" and "a step forward" (p. 100).

## Review of SWB Measures for Children and Adolescents

In line with the tripartite conceptual foundation of SWB described above (Diener, 1984), the measures described in this section will be limited to measures of life satisfaction and generic measures of positive and negative affect (versus measures of specific emotions, such as curiosity or anxiety). Self-reported assessments of SWB, developed primarily for students of about grades three to 12, have received the most attention to date (Huebner, Gilman, & Suldo, 2006; Proctor, Linley, & Maltby, 2009).

Life satisfaction measures have been based on three distinct theoretical models: general, global, and domain-specific life satisfaction. Instruments based on general models of life satisfaction assume that overall or "general" life satisfaction comprises bottom-up judgments of specific life domains (e.g., family, peers, and school domains). Thus, a general or total life satisfaction score on such instruments reflects a simple (or weighted) sum of scores on items tapping life satisfaction across specific domains. Some instruments that attempt to assess life satisfaction "as a whole" or overall life satisfaction are based on a global model.

A global model assumes that overall life satisfaction is best assessed by an exclusive emphasis on items that are domain free (e.g., “My life is going well”) versus domain-specific (e.g., “My *school* life is going well”). In contrast to general life satisfaction scores, in which the number and nature of the domains are predetermined by the instrument developer, global life satisfaction scales allow individual respondents to formulate their overall judgments based on their own criteria. Multidimensional measures have been developed with the intent of eliciting respondents’ judgments across multiple domains of life that are considered to be important to most, if not all, individuals of the particular age group. In this manner, such measures yield profiles of individuals’ reports of life satisfaction, providing more differentiated, contextualized satisfaction reports. Hence, a student who has average global life satisfaction, along with high family and low school satisfaction, can be differentiated from one who has average global life satisfaction, along with low family and high school satisfaction. The resulting context-specific profiles may provide targeted information relevant to the design of more healthy environments for individual students or groups of students.

Examples of global and domain-specific measures of life satisfaction and general measures of positive and negative affect are discussed below. These instruments include the Students’ Life Satisfaction Scale (Huebner, 1991b), Multidimensional Students’ Life Satisfaction Scale (Huebner, 1994), Brief Multidimensional Students’ Life Satisfaction Scale (Seligson, Huebner, & Valois, 2003), and Positive and Negative Affect Schedule—Child Version (Laurent et al., 1999). Strengths and limitations of each scale are highlighted.

### ***Students’ Life Satisfaction Scale***

The rationale for the construction of the Students’ Life Satisfaction Scale (SLSS; Huebner, 1991b) was the previously mentioned increased interest in the promotion of positive psychological well-being in children and adolescents. Prior to the 1990s, research and practice had been hindered by the lack of psychometrically sound SWB instruments for children and adolescents (Bender, 1997).

In contrast to models that infer well-being from the absence of psychopathological symptoms, as early as 1964, the World Health Organization defined health as a state of complete physical, mental, and social well-being. The SLSS was thus designed to differentiate levels of life satisfaction above a neutral point of well-being. In this fashion,

“high” levels of life satisfaction would not be defined simply as the absence of dissatisfaction. For example, students who were “mildly satisfied” could be differentiated from students who were “moderately” and “strongly” satisfied.

The SLSS is a seven-item self-report measure that has been used with children ages eight to 18. The items require respondents to rate their satisfaction with respect to items that are context free (see above). The original version of the SLSS consisted of 10 items, but was subsequently reduced to seven items based on item analysis and internal consistency data (Huebner, 1991b). Supplemental positive and negative affect items were analyzed along with the SLSS items to clarify the boundaries of the construct tapped by the SLSS in relation to other SWB variables (Huebner, 1991a & c).

Early work with the SLSS used a four-point frequency response format, with 1 = never, 2 = sometimes, 3 = often, and 4 = always. Recent studies have used a six-point extent format, with 1 = strongly disagree, 2 = moderately disagree, 3 = mildly disagree, 4 = mildly agree, 5 = moderately agree, and 6 = strongly agree. One study raised issues regarding the comparability of scores across the extent and frequency response formats, thus the extent format is generally recommended (Gilman & Huebner, 1997).

SLSS studies of non-clinical samples of students aged eight to 18 in the US began in the 1990s (e.g., Dew & Huebner, 1994; Huebner, 1991b) and have continued to the present (e.g., Lewis, Huebner, Malone, & Valois, 2011). Additional samples from clinical and other special populations have included at-risk students (Huebner & Alderman, 1993), adjudicated adolescents (Crenshaw, 1998), gifted students (Ash & Huebner, 1998), students with learning disabilities (McCullough & Huebner, 2003), emotional disturbance (Huebner & Alderman, 1993), hearing impairments (Gilman, Easterbrooks, & Frey, 2004), and chronic health conditions (Hexdall & Huebner, 2007). The SLSS has also been used in studies of children and youth from other nations, for example, Portugal (Marques, Lopez, & Pais-Ribeiro, 2011) and South Korea (Park & Huebner, 2005).

### ***Psychometric Properties***

Studies of internal consistency have consistently revealed coefficient alphas in the .70–.80 range across all age groups. For example, Huebner (1991b) reported an alpha of .82 in a sample of students in grades four to eight in an American Midwestern state, and Dew and Huebner (1994) reported an alpha of

.86 in a sample of students in grades nine through twelve in a Southeastern state. Comparisons of alpha coefficients for African-American and Caucasian adolescents have demonstrated comparability across groups (Huebner & Dew, 1993). Studies of test-retest reliability with school-age students have yielded correlations of .76, .64, and .53 across 1- to 2-week (Terry & Huebner, 1995), 1-month (Gilman & Huebner, 1997), and 1-year (Huebner, Funk, & Gilman, 2000) time intervals, respectively.

Studies of the validity of SLSS scores have supported its meaningfulness. Factor analytic studies have consistently demonstrated a unidimensional factor structure (Dew & Huebner, 1994; Gilman & Huebner, 1997; Huebner, 1991b). Convergent validity has been supported by strong correlations between SLSS scores and a variety of other self-report life satisfaction measures (e.g., Huebner 1991b & c; Seligson, Huebner, & Valois, 2003) as well as parent reports of their children's life satisfaction (Dew & Huebner, 1994; Gilman & Huebner, 1997).

The validity of SLSS reports has been further supported by the wide-ranging nomological network of variables related to SLSS scores (see Huebner, 2004 and Proctor, Linley, & Maltby, 2009, for reviews). For example, as expected, SLSS reports of children and youth are significantly positively related to theoretical antecedents of positive life satisfaction, such as temperament (extraversion), positive family and peer relationships, and adaptive cognitions (e.g., self-efficacy and self-esteem). Additionally, SLSS scores are related in expected ways to a variety of positive outcomes, including positive mental health and school behavior and performance.

Evidence of discriminant validity is also available. SLSS reports have been distinguished from several constructs with which life satisfaction is not expected to relate. First, SLSS scores display weak correlations with social desirability responding (Huebner, 1991b) and IQ scores (Huebner & Alderman, 1993). Also, using conjoint factor analysis procedures, SLSS scores have been differentiated from measures of positive and negative affect (Huebner, 1991a; Huebner & Dew, 1996) and self-concept (Huebner, 1995; Huebner, Gilman, & Laughlin, 1999; Terry & Huebner, 1995). Finally, consistent with many studies of adults within countries, SLSS scores are modestly related to demographic variables (e.g., gender, socioeconomic status) at best (Huebner, 1991b & c).

Discriminative validity studies have also been conducted, with SLSS scores distinguishing appropriately among various known groups. On the one

hand, compared to normal students, SLSS scores were lower for students with emotional disorders (Huebner & Alderman, 1993) and adjudicated adolescents (Crenshaw, 1998). On the other hand, consistent with studies in which SLSS scores were unrelated to IQ scores, SLSS scores did not distinguish between normal students and gifted students (Ash & Huebner, 1998).

Lastly, predictive validity studies have been supportive of the SLSS. For example, Huebner, Funk, and Gilman (2000) reported that SLSS scores significantly predicted depression and anxiety scores one year later. Similar results were obtained by Haranin, Huebner, and Suldo (2007) using a two-year time frame. Studies have also shown that low SLSS scores predict peer relational victimization (Martin, Huebner, & Valois, 2008) and student disengagement from school, especially cognitive disengagement (Lewis, Huebner, Malone, & Valois, 2011).

### **Summary of the SLSS**

Two decades of research supports the SLSS as a brief, psychometrically sound measure of global life satisfaction for students from grades three to 12. Predictive validity studies suggest that the SLSS predicts important mental health outcomes. The SLSS has been used effectively with a variety of student populations, including students with emotional disabilities, students with learning disabilities, and gifted students. However, difficulties have been encountered in using the SLSS with adolescents with mild mental disabilities (Brantley, Huebner, & Nagle, 2002), despite the fact that the students were able to reliably respond to other, specific domain-based life satisfaction items. Major limitations of the SLSS include: (a) a lack of nationally representative samples, and (b) a need for additional research with students with cognitive impairments (e.g., children with mental disabilities).

The most important limitation of the SLSS may be that it measures only *global* life satisfaction. The SLSS does not allow for the evaluation of satisfaction across various, important domains of interest to children and youth, such as satisfaction with family, school, community, and so forth. Multidimensional measures, which assess satisfaction with multiple life domains, would offer more differentiated assessments of life satisfaction. For one example, although a large statewide sample of more than 5,000 high school students in a US southeastern state revealed generally positive global life satisfaction scores, scores across five specific domains (family, friends, school, self, living environment) were more variable,

with substantial dissatisfaction observed among students' reports of satisfaction with their school experiences in particular (Huebner, Drane, & Valois, 2000). Furthermore, Antaramian, Huebner, and Valois (2008) found that family structure (intact vs. non-intact families) was related to satisfaction with family experiences, but not to general life satisfaction. Such differences in levels of life satisfaction illustrate the usefulness of considering overall and domain-based measures of life satisfaction separately. Thus, in the next sections, research findings for two multidimensional measures of life satisfaction for children and youth will be reviewed.

### ***Multidimensional Students' Life Satisfaction Scale***

As noted above, early research on children's life satisfaction instruments was limited to the development of unidimensional measures of global or general life satisfaction, which yielded only a single overall score (e.g., Perceived Life Satisfaction Scale: Adelman, Taylor, & Nelson, 1989; Students' Life Satisfaction Scale: Huebner, 1991b). In contrast, the MSLSS was designed to provide a multidimensional profile of children's life satisfaction judgments. Such differentiated assessments enable more focused diagnostic, prevention, and intervention efforts. For example, students who indicate relatively high levels of satisfaction with their families along with low levels of satisfaction with school experiences should necessitate different academic and health promotion strategies than students who indicate dissatisfaction with their families and school experiences. Contextualized life satisfaction assessments may also yield more revealing comparisons with traditional objective indicators used to assess the quality of life of children and adolescents (e.g., divorce rates, family income levels, per-pupil expenditures on schooling).

Specifically, the MSLSS was therefore developed in an effort to:

- (a) provide a profile of children's satisfaction with important, specific domains (e.g., school, family, friends) in their lives;
- (b) assess their general overall life satisfaction;
- (c) demonstrate acceptable psychometric properties (e.g., acceptable subscale reliability);
- (d) reveal a replicable factor structure indicating the meaningfulness of the five dimensions; and
- (e) use effectively with children across a wide range of age (grades three to 12) and ability levels (e.g., children with mild developmental disabilities through gifted children).

The 40-item MSLSS can be administered to individuals or groups of children. Similar to the development of the SLSS, the original version of the MSLSS used a four-point frequency response option scale (e.g., Huebner, 1994). However, more recent work with the MSLSS has used a six-point extent scale, with 1 = strongly disagree; 2 = moderately disagree, 3 = mildly disagree, 4 = mildly agree; 5 = moderately agree; and 6 = strongly agree (Huebner, Laughlin, Ash, & Gilman, 1998). Higher scores thus indicate higher levels of life satisfaction throughout the scale. Because the domains consist of unequal number of items, the domain and total scores can be made comparable by summing the item responses and dividing by the number of domain (or total) items.

Like the SLSS, the MSLSS has been used in a variety of studies with samples of students ranging in age from eight to 18. For some examples, data are available for elementary (grades three to five) (Huebner, 1994), middle (Huebner, Laughlin, Ash, & Gilman, 1998), and high school students (Gilman, Huebner, & Laughlin, 2000). The MSLSS has also been used in studies in other nations, for example, South Korea and Ireland (e.g., see Gilman et al. 2008).

### ***Psychometric Properties***

Internal consistency (alpha) coefficients for subscales have been reported in various publications (Greenspoon & Saklofske, 1997; Huebner, 1994; Huebner, Laughlin, Ash, & Gilman, 1998), with reliabilities ranging from .70s to low .90s. Test-retest coefficients for two- and four-week time periods have also been reported (Huebner, 1994; Huebner, Laughlin, Ash, & Gilman, 1998; Terry & Huebner, 1995) falling mostly in the .70 to .90 range, providing further support for the reliability of the scale.

The results of exploratory factor analyses have supported the dimensionality of the MSLSS (Huebner, 1994). Confirmatory factor analyses have provided further support for the multidimensionality of the instrument (Gilman, Huebner, & Laughlin, 2000; Huebner, Laughlin, Ash, & Gilman, 1998; Irmak & Kuruuzum, 2009), including a study spanning individualistic and collectivistic nations (Gilman et al., 2008).

Convergent and discriminant validity have also been demonstrated through predicted correlations with other self-report well-being indexes (Gilman et al., 2000; Greenspoon & Saklofske, 1997; Huebner, 1994; Huebner et al., 1998), parent reports (Gilman & Huebner, 1997; Huebner, Brantley,

Nagle, & Valois, 2002), teacher reports (Huebner & Alderman, 1993), and social desirability scales (Huebner et al., 1998). Findings of weak relationships with demographic variables (e.g., age, gender) also fit with theoretical expectations (Huebner, 1994; Huebner, Laughlin, Ash, & Gilman, 1998).

### ***Summary of the MSLSS***

As with the SLSS, the major limitations of the MSLSS involve: (a) the lack of representative national standardization data and (b) a need for further research with students with cognitive limitations. For example, Griffin and Huebner (2000) reported that four items from MSLSS needed to be omitted in order to achieve acceptable reliability coefficients for the assessment of middle school students with emotional disorders. Similarly, Brantley, Huebner, and Nagle (2002) had to delete several items to achieve acceptable internal consistency coefficients for use with adolescents with mental disabilities. Another drawback of the MSLSS is the relative length of the scale, which is prohibitive with respect to purposes such as large-scale survey research or clinical screening.

### ***Brief Multidimensional Students' Life Satisfaction Scale***

The Brief Multidimensional Students' Life Satisfaction Scale (BMSLSS: Seligson, Huebner, & Valois, 2003) was designed to fill the need for a reliable and valid measure of life satisfaction that was relevant, developmentally appropriate, and sufficiently brief to be useful in screening contexts or in large-scale surveys of children and adolescents, such as national and cross-national surveys. Specifically, it was designed to reflect the conceptual model underlying the MSLSS. The BMSLSS is thus a five-item self-report measure that assesses satisfaction with respect to each of the five domains included on the MSLSS (see above). That is, students rate their satisfaction on a single item for each of the five domains of family life, friendships, school experiences, self, and living environment. Response options are on a seven-point scale (Andrews & Withey, 1976) that ranges from 1 = terrible to 7 = delighted. An additional item, measuring students' satisfaction with their overall life, has been included in the BMSLSS in some studies.

Like the SLSS and MSLSS, the BMSLSS has been used in studies of children from ages eight to 18. In particular it has been used in two large-scale studies in the US. The BMLSS was included in the 1997 South Carolina Youth Risk Behavior Survey

of the Center for Disease Control and administered to over 5,500 public school students from 63 high schools (Huebner, Drane, & Valois, 2000). It was also used in a study of 2,502 students from grades six to eight in South Carolina (Huebner, Valois, Paxton, & Drane, 2005). The BMLSS has also been employed in studies of children and youth from other nations, such as China (Kwan, 2009) and Turkey (Siyez & Kaya, 2008).

### ***Psychometric Properties***

Coefficient alphas for the total score (i.e., the sum of respondents' ratings across the five items) have been reported ranging from .68 (elementary school students) to .75 (middle and high school students (Funk, Huebner, & Valois, 2006; Seligson, Huebner, & Valois, 2003; 2005). Inclusion of the additional global life satisfaction item in the total score raised the alpha coefficients to .76 for elementary students and .85 for secondary level students. Test-retest coefficients for a two-week interval were .91 (five-item total score), .85 (family), .80 (living environment), .79 (self), .75 (school), and .62 (friends) (Funk, Huebner, & Valois, 2006). A one-year test-retest reliability coefficient of .52 has been reported for the total score (Huebner, Antaramian, Hills, Lewis, & Saha, 2011).

Studies of construct validity have been undertaken. As noted above, the BMSLSS was designed to tap the same dimensions of life measured by the MSLSS (Huebner, 1994). The MSLSS is based on a hierarchical model of life satisfaction with general life satisfaction at the apex, along with the five lower-order domains (i.e., family, friends, school, etc.). Confirmatory factor analyses have supported the hierarchical model underlying the MSLSS (see Huebner, Laughlin, Ash, & Gilman, 1998).

Construct validity of the BMSLSS has been supported in several other ways. First, the meaningfulness of the general or total life satisfaction score has been assessed. Specifically, BMSLSS reports of 221 middle school students were subjected to principal axis factor analysis. Based on an eigenvalue greater than 1 criterion, and the results of a scree test, a single higher-order factor solution was supported (Funk, Huebner, & Valois, 2006; Seligson, Huebner, & Valois, 2005). Additionally, item-total correlations, ranging from .65 to .73, were observed with a middle school sample (Seligson, Huebner, & Valois, 2003).

The construct validity of the five single-item domain scores for the BMSLSS has been supported

by multitrait-multimethod correlation matrix comparisons of the multi-item domain scores from the MSLSS with the single items on the BMSLSS using Campbell and Fiske's (1959) recommendations (see Seligson, Huebner, & Valois, 2003). In all cases, intercorrelations among the measures' corresponding domains were substantially higher than intercorrelations among the BMSLSS domains, as well as between different domains of the BMSLSS and MSLSS (e.g., MSLSS family domain score, BMSLSS friend item score). This pattern was demonstrated in separate analyses of middle and high school samples, with higher convergent validity coefficients observed in the high school students. Acceptable convergent validity correlations have also been obtained between the BMSLSS Total score and other validated measures of life satisfaction, such as the MSLSS Total score ( $r = .66$ ) and the SLSS ( $r = .62$ ) (Seligson, Huebner, & Valois, 2003).

The BMSLSS has demonstrated criterion-related validity through expected relationships with various adolescent problem behaviors. For example, adolescents' BMSLSS reports have shown concurrent, negative relationships with their alcohol, tobacco, and other drug use (Zullig, Valois, Huebner, Oeltmann, & Drane, 2001); violent and aggressive risk behaviors, such as physical fighting and carrying a weapon (Valois, Zullig, Huebner, Oeltmann, & Drane, 2001); sexual risk-taking behaviors (Valois, Zullig, Huebner, Kammermann, & Drane, 2002); inappropriate dieting behaviors (Valois, Zullig, Huebner, & Drane, 2003); suicidal ideation and behavior (Valois, Zullig, Huebner, & Drane, 2004); and lack of physical activity (Valois, Zullig, Huebner, & Drane, 2003). Evidence of predictive validity has been demonstrated by significant one-year correlations in the expected directions with measures of school engagement and grades (Huebner, Antaramian, Hills, Lewis, & Saha, 2011).

Finally, evidence of discriminant validity has been reported. BMSLSS scores yield a low correlation with indicators of social desirability (Seligson, Huebner, & Valois, 2003). In addition, the BMSLSS demonstrated relatively weak relationships with physical health-related quality of life measures (Zullig, Valois, Huebner, & Drane, 2005). Similar to other measures of general life satisfaction, BMLSS scores show modest relationships at best with a variety of demographic variables, such as gender, ethnicity, and so forth (Huebner, Suldo, Valois, Drane, & Zullig, 2004).

### ***Summary of the BMSLSS***

Research has supported the usefulness of the BMSLSS with students from grades –three to 12. The BMSLSS may be most useful in large national and international databases evaluating students' overall subjective well-being as well as pinpointing specific areas of life that may serve as protective or risk factors. In addition, the straightforward, concrete wording of the items lends itself well to large-scale surveys in which data are often analyzed at the item level. It may also be useful in clinical screening contexts, where brevity is also a virtue. For example, Huebner, Nagle, and Suldo (2003) provide examples of interview questions that could be used to follow up on responses of individuals, to provide more comprehensive understanding of students' responses. Nevertheless, as with the previous SLSS and MSLSS, major limitations of the BMSLSS include (1) the lack of nationally representative normative samples, and (b) the need for additional research with children with special needs.

### ***Subjective Well-Being—Positive and Negative Affect***

The Positive and Negative Affect Schedule for Children (PANAS-C; Laurent et al., 1999) assesses students' positive and negative affect. The PANAS-C is the child version of the PANAS designed by Watson, Clark, and Tellegen (1988). The scale includes 27 items that comprise two subscales (Positive Affect and Negative Affect) and is based on the conceptualization that both PA and NA reflect dispositional activations of positive and negatively valenced emotions and are conceptually somewhat independent constructs. The Positive Affect subscale consists of 12 items, such as energetic, interested, excited, cheerful, and proud. The Negative Affect subscale includes 15 items, such as sad, nervous, ashamed, lonely, and frightened. Respondents rate the extent to which they have felt each emotion during the past few weeks on a five-point Likert scale ranging from "very little or not at all" to "extremely or all of the time."

The PANAS-C has been used in studies of children from ages eight to 14. One study involved children with a diagnosed anxiety disorder (Hughes & Kendall, 2009). The PANAS-C has been also been translated and used in a study of Japanese children (Katsuma, Risa, & Akiko, 2006).

### ***Psychometric Properties***

Prior studies investigating the psychometric properties of the PANAS-C suggest preliminary

support. Alpha coefficients reported in the literature range from .87 to .90 for the Positive Affect subscale and from .87 to .94 for the Negative Affect subscale (Antaramian, Huebner, Hills, & Valois, 2010; Laurent et al., 1999). Test-retest reliability coefficients for a 20-item version have been reported as in the lower .70 range (negative emotions) and upper .60 range (positive emotions) across two-week intervals, suggesting adequate stability (Crook, Beaver, & Bell, 1998). Research investigating the construct validity of the PANAS-C has supported a two-factor model of affect in samples of children and adolescents, using exploratory factor analysis procedures with the 27-item version (Laurent et al., 1999) and the earlier 20-item version (Crook, Beaver, & Bell, 1998).

Evidence also provides some support for the convergent and discriminant validity of the PANAS-C. The Negative Affect subscale was strongly, positively correlated with measures of trait anxiety and depression while the Positive Affect subscale was strongly, negatively correlated with the depression measure, but less strongly correlated with the anxiety measure (Laurent et al., 1999). However, concerns have been expressed over the PANAS-C's ability to discriminate social anxiety and depression in a sample of children diagnosed with a principal anxiety disorder (Hughes & Kendall, 2009).

### ***Summary of the PANAS-C***

As mentioned earlier, a significant body of research supports the need to measure positive affect and negative affect to adequately understand persons' SWB. Research has supported the usefulness of the PANAS-C with children and adolescents as one such measure. The relative length of the PANAS-C may be prohibitive with respect to purposes such as large-scale survey research; however, it may be useful in clinical screening and targeted samples to gather important data regarding emotional status and engagement-disengagement. Major limitations of the PANAS-C include (a) the lack of nationally representative normative samples, and (b) the need for additional research further investigating its construct validity, especially its discriminant validity.

### **Needed Future Research on SWB Measures**

Gilman and Huebner (2000) identified a number of issues and associated directions for future research in the assessment of children's SWB. The issues continue to need attention.

First, most SWB measures lack good standardization samples. Most samples are geographically, ethnically, and socioeconomically limited.

Differences in definitions of "a good life" and "positive emotions" necessitate the availability of norms that are representative of the individuals or groups under consideration. Given that norm-referenced interpretations may be desired for some purposes, the development of additional SWB measures with nationally representative samples would be a critical next step.

Second, although preliminary research findings have been positive, additional research on the psychometric properties of SWB scales would be useful. With respect to reliability, investigations of test-retest reliability have been particularly sparse. Studies of test-retest reliabilities across differing time periods are needed for many measures. Investigations of predictive validity have also been quite sparse, thus longitudinal studies using SWB are critical for the future of SWB research. More cross-group construct validity studies are also needed to ensure the comparability of the meaning of various measures across different groups. For example, the equivalence of the factor structure of a multidimensional SWB measure across various groups of students (e.g., age groups, gender, ethnicity) should be evaluated empirically, not assumed.

Third, the use of SWB measures with different age groups and abilities has been understudied. The possibility of important developmental differences in the nature and determinants of SWB reports has received little research attention. The ability of students below the age of eight to respond meaningfully to SWB items remains unclear. The nature and number of relevant domains included in multidimensional measures also remains unclear. Although recognizing that some domains of life satisfaction may be important at some ages but not others (e.g., romantic relationships in adolescence), some instruments (e.g., the MSLSS) have been based on the notion that there are some broad domains that are important across a wide age range. The benefits and limitations of developing scales that attempt to assess multidimensional SWB across a wide age range have not been addressed thoroughly. Furthermore, as noted above, some research has suggested that measures may need to be modified for use with special populations. For example, Griffin and Huebner (2000) demonstrated that five reverse-keyed items on the MSLSS had to be eliminated when used with adolescents with serious emotional difficulties. For another example, global ratings of life satisfaction proved to be difficult to interpret for students with mental disabilities (Brantley, Huebner, & Nagle, 2002), but not for students with learning disabilities

(McCullough & Huebner, 2003). Thus, the SWB reports of students with special needs should be interpreted very cautiously.

Finally, the relationships between SWB measures and other methods needs further study. Although findings overall support the use of self-report techniques to measure *subjective* well-being of students, multi-method, multi-occasion assessments are generally recommended (Diener, 1994). Although little research has been conducted with children and adolescents, research with adults reveals that various situational factors (e.g., current mood, specific previous and current events, memory) can influence SWB reports (Pavot, 2008). Although such effects can be modest, they reflect the complex cognitive processing associated with making SWB judgments and highlight the need to consider alternative methods of assessing SWB. The reports of knowledgeable others (e.g., parent reports) may serve as a useful alternative method in some cases, although some scholars (e.g., Cummins, 2002) have noted the shortcomings of such methods. Other methods showing some promise include physiological and non-verbal indices (e.g., facial expression, vocal tones), experience sampling methodology, in-depth interview, and memories of good and bad events (Diener, 1994). Studies of the convergence and divergence of responding across different methods would be particularly

useful to understand the strength and limitations of the various alternatives.

Overall, scores on a variety of self-report measures of SWB, such as those above, demonstrate reasonable reliability and validity for various purposes (Diener, 1994; Gilman & Huebner, 2000; Proctor, Linley, & Maltby, 2009). Within the context of multi-method, multi-occasion assessments, SWB measures should prove useful in developing more comprehensive pictures of the adaptation of children and youth. Supported by data from other sources (e.g., observations, interview, other tests), SWB instruments should be able to provide incremental validity to the traditional testing armamentarium available to school psychologists, especially when the evaluation of students' psychosocial strengths and optimal functioning are under consideration. Given the lack of large national standardization samples, the use of criterion-referenced interpretation is more appropriate than norm-referenced interpretations. The use of absolute interpretations (e.g., Maggie rates her life satisfaction as "terrible" versus "delighted") is likely to be more meaningful than norm-referenced comparisons (e.g., Maggie is happier than 95 out of 100 children her age) for many purposes. Teachers, parents, and other caregivers may be as interested in a given child's level of SWB relative to the various response options as much as in a comparison to normative data.

### Case Study

The following is a brief case study of "E.S." a 13-year-old male who was referred for evaluation due to poor response to intervention and limited academic progress. The school multidisciplinary team recommended an evaluation for E.S. due to a lack of academic progress and behavioral concerns that were emerging in the classroom. E.S. had attended Tier II reading intervention services for 45 minutes each school day combined with after-school tutoring a few days a week for the past year with minimal progress. He had not been evaluated previously. Cognitive and achievement norm-referenced test results obtained during this evaluation process indicated average to above-average cognitive skills and below-average reading skills; however, his performance on academic measures during the evaluation was higher than expected given his poor academic performance in the classroom.

As part of this evaluation, E.S. was administered two measures of SWB: the MSLSS and the PANAS-C, in addition to a traditional, norm-referenced measure of mental health, which focused on symptoms of psychopathology (i.e., internalizing and externalizing behavior problems). Results of teacher, parent, and self-reports on the norm-referenced measure indicated minimal to no concerns with social and emotional functioning (i.e., symptoms). However, E.S.' total score on the MSLSS ( $M = 3.0$ ) suggested that his perceived satisfaction with life was in the negative range. An examination of the MSLSS individual subscale scores (see Figure 34.1) suggested that E.S. is happy with his family and his living situation; for example, he responded "Strongly Agree" to items like "I like where I live" and "My family gets along well together."

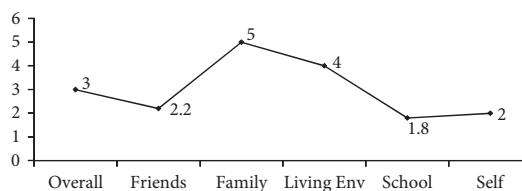

Figure 34.1 MSLSS Scores for E.S.

In contrast to his life satisfaction scores in family and living environment domains, his perceived satisfaction with friends, school, and self was of significant concern. Despite noting existing friendships during the parent, teacher, and individual interview and adequate social skills/relations on the norm-referenced social/emotional measure, E.S. rated his satisfaction with these relationships in the low range. For example, he responded “Strongly Disagree” to items “I have enough friends” and “My friends treat me well.” In response to follow-up questions, he noted that he didn’t see his friends as much as he used to and they didn’t seem to be as interested in hanging out with him, further noting his friends were all in the Honors-level classes and had a different lunch schedule than his. Although during the initial interview E.S. simply reported “none” to a question about participation in extracurricular activities, during the follow-up interview using the MSLSS results to guide questioning, E.S. noted that he used to play sports for the school, but couldn’t this year because of having to attend tutoring after school.

Upon follow-up, it became evident that given the salience of peers throughout adolescence and the positive impact of social relationships on well-being, his peer satisfaction was likely negatively impacting another important area of life satisfaction: self. E.S.’ scores in the self-domain were also low ( $M = 2.0$ ), with responses of “Agree” to statements like “I wish I had a different kind of life” and “Disagree” to many statements like “I like myself.” His level of satisfaction with his school experiences was also of concern, with responses of “Disagree” to statements like “I enjoy school activities” and “I like being in school.” He noted that although he complies with requests to attend tutoring and completing homework, he often remains disengaged throughout these activities, just completing them based on “what it takes to pass.”

Ratings on the PANAS-C indicated that E.S. experiences only moderate levels of positive emotions ( $M = 3.1$ ) and moderate levels of negative emotions ( $M = 3.9$ ). For example, most of his ratings on positive emotion items ranged from 2 (A little) to 3 (moderately), with only a few ratings of 4 (quite a bit). His ratings of negative emotion items suggested that he experiences feelings of sadness (4—quite a bit) and upset (5—all of the time) on a regular basis. When questioned further about these ratings, E.S. indicated that he often felt sad at school, given that he never sees his friends, and is upset with how things are going academically at school, which can lead to his parents’ being upset with him at home. Throughout this follow-up interview, he made several references to the fact that, given his isolation from his identified friends and his minimal academic progress, he has grown to “not care as much about school... because what’s the point?”

Information collected from the MSLSS and PANAS-C was instrumental in the evaluation process to form data-based recommendations for appropriate interventions. Despite average ratings on teacher, parent, and self-report norm-referenced social-emotional measures, suggesting adequate mental health, and few psychological symptoms, results of the SWB scales (MSLSS and PANAS-C) provided information that was key to understanding E.S.’ perceptions of his overall satisfaction with different areas of his life and the type of emotions he regularly experiences. This provides a context to help understand the factors that may be negatively affecting his academic progress. The results within this case study support the notion that gathering information about well-being enhances the information collected with more traditional, routine assessment measures, reflected in the previously mentioned Dual-Factor Model of Mental Health (Greenspoon & Saklofske, 2001). The results of SWB measures provided a

more comprehensive context that allowed the psychologist to elicit information based on the SWB data provided by E.S. These results suggested that his peer isolation and discontinuation of sports participation may be negatively affecting his achievement motivation and causing him to engage in subtle, yet impactful, withdrawal behaviors at school.

As a result of this evaluation, the multidisciplinary team, which included his parents, determined that E.S. was not eligible for special education services; however, they implemented a number of interventions. Many of these interventions capitalized on E.S.' strengths indicated through this assessment. Measures of SWB indicated that his overall perception and satisfaction with his family life and living environment were positive and could be relied upon to provide support and progress monitoring. Throughout this process, it was revealed that his family was friendly with many of his close friends' families and could help with arranging social gatherings to give E.S. time to maintain and strengthen his current, but dwindling (as he perceives) friendships. In the school setting, the nature and time of tutoring was restructured to allow him to continue to participate in activities he values and activities that provide him time to engage socially with peers. Strong neighborhood support made it possible for this restructuring to occur, given the need for assistance with transportation to/from tutoring. The school team worked with the family to help set up neighborhood transportation networks for E.S. and other students in the area to get to/from important events (e.g., tutoring, extracurricular activities).

Although this restructuring did not allow him to participate in the school sports team (due to timing; it was midseason), it did allow him to participate in a recreational sports team in the community until the next sport season arrived. Six months later, he easily transferred to the school sports team, given the new season, his restructured schedule, and the athletic conditioning level he maintained through his participation on a recreational sports team. Combined with this change in his extracurricular activity participation, his trajectory of academic progress had significantly improved, which suggests that E.S.' school engagement and overall achievement motivation increased as well.

## Concluding Comments

Extending beyond the Dual-Factor Theory of Mental Health (Greenspoon & Saklofske, 2001), the value of differentiating levels among average and higher levels of SWB has been suggested by a study by Suldo and Huebner (2006). Based on their life satisfaction scores, they divided secondary-level students into three groups: low (lowest 10%), average (middle 25%), and very high levels (top 10%) of life satisfaction. Not only were the high and low groups different, but the high and average groups differed on a variety of important adolescent variables. More specifically, although rates of clinical levels of behavior problems (e.g., internalizing and externalizing behaviors) did not differ significantly between the very high and average groups, significant differences were observed on measures of adaptive psychosocial functioning, and on academic, social, and emotional self-efficacy, as well as parent, teacher, close friend and classmate social support. A similar study by Gilman and Huebner (2006) revealed comparable findings, including significant differences between high

and average groups of adolescents on measures of global self-esteem, hope, and internal locus of control. Taken together, the findings support the notion that the highest levels of well-being are not captured by the absence of psychopathological behaviors. Rather, assessing mental health requires measures of constructs, such as SWB constructs, that reflect experiences above a neutral point or the absence of indicators of psychopathology. Measures of life satisfaction and positive affect may thus provide a useful complement to the more traditional measures that focus on the presence of psychopathology in comprehensive assessments of child and adolescent mental health. As observed by Beaver (2008), families of children with behavior problems do not simply seek reductions in their behavior problems when they seek psychological assessments and counseling. They want their children to "be happy and to fully engage in the academic and social experiences of childhood" (Beaver, 2008, p. 134). Such a broadened focus, encompassing positive SWB, should aid in the accomplishment of such goals.

# Assessment of Parenting Behaviors and Style, Parenting Relationships, and Other Parent Variables in Child Assessment

Laura G. McKee, Deborah J. Jones, Rex Forehand, and Jessica Cuellar

## Abstract

This chapter provides an historical and theoretical context for the assessment of parenting, including the ways in which the concept of parenting has morphed over time, the ways in which assessment tools have been constructed to capture the complexities of the parent–child relationship, and the ways in which parenting assessment has contributed to basic developmental science and applied intervention/prevention science. The chapter also highlights integral cultural considerations of assessment design, validation, and application by focusing, primarily, on ethnicity. Three questionnaire tools and three observational coding schemes are explored in detail. The impact of parenting relationships and parental physical and mental illness are addressed, with implications for assessment noted. Finally, a summary of the literature provides potential avenues for future research.

**Key Words:** parenting practices, parenting behaviors, parenting style, child behavior, coparenting, culture, socioeconomic status, parental illness

## Overview

Any theoretical model or empirical research designed to explain the development of child psychosocial adjustment must account for the influence of parenting, either directly or indirectly. Borrowing Baumrind's words, "there is no way in which parents can evade having a determining effect upon their children's personality, character, and competence" (1978, p. 239). Consistent with Baumrind's assertion, social, clinical, and developmental psychologists have spent the past half century seeking to answer the questions, "Does parenting contribute to child psychological well-being or psychopathology, and if so, how might parenting best be conceptualized and measured?" Given the now robust empirical evidence indicating "yes," parents do contribute to child psychosocial adjustment, researchers have more recently amended the question to capture the dynamic and reciprocal genetic, behavioral, and environmental interplay that unfolds over

time between the parent–child dyad in the family, neighborhood, and cultural and economic contexts (Belsky & Jaffee, 2006).

Several theoretical models of human development, including ecological systems theory originally proposed by Bronfenbrenner (1979) and updated by others (Cummings, Davies, & Campbell, 2000), as well as Super and Harkness's (1999) concept of the "developmental niche," recognize the influence of caregivers as agents of emotional, cognitive, and relational socialization for their offspring. Bronfenbrenner's model, often presented graphically, consists of a series of concentric circles, with the individual child situated in the innermost circle, surrounded by the microsystem (e.g., parents and siblings, neighborhood, peers, schools), the mesosystem (representing the relations between aspects of the microsystem), the exosystem (e.g., extended family, mass media, community health services, parental workplace), and finally the macrosystem

(e.g. cultural, subcultural, and social and economic class regulations). One of the more proximal forces, the caregiver, exerts influence on the child's development directly via shared genetics, parenting style, and parenting behaviors and, indirectly, as a filter and interpreter of more distal forces. For example, in the case of child aggressive behavior, McLoyd (1990) has argued that the relation between poverty (component of the macrosystem) and child externalizing symptoms is mediated by parental disciplinary strategies (microsystem), and several empirical studies have garnered support for this perspective (Dodge, Pettit, & Bates, 1994; Sampson & Laub, 1994). Super and Harkness's concept of the "developmental niche" emerged from a tradition that has conceptualized the child's *cultural* environment as a set of *proximal* sources of influence, providing an alternative to Bronfenbrenner's hierarchical schematic; nonetheless, caretakers are considered to be powerful direct and indirect regulators of the three subsystems surrounding the child (Super & Harkness, 1999). In sum, both frameworks, representing different lenses through which to examine the influence of the child's environment on development, highlight the central role of caretakers, most often biological parents, but increasingly other caregivers as well, including non-marital coparents (e.g., grandmothers assisting single mothers with childrearing), in the lives of youth.

As will be discussed in more depth in the pages that follow, the construct and assessment of "parenting" has morphed over time; thus, a number of different conceptual perspectives have been presented in the literature and will be reviewed and synthesized here. Parenting variables have also occupied a prominent place in a wide array of empirical studies, with foci ranging from youth academic achievement (e.g., Burchinal, Roberts, Zeisel, & Rowley, 2008; Glasgow, Dornbusch, Troyer, & Steinberg, 1997; Prelow, Bowman, & Weaver, 2007) to perpetration of violent crime (Bradshaw, Glaser, Calhoun, & Bates, 2006; Caspi et al., 2002; Widom, 1989) and diagnosis of major depressive disorder in offspring (Fendrich, Warner, & Weissman, 1990; Hammen, Shih, & Brennan, 2004). Despite the variation in parent predictors and developmental outcomes, researchers studying parenting have focused on remarkably similar underlying parenting dimensions—warmth/acceptance, harshness/hostility, strictness/behavioral control, permissiveness/lax control, involvement, and monitoring (e.g., Barber, Stoltz, & Olsen, 2005; Patterson & Fisher, 2002). As a result of the consistency across studies

of parenting, as well as the sheer number of studies, significant empirical support has emerged for the robust association between parenting practices typified by warmth and affection, positive reinforcement, firm and consistent discipline, and active involvement in and monitoring of child and adolescent activities and child psychosocial well-being (Baumrind, 1978; Brody & Flor, 1998; Gray & Steinberg, 1999), including reduced externalizing (e.g., Barber & Olsen, 1997; Pettit, Laird, Dodge, Bates, & Criss, 2001) and internalizing (e.g., Barber & Olsen, 1997; Gray & Steinberg, 1999) symptoms. The converse—that negative parenting, including high levels of hostility, low levels of warmth and involvement, coercive disciplinary tactics, and inconsistent monitoring, is associated with youth psychosocial maladjustment—also has a broad base of empirical support (e.g., Baumrind, 1978; Ge, Conger, Lorenz, & Simons, 1994; Teicher, Samson, Polcari, & McGreenery, 2006).

Although the unidirectional, deterministic view of parents' influence on the etiology of child and adolescent psychopathology has been overstated at times, either by failing to consider the child evocative effects (e.g., Lytton, 2000; Scarr, 1992) or passive gene-environment correlations (e.g., Foley et al., 2004; Kim-Cohen et al., 2006), sophisticated contemporary research continues to assert that "parenting matters," albeit in complex interactions with heredity, nonfamilial influences, and the broader contexts (e.g., Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Galambos, Barker, & Almeida, 2003). In fact, a number of causal theories of child and adolescent problems implicate parenting behaviors and parent-child interactions. Researchers at the Oregon Social Learning Center, for example, developed a social learning model and have studied extensively the coercive processes at play in families with aggressive or conduct-disordered children (e.g., Patterson et al., 1992; Snyder & Patterson, 1995). According to the theory and empirical tests of it, the irritable, hostile exchanges between parents and children often contain a negative reinforcement mechanism that perpetuates parental harshness and child externalizing problems (see Granic & Patterson, 2006). Consistent with this body of research, the intervention of choice for treating and preventing child and adolescent disruptive behavior problems is Parent Management Training, in which maladaptive parenting practices are replaced with a repertoire of skills to more effectively manage the child's behavior while improving

the broader parent-child relationship quality (e.g., Forehand, Kotchick, Shaffer, & McKee, 2010; McMahon & Forehand, 2003; McMahon, Wells, & Kotler, 2006).

Of note, although interventions for internalizing symptoms have largely grown out of an individual-focused tradition with less emphasis on the parent-child relationship (Clarke, Lewinsohn, & Hops, 1990; Stark & Kendall, 1996), a special issue on evidence-based psychosocial treatments for children and adolescents published by the *Journal of Clinical Child & Adolescent Psychology* admonishes researchers to consider the impact of parental involvement in interventions targeting youth with anxiety and depressive disorders (David-Ferdon & Kaslow, 2008; Silverman, Pina, & Viswesvaran, 2008). In an example of such a program, Webster-Stratton and Herman (2008) recently examined the efficacy of *Incredible Years*, a parent training program with an established history of reducing externalizing problems in young children, for reducing internalizing problems. Importantly, the authors highlight that many of the same mechanisms that contribute to externalizing problems in youth also likely contribute to internalizing problems, including parenting, and that comorbidity between internalizing and externalizing problems in youth makes disentangling specific effects difficult. Findings revealed that the *Incredible Years* program was associated with a significant reduction in internalizing symptoms in youth relative to a wait-list control, particularly for youth who scored in the clinical range on internalizing symptoms at baseline. Moreover, perceived changes in parenting mediated the effect of treatment on children's internalizing symptoms. In sum, the assessment of parenting style and parenting behaviors is an integral component in the pursuit of causal theories of child and adolescent psychopathology, and, thus, in the development and testing of targeted prevention and intervention programs for externalizing, as well as internalizing, symptoms.

### ***Ethnicity, Culture, and Parenting Constructs***

While a vast body of research on parenting style and parenting behavior has produced, replicated, and extended a robust core of findings, and although the treatment literature has been informed and innovated by these consistent outcomes, important questions remain regarding the influence of ethnic, cultural, and socioeconomic contexts on the relations between parenting behaviors and child outcomes. For example, some research on low-income African

American parents and their children, particularly those living in high-risk communities or exposed to high-risk peer groups, suggests that parents who adjust their approach to parenting in response to environmental risk factors (e.g., "no-nonsense parenting"—a term adopted to describe a parenting approach consisting of high levels of behavioral control combined with affectionate behaviors) have children who evidence fewer adjustment difficulties (Brody & Flor, 1998; see also Mason, Cauce, Gonzales, & Hiraga, 1996). Importantly, however, this work does not suggest that heightened monitoring in response to risk is beneficial in the absence of or at the expense of warmth. On the contrary, some work suggests that warmth is an important, if not the most important parenting behavior for children raised in high-risk contexts (Masten & Coatsworth, 1998).

Another example of the importance of considering the cultural ecology when ascertaining the effects of specific parenting behaviors on youth comes from the study of Hispanic American families. A "hierarchical/autocratic" parenting approach, typified by strong parental authority and rules/consequences *not* based on consensus, may more accurately characterize Hispanic American families whose practices are influenced by the values of *familism* and *respeto* (Arcia, Reyes-Blanes, & Vazquez-Montilla, 2000; Harwood, Leyendecker, Carlson, Asencio, & Miller, 2002). As such, some research has shown that a hierarchical or autocratic style is associated with positive outcomes among Hispanic children (Lindahl & Malik, 1999); however, other research has indicated that autonomy granting and democracy is related to adaptive offspring outcomes regardless of ethnicity, class, or family structure (Steinberg, Mounts, Lamborn, & Dornbusch, 1991). In sum, there is a growing body of evidence suggesting that socialization goals and cultural norms within a particular racial, ethnic, or socioeconomic group may determine the effect of a specific parenting style on child outcomes (e.g., Forehand & Kotchick, 1996; Lindahl & Malik, 1999); however, additional fine-tuned analysis is warranted.

Although much of the research focused on minority groups has utilized parenting assessment tools originally designed for use with majority families and may not reflect equivalent constructs/processes (Garcia Coll, & Pachter, 2002; Guerra & Jagers, 1999; Knight & Hill, 1998; Knight, Tein, Shell, & Roosa, 1992), the validation of tools with different populations and culturally

informed measure development is gaining empirical ground (see Taylor, Barnett, Longest, & Raver, 2009; and Smetana, Abernethy, & Harris, 2004, for examples). Given that minorities, who now constitute roughly one-third of the US population, are expected to become the majority by mid-century (U.S. Census Bureau News, 2008), attention to the accurate assessment of diverse parenting practices is of paramount importance. Accordingly, we include examples, when available, not only of Caucasian families, which have been the primary focus of parenting research, but also of empirical data representing ethnic minority families. Although still paling in comparison to the depth and breadth of research on parenting in Caucasian families, the ethnic minority group that has received the most attention in the literature and has been a primary focus of the work by the authors is African American families; however, we make an effort to include studies of other ethnic minority groups as well, including some work on Hispanic families.

### ***Assessing Correlates of Parenting Style and Behavior***

Beyond the more direct effects of parenting style and behaviors on child psychosocial, emotional, and cognitive development, both Bronfenbrenner's (1979) and Super & Harkness's (1999) theoretical models recognize additional factors that may influence the relations between caregiver behavior and child outcomes, including but not limited to marital and coparenting relationships, parental psychopathology, and chronic illness. Each of these broad areas of study has important implications for adaptive and pathological child and adolescent development and will be addressed, in turn, in the chapter.

### ***Parenting Measures: Overview of Content, Administration, and Feasibility***

Just as the theories informing parenting research represent alternative perspectives, the assessment tools designed to assess the constructs of interest vary widely in terms of content, administration, and feasibility. As discussed further in this and the following section, a number of factors contribute to the content, administration, and feasibility, including the age and developmental stage of the child; the racial, ethnic, and class characteristics of the family; and the purpose of the assessment and its intended audience. All of these factors influence, in concert with the guiding theory, the variables included and the format imposed. For example, investigators and clinicians focused on adolescents

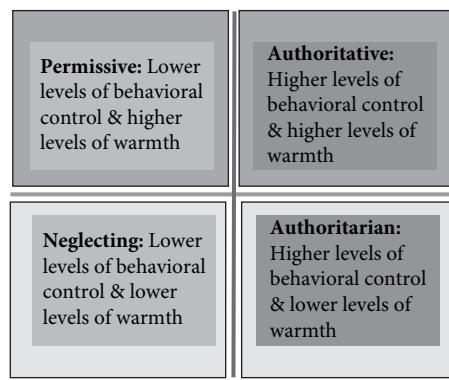

living in single-mother-headed families or urban families of low socioeconomic status may consider monitoring and limit setting as the most salient parenting issues (Bank, Forgatch, Patterson, & Fetrow, 1993; Elder, Eccles, Ardel, & Lord, 1995; Jones, Forehand, O'Connell, Armistead, & Brody, 2005), while intrusiveness and disengagement may be more prominent for researchers working with depressed caregivers (Lovejoy, Graczyk, O'Hare, & Neuman, 2000). Given the wide range of parenting assessment tools available, this chapter will serve not as a comprehensive list but rather will highlight exemplars in each of two broad categories. The reader is referred to the *Handbook of Family Measurement Techniques*, Volumes 1–3 (Touliatos, Perlmuter, & Straus, 2001) for abstracts describing nearly 1,000 instruments utilized in the measurement of the family as well as selected examples of actual instruments. Other resources of interest are provided in subsequent sections.

With regard to administration, parenting assessment techniques fall into two broad categories: questionnaire data (parents reporting on their own practices and children/adolescents reporting on their caregiver's behaviors) and structured observations of dyadic (parent-child) or triadic (parent-parent-child) family interactions. The two general approaches provide different perspectives on parenting behavior and function (Fiske, 1987) and have distinct strengths and weaknesses, which, in turn, have implications for content and feasibility. Questionnaire data are generally less costly (Fiske, 1987; Ramey, 2002), often require little to no training to administer, are easily scored, and may elicit, depending upon the measure employed, response sets that take into account parenting behaviors across time and context (Zaslow et al., 2006). However, as with all questionnaire data, particularly self-reports, threats to validity are inherent, including a social desirability response bias, among others (Schwarz, 1999). While structured observational data are more burdensome to collect and score (more costly in terms of observer time or video equipment, require highly trained coders), advantages include the provision of a standard context and task, reduced likelihood of bias by independent raters, and the opportunity to assess characteristics of parenting not accessible by questionnaires (e.g., tone of voice, physical proximity of parent to child, child's response to particular parenting behaviors). Finally, in addition to issues of cost and ease of administration and scoring, transportability of the assessment tool also affects feasibility. While questionnaire data

can be mailed to parents and children, utilized in telephone interviews, or completed online without a researcher or clinician present and, thus, ostensibly reach a larger and wider audience, observational data must be gathered in a clinical or research setting or in the field.

### **Parenting Behaviors and Parenting Style**

Parenting, both positive and negative, has been explored from a variety of perspectives, ranging from a focus on (1) the effects of broad typologies of parenting to (2) the main effects of particular parenting behaviors (e.g., Baumrind, 1966; Schaefer, 1965; see also McKee, Colletti, Rakow, & Forehand, 2008). One approach to a review of this vast literature is to document the progression and development of concepts and theories from an historical perspective. Such an approach reveals the increasing sophistication of theory, methodology, and analytic strategies over the decades, and also allows for the identification of those concepts that have stood the test of time and empirical inquiry. In one of the earlier conceptualizations of parenting, many researchers suggested that it was particular, fixed constellations of parenting behaviors, as opposed to the unique impact of any single parenting behavior, that contributed to child and adolescent competency or psychopathology. This idea originated in Baumrind's traditional paradigm, which conceptualized parenting as a combination of varying levels of behavioral control and affection (Maccoby & Martin, 1983) (see Figure 35.1). *Authoritative parenting*, for example, was initially conceptualized as high levels of parental affection combined with high levels of behavioral control or supervision (Baumrind, 1966). Over time, the authoritative parenting approach was modified by Steinberg and colleagues to include psychological autonomy, or democracy, to more fully account for adolescent healthy psychological development and school success (Steinberg, 1990; Steinberg, Lamborn, Dornbusch, & Darling, 1992). Importantly, authoritative parenting has been shown to be positively related to healthy adjustment in children and adolescents (Baumrind, 1966; 1967; 1989; Maccoby & Martin, 1983; Steinberg et al., 1992). Conversely, *authoritarian parenting*, which was defined as low levels of affection and high levels of behavioral control or harsh discipline, *permissive parenting*, which consisted of high levels of warmth and caring but low levels of behavioral control, and *neglecting parenting*, which was characterized by a combination of low levels of both warmth and control, have all been associated with child and

X Axis: Behavioral Control  
Y Axis: Warmth and Responsiveness

**Figure 35.1** Representation of parenting styles, based on Baumrind, 1966, and Maccoby & Martin, 1983.

adolescent internalizing and externalizing behaviors (Baumrind, 1989; Heller, Baker, Henker, & Hinshaw, 1996; Jewell & Stark, 2003).

It is worth noting, however, that much of the research using Baumrind's paradigm has focused on Caucasian families. When the paradigm is applied to ethnic minorities, some evidence emerges suggesting that *authoritarian* parenting may not have the same negative consequences demonstrated with Caucasian samples and may, in fact, be related to more positive outcomes (Garcia Coll, Meyer, & Brillon, 1995; Jambunathan, Burts, & Pierce, 2000). Although the findings are mixed, authoritarian parenting has been found to have positive associations with independence in African American children (Baumrind, 1972), mastery orientation in African American college students (Gonzalez, Greenwood, & Hsu, 2001), and school success in first-generation Chinese youth (Chao, 2001). Is it possible, then, that the negative connotation of authoritarian parenting in much of the literature is not accurate when applied to other cultural groups because of the various meaning attached to high levels of control. For example, the concepts of *chiao shun* (Chao, 1994) and *guan* (Tobin, Wu, & Davidson, 1989) in Chinese families, as well as no-nonsense parenting (Brody & Flor, 1998) in African American families, cast monitoring or control as indicative of parental love and concern. To overstate between-group differences at the expense of within-group variability, however, would be a mistake, as few of these studies actually examine the cultural meanings of parenting dimensions across racial/ethnic/cultural groups (Markus, Steele, & Steele, 2002; Takahashi, Ohara, Antonucci, &

Akiyama, 2002). Careful consideration of the ecological context of the parent–child dynamic (e.g., income, child peer group, acculturation status, immigrant status) often highlights important moderators of what may appear to be a “universal” association (see Steinberg, Dornbusch, & Brown, 1992; Ang & Goh, 2006).

Although research based on Baumrind’s typological approach to parenting has yielded an impressive body of findings linking parenting behavior to child outcome, this approach does not allow us to examine the impact of specific components (e.g., warmth) of the constellation on child adjustment (e.g., Bean, Bush, McKenry, & Wilson, 2003; Darling & Steinberg, 1993; Davidov & Grusec, 2006). In other words, the focus on the parenting composite (e.g., warmth plus firm control in authoritative parenting) and its relation to child outcome impedes the dismantling of the typology, by which it might be determined that an individual parenting behavior (e.g., warmth) is primarily associated with a specific child outcome (e.g., decreased levels of child externalizing symptoms) (Jones et al., 2008; McKee et al., 2008; McKee, Colletti, Rakow, & Forehand, 2008). As a result, some researchers have advocated for a more differentiated approach to examining the relation of specific parenting behaviors and specific child outcomes (e.g., Barber, 1997; Herman, Dornbusch, Herron, & Herting, 1997).

Consistent with this line of thinking, three behavioral dimensions, based on Schaefer’s (1965) earlier work, have emerged as key elements of parenting: warmth (e.g., affection, involvement, supportiveness, attentiveness, acceptance); hostility (e.g., criticism, aggression, withdrawal); and behavioral control (e.g., monitoring, limit setting). Some of the behavioral indicators used to operationalize each of these constructs are presented in Table 35.1. Although some investigators have conceptualized warmth and hostility as opposite endpoints of the same spectrum (e.g., Child’s Report of Parental Behavior Inventory; Schludermann & Schludermann, 1970), others have considered them to be distinct categories of behaviors (e.g., INTERACT Coding System; Dumas, 1984; 1986). With the latter approach, withdrawal, or the absence of warmth, and warmth are the opposing poles on the warmth continuum, and the absence of hostility and hostility are the opposing poles of the hostility continuum. Conceptualizing warmth and hostility as separate constructs provides richer information about parenting; it becomes possible, for example, to derive information about warmth, the absence of

**Table 35.1 Behaviors Representative of Parental Warmth, Control, and Hostility**

Warmth	Behavioral Control	Hostile Behavior
Acceptance	Behavioral directives	Aggression
Caring	Firm control	Anger
Involvement	Monitoring	Aversiveness
Positive affect	Rules	Criticism
Positive behavior	Supervision	Disapproval
Positive support	(Laxness) <sup>2</sup>	Intrusiveness
Praise		Irritability
(Withdrawal) <sup>1</sup>		Negative affect
		Overreactivity
		Verbal punishment

<sup>1</sup> Low levels indicate positive behavior

<sup>2</sup> Low levels indicate behavioral control

warmth—which is not necessarily the presence of aversive (i.e., hostile) parenting—and hostility.

Comparable to the body of research inspired by Baumrind’s typologies, there are numerous empirical investigations linking specific parenting behaviors to child outcome. First, in terms of warmth, a number of studies have documented a link between relatively lower levels of parental warmth and negative child outcomes, particularly externalizing symptomatology (e.g., Jones, Forehand, Rakow, Colletti, McKee, & Zalot, 2008; Masten & Coatsworth, 1998; Shaw et al., 1998) and also the protective effects of relatively higher levels of warmth against the development of internalizing symptoms (e.g., Hammen, Shih, & Brennan, 2004; Muris, Meesters, & Van den Berg, 2003). In the case of parental behavioral control, lower levels have been associated with both child and adolescent externalizing symptoms, including conduct disorder, drug use, delinquency, and sexual risk behaviors (Chilcoat, Breslau, & Anthony, 1996; Dishion, Patterson, Stoolmiller, & Skinner, 1991; Li, Feigelman, & Stanton, 2000; Miller, Forehand, & Kotchick, 1999; Gray & Steinberg, 1999), and internalizing

symptoms (e.g., Barber, 1996; Galambos et al., 2003; Kurdek & Fine, 1994). Finally, relatively higher levels of parental hostility have been associated with offspring externalizing behaviors (Conger, Ge, Elder, Lorenz, & Simons, 1994; O'Leary, Slep, & Reid, 1999; Patterson et al., 1992) and identified as a significant correlate of adolescent depressive symptoms (Buehler, Benson, & Gerard, 2006; see also Cole & McPherson, 1993).

In addition to the three well-studied parenting behaviors (i.e., warmth, hostility, and behavioral control), a number of other constructs, including parental overprotectiveness (Lieb, Wittchen, Hofler, Fuetsch, Stein, & Merikangas, 2000; Moore, Whaley, & Sigman, 2004) and psychological control (e.g., Barber & Harmon, 2002; Pettit et al., 2001; Rakow et al., 2011), have more recently been the subject of examination and merit further attention. Psychological control, for example, has been conceptualized as an intrusive and limiting form of control in which the child's autonomy is violated by manipulative guilt inducing and love withdrawal tactics (Barber, 2002). Despite the fact that psychological control has received relatively less attention in the literature, it has recently been linked with a broad array of adjustment problems in both the internalizing (depressed mood, anxiety, low self-confidence and low self-reliance) (Barber, 1996; Conger, Conger, & Scaramella, 1997; Pettit, Laird, Dodge, Bates, & Criss, 2001) and externalizing (delinquency, aggressive behaviors, and risky sexual behaviors) (Barber 1996, Barber & Harmon, 2002, Gray & Steinberg, 1999) clusters of behavior.

Furthermore, researchers studying minority families are increasingly focused on identifying and measuring constructs that are salient for particular cultural groups. For example, Smetana and colleagues (2004) used a conceptual and empirical approach to derive a family interaction scale for middle-income African American families. Principal component analyses revealed two types of composite variables. The first, pertaining to positive communication ability and style, consisted of items almost identical to the composite positive communication factors in Caucasian middle-class families (Smetana, Yau, Restrepo, & Braeges, 1991, as cited in Smetana, Abernethy, & Harris, 2000) while the second, reflecting "relational and reflected parents' supportiveness of their adolescents and adolescents' receptivity to their parents" (Smetana, Abernethy, & Harris, 2000, p. 469), emerged as unique from previous analyses of their Caucasian counterparts. Others have also suggested that the concepts of

respectfulness and obedience toward elders within African American families and "proper demeanor" or respect toward adults in Hispanic families is highly valued (e.g., Harwood, Miller, & Irizarry, 1995). In their examination of parent-adolescent conflict, for example, Dixon and colleagues (2008) created a measure of adolescent respect. Findings revealed that both African American and Hispanic mothers exerted more restrictive discipline (i.e., behavioral control) than the Caucasian mothers and that both African American and Latino adolescents showed higher levels of respect for authority than did their Caucasian counterparts.

In an effort to address the tension in the literature between the two primary theoretical and measurement approaches to understanding parenting and child socialization (i.e., broader parenting styles versus more specific parenting behaviors), Darling and Steinberg (1993) proposed an integrative model that incorporates both distinct but overlapping parenting attributes. Parenting practices are "behaviors defined by specific content and socialization goals" (p. 492). In the domain of academic achievement, for example, germane parenting practices may include attendance at parent-teacher conferences, establishing a specific homework routine with the child, and discussing assignments. Parenting *style*, alternatively, is distinguished as the "emotional climate in which the parents' behaviors are expressed" (p. 492) and includes tone of voice, body language, and temper outbursts as well as actual parenting practices through which children infer the parent's emotional attitude. Darling and Steinberg assert that both practices and style are influenced by parent socialization goals and values and that both influence child development but through different processes. Specifically, they theorize that parenting practices directly impact child outcomes while parenting style acts as a moderator of the relation between specific parenting practices and specific outcomes. Although the widespread adoption of such a model would increase the conceptual uniformity of the vast body of parenting research and allow for comparisons across studies, the current literature continues to represent a variety of orientations and numerous different operational definitions of parenting dimensions.

### Tools for the Assessment of Parenting Behavior and Style Questionnaires

Because an exhaustive review of all parenting assessment tools in questionnaire format is beyond

the scope of this chapter, we have chosen to focus on three representative measures. The choice of these three was guided by an attempt to include tools representing a range of developmental periods (toddlerhood, middle childhood, and adolescence) and reporters (parent versus child). The following assessment instruments are presented in detail and include a discussion of psychometric properties as well as the samples of parents and children with which the tools have been used: The Children's Report of Parental Behavior Inventory (CRPBI; Schaefer, 1965), The Alabama Parenting Questionnaire (APQ; Frick, 1991), and the Parenting Scale (Arnold, O'Leary, Wolff, & Acker, 1993). Because we realize that readers may be interested in a broader representation of parenting assessment tools than we can adequately review here, we refer them to two comprehensive resources. The first represents a review of 76 questionnaires, 27 interviews, and 33 observational systems all designed to assess discipline, nurturance, or both (Locke & Prinz, 2002). The second useful reference, mentioned in the previous section, is *The Handbook of Family Measurement Techniques* (Touliatos, Perlmuter, & Straus, 2001), which abstracts and provides examples of family measurement tools reported in the literature from 1929 through 1996.

### ***Children's Report of Parental Behavior Inventory***

In his initial publication describing the construction and psychometric properties of the Children's Report of Parental Behavior Inventory (CRPBI; Schaefer, 1965), Schaefer began by establishing one of the hypotheses motivating the development of a then-novel set of scales: "A child's perception of his parents' behavior," he wrote, "may be more related to his adjustment than is the actual behavior of his parents" (p. 413). Although the child-focused orientation had, by 1965, already produced volumes of research, and measurement of children's perceptions of parental behavior had proliferated, Schaefer criticized existing methodology for its inattention to "discrete components of parental behavior" (p. 414), its failure to differentiate maternal from paternal behavior, and its inability to discriminate the parent-child interaction from marital conflict and parental psychopathology. In an attempt to address these shortcomings, Schaefer factor analyzed psychologists' ratings of parental behavior. The two orthogonal dimensions revealed by the analyses—love versus hostility and autonomy versus control—were conceptualized as the

molar concepts in the guiding conceptual scheme (Schaefer, 1959). These higher-order factors were then defined by concepts such as ignoring, possessiveness, and lax discipline at an intermediate level of abstraction, and finally, 26 of these concepts were each described by 10 specific, observable parental behaviors. Inventory psychometrics were based on a sample of 165 12- to 14-year-old Caucasian girls and boys and a comparison group of 81 institutionalized delinquent Caucasian and African American boys aged 12 to 18 years. Analyses indicated sufficient internal-consistency reliability for each of the three groups (Caucasian boys, Caucasian girls, and institutionalized Caucasian and African American boys). Furthermore, discriminant validity was indicated by the following findings: 1) when the total scale score distributions for Caucasian boys and institutionalized Caucasian and African-American boys were compared, significant differences emerged for the majority of the 26 scales, and 2) when total scale score distributions for mothers and fathers as reported by the institutionalized sample were compared, significant differences again emerged for the majority of scales.

As stated, the original version of the CRPBI consists of 260 questions, 10 for each of 26 concepts, in which children and adolescents indicate whether each parent is "like," "somewhat like," or "not like" such statements as "Enjoys talking things over with me" and "Acts as though I am in the way." Since its inception, several shorter forms have been developed to decrease the administration time (Margolies & Weintraub, 1977; Raskin, Boothe, Reatig, Schulterbrand, & Odle, 1971; Schludermann & Schludermann, 1970). Although a recent review of the literature by Safford and colleagues (Safford, Alloy, & Pieracci, 2007) suggested that the 108-item version developed by Schludermann and Schludermann (1970) is the most commonly used revision, its 18 conceptually overlapping factors renders interpretation difficult. Alternatively, the 90-item scale (Raskin, Boothe, Reatig, Schulterbrand, & Odle, 1971) derived using a factor analysis of the original CRPBI resulted in 48 items that loaded onto three factors—Positive Involvement (Acceptance versus Rejection), Negative Control (Psychological Autonomy versus Psychological Control), and Lax Discipline (Firm Control versus Lax Control)—with adequate psychometrics including internal consistency ranging from .81 to .94. As with the original, children and adolescents rate scale items to indicate how similar the sample of parental behavior is to their

perceptions of mother and father behavior. Finally, the 56-item CRPBI (Margolies & Weintraub, 1977) also appears to be an acceptable substitute for the original, as it yielded a factor structure approximating the Positive Involvement, Negative Control, and Lax Discipline dimensions with high test-retest reliability at one and five weeks, although the Lax Discipline evidenced less stability.

The CRPBI and its short-form revisions have been utilized widely with a range of child and adolescent respondents to examine the associations between parenting behaviors and myriad child outcomes. For example, the 108-item scale was administered to young adolescents (aged 11 through 14) from intact and recently divorced families to test a model positing parenting behaviors as mediators of the relation between inter-parental conflict and child adjustment (Faubert, Forehand, Thomas, & Wierson, 1990). It has also recently been utilized with African American adolescents from single mother-headed households to examine the impact of maternal behavior and coparent involvement on youth internalizing and externalizing behaviors (e.g., Sterrett, Jones, & Kincaid, 2009). Specific subscales of the original full-length version have also been employed in studies examining the relation between parenting behaviors and self-esteem (Ruiz, Roosa, & Gonzales, 2002) and internalizing and externalizing symptoms, broadly, and depression and conduct disorder, specifically (Dumka, Roosa, & Jackson, 1997; Manongdo & Ramirez Garcia, 2007) among Mexican American and Mexican immigrant children and families. The factor structure of the CRPBI and its revisions has been examined with a variety of samples, including children living with married and divorced parents (Teleki, Powell, & Dodder, 1982), Catholic school children in grades four through eight (Armentrout & Burger, 1972), French-speaking Belgian high school students (Renson, Schaefer, & Levy, 1968), Mexican American middle school children (Knight, Tein, Shell, & Roosa, 1992), and Canadian elementary and high school students (Kawash & Clewes, 1988).

In addition to the adolescent and child report forms of the CRPBI, some researchers have adapted the measure to be utilized by adults, both to gather retrospective reports of parent behavior and to assess parent self-report. Schwartz and colleagues (1985) examined the reliability and validity of the scales from the 108-item short form with a sample of college students, their siblings, and their mothers and fathers reporting on their own and each

other's parenting behaviors; results revealed moderate internal consistency on all 18 subscales for all reporters and replicated the Schludermann and Schludermann (1970) factor structure for all raters. In another example, Fauber et al. (1990) examined both adolescent-report and parent-report on the Schludermann and Schluderman short form of the CRBPI. Both sources were utilized as indicators for the latent variable parenting constructs in a structural equation model testing the direct and indirect effects (via parenting behaviors) of marital conflict on adolescent adjustment in divorced and intact families.

### ***Alabama Parenting Questionnaire***

Like the CRPBI, the Alabama Parenting Questionnaire (APQ; Frick, 1991) was developed to address limitations of standardized questionnaires and observational assessments. Specifically noted in the rationale for constructing the measure was the limitation that a number of questionnaire tools in the research literature measure the emotional climate of the family (i.e., parenting style) as opposed to parent behaviors or practices. Although Schaefer's (1965) CRPBI is an exception, as it assesses distinct parenting behaviors, it does not include items tapping corporal punishment or monitoring and supervision, both of which have consistently been linked to child conduct problems (Frick, 1994). The APQ, a 42-item measure of parenting behaviors, yields five parenting constructs that have been associated with disruptive behaviors and delinquency in children and adolescents (Frick, Christian, & Wootton, 1999; Shelton, Frick, & Wootton, 1996): parental involvement, positive parenting, poor monitoring/supervision, inconsistent discipline, and corporal punishment. The APQ is available in parent- and child- "Global Report" forms and can also be administered to both parents and children via telephone interviews. Items on the Global Report forms are rated on a five-point scale to indicate how often the specific parenting behavior is performed in the home context, ranging from 1 (never) to 5 (always). During the telephone interviews, respondents are asked to respond to each item with his/her best estimate of the frequency (e.g., number of times) that behavior has occurred over the previous three-day period; item frequencies are collected over four telephone interview periods and averaged to compute scale scores.

Because the two positive parenting scales (i.e., involvement, positive parenting) have been found to be highly correlated across informant and

assessment formats (e.g.,  $r = .45\text{--}.85$ ; Shelton et al., 1996) and because the three-item corporal punishment construct has been found to have low internal consistency ( $\alpha = .49$ ) (Shelton et al., 1996), a three-factor model has been adopted and utilized by some researchers. Indeed, Hinshaw et al. (2000) reported that a first-order principal component analysis (PCA) of the APQ parent report with a middle childhood ADHD sample revealed a three-factor structure: positive involvement (16 items; e.g., praise, attends school meetings, helps with homework;  $\alpha = .85$ ), negative/ineffective discipline (11 items; e.g., threatens to punish but doesn't, spanks child, lets child out of punishment early;  $\alpha = .70$ ), and deficient monitoring (8 items; e.g., child out with friends unknown to you, child comes home one or more hours late;  $\alpha = .72$ ). However, most recently, exploratory and confirmatory factor analyses of the Child Global Report version of the APQ with 1,219 10- to 14-year-old urban and rural German school children supported a five-factor solution consistent with the findings of Shelton et al. (1996), with only minor revisions to scale content (Essau, Sasagawa, & Frick, 2006). The findings thus far suggest that both the three-factor and five-factor solutions are acceptable, albeit with different samples in terms of child age and clinical versus community status.

In addition to explorations of the factor structure with distinct samples, several modifications to the original APQ have been suggested and tested. First, Clerkin et al. (2007) put forth a revision for use with preschool-aged children and examined the factor structure and psychometrics with a sample of 160 ethnically diverse children in urban public pre-kindergarten programs ( $M_{age} = 4.47$ ;  $SD = 0.62$ ). From the original version of the scale, the Alabama Parenting Questionnaire—Preschool Revision (APQ-PR) retained 32 items which loaded on three factors: positive parenting (12 items;  $\alpha = .82$ ), negative/inconsistent parenting (7 items;  $\alpha = .74$ ) and punitive parenting (5 items;  $\alpha = .80$ ). Second, a nine-item parent report short form of the APQ was developed and validated with an Australian community sample of families with children ages four to nine years old (APQ-9; Elgar, Waschbusch, Dadds, & Sigvaldason, 2007). Principal components analysis of the original 42-item version of the scale supported a three-factor solution; the first factor was labeled positive involvement, the second, ineffective discipline, and the third, poor supervision; the remaining two domains that emerged, labeled involvement and punishment, were not supported.

The nine-item scale was constructed by drawing the three highest loading items from each of three factors. Internal consistency reliability of the APQ-9 was adequate, with the poor supervision factor evidencing the lowest internal consistency ( $\alpha = .59$  in mothers;  $\alpha = .63$  in fathers). The APQ-9 distinguished between parents of children with ODD or CD, who evidenced less consistent discipline and lower levels of supervision, and parents of children without a behavior disorder—but did not distinguish between parents of ADHD children and parents of non-ADHD children, suggesting the need for research to further explore the stand-alone validity of the shortened form (Elgar et al., 2007).

With regard to validity of the original APQ, data from several investigations suggest APQ scales are sensitive to interventions designed to modify parenting behaviors (e.g., August, Lee, Bloomquist, Realmuto, & Hektner, 2003; Feinfield & Baker, 2004; Lochman & Wells, 2002). Furthermore, a body of evidence supports the relation between problematic parenting practices as indexed by the APQ and conduct problems in clinic-referred children and adolescents (e.g. Chi & Hinshaw, 2002; Hinshaw, 2002; Frick, Christian, & Wootton, 1999) and non-referred children (e.g., Frick, Kimonis, Dandreaux, & Farell, 2003; Oxford, Cavell, & Hughes, 2003). While the use of child-report on the APQ, particularly in the telephone interview format, has raised some concern in the literature when used with younger samples (Shelton et al., 1996) Frick et al. (1999) reported increasing validity of child report in later childhood and adolescence.

The APQ has been used in research primarily as a measure of parenting practices associated with child and adolescent delinquent behavior in community and clinic-referred samples ranging in age from six to 17 years old; however, it has also been used with children as young as three (Brubaker & Szakowski, 2000) and as old as 18 (Stanger, Dumenci, Kamon, & Burstein, 2004). Furthermore, it has also been used to examine the relation between caregivers' self ratings of their parenting behavior and a) treatment outcome for children with Combined-type ADHD (Hinshaw et al., 2000), b) behavior problems in hearing-impaired children (Brubaker & Szakowski, 2000), and c) kindergartners' internalizing symptoms and peer relations (Cummings, Keller, & Davies, 2005).

The APQ was originally developed with clinical and community samples representative of some racial/ethnic and economic diversity (Shelton, Frick, & Wootton, 1996). Beyond the original study, the

APQ has been utilized in research with samples including ethnic minority families and representing a range of family income (e.g., Cummings et al., 2005; Hinshaw et al., 2000; McCoy, Frick, Loney, & Ellis, 1999; Stanger et al., 2004). Furthermore, August and colleagues (2003) examined the APQ factor structure with a culturally diverse urban sample: approximately 81 percent of the children were African American, 42 percent lived in single-parent households, and the mean family socioeconomic status fell in the low to middle-lower range. Similar to Hinshaw et al. (2000), factor analysis using principal components extraction revealed a three-factor structure (positive involvement, deficient monitoring, and harsh/ineffective discipline) as the best fit to the sample's data.

### **Parenting Scale**

Consistent with the impetus behind the development of the CRPBI and APQ, the Parenting Scale (PS; Arnold, O'Leary, Wolff, & Acker, 1993) was developed by Arnold and colleagues as a brief measure of problematic discipline strategies for parents of young children (ages 18 to 48 months). Explicitly stated goals for the measure indicated that it should 1) build upon current empirical knowledge, 2) offer quick and easy administration, and 3) identify dysfunctional discipline strategies with the clinical goal of assisting in treatment and prevention of child externalizing problems. While the PS measures specific parenting behaviors, the format of the tool is distinct from the others reviewed in that its 30 items are rated on a seven-point scale, with each item anchored on one end with a parenting "mistake" and on the other end with its more adaptive counterpoint. For example, parents rate how closely their disciplinary strategy is linked to the mistake anchor (e.g., I coax or beg my child to stop) or the alternative effective strategy anchor (e.g., I firmly tell my child to stop). In this way, all parenting mistakes can be identified regardless of how often they occur, which would not be possible using a format based on frequency of encounters (e.g., How often do beg your child to stop?).

Principal components factor analysis with a sample of 168 mothers (65 of whom had presented for clinical services because of "extreme parenting difficulties") and their preschool-aged children yielded the following three factors: Laxness (11 items reflecting permissive discipline;  $\alpha = .83$ ), Overreactivity (10 items related to irritability, anger, hostility;  $\alpha = .82$ ), and Verbosity (7 items indicating use of lengthy, ineffective verbal strategies;

$\alpha = .63$ ) (Arnold et al., 1993). A Parenting Total Score was also computed by averaging the ratings of all items, including the four items that did not load on any factor, as a global index of parenting dysfunction ( $\alpha = .84$ ). In addition to adequate internal consistency, reliability was further demonstrated with test-retest stability over a two-week period ( $r = .79-.83$ ). PS scores also discriminated between clinic and non-clinic families, correlated strongly with Child Behavior Checklist scores, and related to observational measures of mother and child behavior. Despite the sound psychometrics of the PS in the Arnold et al. (1993) study, three subsequent studies of parents and their children ranging from two to 12 years old yielded a two-factor structure (Laxness and Overreactivity) as the best fit for the data (Collett, Gimpel, Greenson, & Gunderson, 2001; Harvey, Danforth, Ulazek, & Eberhardt, 2001; Irvine, Biglan, Smolkowski, & Ary, 1999).

While the original scale development and validation were performed with a relatively homogenous sample (middle income, well educated), the PS has subsequently been subjected to confirmatory and exploratory factor analyses with ethnically and socioeconomically diverse samples. First, Reitman and colleagues (2001) administered the PS to two primarily African American samples of mothers of 3.5–4.5-year-old children who attended a Head Start program. Confirmatory factor analysis with the first sample indicated that neither the original three-factor solution, nor a two-factor solution, consisting of the original Laxness and Overreactivity factors, fit the data. Exploratory factor analysis revealed a modified two-factor structure (also labeled Laxness and Overreactivity) with five items retained on each scale. The revised scales demonstrated adequate internal consistency ( $\alpha = .70-.74$ ) and were highly correlated with the Arnold et al. (1993) Laxness and Overreactivity factors ( $r = .91$  and  $.89$ ) and Parenting Total Score ( $r = .87$ ). The modified PS was then confirmed with a second sample of Head Start families and evidenced concurrent validity via significant correlations with measures of parenting stress and maternal depression. Second, Steele et al. (2005) examined the goodness of fit indices for both the original three-factor model (Arnold et al., 1993) and the two-factor model proposed by Reitman et al. (2001) with a sample of rural and urban low-income African American children ( $M_{age} = 11.34$ ;  $SD = 1.82$ ) from single-parent households. Results were consistent with the Reitman et al. (2001) two-factor model (Laxness and Overreactivity), which yielded a better fit to the

data than the original model proposed by Arnold and colleagues (1993). Correlational data provided evidence of convergent validity for the Laxness dimension (when compared with Firm/Lax Control scale of the CRPBI), and also revealed an unexpected positive relation between the Overreactivity dimension and two measures of parental warmth (i.e., CRPBI Acceptance/Rejection subscale and Interaction Behavior Questionnaire total score), lending indirect support to Brody and Flor's (1998) concept of "no nonsense" parenting. Third, Karazsia and colleagues (2008) conducted a series of confirmatory factor analyses to test five different factor solutions presented in the literature with a community sample of 408 children ranging in age from two to 12 years old and their parents recruited from pediatric medical practices. The two-factor model proposed by Reitman et al. (2001) once again provided the best fit, and multi-group confirmatory factor analysis results suggested the factor structure was reliable and valid across ethnicity (Caucasian and African American), child gender, and child age.

The Parenting Scale and its multiple revisions have been utilized as a measure of parenting practices with parents and their children ranging from preschool (Arnold et al., 1993; Reitman et al., 2001) to elementary school (Harvey et al., 2001) and middle school (Irvine et al., 1999) age. Furthermore, the factor structure of the scale has been explored with economically, ethnically, and behaviorally diverse samples (Reitman et al., 1999; Karazsia et al., 2008; Steele et al., 2005) with various foci: 1) to test theoretical models linking disciplinary tactics and child psychopathology (e.g., Del Vecchio & O'Leary, 2006), 2) to identify determinants of parenting behaviors (e.g., Dorsey, Forehand, & Brody, 2007; Gerdes et al., 2007; Morawska & Sanders, 2007), and 3) to measure the impact of clinical interventions (e.g., Conners, Edwards, & Grant, 2007; Sanders, Turner, & Markie-Dadds, 2002).

In sum, all three of the measures reviewed—the CRPBI, the APQ, and the PS—share a similar guiding theoretical orientation and common goal of quantifying specific parenting behaviors (as opposed to a focus on a more global parenting style) in order to examine their relation to child adjustment. In addition, the factor structure of all three measures has been subjected to analysis in multiple studies subsequent to original scale development, and the psychometric qualities of each assessment tool are sound. Finally, the three questionnaires have been employed with minority as well as majority samples, reliably predict child/adolescent problem behavior,

and show sensitivity to changes in parenting as a result of intervention programs.

Although the measures reviewed share a number of qualities, each is also rendered distinct by relative strengths and limitations. For example, each scale was designed to target different age groups and, thus, utilizes different reporters. Because the CRPBI was developed with the intention of capturing the child's perception of parenting behaviors, its administration is limited to those children and adolescents with the cognitive capacity to read, comprehend, and respond to the item prompts. In contrast, the PS was designed explicitly to assess parenting of preschool children with the caregiving adult required to read and respond to the scale items. Straddling the two approaches, the APQ was developed to assess parenting from both the caregiver and child perspectives and targets a wide age range of children and adolescents (six to 17 years old). Although this approach increases the scale's applicability, it also implies that the same parenting behaviors are important across all age ranges.

### ***Observational Measures***

Because this section is not intended to represent an exhaustive review of all observational systems that include an assessment of parenting constructs, we refer the reader to several resources. First, Kerig and Lindahl's (2001) edited volume provides resources for clinicians and researchers interested in family observational coding systems: fourteen independent laboratories describe the theoretical bases for their systems, provide psychometric data, detail the content of the measure codes, and discuss the process for coder training. Second, as mentioned in the previous section, Locke and Prinz (2002) review 33 observational systems, all of which assess parental discipline, nurturance, or both in a variety of formats (e.g., structured versus unstructured tasks) and age-group referents. The choice of the three systems reviewed here was guided by an attempt to include tools that represent a range of developmental periods (toddlerhood, middle childhood, and adolescence), vary in terms of level of analysis (e.g., micro- versus macro-analytic) and content of the focal interactions, and are more or less suited to applied clinical work, research, or both. The following assessment instruments are presented in detail and include a discussion of psychometric properties as well as the samples of parents and children with which the tools have been used: The Behavioral Coding System (BCS; Forehand & McMahon, 1981), The Iowa Family Interaction Rating Scales (IFIRS; Melby

et al., 1998), and The Family Interaction Coding System (FICS; Patterson, 1982; Reid, 1967; Reid, 1978) and its successor, the Family Process Code (Dishion, Gardner, Patterson, Reid, Spyrou, & Thibodeaux, 1987).

As will be evident from the review of the aforementioned instruments, relatively less attention has been focused on tool validation with ethnic minority groups. Just as with the questionnaire instruments, it is equally important, if not more so, that an interest in construct validity necessitates the determination that "...the meanings and interpretations associated with an inventory developed in one culture can validly accompany its use in another" (Ben-Porath, 1990, p. 28). When information was extant with regard to a coding system's applicability to an under-studied group, it is noted. However, there are also a number of observational systems that either represent modifications of existing systems or novel contributions to the assessment repertoire that evidence increased sensitivity of code content and coder training to salient cultural nuances. Lindahl and Malik (2001), for example, developed the System for Coding Interactions and Family Functioning (SCIFF) explicitly to assess behavioral family functioning across Caucasian, Hispanic American, and African American ethnic groups. Alternatively, Smetana and colleagues (2000) modified the Global Coding System (Smetana, Yau, Restrepo, & Braege, 1991), which was originally developed for use with divorced and intact middle-class Caucasian parents and their adolescents, to increase its sensitivity and relevance to middle-class African American families. Although both of these systems and others (e.g., Lefkowitz, Romo, Corona, Au, & Sigman, 2000; Taylor, Barnett, Longest, & Raver, 2009) represent progress, the validity of otherwise well-established coding systems across ethnic groups has yet to be empirically established.

### ***Behavioral Coding System***

The Behavioral Coding System (BCS; Forehand & McMahon, 1981) was developed for trained therapists and researchers to utilize in their assessment of parent-child interactions and specific parent and child behaviors, particularly as an integral component in delivering and testing the empirically supported parent training program for caregivers and their two- to six-year-olds, *Helping the Noncompliant Child* (HNC; Forehand & McMahon, 1981; McMahon & Forehand, 2003). The BCS may be used in both the clinic and home settings and, when utilized as a part of HNC, is administered

as a pre-and post-treatment assessment, as well as throughout the intervention, both to measure parent mastery of skills and child compliance and non-compliance and to determine the timing of progression from one skill to the next (i.e., achievement of predetermined behavioral criteria). In the clinic setting, parents are provided with setting instructions to engage in two five-minute play sessions with their child while a trained coder observes from behind a one-way mirror. The first coding session, the "Child's Game," is essentially a free-play task in which parents are instructed to follow the child's lead and to refrain from imposing rules. The second coding session, the "Parent's Game," is a command situation during which the parent is advised to lead the child in activities of the parent's choosing. Six parent behaviors (i.e., verbal rewards, attends, questions, clear and unclear instructions, warnings, and time outs) and three child behaviors (i.e., compliance, noncompliance, and appropriateness of child behavior) are the primary targets of each observational period and are recorded in 30-second increments. The format of the score sheet permits the recording of the parent-child interaction or sequence of behaviors such that for any one interaction, a parent antecedent (e.g., parent issues command), child response (e.g., child complies with command), and parental consequence (e.g., parent provides verbal reward for compliance) may be documented. The BCS also includes an interval sampling component in which inappropriate child behavior is recorded if the child has a tantrum, aggresses, or uses deviant verbalizations at any point during each 30-second time period. At the conclusion of the clinic observation, data are summarized in the following ways: 1) for the Child's Game, rates per minute of each parent behavior and percentage of child inappropriate behavior are calculated, and 2) for the Parent's Game, the number of clear and unclear instructions coupled with the percentage child compliance to instructions, the percentage of parental attention (attends plus verbal rewards) following child compliance, and the total number of time-outs are calculated. As stated, the BCS may also be utilized to code parent and child interactions and behaviors during a naturalistic home observation (for additional information regarding the parental instructions, see McMahon and Forehand, 2003); however, because home observations are not always feasible and because observation sessions in the clinic and in the home have produced similar results (Peed, Roberts, & Forehand, 1977), clinic sessions may be sufficient.

A number of studies utilizing the BCS have established its sound psychometric qualities. First, an average inter-observer agreement of .75 or higher has been obtained for each of the coded parent and child behaviors (e.g., Forehand, Wells, & Griest, 1980; McMahon, Forehand, & Griest, 1981). Second, with regard to test-retest reliability, at least one investigation noted the stability and consistency of parent-child interactions in dyads assigned to a non-intervention condition (Peed, Roberts, & Forehand, 1977). Third, with respect to validity, the BCS discriminates between clinic-referred and non-referred children (Forehand, King, Peed, & Yoder, 1975; Forehand, Sturgis, et al., 1979; Griest, Forehand, Wells, & McMahon, 1980), and is sensitive to acute intervention effects and maintenance effects with clinical samples (e.g., Forehand, Griest, & Wells, 1979; Forehand, Sturgis, et al., 1979; Peed et al., 1977).

### ***Iowa Family Interaction Rating Scales***

The Iowa Family Interaction Rating Scales (IFIRS; Melby et al., 1998) were originally developed at Iowa State's Institute for Social and Behavioral Research as a global observation tool to assess individual-level qualities and behavior displays as well as relationship processes at the individual, dyadic, and group levels (Conger & Elder, 1994). Since its original conceptualization and implementation, the IFIRS has been utilized in myriad longitudinal research studies with diverse age groups (e.g., early adulthood, young adulthood, middle age) to study individuals and relationship processes in multiple contexts (e.g., interactions between parent-child, marital partners, siblings, friend pairs). The theoretical underpinnings of the system, drawn from social interactional, social contextual, and behavioral approaches, posit that relatively brief observations (15 to 30 minutes) of behavior and reciprocal interactions provide a window into dynamic systems that develop and unfold over time. In addition to providing information about the adjustment of the individual and the relationship observed, the snapshots are also purported to capture interaction styles and individual dispositions thought to be relatively stable, even "traitlike" (Melby & Conger, 2001, p. 34).

The IFIRS was initially intended for use in coding interactions during discussion-based tasks. In that case, interviewers provide instructions to the family regarding the content of the discussion, set up videotaping equipment, provide cue cards for the family highlighting the discussion topics, and then leave the room for the conversation to occur

without the intrusion of the interviewer's presence. Although the topics range from project to project (see Melby & Conger, 2001, for additional information), the *parent-child discussion task* and the *family problem solving task* both involve a triadic interaction (two parents and one child or one parent and two children). The foci of the *parent-child discussion task* include enjoyable shared activities, parental expectations and rules, and recent child disappointments or accomplishments. During the *problem-solving task*, family participants are instructed to discuss and work toward resolution of a problem that causes family conflict (e.g., chores, sibling fighting) (Melby & Conger, 2001).

Recently, however, the system has been adapted to capture interactions between parents and their young children (ages two to eight) during a *parent-child teaching task* and/or *clean-up task*. In both five- to 10-minute activity-based tasks, the interviewer provides materials and instructions for the parent-child dyad, and a camera operator tapes the interaction to ensure that movement out of a still-camera range is captured. In the *teaching task*, the parent is instructed to help the child with a puzzle or other activity too difficult for the child to complete independently. In the *clean-up task*, the interviewer instructs the child to put away the toys in provided containers, and the parent is told to offer whatever assistance he or she deems necessary.

Highly trained observers who review and code the videotaped interactions are taught to document behavior without making inferences about motivation or intent on the part of the focal subject(s). Ratings are influenced by the frequency and intensity of behaviors; additional considerations when determining how to categorize a behavior or relationship process include affect, context, and proportion. However, given the macro-level focus of the IFIRS, the scoring of the interaction does not produce actual frequencies of behaviors or exchanges (e.g., in the form of rates per minute) or duration of observed behaviors.

The fifth edition of the IFIRS manual describes 60 behavioral scales, most of which are rated from one to nine, with the odd-numbered points as anchors. For example, many of the scales are scored as: 1 = *not at all characteristic*, 3 = *mainly uncharacteristic*, 5 = *somewhat characteristic*, 7 = *moderately characteristic*, and 9 = *mainly characteristic* of the individual, dyad, or group observed. The scales are designed to rate behaviors and interaction processes at four levels (individual characteristics, dyadic interactions, dyadic

relationships, and group interactions) and are divided into three categories encompassing items from one or more of the four levels. The General Interaction Rating Scales category is the largest and contains 35 scales that rate observed behaviors in all types of interaction tasks at the individual, dyadic, and group levels. Most pertinent to the assessment of parenting behaviors, however, are the two specialty scales: The Parenting Scales (15 scales) and the Problem-Solving Scales (10 scales). The Parenting Scales are all assessed at the dyadic interaction level and are used to rate childrearing behaviors as observed and reported by parents and children. For example, the Child Monitoring scale rates the parent's demonstration of knowledge regarding the child's activities and whereabouts. The Problem-Solving Scales utilize individual and group level ratings to assess problem-solving behaviors during a family or group task. Agreement on Solution, for example, rates the resolution and satisfaction with the resolution of a problem discussed. The number and type of scales employed varies depending upon the observation task and number of participants. In the case of the activity-based tasks with parents and young children, 31 scales are appropriate for use in coding observations of the clean-up task, and 35 scales can be applied to the puzzle task.

Numerous studies have employed the IFIRS to examine the relation between parenting behaviors and child/adolescent healthy adaptation and psychopathology: depending upon the focus of the investigation, researchers have employed single scales and/or composite observational measures (e.g., Conger, Ge, Elder, Lorenz, & Simons, 1994) and have utilized ratings as indicators of latent constructs (e.g., Melby, Conger, Ge, & Warner, 1995). A wide range of relations have been explored with the IFIRS, from the impact of economic stress on parenting and adolescent adjustment (Conger et al., 1992; 1993) to family processes and characteristics related to adolescent alcohol use (Conger, Rueter, & Conger, 1994), academic performance (Melby & Conger, 1996), and problem-solving (Rueter & Conger, 1995; Rueter & Conger, 1998). More recently, parent behaviors in a free-play interaction task with their preschool-aged male children were demonstrated to be significantly related to teacher ratings of boys' problem behaviors (Davenport, Hegland, & Melby, 2008). As with the BCS (Forehand & McMahon, 1981), the IFIRS has also been used to document change in parenting behaviors and affect targeted by interventions (Spoth,

Redmond, Haggerty, & Ward, 1995; Spoth, Redmond, & Shin, 1998).

The psychometric properties of the system have been shown to be acceptable. A technical report summarizing over 50 published works that utilize the IFPRS (Franck & Anderson, 2004) documented inter-rater reliability (as measured by ICCs) ranging from .33 (father's warmth toward youth summed across two tasks; Fletcher, Elder, & Mekos, 2000) to .97 (solution quality; Rueter & Conger, 1995). Additionally, evidence presented for convergent validity in the form of positive correlations between observational scales and self report (see Ge et al., 1996, for an example) and discriminant validity in the form of negative correlations between scales that theoretically should be inversely related (e.g., see Simons, Lorenz, Wu, & Conger, 1993) further attest to the scale's sound properties.

Although the IFIRS scales were originally developed for use with primarily lower- to middle-class intact Caucasian families living in rural communities, they have also been used by trained African American coders to characterize caregiver relationship quality and nurturant-involved parenting among African American families in rural and suburban Iowa and Georgia (Conger, Wallace, Sun, Simons, McLoyd, & Brody, 2002). Furthermore, in an attempt to investigate the relations between coder training and rater bias, Melby and colleagues (2003) examined observations by African American and Caucasian coders on 30 IFIRS scales when characterizing two videotaped interactions, one of an African American mother-child dyad and the second of a Caucasian mother-child dyad. Although the majority of scales showed a reduction in rater bias as training progressed, race-related bias did not seem to decrease with training; in particular, main effects for coder race were evident for scales assessing emotional state (i.e., positive mood, sadness, anxiety, avoidant). Accordingly, although more research on the role of race in observational coding using the IFIRS, as well as other observational coding systems, is necessary before the nuances detailed in the Melby et al. study can be fully understood, the findings suggest that conventional training techniques may not be adequate to reach reliable consensus on what may be more culturally mediated interpretations of behavior and affect.

### ***Family Interaction Coding System and Family Process Code***

The Family Interaction Coding System (FICS; Patterson, 1982; Reid, 1967; Reid, 1978) is a

microanalytic coding system developed by researchers at the Oregon Social Learning Center (OSLC) as a portable observational tool designed to characterize the aggressive behaviors, as well as their antecedents and consequences, of children with conduct disorder (Patterson, 1982). Patterson, Reid, and colleagues revised the system six times over three years, yielding a coding system that captures the unfolding processes of family aggression, measures change in interaction styles, and identifies entry points for intervention.

The FICS is composed of 29 code categories, approximately half of which identify aversive behaviors (e.g., destructiveness, noncompliance, humiliate) and half that recognize pro-social or neutral actions (e.g., play, laugh, physical positive). Originally, the system developers intended to observe family members in the natural home setting without formal rules for structuring the session; however, in order to maximize actual interactions (e.g., all family members in the same room) and limit interruptions (e.g., telephone calls, visitors), several boundaries were established. During the session, which varies in length depending upon number of family members present, each member is identified as the "target" and coded during two separate five-minute periods. For each 30-second period, approximately five interaction units can be recorded to document the behavior of the target as well as the precipitant or response behaviors of another family member. Although data are coded continuously, each 30-second period is divided into six-second intervals, which precludes differentiating recurrence of a behavior from duration. For example, a child crying for 24 seconds is coded as three instances of "Cry" (Patterson, 1982). Behaviors then are summed over the coding period and expressed as rate per minute. A Total Aversive Behavior (TAB) score may also be calculated by summing 14 of the 29 code categories.

Because of the limitations of the FICS, particularly with regard to its inability to denote duration of behaviors, modifications to the system were made by a group of researchers at the OSLC to capture interactions in real time. Research and modification yielded a new coding system called the Interaction Coding System (ICS; Moore, Forgatch, Mukai, Toobert, & Patterson, 1978), which included 26 behaviors (14 aversive, seven neutral, and five positive). Observers used voice recorders to capture onset and sequencing of behaviors as well as frequency and duration, and transcriptions of recordings were then transferred to coding sheets divided

into 30-second increments. Despite the improvements of the ICS, several deficiencies in both the FICS and ICS remained. Specifically, neither system was sufficiently sensitive to pro-social behavior or changes in affect. As a result, an additional iteration of the system called the MOSAIC was developed, which culminated, finally, in the Family Process Code (Dishion, Gardner, Patterson, Reid, Spyrou, & Thibodeaux, 1987).

The Family Process Code, like its predecessors, is designed to code interactions between the targets of the observation period and their family members. Two features of the FPC, however, distinguish it from prior systems. First, a unique coding device, referred to as the OC-3, is utilized by the observers to record data. Second, each interaction is coded with regard to the following five factors. First, the initiator of the behavior is denoted. Second, an activity code is designated to characterize the general context of the interaction as Work, Play, Read, Eat, Attend, or Unspecified. Third, 25 content codes, divided among five independent categories (Verbal, Vocal, Nonverbal, Physical and Compliance Behavior), are available to document the actual behavior. Fourth, the recipient of the behavior is denoted. Finally, the valence or emotional flavor of the exchange is rated based upon observations of body language and other nonverbal gestures, tone of voice, and inflection (Dishion, Gardner, Patterson, Reid, Spyrou, & Thibodeaux, 1987).

The psychometric properties of the FICS have been extensively evaluated. First, Patterson and colleagues have considered several factors that may influence the reliability and validity of data collected over a number of observational sessions. The first is the possibility that family members would display less pro-social and more deviant behavior in later versus earlier sessions (i.e., the habituation hypothesis), which would result in smaller correlations of behavior over time. Several attempts to examine possible habituation effects, however, revealed no significant changes in mean levels of parent or child behavior across sessions for any of the coded behaviors (Johnson & Bolstad, 1973; Patterson & Cobb, 1971; Patterson & Cobb, 1973). The second consideration was how many samplings of behavior would be necessary to produce a stable estimate of behavior, particularly given that the contextual variables may change substantially across coding sessions. Several sets of findings suggest that behavioral scores based on 60 to 120 minutes of data provide stable estimates (Jones et al., 1975; Patterson, 1982). Utilizing these findings, Patterson (1974a) demonstrated

adequate reliability of the Total Aversive Behavior (TAB) score based on at least 60 minutes of observational data per subject from at least six sessions conducted over two weeks. With regard to validity, the FICS significantly differentiates families with an antisocial child, characterized by higher levels of a coercive interaction style, from control families (Burgess & Conger, 1978; Patterson, 1976; 1981b; Reid, Taplin, & Lorber, 1981). It also shows convergent validity with a parent-report questionnaire measure of child deviant behavior both before and after intervention (Patterson, 1974b).

The FICS was used from 1968 until 1977 as a data collection tool for families treated at the OSLC. The sample is characterized by target children and adolescents (median age seven to eight years old, largely male), referred primarily for antisocial behavior, approximately 80 percent of whom were from working-class families. The modified FPC has been utilized in research, again primarily with male children and adolescents identified as engaging in delinquent behaviors. Dishion and colleagues (1991), for example, used the FPC to examine longitudinal relations among poor disciplinary practices (i.e., nattering and punishment density, or the proportion of negative relative to positive parent-child interactions), parental monitoring, youth antisocial behavior, and deviant peer affiliation in a sample of predominantly Caucasian preadolescent boys. In fact, the group of scientists employing the FPC has provided the field with a body of research documenting the trajectories of young antisocial males (Patterson, Forgatch, Yoerger, & Stoolmiller, 1998; Vuchinich, Bank, & Patterson, 1992), detailing both the temperamental, familial and peer antecedents (Capaldi, Peers, Patterson, & Owen, 2003; Dishion, Patterson, Stoolmiller, & Skinner, 1991; Patterson, DeGarmo, & Knutson, 2000) and the effects of clinical intervention on that trajectory (Patterson & Forgatch, 1995).

As with the questionnaire measures reviewed, each of the observational systems has relative strengths and challenges, depending upon the purpose of the assessment. One perhaps obvious advantage of all the observational tools reviewed is that they provide a window into dynamic relationship systems and thus reach beyond what may be captured at an individual-focused level of analysis. Furthermore, some have argued that the observational methodology aids in the identification of mechanisms linking parenting behaviors and a host of child outcomes and may, in fact, capture behaviors that

would otherwise be outside the researchers' purview (Brody & Stoneman, 1990; Cowan & Cowan, 1990). The BCS, for example, is designed to assess the contingency of child compliance / noncompliance to parental directives, and in turn, the parental response to child compliance / noncompliance in a structured parent-directed analog task, which produces both frequency and sequencing data that may be difficult to measure with a questionnaire-based tool. Similarly, both the IFIRS and the FPC are sensitive to the emotional valence or flavor of the parent-child exchanges; this component of parenting style, again, may be more difficult to access with other tools.

Despite the advantages afforded by the observational methodology, there are also significant challenges to the validity and integrity of the data collected. Patterson (1982), for example, warns against systematic observer bias and observer presence effects, the latter which he characterizes as non-specific reactivity (e.g., "orienting" behaviors that typically habituate over the observation period(s)) and impression management (e.g., attempts to perform in socially desirable ways that are less likely to habituate). Explicit coder training procedures and reliability checks to prevent "coder drift" combined with coder "blindness" to research hypotheses may address observer bias. With regard to observer presence effects, Patterson suggests that "habitual models of interaction provide powerful constraints for familial interactions" (1982, p. 56) such that even mothers aware that they were being observed because of reports of child abuse hit their children during sessions at 10 times the rate of comparison mothers (Reid et al., 1981). In sum, the decision to employ an observational approach to the measurement of parenting style and behaviors must be driven by a cost-benefit analysis of the time and resource investment required by the methodology relative to the type and quality of the data, the choice of the appropriate unit of analysis (e.g., the individual versus the family unit; macro versus micro level codes), and the practicality of the tool for repeated measurement in longitudinal research and clinical work.

## Focus on Parenting Relationships

Thus far, we have focused almost exclusively on the "what" and "how" in our discussion of the assessment of parenting without much regard for the "who" and "why." If we return briefly to our starting point and the theoretical framework on which our discussion of parenting has been built, we are reminded by an ecological systems perspective

that parents (and parenting behaviors and style) are influenced by a host of inter- and intra-personal, social, economic, and cultural factors. The three sections that follow, then, serve to highlight three such factors—marital relationships, coparenting relationships, and parent psychological and physical health—that are integral considerations in the assessment of parenting.

With regard to the “who” of parenting, it may be concluded by research presented herein that the constructs examined, such as warmth and responsiveness, and the methodologies employed may have been informed by the implicit assumption, borne out by decades of research privileging the mother–child relationship, that the child’s primary caregiver is the mother. Only one of the questionnaire measures discussed extensively here, the CRPBI, explicitly denotes the father’s contribution by requiring the child or adolescent reporter to consider the behaviors of mothers *and* fathers separately. Needless to say, even when the mother is the primary or sole caregiver, other adults with whom she is in relationship (e.g., child’s biological father and/or stepfather, mother’s parents and other kin, mother’s residential and non-residential romantic partners, mother’s friends and coworkers) make contributions to the child’s caregiving environment, directly and/or indirectly.

We begin with a brief description of research linking the quality of the marital relationship, typically characterized in the literature by the mother’s relationship with the child’s biological father (i.e., intact families), to parenting behavior and the quality of the parent–child relationship. Then, we proceed to a brief discussion of coparenting—a construct related to marital relationship quality in intact families—that is also of relevance to divorced and single parents, as it captures how well two caregivers coordinate their childrearing efforts. Finally, we turn to a brief discussion of the role of parental mental and physical health in parenting. Building upon our own research, we review the research on maternal depression as an example of the link between parental mental health and parenting, and on maternal HIV/AIDS as an example of the link between parental physical health and parenting.

### ***Marital Relationship Quality***

As with the bulk of work on parenting, research on the link between the quality of the marital relationship between two parents and parenting behavior has focused almost entirely on Caucasian, middle-class families and the mother–child (rather

than the father–child) relationship. Thus, it must be clarified up front that the generalizability of much of this work to families that are separated/divorced, headed by a single parent, lower income, or ethnically diverse is questionable. With this caveat in mind, the interrelatedness of marital quality, parenting, and parent–child relationship quality has been well established, and several seminal reviews highlight advancements in this literature (e.g., Erel & Burman, 1995; Fincham, 1998). Collectively, this work suggests that the link between marital and parent–child relationship quality may best be characterized by a “spillover” of negative mood, affect, and behavior between the two individuals in a marital relationship to the parent–child relationship (Erel & Burman, 1995). Numerous mechanisms by which such spillover is posited to occur have been detailed elsewhere, but range from more family systems–oriented processes such as “scapegoating,” or the process by which parents distract themselves from their own problems by focusing on the problems of their child (e.g., Minuchin, Rosman, & Baker, 1978; Vogel & Bell, 1960), to more behavioral processes such as modeling, by which children model the maladaptive patterns of their parents’ marital conflict in the parent–child relationship (e.g., Easterbrooks & Emde, 1988). In addition, marital conflict is thought to directly influence the quality of both maternal and paternal parenting behaviors, such that more discordant parents are more likely to evidence disrupted and less consistent parenting behaviors (e.g., Frosch & Mangelsdorf, 2001; Kitzmann, 2000). Regardless of the specific mechanism by which marital conflict spills over into compromises in parenting, most agree that the interrelationship of the marital discord, parenting disruptions, and parent–child conflict is cyclical: namely, the strain of marital discord may compromise the extent to which a parent can be available to a child, which negatively impacts the parent–child relationship, which, in turn, likely exacerbates the strain on the marital relationship (e.g., Emde & Easterbrooks, 1985; Kerig, Cowan, & Cowan, 1993).

Although much more work has focused on marital quality in intact families, the quality of the relationship between ex-marital partners has also been implicated in parenting behavior and, in turn, child adjustment (e.g., Fauber, Forehand, Thomas, & Wierson, 1990; also see Kelly, 2000, for a review). Of note, although it was once believed that divorce in and of itself was harmful for children, evidence now more clearly suggests that it is not divorce

that necessarily compromises children's outcomes. Rather, it is more likely that parents continue to experience conflict after their divorce, which compromises their parenting relationship and the quality of parenting behaviors as well (Fauber et al., 1990).

Building upon the well-established link between marital quality, parenting behavior, and parent-child relationship quality, a thorough assessment of parenting behavior should also consider the quality of the parents' marital relationship. Although a comprehensive review of potential measures is beyond the scope of the current chapter, others (e.g., Fincham, 1998) have provided detailed guidelines for researchers and clinicians interested in the assessment of various domains of the marital relationship as they may relate to child development. Like parenting, the assessment of marital quality is nuanced and includes measures of different domains of the marital relationship (e.g., satisfaction, conflict, communication), as well as different methods to assess these domains (e.g., self-report, observational) (Fincham, 1998).

Next, we turn to the literature on the interrelationship of coparenting, or the process by which two individuals coordinate childrearing efforts, and parenting behavior. The following section highlights a rich body of research examining a range of parenting relationships, from coparenting in traditional marital relationships to coparenting after divorce and, finally, to coparenting dyads that characterize a growing number of ethnic minority families in the United States, including single mothers coparenting with the child's biological father, grandmothers, and other extended family members.

### ***Coparenting***

As previously noted, one focus of many married couples is childrearing. Although the quality of the marital relationship is associated with how well two individuals work together in their role as parents to coordinate their childrearing responsibilities (i.e., coparenting), coparenting has been shown to be a unique construct of relevance to a broader sample of families than only those which are intact. Interest in the study of "coparenting" can be traced to the advent of family systems theory and the subsequent increase in attention to triadic (e.g., mother, father, child) interactions, rather than dyadic (e.g., mother-child) interactions alone (Minuchin, 1974; 1985). Coparenting is conceptualized as a triadic, or whole family, level of analysis within the family system (Belsky et al., 1996). Thus, the construct of

coparenting is typically characterized along varying dimensions of supportive interactions, or the extent to which two parents support and reinforce one another's parenting activities, as well as unsupportive interactions, or the level of inconsistent parenting, amount of conflict, and extent to which parents undermine one another's parenting efforts.

Initially, coparenting research focused on Caucasian parents who were divorced or in the process of divorcing (e.g., Ahrons, 1981; 1983). Prevention and intervention researchers were interested in identifying the processes that characterized the parenting efforts of divorcing parents who potentially had very negative feelings for one another, but managed to successfully parent together. Not surprisingly, divorcing parents who were more supportive of one another's parenting efforts and goals, despite their feelings for one another, had children who adjusted more favorably to the divorce (e.g., Coiro & Emery, 1998). Subsequently, researchers turned their attention to intact or two-parent Caucasian families and the processes by which married parents successfully parented together (e.g., McHale, 1995; 1997). Again, children whose parents evidenced more support for one another's parenting efforts, and less conflict regarding parenting goals and values, evidenced fewer difficulties.

Given the importance of coparenting for predicting child and adolescent adjustment, research on Caucasian families has also focused on predictors of successful coparenting relations (e.g., Straight & Bales, 2003). With regard to sociodemographic factors, a higher level of education has been associated with more stable levels of coparenting support than lower levels of education (e.g., Straight & Bales, 2003). Parental psychosocial variables are predictive of the quality of the coparenting relationship as well. Parents with fewer psychological problems are more likely to have coparenting relationships that are initially more positive and stay more positive over time compared to parents with more severe psychological problems (e.g., Straight & Bales, 2003; Moore, Florsheim, & Butner, 2007). Finally, parents who experience lower levels of stress enjoy more positive coparenting relations (e.g., Belsky, Crnic, & Gable, 1995).

Although leaders in the coparenting field have highlighted that coparenting is a construct of relevance to diverse (Feinberg, 2002) and single-parent (Van Egeren & Hawkins, 2004) families, far less attention has been devoted to the role of coparenting in ethnic minority or single-parent families (see Jones, Zalot, Foster, Sterrett, & Chester, 2007, for

a review). In our own work, young adult and adult (age range = 28 to 40 years old) African American single mothers of preadolescent children were asked whether another adult or family member assisted them with childrearing and, if so, were asked to identify the most important person. Only 3 percent of mothers failed to identify another adult or family member who assisted with childrearing; the majority identified the child's maternal grandmother (31%) or biological father (26%). Others identified a maternal aunt (11%), the child's older sister (11%), and a diverse group of other relatives and non-relatives, such as friends and neighbors (Jones, Shaffer, Forehand, Brody, & Armistead, 2003).

Building upon the coparenting literature more broadly, the quality of the relationships that these single mothers evidenced with their nontraditional coparents was associated with both maternal and child adjustment (Jones et al., 2003; Jones et al., 2005a). African American single mothers who reported experiencing greater conflict regarding childrearing issues with their nontraditional coparents had children who reported greater internalizing and externalizing difficulties than mothers who reported less conflict. The link between mother-coparent childrearing conflict and child adjustment was shown to be mediated, in part, by parenting behavior, as well as maternal mental health (Dorsey et al., 2007; Jones, et al., 2003). Mothers who experienced more conflict with their coparents experienced more compromises in parenting, as well as more depressive symptoms which, in turn, negatively affected child outcomes. Finally, research to date also suggests that the quality of the coparenting relationship may affect other contextual factors that influence the parenting behaviors of African American single mothers, including neighborhood risk. For example, African American single mothers who reside in riskier neighborhoods are more likely to appropriately heighten their monitoring behavior in the context of better relationships with their nontraditional coparents than in the context of poorer ones (Jones et al., 2005b).

With regard to the assessment of coparenting, it is important to note here that the methods utilized to assess coparenting in ethnic minority families lag behind the methods generally considered to be gold standard in the broader coparenting literature. For example, the research on the role of nontraditional coparents in African American single mother families has focused almost exclusively on mother-report of the quality of her relationship with her nontraditional coparent (e.g., Forehand & Jones, 2003;

Jones et al., 2005a; Jones et al., 2005b). In contrast to the broader coparenting literature with Caucasian two-parent families, the other adults or family members identified by mothers as coparents have not been included in the previously mentioned work. Rather, all data have been based on the mother's report of the coparent and the coparenting relationship. Moreover, while children have been included, the bulk of prior research has not considered their reports of the quality of the mother-coparent relationship or their perception of the nontraditional coparents' involvement (see Sterrett, Jones, & Kincaid, 2009, for a notable exception). Given the triadic nature of the coparenting construct, assessment of the single mother alone ignores two important contributors to the coparenting relationship, namely, the coparent and the child.

In extant coparenting research focused on ethnic minorities, young adult and adult African American single mothers in prior research have been asked about two relatively broad domains of the coparenting relationship: support and conflict regarding childrearing activities. State-of-the-field coparenting measures, however, include much richer assessments of the coparenting relationship, including division of childrearing labor and parental relationship quality (e.g., Belsky & Hsieh, 1998). Coparenting is now considered a multidimensional (rather than two-dimensional) construct, including more nuanced aspects of communication between parents, such as verbal sparring (e.g., hostility), conflict (e.g., arguing), and disparagement (e.g., undermining) (e.g., McHale, Kuersten-Hogan, Lauretti, & Rasmussen, 2000).

Finally, in addition to self-report methods, the broader coparenting literature includes observation and coding of interactions between married parents and children, which we did not include in our work on adult African American single mothers parenting with their nontraditional coparents. Observational methods have been notably underutilized in research on African American families in general (McLoyd et al., 2000), and the research on coparenting in African American families headed by a young adult or adult single mother is not an exception.

We cannot leave a review of the interrelationship of coparenting and parenting behavior without mentioning the dearth of research in this area on families with gay and lesbian parents. Such families have not been the focus of much empirical research; therefore, we know relatively little about their coparenting relationships or the links between coparenting and parenting in same-sex

parents (see Patterson & Farr, 2011, for a recent review). That said, the literature that has begun to accumulate suggests that the experiences of these families may be more similar than different from families with opposite-sex parents (see Tasker, 2005, for a review). In part, this may be due to the growing number of “diverse” family structures in the United States, including some we have already discussed (e.g., parents coparenting after divorce, single mothers coparenting with grandmothers, etc.). More research is needed, however, to determine how the unique factors facing same-sex parents may influence their coparenting efforts and, in turn, parenting behavior and the quality of the parent–child relationship. Among these unique factors are the extent to which children are aware of lesbian and gay relationships and homophobia (Tasker, 2005).

### **Focus on Other Parent Variables in Child Assessment**

Returning to the “why” of parenting—why parents utilize particular strategies and/or create specific caregiving environments—entails consideration of a vast number of influences, including, but not limited to, parental beliefs and values, parent knowledge of and expectations for child development, economic and social pressures, cultural norms and the prevailing folk psychological theories, child and parent temperament and the relative fit between the two, and siblings. However, no discussion of factors shaping parental behavior would be complete without mention of several key intrapersonal variables, namely, parental psychological and physical health or, alternatively, psychopathology, disease, and disability.

Scientific interest in parental psychopathology as it relates to parenting behaviors and offspring outcomes has burgeoned in the last two decades from its origins in developmental and clinical science in the 1950s and 1960s (Zahn-Waxler, Duggal, & Gruber, 2002). The nature of the questions and the sophistication of the models and methodologies utilized have evolved from simple correlational relations (assumed to be unidirectional) to include the gene x environment interactions and correlations that typify the intergenerational transmission of mental illness. The general pattern detected for any number of psychiatric diagnoses fits the following oversimplified formula: parental psychological symptoms and/or clinical disorders affect parenting behaviors and the family environment and are reflected in the quality of the parent–child relationship, which, in turn,

has bearing on concurrent and long-term offspring outcomes (Zahn-Waxler, Duggal, & Gruber, 2002). Specificity of the formula, however, is required to delineate which domains of parenting are affected by the particular psychiatric symptoms or disorders under study and to highlight the relative influence of specific parenting deficits or excesses on domains of child development. Important considerations in the specificity of the model include the timing, chronicity, and severity of the parental mental illness, the age and developmental stage of the child, and the availability and quality of additional coparenting relationships.

### **Major Depressive Disorder and HIV/AIDS: Two Cases in Point**

Given that depression is 1) one of the leading causes of disease-related disability worldwide (Murray & Lopez, 1997), 2) estimated to be twice as common in women than in men (see Nolen-Hoeksema, 1987, for a review), and 3) related to childbirth and childrearing (Zahn-Wexler, Duggal, & Gruber, 2002), the likelihood of exposure to parental depression in a child’s lifetime is relatively high (Zahn-Wexler et al., 2002). Data amassed over the past half century indicate that children and adolescents living with depressed caregivers are at substantial risk for a variety of developmental and adjustment difficulties across the lifespan (Goodman & Gotlib, 1999). Such difficulties include, but are not limited to, an increased risk for psychiatric disorders, increased guilt, problems with attachment, and sub-optimal interpersonal functioning (Beardslee, Versage, & Gladstone, 1998).

The detrimental effects of parental depression on their offspring are apparent in infancy. Some work suggests that newborns of mothers with significant depressive symptoms exhibit a profile or symptom cluster of dysregulation in their behavior, physiology, and biochemistry; these infants are typified by elevated norepinephrine and cortisol levels, lower vagal tone, and disrupted sleep patterns (Field, 1995). Additionally, newborns of clinically depressed mothers have shown poorer performance on a measure of motor tone and activity levels and increased irritability when compared to newborns of non-depressed mothers (Abrams, Field, Scafidi, & Prodromidis, 1995). Finally, infants of depressed caregivers evidence atypical frontal lobe activity (reduced left versus right activity) during interactions with mothers and non-depressed familiar adults (Dawson, Frey, Panagiotides, Yamada, Hessl, & Osterling, 1999).

Research on offspring at the preschool age suggests that attachment security is compromised when a caregiver suffers from depressive symptoms: toddlers born to mothers with both intermittent and chronic depressive symptoms and decreased sensitivity were more likely to be classified as having insecure attachments (Campbell et al., 2004). Additionally, research focused on behavioral and cognitive indices of dysfunction indicate that preschool offspring of mothers with severe or chronic depressive symptoms evidence higher levels of child behavior problems of both a hostile/aggressive and anxious/withdrawn nature, as well as lower vocabulary test scores (Alpern & Lyons-Ruth, 1993; Brennan, Hammen, Andersen, Bor, Najman, & Williams, 2000).

School-aged children and adolescents of depressed parents evidence more physical and psychological problems, including greater depression and anxiety, than do controls. They also exhibit significantly more difficulty with academics, school discipline, and social interactions than same-age peers with never-depressed caregivers (Anderson & Hammen, 1993; Billings & Moos, 1983). In terms of actual diagnostic outcomes, children and adolescents of depressed parents are three times more likely to qualify for any affective disorder, six times more likely to be diagnosed with Major Depressive Disorder (Downey & Coyne, 1990), and at least two to five times more likely to experience externalizing disorders than are controls (Billings & Moos, 1983; Cummings & Davies, 1994).

The literature reviewed here, which is reflective of the literature at large, has focused primarily on depressed mothers. Relatively recently, however, investigators have begun to include depressed fathers in their explorations of the effects of parental depression on child psychological health. A recent meta-analysis by Kane and Garber (2004), for example, suggests that outcomes for preschool, middle childhood, and adolescent-aged offspring of depressed fathers are very similar to those reported for children of depressed mothers.

Over the past ten to twenty years, empirical attention has shifted from establishing the risk of parental depression to exploring potential pathways or mechanisms of risk. What factors are responsible for predisposing children of depressed parents to abnormal development? In a developmentally sensitive, integrative theoretical model of the transmission of depression from parent to offspring, Goodman and Gotlib (1999) suggest four mechanisms: (1) heritability of depression; (2) innate dysfunctional

neuroregulatory mechanisms; (3) exposure to negative maternal cognitions, behaviors, and affect; and (4) the stressful context of the child's life. The first two proposed mechanisms are primarily genetic in nature, while the latter two focus on interpersonal and environmental contributions.

The third transmission pathway highlighted by Goodman and Gotlib (1999) concerns the offspring's exposure to maternal maladaptive cognitions, behaviors, and affect. Several distinct but interrelated lines of research suggest that two parallel processes inflate the offspring's risk: (1) depressed mothers are unable to parent effectively because of their distorted cognitions, behaviors, and affect and, thus, are unable to meet their children's social and emotional needs; and (2) a social learning dynamic unfolds, by which children acquire the cognitions, behaviors, and affect exhibited by their depressed mothers. Both the inadequate parenting and the depressogenic style characteristic of depressed caregivers negatively impact the development of the offspring's cognitive and social skills and restrict the child's range of affect and behavior, placing the youth at a heightened risk for the development of depression and other psychopathology.

Each piece of the proposed process constituting the third mechanism has garnered convincing empirical support. First, it is well established that depressed adults demonstrate more negative self-perceptions and cognitions (e.g., Beck, 1967, 1987; Ingram, Miranda, & Segal, 1998), including negative views of themselves as parents (Gelfand & Teti, 1990), more negative behaviors in interactions with others (Jacobson & Anderson, 1982), and more sad and irritable affect (Hops, Biglan, Sherman, Arthur, Friedman, & Osteen, 1987). This cognitive, behavioral, and affective symptomatology makes it difficult for depressed mothers to provide the requisite sensitivity, stimulation, and affectionate contact with their infants (e.g., Egeland & Farber, 1984; Fleming, Ruble, Flett, & Shaul, 1988; Livingood, Daen, & Smith, 1983), adequate scaffolding to support the social and cognitive developmental transitions of their toddlers and preschool-aged children (e.g., Breznitz & Friedman, 1988; Goldsmith & Rogoff, 1997), or the general emotional support and consistent discipline integral to the social and academic success of their school-aged children and adolescents (e.g., Hops et al., 1987; Sheeber, Hops, & Davis, 2001; Patterson, 1982).

In a meta-analytic review of 46 observational studies, Lovejoy, Graczyk, O'Hare, and Neuman (2000) highlight specific deficits and excesses

typical of depressed mothers. Namely, the authors report a positive association between maternal depression and both of these parenting behaviors: (1) negative or coercive parenting (i.e., threatening gestures, negative facial expressions, criticism, and negative commands) and (2) disengaged parenting (i.e., decreased vocalization, responsiveness, positive affect, and participation in play). In addition, some support emerged for a negative association between maternal depression and positive parenting behaviors (i.e., positive tone of voice, affectionate gestures, expression of pleasure and enthusiasm, and praise). Research suggests that offspring are not only negatively affected by the parenting deficiencies and emotional unavailability of their caretakers, but that they also are at a higher risk for dysfunction because they model or internalize their caretakers' negative cognitions, behaviors, and affect. As an illustrative example, school-aged children and adolescents of depressed parents are more likely to be self-critical, have lower self-concepts, and report more negative cognitive styles when compared to children of well mothers (Garber & Robinson, 1997); they are, in effect, potentially modeling their mothers' negative cognitions.

Given the research suggesting that caregiver depression affects the quality of the parent-child relationship and is associated with particular problematic parenting behaviors and patterns, which in turn impact offspring cognitive, emotional and, social health, and well-being, clinicians and developmental scientists may wish to explore parental depression as one of many contributors to individual differences in parenting beliefs, style, and behaviors. A number of self-report screening tools, structured and semi-structured interviews, and clinician-rated measures are available (see Nezu, Nezu, McClure, & Zwick, 2002, for a review of depression assessment tools). Both the Beck Depression Inventory-II (BDI-II; Beck, Steer, & Brown, 1996) and the Center for Epidemiological Studies Depression Scale (CES-D; Radloff, 1977) are psychometrically sound self-report questionnaires that provide an assessment of depressive symptoms with suggested clinical cut-offs. Often cited as the gold standard for clinical diagnosis of Major Depressive Disorder in research are standardized clinical interviews, such as the Structured Clinical Interview for *DSM-IV* Axis I Disorders (SCID-I; First, Spitzer, Gibbon, & Williams, 1997) and the Diagnostic Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978). Clinician-rated measures, such as the Hamilton Rating Scale for

Depression (HRSD, Hamilton, 1960), have also been utilized widely in psychiatric and primary care settings as well as in research protocols.

In addition to psychological illness, many parents face physical health problems as well, and a review of procedures for assessing parenting would not be complete without a discussion of how parenting behavior may be influenced by parental physical illness. Although there are literatures on a range of parental illnesses (see Armistead, Klein, & Forehand, 1995, for a review), our focus here will be on HIV/AIDS, since it is a primary focus of our own work and an illness confronting more families, particularly ethnic minority families, in the United States than many realize.

Early in the HIV/AIDS epidemic, women were rarely diagnosed with the disease; however, today women account for more than 25 percent of all new HIV/AIDS diagnoses, and African American women are especially affected by the disease (Corea, 1992; Centers for Disease Control and Prevention [CDC], 2005). Sixty-four percent of the women currently living with HIV/AIDS are African American, a rate that is more than three times that of the percentage (19%) of Caucasian women living with the illness (CDC, 2005). Moreover, HIV/AIDS is the leading cause of death for African American women aged 25 to 34 years and the third-leading cause of death for African American women aged 35 to 44 years (CDC, 2005). Both of these time periods represent prime childbearing and childrearing years for women.

Given that many African American women with HIV/AIDS are also mothers, the extent to which the illness influences maternal parenting behavior and the quality of the mother-child relationship is of critical public health importance for understanding the psychosocial adjustment of the growing number of African American youth being raised by mothers infected with the disease (e.g., Forehand et al., 2002; Stein, Rotheraum-Borus, & Lester, 2007; Tompkins & Wyatt, 2008). Collectively, the findings of research to date suggest that maternal HIV/AIDS may disrupt both maternal parenting behaviors and the quality of the relationship that the infected mother has with her child. For example, infected mothers have been shown to evidence compromises on both the warmth/support and monitoring/control domains of parenting behaviors (e.g., Forehand et al., 2002; Tompkins & Wyatt, 2008).

Importantly, the extent to which HIV compromises maternal parenting and mother-child relationship quality depends on several factors related

to parenting in general, but also on factors specific to HIV/AIDS in particular, including whether or not mothers disclose their illness to their children (e.g., Antle et al., 2001; Armistead, Tannenbaum, Forehand, Morse, & Morse, 2001; Shaffer et al., 2001). A mother's disclosure of any chronic or life-threatening illness to her child is often accompanied by some level of hesitation or worry regarding the child's reaction (Semple et al., 1993; Tompkins, Henker, Whalen, Axelrod, & Comer, 1999). Mothers with HIV/AIDS may be particularly worried about their children learning of their illness given the stigma associated with the disease, as well as the methods of transmission (Armistead et al., 2001; DeMatteo et al., 2002; Kirshenbaum & Nevid, 2002). Perhaps for these reasons, maternal disclosure of HIV/AIDS has not been associated with the same sense of relief experienced by mothers who disclose other life-threatening, but less stigmatized diseases, such as cancer (Armistead, Morse, Forehand, Morse, & Clark, 1999; Levy et al., 1999). It is not surprising then that only about one-third of mothers with HIV/AIDS disclose their disease to their children, even as the disease progresses and death becomes more imminent (Armistead et al., 2001; Murphy, Koranyi, Crim, & Whited, 1999; Murphy, Steers, & Stritto, 2001).

Although initial work suggested that maternal HIV/AIDS had negative effects on parenting and, in turn, on child adjustment, more recent work suggests that the impact of maternal HIV/AIDS is more heavily dependent on whether the child is aware of the mother's illness and the extent to which the mother-child relationship has been compromised by the illness. For example, in our own work we have found that children who knew of their mothers' diagnosis, but who viewed their relationships with their mother as more warm and supportive, evidenced fewer adjustment difficulties than children who viewed their relationships with their mother as less warm and supportive (Jones et al., 2007). In contrast, mother-child relationship quality was not associated with the psychosocial adjustment of children who were not aware of their mothers' diagnosis.

In addition to the direct effects of HIV/AIDS on parenting behaviors, we have already noted that maternal depressive symptoms are associated with a range of compromises in parenting behaviors (e.g., Lovejoy et al., 2000). Of note, mothers with HIV/AIDS evidence higher levels of depressive symptoms than demographically matched non-infected women (e.g., Jones, Beach, Forehand, & the Family

Health Project Research Group, 2001; Miles, Gillespie, & Holditch-Davis, 2001). Accordingly, more attention needs to be devoted to understanding whether parenting behavior may be particularly compromised in mothers who are both HIV positive and depressed; however, research to date is mixed (e.g., Cho, Holditch-Davis, & Miles, 2008; Jones et al., 2008; McKee et al., 2007).

Before concluding our discussion of maternal HIV/AIDS, it should be noted that far less attention has been devoted to paternal than maternal illness in general and the area of HIV/AIDS is no exception. As previously noted, the focus on mothers in the HIV/AIDS literature is likely due in large part to increased awareness of HIV/AIDS as a disease affecting women over the past two decades. In addition, the focus on mothers has come from the increased rates of HIV/AIDS among African American women of childbearing age, drawing attention to the disproportionate number of African American youth in this country being raised by an infected mother. Of course, as with the parenting literature more generally, our understanding of the impact of HIV/AIDS on parenting depends on greater attention to infected fathers and paternal parenting as well.

Our review of the associations of parental depression and parental HIV/AIDS with parenting, and, in turn, child adjustment provides evidence for the role that parental psychiatric and physical health can play in parenting. Any assessment or intervention focused on parenting behaviors should, therefore, consider these and other intrapersonal variables (e.g., personality) and their impact on parenting behaviors, coparenting relationships, and offspring development.

## Conclusions and Future Directions

Throughout this chapter, a number of theoretical and methodological contributors to the assessment of parenting style and behaviors have been articulated, accompanied by an in-depth exploration of three questionnaire-based measures and three observational tools. Despite the surprising similarity in the molar constructs that have been the focus of parenting research and assessment both over time and across theoretical orientations, decisions regarding which of several hundred assessment tools to employ require thoughtful consideration. Nezu and colleagues (2009) highlight key issues and relevant questions to guide those decisions, including: (1) the goals of the assessment (e.g., case formulation versus outcome evaluation), (2) the intended

target of the assessment (e.g., considerations of age and ethnicity), (3) the value assigned to a given assessment strategy (i.e., the likelihood that the tool will yield the desired information in the context of a cost-benefit analysis), and (4) the source of the information (e.g., the parent or the child versus a neutral observer). From the vast collection of assessment tools available, both a behavioral scientist seeking to explore the relation between parental monitoring and adolescent alcohol use and a clinician evaluating the outcome of a behavioral parent training intervention can be served well.

Despite advances in the assessment of parenting over the last five decades, a number of challenges in the field remain. First, as we have highlighted throughout the chapter, the cultural relevance and sensitivity of assessment tools initially designed for use with a specific segment of the population (e.g., Caucasian middle class parents) may or may not yield meaningful or valid data when utilized with subjects outside that population segment. This issue, of course, is particularly relevant to research and clinical assessments targeting historically understudied groups (e.g., working-class African and Hispanic Americans, same-sex parents). Although advances in the modification, creation, and validation of culturally appropriate parenting assessment tools have bolstered the confidence with which claims about the relation between parenting behaviors and child development can be made, a host of questions remain unanswered and beg continued study. For example, how have class and ethnicity been confounded in the study of parenting? Furthermore, how might within-group factors, such as acculturation status and racial socialization, impact the validity of a tool designed for an ethnic minority group?

Second, there are distinct advantages and disadvantages to the sheer number of assessment tools available and the disparate ways in which parenting behaviors have been defined. Although there is considerable overlap in the broad underlying parenting dimensions measured by different tools, the ways different research groups have operationalized these dimensions vary greatly. For example, warmth may be defined in one measure by displays of positive affect and in a different measure by an index of involvement in the child's life (see Table 35.1). As a result, drawing conclusions across studies regarding the effects of parental warmth on child disruptive behavior, for example, can prove difficult. Some might argue, then, that the field would benefit from widespread adoption of a model (such as the one

proposed by Darling and Steinberg [1993]) that may serve to increase both the conceptual uniformity and operational definitions of parenting constructs. In a related vein, the situational specificity of particular parent-child exchanges could be further refined. Warmth, for example, may be appropriate in some contexts (e.g., dinnertime conversation) but counter-indicated (depending upon the definition) if a child has just engaged in an aggressive act at which time limit setting or a combination of warmth and behavioral control may be a more appropriate response. A similar argument is made by Caron et al. (2006) in that the "effects of at least some parenting behaviors may differ as a function of the interaction task or larger context in which the behavior occurs" (p. 35). Although observational assessment tools may have a relative advantage over questionnaire-based tools in this regard, a number of studies have averaged across different tasks, perhaps masking subtleties, or examined only one task; as a result, cross-study comparisons examining the same parenting behavior but during different tasks render interpretation difficult.

Because parenting is a complex, multifaceted, and dynamic process, the assessment tools designed to capture such a wide range of nuanced behaviors must be sophisticated and sensitive to micro- and macro-level interactions. And because no one tool can meet the demands of every researcher and practitioner, the assessment pendulum swings between generality and specificity, and the field, as a whole, balances the advantage of a grand, unifying theory with the allure of methods and measures that can address the needs of increasingly specialized interest groups.

# Linking Children and Adolescent Assessment to Effective Instruction: An Evidence-based Perspective from the Experimental Literature

H. Lee Swanson

## Abstract

This chapter reviews the outcomes of meta-analysis studies that provide potential links between assessment and instruction. The review covers three areas: (1) dynamic assessment, (2) general models of instruction that combine the components of direct and strategy instruction, and (3) treatment outcomes related to definition  $\times$  treatment interactions. The implications of the review were (a) when dynamic assessment procedures are coupled with static assessment, they provide important differential weights in predicting learning outcomes, (b) effective instruction is neither a bottom-up nor top-down approach in isolation, and (c) variations in IQ and reading cannot be ignored when predicting treatment outcomes.

**Key Words:** Dynamic assessment, meta-analysis, evidence-based intervention, direct instruction, and strategy instruction

The purpose of this chapter is to link effective assessment practices to effective instruction for children and adolescents at risk for learning problems. No doubt, this first sentence begs the question as to what is effective assessment and what is effective instruction. We will attempt to answer these questions by considering outcomes related to quantitative syntheses (meta-analyses) of the intervention and assessment literature. Prior to reviewing this research, however, some of the goals of assessment and effective instruction need to be stated. The goal of assessment in the educational and/or instructional context is to determine those underlying cognitive, social, and environmental variables that contribute to a student's academic performance. Effective instruction, on the other hand, complements assessment by monitoring the intensity of instruction and making systematic changes in the instructional context as a function of a student's overt performance. These two activities are complementary. One focuses on systematic manipulation of the environmental

context (e.g., instruction, classroom, school) to determine procedures that maximize learning, whereas the other focuses on mapping the internal and social dynamics of learning for the purposes of informing instruction. Given these assumptions, we now review our meta-analyses that attempt to link assessment with instruction (also see Swanson, 2011, for further discussion). Prior to our review we define meta-analysis.

## Meta-analysis

*Meta-analysis* refers to a statistical technique used to synthesize data from separate comparable studies in order to obtain a quantitative summary of research that addresses a common question. Prior to conducting a meta-analysis, the researcher defines the problem (i.e., determining interventions that work), collects the research relevant to the problem (i.e., evidence-based reading interventions), and evaluates the quality of the data (i.e., experimental designs). The procedures for

conducting a meta-analysis are described in detail in Cooper and Hedges (1994), Lipsey and Wilson (2001), and Rosenthal and DiMatteo (2001). There are at least two advantages of meta-analysis over traditional narrative techniques for synthesizing research. First, when discussing research linking assessment to instruction, the structured methodology of meta-analysis requires careful review and analysis of all contributing methodologically sound research. As such, meta-analysis overcomes biases associated with the reliance on single assessment or intervention studies, or on subsets of studies that inevitably occur in narrative reviews of a literature. Second, meta-analysis can address questions about variables that moderate effects. For example, questions such as whether key assessment information (e.g., variations in intelligence and reading in samples at risk for learning problems) plays a significant role in moderating treatment outcomes can be addressed. Specifically, meta-analysis provides a formal means for testing whether different features of studies explain variation in their outcomes (e.g., see Gersten, Chard, Jayanthi, Baker, Morphy, & Flojo, 2009).

Although there are many different metrics to describe an effect size, in this chapter we use the *d*-index by Cohen (1988). The *d*-index is a scale-free measure of the separation between two means that is used when one variable is dichotomous (e.g., children at risk for learning problems versus children not at risk; control vs. treatment group) and the other is continuous (e.g., dependent measures related to cognitive processes, reading, and/or math). Calculating the *d*-index for any study involves dividing the difference between the two group means by either their average standard deviation or the standard deviation of the control group. To make *d*'s interpretable, statisticians have usually adopted Cohen's (1988) system for classifying *d*'s in terms of their size (i.e., .00–.19 is described as TRIVIAL; .20–.49, SMALL; .50–.79, MODERATE; .80 or higher, LARGE). Cohen's *d* (1988) is further weighted by the reciprocal in the sampling variance (Hedges & Olkin, 1985). The dependent measure for the estimate of effect size (ES) can be defined as  $ES = d/(1/v)$ , where  $d$  [(Mean of treatment group – Mean of comparison group)/ average of standard deviation for both groups)], and  $v$  is the inverse of the sampling variance,  $v = (N_{rd} + N_{nrd})/(N_{rd} \times N_{nrd}) + d^2/[2(N_{rd} + N_{nrd})]$  (Hedges & Olkin, 1985). Thus, ESs are computed with each ES weighted by the reciprocal of its variance, a procedure that gives more weight

to ESs that are more reliably estimated. As suggested by Hedges and Olkin (1985), the majority of syntheses remove outliers from the analysis of main effects. Outliers are defined as ESs lying beyond the first gap of at least one standard deviation between adjacent ES values in a positive direction (Bollen, 1989).

## Dynamic Testing

One of the clearest links between assessment and instruction are procedures referred to as dynamic assessment (e.g., Caffrey, Fuchs, & Fuchs, 2008; Fuchs, Compton, Fuchs, Hollenbeck, Craddock, & Hamlett, 2008; Hasson & Joffe, 2007; Jeltova, Birney, Fredine, Jarvin, Sternberg, & Grigorenko, 2007; Macrine & Sabatino, 2008; Sternberg & Grigorenko, 2002; Swanson & Lussier, 2001; Tzuriel & Flor-Maduel, 2010). Dynamic assessment has long been argued as a direct means to integrate assessment with instruction. For example, several authors (e.g., Campione & Brown, 1987; Feuerstein, 1980; Haywood, Brown, & Wingenfeld, 1990; Lidz, 1996) suggest that traditional testing procedures that rely on intelligence or aptitude tests underestimate general ability. That is, traditional or static approaches to assessment of aptitude typically provide little feedback or practice prior to testing, and therefore performance on such measures often reflects the child's misunderstanding of instructions more than his ability to perform the task (e.g., Brown & Ferrara, 1999; Campbell & Carlson, 1995). A supplement to traditional assessment is to measure a child's performance when given examiner assistance. This procedure that attempts to modify performance, via examiner assistance, in an effort to understand learning potential, captures the essence of dynamic assessment (DA). Thus, DA is defined as a procedure that determines whether substantive changes occur in examinee behavior if feedback is provided across an array of increasingly complex or challenging tasks. This procedure contrasts with traditional models of assessment in which there is no feedback on student performance from the examiner.

## Traditional DA Approaches

Traditional approaches of DA include learning potential assessment (e.g., Budoff, 1987), testing-the-limits (Carlson & Wiedl, 1979; Swanson, 1995b), mediated assessment (e.g., Feuerstein, 1980; Tzuriel & Flor-Maduel, 2010), and assisted learning and transfer (e.g., Bransford, Delclos, Vye, Burns, & Hasselbring, 1987; Campione, Brown, Ferrara, Jones, & Steinberg, 1985). Although DA

is a term used to characterize a number of distinct approaches (see Sternberg & Grigorenko, 2002, for a review), two common features of this approach are to determine the learner's potential for change when given assistance, and to provide a prospective measure of performance change independent of assistance (e.g., Embretson, 1987; 1992). Unlike traditional testing procedures, score changes due to examiner intervention are not viewed as threatening task validity. In fact, some authors argue that construct validity increases (e.g., Carlson & Wiedl, 1979; Lidz, 1996; Swanson, 1995; also see Sternberg & Grigorenko, 2002, for a review). To obtain information about a child's responsiveness to hints or probes, DA approaches require the interaction of an examiner and the examinee. When a student is having difficulty, the examiner attempts to move the student from failure to success by modifying the format, providing more trials, providing information on successful strategies, or offering increasingly more direct cues, hints, or prompts. The intensity of the intervention ranges from several sessions to brief intensive prompts in one session. Thus, "potential" for learning new information (or accessing previously presented information) is measured in terms of the distance, difference between, and/or change from unassisted performance to a performance level with assistance.

Although DA has been suggested as an alternative and/or supplement to traditional assessment, only a few critical reviews of such procedures have been published (e.g., Caffrey et al., 2008; Elliott & Lauchlan, 1997; Grigorenko & Sternberg, 1998; Jitendra & Kameenui, 1993; Laughon, 1990). The most comprehensive qualitative review of DA procedures to date was conducted by Grigorenko and Sternberg (1998; also see Sternberg & Grigorenko, 2002). Their study reviewed the strengths and weaknesses of five different dynamic testing models: Feuerstein and colleague's model of structural cognitive modifiability (e.g., Feuerstein, Miller, Hoffman, Rand, Mintzker, & Jensen, 1981; Feuerstein & Schur, 1997), Budoff's (1987) learning potential testing model, Campione and Brown's (Campione & Brown, 1987) transfer model, Carlson's (Carlson & Wiedl, 1978, 1979) testing-the-limits model, and an information-processing framework as conceptualized by the Swanson Cognitive Processing Test (S-CPT, Swanson, 1994, 1995a, 1995b; Swanson & Howard, 2005). In general, after reviewing these different approaches, Grigorenko and Sternberg (1998) concluded "that it is difficult to argue that this approach (DA) has proved its usefulness and

has shown a distinct advantage over traditional static testing relative to the resources that need to be extended ..." (p. 105).

### **Goals of DA**

More specifically, Grigorenko and Sternberg (1998) questioned whether the experimental literature supports the goals of DA. These goals are related to (a) providing a better estimate of ability, (b) measuring new abilities, and (c) improving mental efficiency when compared to static testing procedures (see Embretson, 1987; then see Grigorenko & Sternberg, 1998, p. 103). For example, Grigorenko & Sternberg review questioned whether DA increased the comparability of performance among students from differing backgrounds and handicapping conditions when compared to static conditions. That is, when compared to static measures, DA has not been shown to equate the performance among children with differing learning abilities (i.e., level the playing field). In addition, Grigorenko and Sternberg (1998) suggested that cognitive modifiability (a psychological construct frequently referred to in the DA literature) has not been shown to be independent of initial learning ability. Likewise, their review questioned whether changes in mental processing come about because of DA or merely reflect artifacts related to retesting. That is, they argue that approximately 30 percent of children improve to a statistically significant extent simply because of retesting (see Grigorenko & Sternberg, 1998, p. 104). Thus, changes in performance may be unrelated to intervention instructions.

### **DA Outcomes**

So, what's the data on dynamic testing? Swanson and Lussier (2001) addressed this question with meta-analytic techniques. Their synthesis included those studies cited in the comprehensive review by Grigorenko and Sternberg (1998) ( $N = 229$  articles), but was also expanded by a review of the PSYCINFO database over a 35-year period. The search resulted in a list of 303 potential articles for analysis. Most of these articles were eliminated because ESs could not be computed. Thirty articles were included for the final analysis. Each of these articles contained at least a pretest/post-test situation and appropriate statistical information (means, standard deviations, or  $F$  tests) to calculate ESs. Each article was coded for: sample size, type of ability group, assessment instruments, mean age of participants, IQ range of participants, gender ratio, length of treatment

sessions, amount of time per session, and type of experimental design.

The majority of information coded is shown in Table 36.1. For example, studies were coded on whether participants were average achievers or reflected special education categories. This resulted in five classification categories: Average Achievers, Mentally Retarded, Learning Disabled, Under Achieving, and Hearing Impaired. Participants were

classified as Average Achieving if the article stated participants were of “average ability” or served as “age matched” participants when compared to a special education group, or if the study stated that the sample was considered a normal representation of the population. Participants were coded as Mentally Retarded if IQs were 71 or lower on a standardized intelligence test (e.g., Wechsler Intelligence Scale for Children). Participants were

2. Training	1,695	14	0.21	0.15	0.28
3. General-Feedback (strategy)	2,000	22	0.85	0.58	0.71

K = Number of Dependent Measures, Ach = Achievers, Inst = Instruction, Imp = Impaired, Test. Limits = Testing the Limits, Train = Test-Train-Test Model

labeled Learning Disabled if so designated by the primary author and/or if IQ scores were in the normal range (85 – 115) and achievement scores in one or more domains (e.g., reading) were below the 25th percentile. Participants were coded Under Achieving if samples were labeled by the primary author as “under achieving,” “slow learning,” or participants in a Head Start program. The final category, Hearing Impaired or Deaf, included participants who were identified as pre-lingually deaf or classified as “deaf.”

Dependent measures were also coded as reflecting primarily visual-spatial or verbal assessment measures. Tasks coded as visual-spatial measures included: the Test of Early Math Ability, the Kohs Block Design, Piagetian Matrices Task, The Order of Appearance Test, The Representational Stencil Design Test, Number Finding Task, Visual Search Test, Child’s Analogical Thinking Modifiability Test, The Differential Ability Test, The Raven’s Colored Progressive Matrices Test and its sub-tests (including the picture booklet and puzzle forms), the Wechsler Preschool and Primary Scale of Intelligence—the Block Design subtest, the Picture Analogy Test, the Leiter International Performance Scale, and the “balance-scale strategy using moving pegs” (Day & Cordon, 1993). Tasks labeled as primarily verbal were verbal subtests from the Swanson-Cognitive Process Test (e.g., Story Retelling, Semantic Association, Rhyming, Semantic Classification, Phrase Sequencing, Digit-Sentence), verbal subtests from the Wechsler Preschool and Primary Scale of Intelligence (e.g., Similarities subtest), the Yopp-Singer Test (phoneme segmentation task), the Picture Vocabulary Test, and the Electricity Knowledge Test.

In terms of design, studies were classified as “between comparisons” if two *independent* samples in two treatment conditions (i.e., static vs. dynamic) were compared or “within design comparisons,” if the *same* participants were compared on both the static and dynamic measures. The later condition reflects pretest–post-test only situations (i.e., the pre-test reflects the static measure, usually, followed by a scaffolded/mediated learning period, and then a post-test). If a study was classified as a “Within Design Comparison,” then the pre-test was considered the static test and the post-test (i.e., after interaction) was considered a measure of dynamic testing.

Studies were also divided into three general models. One set of studies tested the limits by using systematic scaffolding, via verbal mediation or probes,

to push performance to *upper* limits (e.g., Carlson & Wiedl, 1979; Swanson, 1992). These studies compared various cuing procedures but had the goal of maximizing performance at an upper or asymptotic level. A second set of studies used techniques that trained participants to solve problems or intervened on performance in order to instruct (e.g., Budoff, 1987). This set of studies used a test-train-test format usually involving coaching and/or mediated training. The final set of studies relied on structured strategy training, modeling, and/or general feedback (e.g., Larson et al., 1991). The terms “scaffolding” (pushing the limits), “mediated learning” (training), and “general feedback” are used to reflect, respectively, the three models.. Clearly these overlapped in some areas (cues, instruction, and practice), but the primary form of assessment in each study was assessed.

All together, 170 effect sizes (ESs) were generated. Table 36.1 provides a summary of the mean ESs and standard deviations across studies as a function of the categories of variables. Column one reports the sample size ( $N$ ); column 2, the number of dependent measures ( $K$ ); column 3, ES; and columns 4 and 5, the confidence intervals. As shown in Table 36.1, the magnitude of the ESs varied significantly ( $ps < .05$ ) as a function of age (ages 10 to 13 = samples less than 10 years > samples with ages > 13), sample size (samples < 80 but larger than 39 yield larger ES than samples > 79 or < 40), and type of dynamic assessment (scaffolding and general feedback yields higher ESs than explicit training). Comparisons were made between studies that only included pretest/post-test designs (within or repeated design) and those that made between-conditions comparisons. When a correction was made related to pretest–post-test correlations, a significant difference in ESs emerged in favor of between-comparison designs ( $M = .91$ ) when compared to within designs (.17).

The most important findings were related to ability group. When compared with the other ability groups, the highest mean ES ( $M = .98$ ) emerged for underachieving participants, whereas the lowest ES emerged for learning-disabled participants ( $M = .10$ ). These findings on children with learning disabilities (LD) will also be discussed later when we discuss evidence-based practices below.

### **Links to Instruction**

How does DA inform us about child performance? First, DA procedures positively influence the magnitude of ES. The overall magnitude of

ES was found to be 1.69 for between-comparison studies (samples are assigned to either static or DA testing condition) and 1.40 for studies that use the same sample in a pretest–post-test only design. Thus, based on Cohen's criterion of .80 as a large ES, DA procedures substantially improved testing performance over static testing conditions. However, the magnitude of the ES was substantially reduced for between-comparison design studies when weighted for sample size (ES = .91) and when pretest–post-test only designs were corrected for upward biases and artifacts-related retesting (ES = .16). The positive ES does suggest, however, that dynamic testing does make positive changes in performance.

Second, the magnitude of ES was directly influenced by the type of assessment used. ESs were higher for studies that included strategy training, general feedback, and modeling (ES = .85), followed by those that allowed for testing the limits (e.g., scaffolding, ES = .48), followed by those conditions that focused on coaching and/or mediated training (ES = .21). Further, these effects were not an artifact of ability group, number of assessment sessions, or the age of the sample.

Third, the conditions under which ability-group differences across diverse dependent measures are reduced or maximized were identified. Through various regression modeling Swanson and Lussier (2001) found that ability group differences in responsiveness to DA procedures were non-significant. However, advantages were found for underachievers when variables related to age, number of sessions, and types of assessment were left to co-vary. Their synthesis suggested that DA equated ability groups in terms of *responsiveness* to dynamic test conditions when variables related to instruction, type of measure, age, and type of design were held constant in the analysis. This finding supports the contention that changes in performance as a function of DA procedures reflected abilities independent of measures of traditional classification and procedures. That is, in reference to the goals of DA discussed earlier (providing better estimates of ability and providing a measure independent of ability), comparability of ES as a function of ability group was supported. However, the playing field was only equalized when all variables are entered into the regression model. Given the common finding that normal and handicapped groups differ on a host of verbal and visual-spatial measures, finding no significant differences in the magnitude of ESs related to ability group suggests that some new abilities are being tapped.

Fourth, the results support the notion that the magnitudes of ESs are not merely an artifact of length of intervention. No differences in ES emerged related to the number of treatment sessions. Rather, the results clearly supported the notion that treatment effects, particularly those studies that emphasized general feedback or scaffolding, contributed independent variance to the magnitude of the ES. These findings suggested that changes in mental efficiency are related to DA conditions and not merely to re-testing conditions.

Finally, the synthesis complemented the findings of Grigorenko and Sternberg (1998) and others more recently (Caffrey et al., 2008; Fuchs et al., 2008; Swanson & Howard, 2005; Yeomans, 2008), but also suggested that DA procedures may provide an estimate of processing potential not necessarily tapped by traditional assessment approaches. DA training resulted in better performance than traditional (referred to as static testing), even when studies under different conditions were considered (multiple sessions versus single, between groups versus within groups) and ESs were corrected for pre-test sensitivity and upward biases. In terms of new abilities, a relationship was found between ES and responsiveness to the type of DA procedures used; this pattern holds true in the full regression model (with all variables present). It is important to note, however, that the results did not hold up when only main effects were considered in isolation from the influence of other variables. When the categories of studies were considered in isolation, underachievers clearly yield higher ESs, and LD children lower ESs than other ability groups. Further, there is a trend to find higher ESs in younger age groups (younger participants yield higher ESs than the older ages).

### **Qualifications in Using DA**

Although the analyses by Swanson and Lussier (2001) suggested some positive benefits to using DA techniques when linking assessment and instruction, there are at least three qualifications to their findings when linking the results of DA to practice. First, most DA procedures in the studies we reviewed have been validated primarily on tasks that may have weak contextual validity within the classroom. For example, some of the tasks in which changes in performance have been shown (e.g., Raven Progressive Matrices, and Block Designs) may have very little relevance to areas in which high-risk children experience difficulties—such as reading (reading comprehension and writing) or math (calculation, problem solving).

Second, there is some question about the “level” or “meaning of” the dependent measures used in DA procedures. Some DA approaches focus on change scores (products), rather than the processes that are changing. Although the assessment of children at risk can certainly focus on “how much change can occur in a score,” of greater interest to the educator are the cognitive processes or strategies that may have been influenced by such changes. For example, in some of the DA approaches reviewed by Swanson and Lussier, it is uncertain whether changes in performance reflected information that is available or accessible in the “mind” of the child tested or merely reflected changes in testing format. That is, in some DA procedures changes in performance may be related to increasing task familiarity, instructions, expectations, and/or individual attention. Thus, changes are not necessarily influencing any deep cognitive structures, as much as they are directing the child’s attention to important task parameters.

Finally, it is uncertain in some studies whether examiner feedback to the child suspected of being at risk for learning activates the information that is already in the child’s mind or reintroduces the concept again to a poorly stored original memory trace. The differences between learners on these later issues are important if gains in scores are to be attributed to changes in environment or changes in cognition, or both.

### **Summary**

A meta-analysis of the literature shows that DA procedures improve testing performance of children and adolescents over traditional (static) conditions. Other important findings were that the influence of ability-group classification, except for learning disabilities, was mitigated with DA procedures when a full array of contextual variables was considered. Clear advantages were found for DA procedures that use general feedback and modeling during testing. We now review a meta-analysis related to evidence-based instruction for children and adolescents with learning disabilities (LD). A focus is placed on children and adolescents with LD because this group reflects the largest incidence of children in special education.

### **Effective Instruction and Role of Psychometric Information**

Children with LD are a heterogeneous group and, therefore, no general instructional effective model can be recommended for all of them. However, we

think some common general principles from the experimental intervention literature have emerged, and effective instructional programs capitalize on these principles. We summarize findings related to our meta-analysis of the literature (Swanson, Hoskyn, & Lee, 1999; Swanson & Deshler, 2003). There have been several excellent meta-analyses on instructional research in LD (Gersten et al., 2009), but none to our knowledge have considered intervention research across a broad array of academic domains and/or controlled for variations in methodology. In addition, none of these syntheses have attempted to link instructional outcomes with variations in definitions of LD.

The primary meta-analysis referred to (Swanson et al., 1999) was funded by the U.S. Department of Education. This research synthesized experimental intervention research conducted on children with LD over a 35-year period. Swanson and several colleagues (e.g., Swanson, 1999a; 2000, Swanson & Deshler, 2003; Swanson & Hoskyn, 1998; Swanson & Sachse-Lee, 2000) synthesized articles, technical reports, and doctoral dissertations that reported on group design and single design studies published between the years of 1963 and 2000. Condensing over 3,000 ESs, they found a mean ES of .79 for LD treatment versus LD control conditions for group design studies (Swanson & Hoskyn, 1998) and 1.03 for single-subject design studies (Swanson & Sachse-Lee, 2000). According to Cohen’s (1988) classification system, the magnitude of the ES was large. Thus, on the surface, the results are consistent with the notion that children with LD are highly responsive to intense intervention. However, when children with LD were compared to non-disabled children of the same grade or age who also were receiving the same best evidence intervention procedure, ESs ( $ES\ M = .97$ ,  $SD = .52$ ) were substantially in favor of non-disabled children (see Swanson et al., 1999, pp. 162–169).

There were two other important findings from this synthesis as applied to effective instruction. First, the analysis showed that combined direct and explicit strategy instruction (explicit practice, elaboration, strategy cuing) and small group interactive settings best predicted the size of treatment outcomes across various academic domains. The implication of this finding is that a combination of direct instruction (DI) and cognitive strategy (SI) instruction provided the best evidence-based instructional heuristic for improving academic performance (effect sizes  $>.80$ ) in children with LD. However, these components accounted for less that

15 percent of the variance in predicting outcomes (Swanson, 1999b). This finding held when controls were made in the analysis for methodology, age, and type of academic domain (e.g., reading, math, and writing).

A further analysis of the data divided the studies up in terms of their emphasis on key activities or components of instruction. Swanson (2000) divided studies into eight models based on key instructional tactics: direct instruction (a focus on sequencing and segmentation of skills), explicit strategy training, monitoring (teaching children strategies), individualized and remedial tutoring, small interactive group instruction, teacher-indirect instruction (teacher makes use of homework and peers' help for instruction), verbal questioning/attribution instruction (asking children key questions during the learning phase and whether they thought what they were learning would transfer), and technology (using computers to present concepts). The results indicated that explicit strategy instruction (explicit practice, elaboration, strategy cuing) and small group interactive settings best improved the magnitude of treatment outcomes.

In terms of presentation format, Swanson (1999b) found that effective instructional models follow a *sequence of events*:

1. State the learning objectives and orient the students to what they will be learning and what performance will be expected of them.
2. Review the skills necessary to understand the concept.
3. Present the information, give examples, and demonstrate the concepts/ materials.
4. Pose questions (probes) to students and assess their level of understanding and correct misconceptions.
5. Provide group instruction and independent practice. Give students an opportunity to demonstrate new skills and learn the new information on their own.
6. Assess performance and provide feedback. Review the independent work and give a quiz. Give feedback for correct answers and reteach skills if answers are incorrect.
7. Provide distributed practice and review.

Swanson also found that some instructional components were far more important than others in various instructional domains. For example in the domain of reading comprehension (Swanson, 1999b), those key instructional components that contributed in significantly (as shown in regression

analyses) improving the magnitude of outcomes (ES) were:

1. *Directed Response/Questioning.* Treatments related to dialectic or Socratic teaching, the teacher directing students to ask questions, the teacher and a student or students engaging in reciprocal dialogue.

2. *Control Difficulty or Processing Demands of Task.* Treatments that included short activities, level of difficulty controlled, teacher providing necessary assistance, teacher providing simplified demonstration, tasks sequenced from easy to difficult, and/or task analysis.

3. *Elaboration.* Treatments that included additional information or explanation provided about concepts, procedures, or steps, and/or redundant text or repetition within text.

4. *Modeling by the Teacher of Steps.* Treatments that included modeling by the teacher in terms of demonstration of processes and/or steps the students are to follow to solve the problem.

5. *Small Group Instruction.* Treatments that included descriptions about instruction in a small group, and/or verbal interaction occurring in a small group with students and/or teacher.

6. *Strategy Cues.* Treatments that included reminders to use strategies or multi-steps, use of "think aloud models," and/or teacher presenting the benefits of strategy use or procedures.

In contrast, the important instructional components that significantly increased the ESs for word recognition were:

1. *Sequencing.* Treatments included a focus on breaking down the task, fading of prompts or cues, sequencing short activities, and/or using step-by-step prompts.

2. *Segmentation.* Treatments included a focus on breaking down the targeted skill into smaller units, breaking into component parts, segmenting and/or synthesizing components parts.

3. *Advanced Organizers.* Treatments included a focus on directing children to look over material prior to instruction, directing children to focus on particular information, providing prior information about task ahead, and/or the teacher stating objectives of instruction prior to commencing.

The importance of these findings is that only a few components from a broad array of activities were found to moderate treatment outcomes. Regardless of the instructional focus (math, writing, reading),

two instructional components emerged in Swanson et al.'s analysis of treatments for children with LD. One component was explicit practice, which included activities related to distributed review and practice, repeated practice, sequenced reviews, daily feedback, and/or weekly reviews. The other component was advanced organizers, which included: (a) directing children to focus on specific material or information prior to instruction, (b) directing children about task concepts or events before beginning, and/or (c) the teacher stating objectives of the instruction.

There is a note of caution when interpreting best evidence studies. This is because the results of "best evidence studies" (or in this case, studies reporting on effective instruction) are influenced by a host of moderating variables. For example, in the Swanson and colleagues' meta-analysis (Swanson & Hoskyn, 1998; Swanson et al., 1999), all studies for comparative purposes had well-defined control groups and treatments and/or baseline conditions before their inclusion in the synthesis. The synthesis eliminated the analysis of all studies of poor methodological quality (see Valentine & Cooper, 2005, for a rationale). Simmerman and Swanson (2001) analyzed these best evidence studies and found that slight variations in the internal and external validity significantly moderated the magnitude of treatment outcomes.

More specifically, Simmerman and Swanson (2001) analyzed studies in the Swanson et al. (1999) synthesis and found that slight variations in the internal and external validity moderated that magnitude of treatment outcomes for students with LD. Violations that were significantly related to treatment outcomes included the following:

- teacher effects (studies that used the very same experimenter for treatment and control in administering treatments yield smaller ESs than those studies that used different experimenters in administering treatments);
- establishment of a criterion level of instructional performance before moving to the next level (studies that specified performance criteria yield significantly larger weighted ESs than those that did not);
- reliance on experimental measures (studies that did not use standardized measures had much larger ESs than those that reported using standardized measures), using different measures between pretest and post-test (larger ESs emerge for studies that used alternative forms when compared to those that used the same test);

- use of a heterogeneous sample in age (studies that included both elementary and secondary students yielded larger ESs than the other age level conditions);

- and use of the correct unit of analysis (those studies that applied the appropriate unit of analysis [i.e., when small groups were presented, the interventions and the unit of analysis was groups instead of individuals], yield smaller ESs than those that used the incorrect unit of analysis).

Furthermore, studies that left out critical information inflated treatment outcomes in a positive direction. The under-reporting of information related to the following yielded larger ESs than those that positively inflated the magnitude of treatment outcomes:

- ethnicity (studies that reported ethnicity yielded smaller ESs than those that did not report ethnicity);
- locale of the study (larger ESs occurred when no information was provided about the locale of the study);
- psychometric data (larger ESs occurred when no psychometric information was reported when compared to the other conditions); and
- teacher application (studies that provide minimal information in terms of teacher implications and recommendations yielded larger ESs than those that provide more information).

The magnitude of ESs was also influenced by whether studies relied on federal definitions (studies that did not report using the federal definition yielded a larger weighted effect score than those that did) or reported using multiple definitional criteria (studies that included multiple criteria in defining their sample yielded smaller ESs than those that did not report using multiple criteria) in selecting their sample. In addition, they found that some methodological variables that influenced the magnitude of ESs were not violations of internal or external validity, but rather were moderating variables that appear to maximize the effects of treatment. These variables relate to the instructional setting (small instructional groups yield larger ESs than individual or large group instruction), direct teaching of transfer (studies that trained for transfer to different abstract skills yield larger ESs than those that do not), and the degree to which treatments were implemented as intended (studies that indicated the specific sessions in which treatment integrity was assessed yielded larger ESs than those

that did not). In sum, studies considered as “best evidence” for intervention effects must be carefully scrutinized.

More importantly, when applied to the issues of assessment, studies that left out critical information commonly used in most assessment test batteries (e.g., IQ and achievement scores) greatly inflated treatment outcomes. More specifically, the analysis addressed the question, “Does it matter, in terms of treatment outcomes, whether samples with LD have high or low IQ scores or have large or minimal discrepancies between IQ and achievement or if such children are merely defined by cut-off scores?” Quite simply, do variations in how samples with LD are defined interact with treatment outcomes? No doubt, research efforts in search of definition  $\times$  treatment interactions may suffer the same fate as research that has focused on aptitude  $\times$  treatment interactions. These latter interactions among children (either with or without LD) have been equivocal, and few studies have shown that children are differentially responsive to teaching methods. However, this may be because, among other things, aptitude and treatment are multivariate variables. One means of evaluating whether aptitude variations in the LD sample interact with treatment is to compare the relationship between treatment outcomes with multivariate data that include different configurations of how samples with LD are defined. This can be accomplished by placing studies on the same metric (effect size) and comparing the magnitude of these outcomes as a function of variations in the sample definition (e.g., on measures of intelligence and reading).

Thus, we briefly review some of the results of Swanson et al. (1999) testing whether variations in how the samples of students with LD are defined interact with treatment outcomes. Specifically, we review whether (a) those studies that include samples with large differences in intelligence and reading (defined by discrepancy criteria) and/or (b) those studies defined by cut-off score criteria (children and adolescents with LD suffer a discrepancy between their actual achievement and their expected level of achievement based upon IQ scores) yield quantitatively different outcomes as a function of the type of treatment (e.g., strategy or direct instruction) when compared to competing conditions.

The two aptitude measures (intelligence and reading) were isolated because they are the most frequently reported psychometric measures across all studies. Thus, aptitude in this context is defined narrowly by focusing only on variations in reported

intelligence and reading scores across studies. Various treatments in the synthesis were categorized as reflecting a critical threshold of instructional components related to strategy instruction (SI), direct instruction (DI), and/or both instructional models (SI + DI). The models of instruction were operationally defined as the occurrence or nonoccurrence of specific instructional components (to be described in the methods section) reflected in the treatment description (see Swanson et al. 1999, for a detailed description). Based upon a set number of activities, studies were classified as a Combined SI and DI model (referred to as the combined model), DI-alone (DI), SI-alone (SI) and a model (non SI & non DI) that failed to reach a critical threshold of “reported” information. We drew upon the literature to operationalize direct instruction and strategy instruction approaches. Several reviews suggested that direct instruction emphasizes fast-paced, well-sequenced, highly focused lessons. The lessons are delivered usually in small groups to students who are given several opportunities to respond and receive feedback about accuracy and responses (see Kaméenui, Jitendra, & Darsch, 1995, for a review of model variations). Those activities coded that reflect direct instruction in the present synthesis include breaking down a task into small steps, administering probes, administering feedback repeatedly, providing a pictorial or diagram presentation, allowing for independent practice and individually paced instruction, breaking the instruction down into simpler phases, instructing in a small group, teacher modeling a skill, providing set materials at a rapid pace, providing individual child instruction, teacher asking questions, and teacher presenting the new (novel) materials. A second instructional variable coded was strategy instruction. Components related to effective strategy instructional programs are reviewed elsewhere (see Wong, Harris, Graham, & Butler, 2003, for review). Based upon these reviews, we categorized studies as reflecting strategy instruction if they include at least three of the following instructional components: elaborate explanations (i.e., systematic explanations, elaborations, and/or plans to direct task performance), modeling from teachers (i.e., verbal modeling, questioning, and demonstration from teachers), reminders to use certain strategies or procedures (i.e., cued to use taught strategies, tactics, or procedures), step-by-step prompts or multi-process instructions, dialogue (i.e., the teacher and student talk back and forth), teacher asks questions, and teacher provides only necessary assistance. Based upon these criteria,

studies were classified into one of the four aforementioned models: (SI + DI, SI-alone, DI-alone, or non SI and non DI). As a validity check on our classifications, we compared our classification of the treatment conditions with that of the primary author's general theoretical model and/or the label attached to the treatment condition. There was substantial overlap (approximately 70 percent of the studies) between those studies we classified as DI and strategy instruction models with the primary authors' titles or descriptions of the independent variables. For example, frequent terms provided by the author were strategy, cognitive intervention, monitoring, metacognition, self-instruction, and cognitive-behavior modification for the strategy model. Those that were classified as DI by our criteria used such labels as directed instruction, advanced organizers, adapting materials, corrective feedback, or direct computation.

Although the majority of studies had samples identified as LD, studies varied tremendously on the criteria and detail for participant selection. In terms of reporting group mean scores on psychometric information, only 104 studies reported group mean scores for intelligence, 84 studies reported group mean scores on achievement scores in reading, and 22 studies reported group mean scores in mathematics. Beyond IQ, reading, and mathematics scores, psychometric information on other characteristics of the sample was infrequently reported (< 3% of the studies). In terms of those studies that reported scores, 83.7 percent of the studies that reported IQ scores used tests from the Wechsler series (e.g., WISC-III) as the measure of intelligence, and 80 percent of the studies that reported achievement scores used the Wide Range Achievement Test, Peabody Individual Achievement Test, Woodcock-Johnson Reading Mastery Test, or the reading section (cluster) from Woodcock-Johnson Psycho-educational Inventory as the measure of reading achievement. The mean reported treatment IQ for the LD sample was 93.51 (SD = 16.51, range of 85 to 115). Of those studies reporting standardized reading scores (42%), the mean reported standard score was 71.44 (SD = 25.38). For the studies that report descriptive criteria for selecting subjects identified as LD, 73 percent mention the concept of a discrepancy between achievement and IQ, and differences in IQ and achievement scores, and/or that children with LD were presently placed in a special education class (e.g., pull-out classroom).

Table 36.2 shows the variations in ES as a function of the reported sample psychometric characteristics.

The table shows the total sample of students with LD, number of studies in each category, unweighted ES, standard deviation, and weighted ES, averaged within each study. The general pattern was that studies that fail to report psychometric information on participants with LD yield significantly higher ESs than those studies that report psychometric information. For example, as shown in Table 36.2, studies were categorized by the amount of psychometric information reported. Four categories were developed for comparisons (no information, standardized intelligence test scores, standardized intelligence scores + standardized reading test scores, and standardized intelligence test scores + reading scores + mathematics scores). The results indicated that those studies providing no psychometric information on the LD sample produced significantly larger ESs than those studies that reported intelligence, reading, and/or mathematics scores. No significant differences (all  $p > .05$ ) were found between those studies that reported intelligence scores and those that reported standardized intelligence scores and reading and/or mathematics scores. Our best explanation for this pattern is that samples that are poorly defined in the assessment process inflate treatment outcomes by introducing greater heterogeneity into the sample when compared to studies that select samples based upon psychometric criteria.

Given that psychometric information is related to ES, the reported sample characteristics were further categorized by the reported range in intelligence scores and the reported range of reading scores. As shown in Table 36.2, three categories for comparison were created for intelligence: those studies that reported mean standard scores between 85 and 92, those that reported mean standardized intelligence scores greater than 91, and those that did not report standardized information. If studies provided multiple IQ scores (verbal, performance, nonverbal, etc.), these scores were averaged within studies. As shown in Table 36.2, the results indicated that the highest ESs occurred when no information about IQ was presented (.77) when compared to conditions that reported IQ (.60 range). No significant differences in ES emerged between studies that report high-average or low-average IQs.

The next category considered in our sample analysis was reading severity. The majority of studies that reported reading scores included measures of word recognition. If multiple standardized reading measures were provided in the study, reading scores were averaged across word recognition and reading comprehension. Four categories of reading

**Table 36.2 Effect Size Estimates as a Function of Reported Psychometric Information**

I. All Studies	Sample	N	Mean	SD	Weighted
	Size				Mean

4. > 90					
	293	14	0.69	0.44	0.55

<sup>a</sup>Standard Score Range

level were created for comparisons: scores below 85, scores above 84 and less than 91, scores greater than 90, and no standardized scores reported. The results indicated that ESs for studies that reported scores below 85 were comparable to those studies that reported no scores. The lowest ESs occurred

between studies that reported reading scores between 84 and less than 91 when compared to other conditions ( $p < .05$ ).

In summary, our analysis shows that reported intelligence and reading level in isolation had minimal influence on the magnitude of ES (see Table 36.2).

This was not the case, however, when the simultaneous impact of *both* aptitude variables on treatment outcome was taken into consideration. The important findings were that samples that would be considered as reflecting slow learners (IQ and reading scores in the same low range,  $< 90$  standard score), yielded larger ESs (Mean ES = .95) in terms of treatment outcomes than did children with the same low level of reading but higher IQ scores ( $> 90$ ) (Mean ES = .52). The results also indicated a depressed pattern of performance for studies that reported intelligence scores above 90. For this IQ range, ESs were significantly lower when reading scores were in the 85 to 90 range ( $M = .52$ ) when compared to studies that included severe readers ( $< 85$ ,  $M = .78$ ) and readers in the average range (reading score  $> 90$ ,  $M = .68$ ,  $p < .05$ ).

### **Definition x Treatment**

As previously stated, a combination of direct instruction and cognitive strategy instruction (SI + DI) provided the best evidence-based instructional heuristic for improving academic performance (effect sizes  $>.80$ ) in children with LD across various academic domains. An investigation was conducted to investigate whether various configurations of IQ and reading scores were related to the magnitude of ES as a function of the type of treatment (Swanson & Hoskyn, 1999). The Swanson

and Hoskyn analysis found that the level of cut-off scores (study meets a cut-off score criteria vs. study does not meet cut-off score) significantly interacted with the instructional contrast variables of orientation (SI-alone vs. DI-alone) and Combination (Combined vs. DI-alone & SI-alone). This finding was important because reading scores at or below the 25th percentile in reading recognition and standardized intelligence performance above 84 have been considered as critical cut-off scores for defining LD (e.g., Francis, Fletcher, Stuebing, Lyon, Shaywitz, & Shaywitz, 2005).

Table 36.3 shows the comparison of the studies reflecting the four models that meet or do not meet “cut-off score criteria.” Also shown are the mean IQ and reading scores as a function of the four models. As shown, the ES means for studies that meet cut-off score criterion vs. those that do not were .81 vs. .72, .77 vs. .59, .67 vs. .52, .58 vs. .57 for the Combined model, DI-only, SI-only model, and non DI & non SI models, respectively. The post hoc tests indicated that significant differences emerged in favor of the Combined model (Combined  $>$  DI-only = SI-only = non DI & non SI). Except for studies that did not reflect either strategy or direct instruction, the remaining models yielded higher ESs when studies met cut-off score criteria when compared to studies that do not meet criteria.

**Table 36.3 Effect Sizes as a Function of Instruction and Definition (Cut-off Scores)**

	Sample N	Study N	Effect Size	IQ Scores	Reading Scores
<b>Strategy Instruction—Alone</b>					
	544	15	0.67	93.5	73.94
	1,514	42	0.52	100	92.00

Effect Size = Mean Weighted Effect Size

## **Summary and Implications**

The obvious implication is that variations in IQ and reading have relevance to the magnitude of instructional outcomes. On this issue there are two important findings: First, studies that produced the highest ESs reported both intelligence and reading scores in same low average range (intelligence scores between 84 and 91 and reading scores between 84 and 91) when compared to other studies reporting higher IQ (intelligence scores > 91) but low reading scores (scores between 84 and 91). Although these findings are not related to a particular type of treatment, they support the notion that greater changes emerge in studies whose samples have mean intelligence and reading scores in the same low range (we refer to this sample as a nondiscrepancy or low-discrepancy group).

Second, outcomes related to an instructional approach (e.g., SI, DI) vary across studies that can be separated into those that meet operational definitions (meet cut-off score criteria) and those that do not meet operational definitions. ESs were higher for strategy instruction and/or direct instruction for studies that meet cut-off score criteria when compared to studies that do not meet cut-off score criteria. Thus, the magnitude of outcomes for both direct instruction and strategy instruction models are moderated by sample variations in IQ and reading.

What are the implications of our findings for assessment? There are two clear applications: First, groups of students at risk for LD who have aptitude profiles similar to generally poor achievers or slow learners (low IQ and low reading), produced higher ESs than those samples whose level of IQ is higher than the level of reading. Second, we identified a general approach to instruction (strategies + direct instruction) that remains robust across a diversity of studies.

## **Traditional Assessment in the Context of RTI**

We would be remiss in discussing the link between assessment and effective instruction if we did not discuss links to current procedures referred to as response to intervention (RTI). RTI models are partially based on intervention programs that have distinguished children experiencing academic difficulty due to instructional deficits from those with disability-related deficits (Al Otaiba & Fuchs, 2002; Fuchs & Fuchs, 2006; Vellutino, Scanlon, Sipay, Small, Pratt, Chen, et al., 1996). The RTI model identifies whether a student's current skill

level is substantially lower than the instructional level (based on predetermined criteria: e.g., below the 25th percentile in reading achievement). Low academic performance is established using standardized, norm-referenced and/or curriculum-based measurements (Compton, Fuchs, Fuchs & Bryant, 2006; Fuchs, Fuchs, & Compton, 2004). After establishing low performance, empirically based interventions are implemented to determine if a disability is present. Student progress is monitored during the intervention. The impetus for using RTI models for identifying children at risk for learning problems has been partly in response to validity issues related to using discrepancy criteria in defining LD. The controversial question has been whether IQ is a relevant construct in the assessment process. Some research has argued that IQ has little relevance in the assessment process when groups are defined at low levels of reading (e.g., Francis, Fletcher, Stuebing, Lyon, Shaywitz, & Shaywitz, 2005). This question is important since the Individuals with Disabilities Education Improvement Act (IDEA, 2004) and the final regulations published August 14, 2006, by the federal government recognized potential problems with the IQ-discrepancy method for the diagnosis of children with LD. Three criteria were included in IDEA (2004) to better identify children with LD:

1. States are not required to use a severe discrepancy between intellectual ability and achievement.
2. The procedure must include a process where the children's response to scientifically based research interventions is considered in the assessment process.
3. States are permitted to use alternative research-based procedures to determine a specific learning disability.

This law has spurred an intense interest in RTI procedures. We have provided some evidence above that high IQ levels in context of low reading are related to variations in the magnitude of instructional outcomes. However, are variations in IQ important in the assessment process in separating children at risk for RD and those children who are generally poor achievers?

Three meta-analyses addressed this issue prior to the passage of IDEA (2004; Fuchs, Fuchs, Mathes, & Lipsey, 2000; Stuebing, Fletcher, LeDoux, Lyon, Shaywitz, & Shaywitz, 2002; Hoskyn & Swanson, 2000). The contradictions in the three meta-analyses are reviewed in Stuebing et al. (2002). Stuebing et al. considered the Hoskyn and Swanson (2000)

selection process of studies most conservative of the three, and therefore I want to highlight the findings related to the relevance of IQ. Hoskyn and Swanson (2000) analyzed only published literature comparing children who were poor readers but either had higher IQ scores than reading scores or had IQ scores commiserate with their reading scores. The findings of the synthesis were consistent with previous studies outside the domain of reading that report on the weak discriminative power of discrepancy scores. Although the outcomes of Hoskyn and Swanson's synthesis generally supported current notions about comparable outcomes on various measures among the discrepancy and non-discrepancy groups, verbal IQ significantly moderated ESs between the two groups. That is, although the degree of discrepancy between IQ and reading was irrelevant in predicting ESs, the magnitude of differences in performance (effect sizes) between the two groups was related to verbal IQ. Hoskyn and Swanson (2000) also found that when the ES differences between discrepancy (reading disabled group) and non-discrepancy groups (low achievers in this case) on verbal IQ measures were greater than 1.00 (the mean verbal IQ of the reading disabled [RD] group was approximately 1.00 and the verbal IQ mean of the low achieving [LA] group was approximately 85) the approximate mean ES on various cognitive measures was 0.29. In contrast, when the ES for verbal IQ was less than 1.00 (the mean verbal IQ for the RD group was approximately 95 and the verbal IQ mean for the LA group was at approximately 90), estimates of ES on various cognitive measures was close to 0 ( $M = -0.06$ ). Thus, the further the RD group moved from IQs in the 80 range (the cut-off score used to select RD samples), the greater the chances their overall performance on cognitive measures would differ from the low achiever. In short, although the Hoskyn and Swanson's (2000) synthesis supports the notion that "differences in IQ and achievement" are unimportant in predictions of ES differences on various cognitive variables, the magnitude of differences in verbal IQ between these two ability groups did significantly moderate general cognitive outcomes as measured by ESs. Moreover, robust differences on measures between the two groups were found by Fuchs, Fuchs, Mathes, and Lipsey (2000). For example, Fuchs et al. (2000), comparing low-achieving students with and without LD, found moderate ESs ( $ES = .61$ , see p. 94) in favor of low achievers without LD. My point in reviewing these major syntheses of the literature is to suggest that removing IQ from the assessment battery in

classifying children as LD, especially verbal IQ, is not uniformly supported by the literature.

## Summary

The results of these syntheses have enhanced understanding of the potential links between effective assessment and effective instruction in three ways: First, measuring responsiveness of an individual's performance to feedback has long been viewed as an alternative (or complement) to traditional (static) ability assessment (e.g., Dearborn, 1921; see Embretson, 1992, for a review). Dynamic assessment has been suggested to teachers as a means to enhance children's performance and tap potential that might otherwise be undiscovered by traditional testing approaches. For example, children with identical performance on psychoeducational tests may profit differentially from feedback.

Furthermore, DA provides information necessary to design intervention programs. For example, Day and Cordon (1993) provided third-graders with either scaffolding or complete explanations to solve balance scale problems. As children worked on the problems, scaffolding was provided only if someone experienced difficulties. Thus, the procedures determined what children had already learned (pretest or static measure), as well as how easily they learned (the number of hints needed, the number of explanations required, or DA measure). The application of DA also appears practical to most testing situations. That is, increased validity (changes in ES) in the Swanson and Lussier (2001) synthesis was not due to the labor-intensive time spent with children, but was derived from variations in the type of DA model used. Thus, an assessment of the effects of feedback does not require multiple sessions to assess responsiveness (or too much time to be practically feasible). Further, it could be argued that when DA procedures are coupled with static assessment, they may each provide differential weights in predicting learning criteria. Thus, under some circumstances, static measures may have equal or greater weight in predicting response to instruction than DA measures in some children (children with LD), but not others (underachievers).

Second, an effective general model of instruction that combines the components of direct and strategy instruction supersedes other models for children with LD. There has been some lively debate over the years in the literature about whether instruction should be top-down, via emphasizing the knowledge base, heuristics, and explicit strategies; or a bottom-up emphasis that entails hierarchical

instruction at the skill level (e.g., Adams & Carnine, 2003). Based on previous meta-analyses, we conclude that effective instruction is neither a bottom-up nor top-down approach in isolation. Lower-order and higher-order skills interact to influence treatment outcomes. What is clear from the aforementioned syntheses, however, is that varying degrees of success across treatment domains draw from treatments that focus on both high- and low-order instruction (i.e., strategy and direct instruction).

A final application is that the extant literature suggests that significant definition  $\times$  treatment interactions exist across evidence-based studies (see Swanson & Hoskyn, 1999, for review). Individual variations in IQ and reading level are important moderators of instructional outcomes in group design studies (Swanson & Hoskyn, 1998, 1999). Although not reviewed here, IQ and reading level also serve as significant moderators for single-subject design studies (Swanson & Sachse-Lee, 2000). We find in our meta-analysis of intervention studies that variations in standardized IQ and reading influenced the magnitude of treatment effects (Swanson & Hoskyn, 1998). The general pattern in our data is that poorly defined samples (i.e., minimal information on IQ and achievement) inflated treatment outcomes by introducing greater heterogeneity into the sample when compared to studies that selected samples based on psychometric criteria. The influence of IQ scores on the magnitude of the treatment outcomes became especially relevant when reading scores were below the 25th percentile. Thus, the implication of these findings is that variations in IQ and reading cannot be ignored when predicting treatment outcomes and therefore are a critical ingredient to the identification process.
