It has also been shown that, contrary to initial belief, there may be a positive association between discrimination and self-image. One might assume that an individual's self-image would decrease in the face of perceived discrimination but the opposite appears to be true. Perceived

discrimination has been shown to be uncorrelated with adolescents' racial identities. In addition, a positive correlation has been found between perceived discrimination and self-image, indicating that, as adolescents reported more experiences with discrimination, they also tended to report a better self-image (Berkel et al., 2009). In addition to causing a boost in self-image, perceptions of discrimination have also been shown to positively affect self-pride. In facing frequent discriminatory events, some youth feel as if they are being “truly socialized” into their own ethnic/racial group and are really beginning to understand what it means to be members of marginalized groups (Berkel et al., 2009).

Additionally, some studies have shown that individuals who are members of ethnic/racial minority groups have a psychological well-being “advantage” over individuals who are members of a majority group, even when controlling for the effects of perceived discrimination/racism (Astell-Burt, Maynard, Lenguerrand, & Harding, 2012). Unfortunately, discriminatory events are rarely ever one-time occurrences; members of ethnic/racial minority groups tend to experience discrimination throughout their lives. However, this “repeated” discrimination effect may also give members of ethnic/racial minority groups a psychological advantage in the face of discrimination relative to members of a majority group who have not experienced such events before (Astell-Burt et al., 2012).

Mental Health Outcomes

The developmental domains of physical health, well-being, socioemotional functioning, and academic achievement have all been shown to be influenced by perceptions of discrimination. It does appear, however, that the domain of mental health is affected most profoundly. Depression, anxiety, internalizing and externalizing problem behaviors, attention-deficit hyperactivity disorder (ADHD), conduct disorder (CD), and antisocial behaviors are just a few of the many mental health consequences that have been found to be predicted by or correlated with perceived discrimination (Almeida, Johnson, Corliss, Molnar, & Azrael, 2009; Behnke et al., 2011; Coker et al., 2009; Gaylord-Harden & Cunningham, 2009; Oppedal, Røysamb, & Heyerdahl, 2005; Simons et al., 2002; Smokowski, Bacallao, & Buchanan, 2009; Smokowski, Chapman, & Bacallao, 2007; Tynes, Umaña-Taylor, Rose, Lin, & Anderson, 2012).

These consequences are far from transitory; longitudinal analyses have shown that most, if not all, of these behaviors become increasingly linked with perceived discrimination

over time (Benner & Kim, 2009; Kim, Wang, Deng, Alvarez, & Li, 2011; Seaton, Caldwell, Sellers, & Jackson, 2008). Gibbons and colleagues (2007), using data from the *Family and Community Health Study* (FACHS; see Cutrona, Russell, Hessling, Brown, & Murray, 2000), established that the effects of perceived discrimination persisted over time. As part of the FACHS, adolescents and their families were interviewed and filled out survey questionnaires on three separate occasions. Discrimination measured at the first time point was significantly related to conduct disorder symptoms at both the first and second time points, such that increases in perceived discrimination were associated with increases in conduct disorder symptoms at time points 1 and 2. Simons, Chen, Stewart, and Brody (2003) found similar results in a study of African American youths—that increases in discrimination as measured at the first time point were associated with increases in affiliations with deviant peers, justified anger, depression/hopelessness, and delinquency at the first time point, as well as delinquency at the second time point.

These detrimental effects are also far-reaching; they cross myriad racial/ethnic groupings, and are present both within and outside of the classroom, school, or neighborhood. These effects are seen both within and outside of the United States; in looking at predictors of mental health in Portuguese adolescents from immigrant families, it was seen that, as adolescents reported more perceived discrimination, they also tended to report more mental health problems (Neto, 1999). In their assessment of the mental health of Somali adolescent refugees, Ellis, MacDonald, Lincoln, and Cabral (2008) and Ellis et al. (2010) uncovered moderate-to-strong correlations between perceived discrimination and symptoms of posttraumatic stress disorder (PTSD), depression, postwar daily life hassles, and acculturative hassles. Increases in discrimination were associated with increases in PTSD symptoms and both daily life and acculturative hassles. In their study of acculturative stress in Arab American adolescents, Ahmed, Kia-Keating, and Tsai (2011) discovered several correlations between perceived discrimination and mental health outcomes; the associations were all moderate and moderate-to-strong. Adolescents who reported more perceived racism also reported more acculturative stress, more depressive symptoms, more anxiety, and more internalizing and externalizing symptoms. As part of a baseline study about working conditions in Salvador, Brazil, Santana, Almeida-Filho, Roberts, and Cooper (2007) conducted in-home interviews to determine the effects of discrimination on the daily lives of adolescents. The researchers determined that, after

adjusting for age, sex, and socioeconomic status (SES), adolescents who reported perceiving discrimination in their lives were 97% more likely to also report symptoms of major depression, and 69% more likely to report feeling unhappy than individuals who did not report discrimination (Santana et al., 2007). Finally, Oppedal (2011) aimed to determine the role of social support in the association between perceived discrimination and mental health among young immigrants in Norway. He discovered that perceived discrimination was indeed related to internalizing symptoms for all Turkish, Somali, Vietnamese, and Sri Lankan adolescents and preadolescents, such that increases in perceptions of discrimination were associated with increases in reported internalizing mental health symptoms.

Depression

Although it is clear that many areas of mental health and functioning are influenced by the perception of discrimination, depression and depressive symptoms seem to be the most frequently measured and often the most strongly associated outcome (Burton, Marshal, Chisolm, Sucato, & Friedman, 2013; Coker et al., 2009; Dabbagh, Johnson, King, & Blizard, 2012; Delgado, Updegraff, Roosa, & Umaña-Taylor, 2011; Simons et al., 2002). Benner and Kim (2009) not only found that depressive symptoms were correlated with perceived discrimination among Chinese American adolescents, but, further supporting the notion that adolescents tend to perceive more discrimination as they age, they found that perceptions of discrimination increased from their first to their second wave of data collection.

Additionally, perceptions of discrimination may have different mental health outcomes for males and females, particularly in the realm of depression and depressive symptomology (Umaña-Taylor & Updegraff, 2006). In their study of the changes in ethnic identity undergone by Latino adolescents, Umaña-Taylor and Updegraff (2006) discovered a three-way interaction between gender, acculturation, and discrimination in predicting depression, such that, when boys reported low enculturation, there was a negative association between discrimination and depression. For girls, the negative association between discrimination and reported depressive symptomology existed across the board—for those who reported high enculturation, and for those who reported low enculturation.

In looking at the outcome measures of depressive, ADHD, ODD, and CD symptoms, Coker et al. (2009) discovered that children who reported perceived ethnic/racial discrimination were at the highest risk for experiencing

depressive symptoms—children who perceived discrimination were almost 3 times more likely to report symptoms of depression than youths who did not perceive discrimination. Potochnick and Perreira (2010) found that first-generation immigrant Latino youth who had *ever* experienced discrimination in their lives were almost 8 times more likely to report symptoms of depression than immigrant adolescents who had never experienced any discrimination. In their study of the relation between perceived discrimination and depressive symptoms among Turkish-Dutch and Moroccan-Dutch individuals in the Netherlands, van Dijk, Agyemang, de Wit, and Hosper (2010) presented more conservative but still significant numbers. Individuals who reported experiencing personal discrimination were 3.2 times more likely to report depressive symptoms than individuals who did not report experiencing personal discrimination. Consequently, this association was stronger for Moroccan-Dutch individuals (5.32 times more likely) than it was for Turkish-Dutch individuals (2.76 times more likely). Overall, Moroccan-Dutch individuals were 2.8 times more likely to experience depressive symptoms than Turkish-Dutch individuals, although this relationship was dependent on the extent to which they experienced school-based discrimination. Similarly, Grossman and Liang (2008) found that discrimination distress was positively associated with depressive symptoms, such that increases in discrimination distress were associated with increases in depressive symptoms. Simons et al. (2003) found that, in addition to being correlated with increases in anger, aggression, and delinquency, increases in perceived discrimination were also associated with increases in reported depression/hopelessness for both male and female African American adolescents.

Externalizing Problems

Although any and all mental health issues are problematic, externalizing behaviors, like those associated with conduct disorder, oppositional defiant disorder, other anti-social behaviors, and ADHD often make themselves more apparent to those surrounding the individual, and perhaps warrant the most immediate attention. These behaviors are captured both via individual self-report and parent report; for example, Szalacha, Erkut, García Coll, Alarcón, et al. (2003) found that the parents of children who reported having been discriminated against reported significantly higher levels of behavioral maladjustment in their children. Rivera and colleagues (2010) found that participants who reported perceived discrimination were more than 15 times more likely to engage in antisocial behaviors

than individuals who did not report discrimination. Anti-social behaviors are generally viewed as symptoms of oppositional-defiant disorder (ODD) or conduct disorder (CD) and include, but are not limited to, aggression toward people or animals, destruction of property, deceitfulness or theft, and/or serious violation of rules (American Psychiatric Association, 2000).

Roberts and colleagues (2012) found that increases in perceived discrimination were associated with moderate-to-strong increases in negative affect over time, affiliations with deviant peers, and engaging in risky sexual behaviors (i.e., having unprotected sex, having sex with multiple partners). Negative affect was found to mediate the effects of discrimination on deviant affiliations at two of the study's four time points. Discrimination was also found to have an indirect effect on risky sexual behaviors through deviant affiliations and through negative affect at three of the four time points. Further, according to Coker et al. (2009), children who felt that they had been discriminated against in the past were more than 2 times more likely to report symptoms of conduct disorder, 60% more likely to report symptoms of ADHD, and 80% more likely to report symptoms of oppositional defiant disorder (ODD) than children who did not report any perceived discrimination. Smokowski et al., (2007) found that perceived discrimination was positively correlated with Achenbach's Youth Self Report (YSR) social problems scores, total behavior problems, and other externalizing problem scores (perceived discrimination was also associated with total internalizing problem scores on the YSR).

Aggression

Brook, Rosenberg, Brook, Balka, and Meade (2004) and Brook, Brook, Balka, and Rosenberg (2006) also uncovered a relation between discrimination and aggressive behavior in their studies of the correlates of aggression in both African American and Puerto Rican children and adolescents. Brook et al. (2004) discovered that both the experience of discrimination and low levels of ethnic identification (as assessed via combining levels of ethnic identity affirmation and belonging) were positively and moderately associated with child aggression. Ethnic identification and discrimination explained aggression in the presence of all other study variables, indicating that an increase in discrimination and low ethnic identification predicted child aggression. However, when controlling for the mother-child relationship and the child's personality and behavior attributes, this relation was no longer significant. This change in significance may indicate that

there are other factors, such as the children's own unique personality and behavior styles, and the parenting styles their caregivers had employed, that play important roles in the impact of perceived discrimination on aggressive behavior (Brook et al., 2004).

Similar relations were observed by Brook and colleagues (2006) and Simons and colleagues (2006) with adolescent cohorts; perceived discrimination was positively associated with rebellious adolescent behavior and violent delinquency. However, Brook et al. (2006) were also able to ascertain that ethnic identity achievement, ethnic identity affirmation and ethnic belonging were negatively associated with rebellious adolescent behavior. Increases in discrimination were associated with increases in rebellious behavior in adolescents, whereas increases in affirmation and belonging as well as ethnic identity achievement were associated with decreases in rebellious behavior (Brook et al., 2006). Ethnic identification and discrimination both explained rebellious behavior in the presence of all other predictor variables, indicating that an increase in discrimination predicted rebellious adolescent behavior. However, when controlling for school environment or the children's personality and behavior attributes, this relation was no longer significant.

In addition to aggressive tendencies, Simons et al. (2006) demonstrated that discrimination was associated with both anger and hostility in a sample of African American adolescent males and females. However, the results also indicated that supportive parenting had a moderating effect on the relation between discrimination and violent delinquency. The deleterious effects of discrimination were less for males who also reported high levels of supportive parenting. On the other hand, anger and hostile view of relationships increased the effect of higher levels of discrimination on violent delinquency.

Violence

Although exposure to drugs and violence are often attributable to "third" factors, Surko, Ciro, Blackwood, Nembhard, and Peake (2008) uncovered relations between perceived discrimination and such exposures. Early adolescents reporting racism were more likely to have witnessed violence, and were more likely to have been victims of violence than adolescents who did not report racism. The experience of racism was also associated with most risk indicators for most middle adolescents (related to drug use and violence), and was associated with a substantially higher risk for having been threatened with weapons, having been victims of violence, having been touched

uncomfortably, and having used drugs in the prior month. Late adolescents reporting racism were more likely to report environmental risks such as having been threatened by weapons, having been victims of violence, having been touched uncomfortably, and being able to access guns. It is also important to note that females, but not males, who experienced racism were more likely to also report being touched uncomfortably, being offered drugs, and trying drugs other than tobacco, alcohol, or marijuana. Males, but not females, who experienced racism were more likely to have had sex and to have used drugs in the month prior to the onset of the study.

Negative Affect

Vera and colleagues (2011) have also demonstrated the link between perceived discrimination and negative affect. In their examination of culturally relevant stressors, coping, and ethnic identity in urban, ethnic minority adolescents, a moderately strong positive correlation was found between negative affect and perceived discrimination such that, as levels of perceived discrimination increased, so did assessed levels of negative affect. However, the results also indicated that a coping style that was considered "avoidant" moderated the relation between urban hassles/perceived discrimination and negative affect, such that individuals who used avoidant coping did not experience the deleterious relation between urban hassles/perceived discrimination and negative affect.

Intelligence

Although not typically considered to be in the mental health domain, perceptions of discrimination have also been shown to adversely affect children's performance on tests of nonverbal intelligence (Appel, 2012). Although these effects may be transient, Appel (2012) uncovered that political propaganda in Austria that displayed images and text that discriminated against immigrant populations had a deleterious effect on adolescents' performance on nonverbal intelligence tests. Adolescents who self-identified as being from immigrant backgrounds like those addressed in the anti-immigrant political propaganda performed worse on a test of nonverbal intelligence after exposure to the propaganda than when they were tested before exposure. No such decrease in intellectual performance was shown for immigrant-background participants who were exposed to neutral pamphlets. The intelligence scores of nonimmigrants remained stable before and after both the neutral and anti-immigrant conditions. Closer analyses also revealed a moderating effect of ethnic identity; the

anti-immigrant propaganda significantly affected only the intelligence scores of immigrant-background adolescents who reported low ethnic identity (i.e., 1 standard deviation below the sample average). The intellectual performance of immigrant-background adolescents who reported high ethnic identity (1 standard deviation above the sample average) was unaffected by exposure to discriminatory propaganda.

Sexual Orientation Discrimination

In light of these findings, however, it is important to recognize that these substantial mental health consequences do not only arise for children and adolescents who are victims of racial and/or ethnic discrimination; youth who face discrimination based on their sexual orientation status face equally negative consequences (Almeida et al., 2009; Burton et al., 2013). Youth who are victims of discrimination based on their sexual orientation may even face unique mental health challenges that are not faced by victims of racial/ethnic discrimination.

In the expansive literature describing both victims and perpetrators of racial/ethnic discrimination, self-harm and suicide ideation are rarely viewed as common consequences of discrimination whereas in the literature describing victims of sexual orientation-based discrimination, self-harm and suicidal ideation are two of the most frequently measured outcomes (Burton et al., 2013). Heterosexual youth who report sexual-orientation-based victimization also tend to report depressive symptoms; however, the strength of this association is considerably stronger for non-heterosexual youth. Additionally, unlike heterosexual youth, there also appears to be a moderately strong relation between victimization and suicidality for nonheterosexual youth (Burton et al., 2013).

EXAMINING THE DISCRIMINATION-OUTCOME LINKS IN CHILDHOOD AND ADOLESCENCE: ROLES OF MEDIATORS AND MODERATORS

With a wide variety of effects of discrimination observed, we also observed numerous types of potential mediators and/or moderators of these effects. Mediators and moderators can be thought of as underlying or third psychological processes or child characteristics that may attenuate or change the way discrimination influences development. Such mechanisms are key not only to understanding how discrimination influences development, but also for intervening upon or preventing the influence of discrimination on development. Not all of the following factors

are relevant to intervention. Take child age, or gender, for example. Neither are malleable from the point of view of intervention or prevention. They can, however, be key considerations when designing treatments that are developmentally appropriate, and when tailoring preventive efforts to meet the unique needs of females or males. Other mediators/moderators identified here, such as coping skills, may be worth considering when designing direct intervention efforts moving forward.

Child Age

In aiming to recognize the implications of perceived discrimination on child and adolescent development, there are several relevant individual-level child characteristics that need to be taken into consideration as potential mediators and/or moderators. Firstly, child age can play an important role in tempering the relation between perceived discrimination and adverse development outcomes. Both longitudinal and cross-age cohort studies have consistently demonstrated that the associations among perceived discrimination and the developmental and educational domains of mental and physical health, socioemotional functioning, well-being, and academic achievement strengthen with age (Augoustinos & Rosewarne, 2011; Delgado et al., 2011; Seaton, Cadwell, Sellers, & Jackson, 2010). Looking to determine the correlates of risky behavior among siblings, Delgado and colleagues (2011) found that the correlation between perceived discrimination and risky behavior was much weaker for younger siblings than it was for older siblings. For younger children, there was a weak-to-moderate positive correlation between perceived discrimination and risky behavior, such that, as children's perceptions of discrimination increased, so did the intensity and number of the children's risky behaviors. For older siblings, this correlation was much more robust. Using perceived discrimination to explain life satisfaction, Seaton and colleagues (2010) found an interaction between age and perceived discrimination in explaining individual life satisfaction; older adolescents reported greater decreases in life satisfaction in the presence of higher levels of perceived discrimination than younger adolescents. In general, older children and adolescents tended to report more perceptions of discrimination than younger children and adolescents (Romero & Roberts, 1998).

It has also been documented that older children and adolescents are more likely than younger children to cite discrimination as the reason for the differential treatment of others (Bigler, Arthur, Hughes, & Patterson, 2008).

In their study of children's reasoning about the lack of diversity in past and present U.S. presidents, Bigler et al. (2008) demonstrated that 9- to 10-year-olds were almost 3 times more likely to attribute the lack of African American presidents to institutional and personal discrimination than both 5- to 6-year-olds and 7- to 8-year-olds. As would be expected, compared with racial majority children, ethnic/racial minority children were also more likely to attribute discrimination in both ambiguous and nonambiguous situations in which there may have been differential treatment of European American children and children of their race (Brown, 2006). Further, this relation has been shown to be moderated by theory of mind capabilities—it appears that these abilities are needed in order for children to make discrimination designations when they are not directly involved (i.e., they are neither victims nor perpetrators; Brown, 2006).

This is not to say, however, that younger children are completely immune to the adverse effects of perceived discrimination. Coker and colleagues (2009) demonstrated that children as young as 11 years (and likely even younger, as well) may be at risk for a host of negative developmental outcomes in the face of perceived discrimination. Drawing their data from a cohort of fifth-grade students taking part in the Healthy Passages Study (see Windle et al., 2004), they found that children who reported perceptions of discrimination were almost 3 times more likely to report symptoms of depression than children who did not report perceptions of ethnic/racial discrimination (Coker et al., 2009).

From this collection of findings, it does seem that interventions and particular attention need to be paid to ameliorating the more severe consequences of discrimination as experienced in adolescence. Furthermore, young children are learning to understand and deal with discrimination in their own ways; it may be that teaching healthy coping strategies and promoting positive ethnic/racial socialization at earlier ages may be particularly effective at providing a basis for adolescent resiliency later. If these age-related findings are considered along with cognitive theories of the ways in which children and adolescents develop in social and cognitive domains, it seems clear that both early preventive approaches in childhood and targeted intervention strategies during the adolescent years are needed.

Gender

Whereas age appears to be a central characteristic in children in determining the implications of discrimination, gender has also been shown to significantly moderate the

relation between perceived discrimination and the aforementioned developmental domains. Females not only tend to perceive more discrimination than males, but the association between perceived discrimination and negative developmental consequences (with the exception of self-esteem) is often weaker (or nonexistent) for females than it is for males (Alfaro et al., 2009; Almeida et al., 2009; Behnke et al., 2011; Benner & Graham, 2011; Seaton et al., 2010). As noted above, adolescents' perceptions of discrimination increase over time; however, research indicates that this increase may occur at a slower rate for females than for males (Benner & Graham, 2011). In determining predictors of academic motivation, Alfaro and colleagues (2009) found that perceived discrimination explained academic motivation for males, while this relation was not significant for females.

Not only are gender group differences common in the literature on discrimination and child development, gender itself may help to explain particular ways in which the negative effects of discrimination affect mental health functioning. For example, when perceived discrimination was entered into a model as a mediator instead of as a predictor, Almeida et al. (2009) found that perceived discrimination mediated the relation between lesbian, gay, bisexual, and transgender (LGBT) status and self-harm for males, but not for females. In other words, in the face of higher levels of perceived discrimination, the relation between LGBT status and self-harm was strongest for males. A similar pattern of effects were found for the relation between LGBT status and suicidal ideation, which was also mediated by perceived discrimination for males, but not for females. Shrake and Rhee (2004) obtained similar results in their study of predictors of problem behaviors among Korean American adolescents—perceived discrimination was associated with gender, such that, in general, girls experienced less racial discrimination than boys.

Acculturation

Cultural orientation is another important individual-level child factor to consider when examining the developmental consequences of discrimination in childhood and adolescence. Considering discrimination events in Western cultural societies, several researchers have demonstrated that the stronger an individual's non-Western cultural orientation is, the stronger the relation between perceived discrimination and negative outcomes (Deng, Kim, Vaughan, & Li, 2010). Put another way, when immigrant children identify strongly with their family's culture of

origin, the detrimental effects of perceived discrimination are strongest. It is interesting to consider the possibility that acculturation may negatively influence some developmental domains, such as academic achievement or future aspirations (i.e., the “immigrant paradox”; García Coll & Marks, 2011; C. Suárez-Orozco, Rhodes, & Milburn, 2009), but may also be a positive, protective factor in other domains. In looking solely at the association between chronic daily discrimination and delinquent behavior, Deng and colleagues (2010) uncovered interaction between discriminatory victimization and Western cultural orientation in predicting delinquent behaviors over time. The relationship between perceived discrimination and delinquency was significant for Chinese American adolescents who reported high levels of Chinese cultural orientation, but not for adolescents who reported low levels of American orientation. Additionally, there was a similar interaction found between Western cultural orientation and daily perceived discrimination; when youth reported low levels of Western cultural orientation, the relation between chronic daily discrimination and delinquent behavior was significant. This association was not significant for youth who reported high levels of Western cultural orientation.

In the same study, Deng et al. (2010) found the same interaction between discriminatory victimization and cultural orientation in predicting delinquency—the positive relationship between discriminatory victimization and delinquent behavior was only significant for individuals who reported a low Western cultural orientation. In the face of high levels of discriminatory victimization, the association between discrimination and delinquency was not significant for Chinese American adolescents who reported high levels of Western cultural orientation. Ellis et al. (2010) also found interaction between discrimination and American acculturation in explaining depressive symptoms among Somali adolescent refugees, such that, for adolescents who reported a high level of American acculturation, the relation between perceived discrimination and depressive symptoms was weaker than for individuals who reported a low level of American acculturation.

In their analysis of discriminatory events experienced by Chinese American adolescents, Benner and Kim (2009) used a longitudinal design and found that respondents who were considered low in American cultural orientation were at greater risk of reporting higher levels of perceived discrimination at the first time point than individuals who were considered high in American cultural orientation at the first time point. Additionally, respondents low in American cultural orientation were more likely to report more

frequent depressive symptoms and feelings of alienation. Brittan et al. (2013) found similar results in their study of the mediating role of Mexican American values on the negative relationships between perceived discrimination and prosocial tendencies. Their results indicated that there were correlations between adolescents’ perceptions of discrimination and Mexican American values over time, such that increased perceptions of discrimination at the first time point were associated with increased endorsement of Mexican American values at the second time point. Taken together, these findings are consistent with the intergroup and social prejudice theories reviewed previously. It makes sense that, in order for discrimination to have detrimental effects, children or adolescents must first identify with the threatened label or social group (i.e., be high in their culture-of-origin orientation). Once identification occurs, identity threat and psychological distress are likely to follow. These results also provide support for previous studies documenting the need for individuals who face discrimination to seek support and refuge in stronger ethnic/racial identification (Brittan et al., 2013). In further support of this proposition, Romero and Roberts (1998) and Umaña-Taylor and Updegraff (2006) found that perceived discrimination was associated with ethnic identity affirmation and ethnic identity exploration, such that increases in perceived discrimination were associated with increases in both ethnic identity affirmation and ethnic identity exploration. Umaña-Taylor and Guimond (2012) similarly found that discrimination was associated with ethnic identity exploration, affirmation, and resolution over time, although they observed some cross-gender differences. For females, increases in discrimination were associated with increased exploration and resolution, but decreased affirmation. For males, increases in discrimination were also associated with increases in exploration and decreases in affirmation, but remained uncorrelated with ethnic identity resolution.

Ethnic/Racial Identities

In addition to acculturation, ethnic identity is another important factor to consider when assessing the relationship between perceived discrimination and developmental outcomes. Self-esteem has been shown to be related to perceived discrimination, such that increases in perceptions of discrimination were associated with decreases in self-esteem (Cogburn, Chavous, & Griffin, 2011; DuBois, Burk-Braton, Swenson, Tevendale, & Hardesty, 2002; Fisher et al., 2000; Galliher et al., 2011; Umaña-Taylor &

Updegraff, 2006). However, ethnic identity, and more particularly ethnic identity affirmation and ethnic identity achievement, have been shown to moderate this relationship (Greene, Way, & Pahl, 2006). In identifying the trajectories of perceived adult and peer discrimination in Black, Latino, and Asian American adolescents, Greene et al. (2006) discovered that, for adolescents who were low in ethnic identity affirmation, perceptions of discrimination by peers led to a greater decline in self-esteem than for adolescents higher in ethnic affirmation. Ethnic identity achievement had the opposite moderating effect: For adolescents who were high in ethnic identity achievement, perceptions of discrimination from peers led to a greater declines in self-esteem than for adolescents lower in ethnic identity achievement. Ethnicity, in addition to ethnic identity, can also play an important role in determining developmental outcomes of discrimination. Seaton et al. (2008) found that perceived discrimination was, as expected, associated with increased depressive symptomology, decreased self-esteem, and decreased life satisfaction. There was also a significant interaction between ethnicity and perceived discrimination that explained both depression and self-esteem. Both African American and Caribbean Black youth reported high levels of depressive symptoms in relation to high levels of perceived discrimination. However, Caribbean Black youth reported a greater decrease in self-esteem in relation to high levels of discrimination than African American youth.

Similarly, race centrality (i.e., the degree to which people consider their own race as part of their identity and self-concept; Sellers, Smith, Shelton, Rowley, & Chavous, 1998), and has been shown to partially or fully attenuate the relation between perceived discrimination and developmental consequences. Chavous and colleagues (2008) demonstrated that racial centrality mediated the relation between racial discrimination and GPA, such that, for boys who were higher in racial centrality, the negative relationship between racial discrimination and GPA was weakened relative to that for boys who were lower in racial centrality. A similar attenuating effect of racial centrality was evident in the negative relation between racial discrimination and school importance, such that there was a weaker negative relation between racial discrimination and lower school importance for boys who were higher in racial centrality. Similar results were seen for girls. In sum, girls who were from higher SES backgrounds were more vulnerable to the effects of both peer and classroom discrimination on self-concepts. As for males, racial centrality served as

a protective factor in the negative relation between peer discrimination and school importance.

Family Factors

As mentioned earlier, there are several variables that can attenuate the relation between perceived discrimination and mental health outcomes. Family factors such as support, socialization, and family cohesion can also play a regulating role. In their study of adjustment in a cohort of Chinese American adolescents, Juang and Alvarez (2010) found that perceived discrimination was moderately correlated with loneliness, anxiety, and somatization, such that youth who tended to report higher levels of perceived discrimination also tended to report higher levels of loneliness, and more frequently endorsed symptoms of anxiety and somatization. Two interactions were found in determining predictors of these mental health outcomes. The interactions between perceived discrimination and family cohesion in explaining both loneliness and symptoms of anxiety were significant. For individuals who reported higher family cohesion, the relation between perceived discrimination and loneliness, and between perceived discrimination and anxiety symptoms, were significantly weaker than they were for individuals who reported lower family cohesion. In their study of discrimination stress in transracially adopted children, Leslie, Smith, and Hrapczynski (2013) found that individuals who experienced greater discrimination in the past year also tended to experience more depressive symptoms, higher levels of perceived stress, and lower levels of well-being at the time of the second assessment, but this relation was mediated by high levels of parental socialization.

Public and Private Regard

Public and private regard can also both moderate the relation between perceived discrimination and developmental outcomes. Public regard refers to the way individuals make judgments about how the rest of the world views members of their own ethnic/racial group and/or the group as whole. Private regard concerns individual feelings about being members of specific racial/ethnic groups (i.e., how African American individuals feels about being Black or African American; Ho & Sidanius, 2009). Rivas-Drake, Hughes, and Way (2008) have demonstrated that the buffering effects of public and private regard can indeed be different for individuals from different racial/ethnic groups. Whereas increases in peer discrimination were associated

with strong decreases in self-esteem, and strong increases in depressive symptoms, increases in peer discrimination were also strongly associated with decreases in public regard. Additionally, two important three-way interactions were found between ethnicity, peer discrimination, and private regard and between ethnicity, peer discrimination, and public regard. Having a more positive private regard was associated with fewer reported depressive symptoms among African American youth who reported more perceived discrimination; this buffering effect of private regard was not evident with Chinese American youth. Having a more positive public regard was associated with fewer reported depressive symptoms among Chinese American youth who reported more perceived discrimination; this buffering effect of public regard was not shown for African American youth.

Coping Profiles

Seaton (2009) took these analyses a step further and determined that public regard was correlated with both collective/institutional racism and cultural racism, such that increases in collective/institutional and cultural racism were associated with decreases in public regard. Collective racism involves members of a dominant group denying members of a minority group(s) rights and/or privileges (Essed, 1991), while institutional racism refers to the unequal access to goods and services resulting in inequality for minority group members (Jones, 1997). Cultural racism concerns the degrading of minority groups' beliefs and practices by a majority group (Jones, 1997). In assessing participants' experiences with perceived individual, collective/institutional, and cultural racism, individual coping styles were assessed and then categorized into one of three categories: Buffering/Defensive type, Idealized type, and Alienated type based on a cluster analysis by Chavous et al. (2008). Individuals who displayed a Buffering/Defensive coping profile had high levels of race centrality and private regard and low levels public regard, indicating that, whereas they believed others viewed members of their own ethnic/racial group negatively, they believed that their race/ethnicity was important to their identities and positive feelings about being members of their group. The Idealized individuals were high in all areas; unlike the Buffering/Defensive individuals, they believed that people viewed their own racial/ethnic groups in a positive manner. Members of the Alienated group were the opposite—they were low in all areas. In addition to endorsing the beliefs that people negatively viewed their

own racial/ethnic group, they also felt less positive about their groups and felt their race/ethnicity was unimportant to their overall identity.

In using these profiles, Seaton (2009) found a significant interaction between coping types and racism when explaining depressive symptoms, such that high levels of individual racism were associated with greater depressive symptoms for individuals with Alienated coping profiles; the relation was nonexistent for individuals who had Buffering/Defensive profiles. In addition, higher levels of individualized racism were associated with higher levels of depressive symptoms for Alienated youth; the relation was not significant for individuals with Idealized profiles.

THE FUTURE OF RESEARCH ON DISCRIMINATION'S INFLUENCE ON CHILD AND ADOLESCENT DEVELOPMENT

Although there has been a surge of research productivity exploring the effects of discrimination on child and adolescent development, there is a growing sense of urgency and importance for moving this field forward. This forward movement is extremely promising, and at the heart of most researchers' efforts is the desire to help children and adolescents live long, healthy, and happy lives—regardless of their social position of power or their status as "minority" group members. Having summarized the theoretical foundations of this area of scholarship, and presented the results of a systematic review of this nascent literature, we end this chapter with several thoughts intended to help propel this exciting and important line of work forward. The first set of considerations we offer are practical ones: how to think about measurement strategies when conducting research on discrimination as it relates to child development outcomes. The second set of considerations focus on the importance of social contexts and everyday settings (e.g., families and schools) as they may inform children's abilities to respond to discrimination in healing and healthy ways. We believe these two areas represent important areas for future research and intervention efforts alike.

From Theory to Measurement: Capturing Discrimination in Childhood and Adolescence

In order to capture children's perceptions of discrimination and the effects of discrimination on development, numerous measurement strategies have been employed in empirical research. These typically include questionnaire-style

measures (for older children and adolescents who can read and write) and interview questions (for children and adolescents of a wide range of ages), including structured and open-ended questions. The literature also relies heavily on self-report measures, which may not capture the full picture of discrimination in children's experiences or environments. It is important to note that there are many experimental procedures used in the social psychology literature to study stereotypes and prejudice. Here, we are concerned with the current methodological approaches used by researchers attempting to assess the link between discrimination and some developmental processes or outcomes. Of particular interest for assessing the state of the field's understanding of discrimination and its influence on children and adolescents is understanding (a) the constructs and content of measures typically used to assess discrimination among children and adolescents, and (b) how such measures do (or do not) correspond with the predominant theoretical frameworks noted above. As the subfield of developmental psychology dealing specifically with the effects of discrimination on child and adolescent well-being is still emerging, measurement of discrimination and documentation regarding how well these methods may apply to theoretical views (i.e., their validity) is in a nascent stage as well.

Because being able to perceive discrimination is, as defined and presented in the Brown and Bigler (2005) model above, a multifaceted and context-dependent psychological skill with varied cognitive and social components, the measurement of discrimination and its implications for development is itself complex. Because research linking child and adolescent perceptions of discrimination to child developmental outcomes is quite new, it is very common for researchers to self-design and/or tailor their own measures of discrimination—either questionnaires or interviews—sculpting them for the ethnic, racial, cultural, language, and/or religious groups of interest. This is likely due, in part, to the fact that a relatively limited number of previously validated measures have been designed for and with children. Importantly, though, researchers need to use a combination of methods, mixing qualitative interview strategies and questionnaire-type methods, to provide as complete, developmentally appropriate, and nuanced a picture as possible of discrimination in childhood.

Questionnaire-Based Approaches

On paper, most researchers assess discrimination by asking how frequently individuals have perceived discriminatory behaviors occurring either in the past year

(Landrine & Klonoff, 1996) or on a day-to-day basis (Kessler, Mickelson, & Williams, 1999; Williams, Yu, Jackson, & Anderson, 1997). A wide variety of measures have been adopted from the adult literature, largely for use in adolescence. For example, one of the more commonly used measures, the Schedule of Racist Events, has been used and adapted for studies involving adolescents (e.g., Berkel et al., 2009, 2010; Brittian et al., 2013; Brody et al., 2006; Brody, Kogan, & Chen, 2012; Gibbons et al., 2004, 2012). Originally developed for and validated on an adult sample of African Americans, this measure asks respondents to rate how many times a variety of racist events have occurred over the past year and across the lifetime, and how stressful these events were. A sample question is, "How many times have you been treated unfairly by people you thought were your friends because you are Black?" The measure taps multiple contexts for unfair treatment, including schools, workplaces, and even larger "institutions."

A limited number of researchers have endeavored to assess not only the frequency and source of the perceived discrimination, but have also aimed to measure both the stressfulness (Utsey & Ponterotto, 1996) and intensity of these events (Harrell, 1997). For children aged 5–13, for example, Rivera and colleagues (2010) have modified a version of the Hispanic Stress Index as a measure of discrimination. For tapping an individual's simultaneous recognition of and upset by discrimination in his or her life at large (i.e., not attributed to personal experiences, but to observations of society), the Index of Race-Related Stress (Utsey & Ponterotto, 1996) has also been adapted for use in adolescence (e.g., Seaton, 2009). Originally validated and designed with adults (two groups comprised of "Blacks" and "Non-Blacks"), this measure asks the respondent to rate (0 = the event never happened to me, to 4 = the event happened and I was extremely upset by it) items such as "You notice that crimes committed by White people tend to be romanticized, whereas the same crime committed by a Black person is portrayed as savagery, and the Black person who committed it, as an animal."

Linking more to contexts of discrimination, some studies also measure how often discrimination is performed by peers as opposed to adults or teachers (Way, 1997; Wong et al., 2003). For example, Rivas-Drake and colleagues (2008) employed an 18-item binary checklist to measure peer ethnic discrimination in the school context among 10- to 11-year-olds. One of the few measures developed with and for adolescents initially, the Adolescent Discrimination Distress Index, asks questions about perceived discrimination in institutional, educational, and peer domains,

and measures how upsetting those instances of discrimination were (Fisher et al., 2000). This measure is also unique in that it was developed with a multiethnic sample of African American, Hispanic, East-Asian, South-Asian, and Non-Hispanic White public high school adolescents in the United States. It has since been used and adapted by numerous researchers for use in a variety of ethnic and racial adolescent samples (e.g., Benner & Graham, 2011; Grossman & Liang, 2008; Harris-Britt, Valrie, Kurtz-Costes, & Rowley, 2007). The Racism Life Experience Scale (Harrel, 1997) is another frequently used measure. This questionnaire targets racism-related socialization, coping, knowledge, and experience. As with the Index of Race Related Stress, this measure was developed with adults and also captures the frequency and associated distress surrounding race-related discrimination; it too has been adapted for use with adolescents (e.g., Lambert, Herman, Bynum, & Ialongo, 2009; Neblett, Chavous, Nguyen, & Sellers, 2009; Seaton, Yip, Morgan-Lopez, & Sellers, 2012).

Qualitative and Mixed-Methods Approaches

Researchers interested in studying perceptions of discrimination in childhood have a slightly more complex task at hand than those studying it during adolescence. This is due, in large part, to the still-forming social-cognitive and individual-level skills essential for perceiving discrimination during the earlier childhood years (Brown & Bigler, 2005). Additionally, young children may be unable or unwilling to read or write in questionnaire format. It is more common, then, that researchers focusing on the earliest evidence of perceived discrimination rely on interviewing techniques, gathering both qualitative and quantitative data regarding discrimination. Researchers, for example, may combine both quantitative questions with picture and storytelling tasks to elicit perceptions, attitudes, and understanding of discrimination in early childhood. Augoustinos and Rosewarne (2001) used a subset of quantitative items from a foundational measure of childhood prejudice called the Preschool Racial Attitude Measure (PRAM; Williams, Best, & Boswell, 1975), in conjunction with pictorial stimuli and rating scales, to tap into British children's prejudicial beliefs, stereotype knowledge, and racial prejudice in early childhood (5–9 years). Although we noted above a deep and rich history of using experimental approaches (including implicit measurement strategies) to measure intergroup social prejudice and biases in childhood, such methods and measures are currently less common in the literature linking discrimination to childhood developmental outcomes.

In sum, although a wide variety of measurement strategies are currently employed in the developmental literature on discrimination, there are a few areas in need of growth and attention. The first is that the plethora of individually tailored and self-designed scales limits researchers' abilities to validate the constructs captured in different studies, contexts, ethnic/racial groups, age ranges, and other meaningful participant characteristics. There is also a tendency to simply describe the effects of "discrimination" broadly in research results, without acknowledging or describing nuanced differences associated with the use of different measures. For example, a researcher employing a perception of discrimination measure focused on self-related discrimination may be speaking to a meaningfully different developmental process (i.e., social identity) linking perceived discrimination with a health outcome, than a researcher using a measure capturing racism at large in the community (i.e., empathy). In the former case, it is plausible that self-perceived discrimination might undermine some salient aspect of self-identity, thereby causing psychological distress. In the latter case, a measure tapping empathy when others are discriminated against may not show the same type of association with psychological distress. When researchers employ, tailor, or create any given measure of discrimination it is imperative to understand what psychological mechanism and/or construct(s) is tapped by the instrument, in order to interpret and understand fully the "effects" of discrimination in childhood. Nevertheless, researchers oftentimes do not speak with this level of precision regarding the type of construct they have measured and how their results may or may not support theorized processes at play linking perceived discrimination to aspects of the self. Put another way, many researchers measuring discrimination in the hope of linking perceived discrimination to developmental outcomes do so without explaining the underlying theories tapped by the measures they use. In this way, the current literature on the implications of discrimination for child and adolescent development risks describing discrimination "effects" without advancing theories regarding the ways in which these effects occur.

Moving forward, greater attention to theory and construct specificity and detail in measurement strategy will be necessary if we are to unpack (and perhaps ameliorate) the many processes linking perceptions of discrimination to child and adolescent developmental outcomes. For example, combining quantitative and qualitative methods may help contextualize the experiences of discrimination at various points throughout development, providing

bases for updating the field's theoretical understanding of the contexts of discrimination in childhood. Although many researchers have tailored questionnaires to target experiences of discrimination in a variety of settings, relatively little is known about characteristics of the settings themselves as they are directly measured and linked with child and adolescent perceived discrimination and psychological outcomes. Along these lines, widening the toolset to include implicit measures (i.e., measures that tap a construct outside of explicit control) may be a very useful technique for use with ages (e.g., middle childhood) and social groups that are particularly prone to respond in socially desirable ways. For example, if children are socialized to downplay, ignore, or even accept discrimination, these youth may be less likely to report perceiving or being distressed by discrimination than youth who have been socialized to recognize discrimination and name it as such. In this case, differences observed in the frequency of discrimination perceptions or distress caused by discrimination would be attributed to socialization, not to actual experienced or perceived discrimination itself. Some researchers have successfully employed implicit measures in this way (e.g., Brown, 2006), although mixing implicit and explicit measures is far from common. It is interesting that, although the field began using projective tests and implicit measures (e.g., the Clark studies noted above), researchers currently rely heavily on questionnaire-based approaches. It may be time to find a middle ground. Combining implicit with explicit measures, and incorporating quasi-experimental manipulations in naturalistic settings may help draw a deeper picture of the connections among socialization, beliefs, attitudes, and experiences with discrimination in childhood development. Advancing the methodology used to study discrimination in childhood and adolescence may, in turn, promote updates to extant theories and bases for new ones needed to help understand and intervene on behalf of children and adolescents suffering from discrimination.

Discrimination in Context: Considering Everyday Settings

The future of the study of discrimination's influence on child and adolescent development must include a deeper understanding of the everyday social settings in which children experience discrimination. Do the abilities to recognize discriminatory acts in one context (e.g., peer group play at school) translate to the abilities to recognize discrimination in another context (e.g., at the supermarket)?

How can measures be modified to test such hypotheses? Drawing on Bronfenbrenner's (1979, 1986) ecological theory, it is widely accepted wisdom that children's development is influenced by the many groups and institutions with which children interact, including their families, neighborhoods, and schools. Such ecocultural perspectives highlight the importance of the interconnection between nested contexts—how circumstances in one context (e.g., immigrant families) can moderate the influence of another context (e.g., neighborhood schools) on developmental processes. Consequently, individual differences within the same context (e.g., school) are expected as a function of how each individual interacts with the context. Weisner (1996, 2002) and others (C. R. Cooper & Denner, 1998; Gallimore, Weisner, Bernheimer, Guthrie, & Nihira, 1993) have used ecocultural frameworks to examine the adaptation of ethnic/racial minority families and students in the United States. In particular, daily family routines can inform researchers about how a particular family's culturally guided practices at home influence and interact with other ecological niches in demanding and supporting, and, in turn, responding and adapting, to children's own developmental pathways.

As the study of discrimination effects on child development itself evolves, we suggest borrowing from the well-formed line of research by Hughes and colleagues (2006) who have established the central importance of racial family socialization practices for helping prepare Black and African American children for perceiving and responding to racial discrimination. We suggest expanding these lessons beyond racial discrimination to socialize children to understand other forms of discrimination at home, to perceive it and deal with its effects. Research looking at the generalizability of discrimination socialization across contexts (e.g., home and school) and its transportability across contexts as an effective tool is needed.

Schools and Peers

Schools are a major context of influence on ethnic/racial minority youth development (García Coll et al., 1996; C. Suárez-Orozco & Suárez-Orozco, 2001). Specifically, the percentage of minority children, and the percentage of children eligible for federally subsidized lunches at the schools they attend, and whether they attend inner-city, suburban, public, or independent schools have been associated with academic performance among minority children and immigrant youth (Perez, 2001; Portes & Rumbaut, 2001). Schools are highly segregated environments in the United States (Frankenberg, Lee, & Orfield, 2003),

and, as such, do not equally provide the resources critical to children's development. For example, segregation by language skills into particular classrooms can provide a good learning environment for an ESL student, yet it might isolate him or her from mainstream peers and inhibit the acquisition of important cultural capital. In turn, ethnic enclaves are important sources of support for recently arrived immigrant families, even as they differ in their knowledge and the nature of interactions with more mainstream institutions such as schools. Schools and the ethnic enclaves can be simultaneously inhibiting and promoting contexts for a child, depending on the developmental process being ascertained. Thus, for example, an ethnic enclave that on the one hand has not developed the tools to support communication between immigrant families and schools might on the other hand be a cultural safe haven for a child who feels out of place in a mainstream institution (García Coll & Magnuson, 1998; García Coll et al., 1996).

Furthermore, interactions with other students, teachers, and administrators in schools work to shape students' motivations and aspirations to learn. For instance, many researchers have concluded that immigrant children enter the United States with very positive attitudes toward school (Fuligni, 1997; Kao & Tienda, 1995; Portes & Zhou, 1993; C. Suárez-Orozco & Suárez-Orozco, 1995, 2001). On the other hand, some children have more negative attitudes toward school. Phrases like "oppositional" or "adversarial identities" are used to describe the adaptations of some children of immigrants and other children of color toward schooling, especially during adolescence (Ogbu & Simons, 1998; Portes, 1996; C. Suárez-Orozco & Suárez-Orozco, 2001). Nevertheless, from our review of the literature above, it is clear that school environments—including interactions among teachers, students, and peers—exert strong influences on children's academic achievement and outcomes when discrimination is experienced in the school setting. We are at a critical point for deepening our understanding of how multiple settings (e.g., the meso and exosystems) interact with one another to promote or hinder child development among youth exposed to discrimination.

Immigration as a Context and the Role of Social Mirroring

Another area of growth for the scholars of discrimination in childhood is the experience of discrimination specifically in immigration contexts. The number of foreign-born and first-generation U.S. residents has reached the highest level in U.S. history (U.S. Census Bureau, 2002), with international migration and refugee patterns on the rise as well.

Because these new waves of immigration are unparalleled both in size and diversity (ethnicity, language, and cultural origins), there are profound implications for the study of immigration and its influence on child developmental and social processes. This increasing diversification is not one just of skin color, but includes a growing population of children who are multilingual and must learn to form healthy bicultural identities (LaFromboise, Coleman, & Gerton, 1993), managing home and school environments with different cultural practices. How immigrant children and adolescents experience discrimination as migrants or "newcomers"—separate from or in addition to their experiences as minorities in other U.S.-ascribed ethnic or racial groups—is an area of research that is warranted. C. Suárez-Orozco and Suárez-Orozco (2001) depict the many nuances of culture, language, race, and socialization that shape the ethnic identities among children of immigrants. According to that study's description of second-generation Latino youth development, children become aware of the social stratification of race in the United States at an early age. Children are also influenced by their parents' dual frames of reference (i.e., culture of origin and mainstream American culture) to interpret and understand all aspects of their life, including education, socialization with peers, community resources, and their identity. Importantly, C. Suárez-Orozco and Suárez-Orozco (2001) note that the type of ethnic identity development a child goes through is influenced by the family's adaptation (i.e., acculturation) to the United States. In this and other qualitative accounts of immigrant child development (e.g., Portes & Rumbaut, 2001), socialization with peers provides early influence on identity development.

C. Suárez-Orozco and Suárez-Orozco (2001) also have discussed social mirroring theory to explain the toll that repeated and systematically held discriminatory behaviors and beliefs by society at large may have on adolescent self-image and psychological functioning among immigrant youth. The theory, which has its roots deep in anthropological philosophy, has been depicted as the basis for social cognition, such as pretend role-playing, in early childhood. As constructed by Whitehead: "'Social mirror theory' holds that we cannot have mirrors in the mind without mirrors in society. . . . Introspection depends on public performance, for we can discover our own 'subjective depths' by interpreting the 'meaningful objectifications' expressed by others" (Whitehead, 2001, p. 18). It follows from this theory, then, that minority children and adolescents are often faced with negative stereotypes and images about their social group(s) from individuals, other social

groups, and media, which will then be incorporated into the children's own identities and behaviors. Adolescents who belong—either through ascribed or personally identified affiliation—to negatively stereotyped and marginalized social groups (groups placed in a position of low power, for example, Muslim adolescents in post-9-11 U.S. society; Aroian, 2012) therefore suffer increased rates of psychological distress when compared to nonmarginalized youth. Muslim youth and young adults living in the United States who wear traditional dress, for example, are more likely to perceive discrimination than those wearing nontraditional dress (Sirin & Katsiaficas, 2011). Such findings speak to the potency of public perceptions of dress and religiosity for projecting negative social mirroring images and acts of discrimination.

Such negative social-contextual cues and messages, which can emanate from many settings at macro- and microsystem ecological levels, have been documented by children and adolescents in schools and their communities, for example:

“Most Americans think that we are lazy, gangsters, drug addicts that only come to take their jobs away” (14-year-old Mexican boy).

“Most Americans think that we are bad like all Latinos” (12-year-old Central American boy).

“Most Americans think that we don’t exist” (12-year-old Mexican boy). (M. Suárez-Orozco & Suárez-Orozco, 2000, p. 27)

In our own research with mixed-ethnic and mixed-racial second-generation immigrant adolescents, we also saw qualitative evidence of the power of social mirroring for shaping ethnic identities (Marks, Patton, & García Coll, 2011). When asked why a student provided the low rating of “pride” in the cultural immigrant group she selected, one student told us:

I don’t know because when I was little there were a lot of Chinese jokes and I’d feel like “Oh being Chinese, they make fun of Chinese and so they are not as good as Americans.” It could be kind of like racist and so I’d feel like oh I am not as good as Americans.

Although the research base examining the unique psychological and social experiences of immigrant children and adolescents is rapidly growing, more comprehensive examination of threats to well-being—by virtue of being an immigrant and all of the associated biases, prejudices, and stereotypes—is of critical importance. The United

States has seen unprecedented diversity among its child population in the past few decades, alongside sometimes extreme and polarizing political rhetoric about how to handle America’s borders. How immigrant children understand themselves, their friendships, and their life prospects within this additional level of social stratification in the United States requires new attention.

Final Thoughts

Although we advocate understanding more fully the potentially facilitating and inhibiting influences of everyday settings on the abilities of youth to manage the detrimental consequences of discrimination, we also recognize that children co-construct their own realities. Children do not solely react to their interacting contexts. As Modell (2000) notes, the socio-historical context of development does not have a unique and solely unidirectional influence on children, rather the processes of immigration and their adaptations also change the contexts of schools, neighborhoods and communities. It is likely, then, that discrimination’s influences on child development are not only built from social perceptions, biases, and prejudices from perpetrator to victim, but that there may be victim-related implications for perpetuating discrimination as well. Take, for example, the growing literature on bullying and bullying’s effects on child well-being. It is well recognized that a meaningful portion of victims of bullying (approximately 10%) later become bullies themselves (e.g., Perren & Alsaker, 2006). It is this group—the “bully-victim” group—that is at *greatest risk* for myriad, and severe, behavioral and mental health problems throughout the life course (e.g., both internalizing *and* externalizing problems, along with peer/relational issues as well; O’Brennan, Bradshaw, & Sawyer, 2009). As is the case with cycles of abuse in general—whether bullying, emotional abuse, or discrimination—understanding how discrimination is perpetuated across generations and lifetimes is of great importance. Whether and how victims of discrimination may be prone to becoming perpetrators later, and if so, the unique psychological problems this may incur, has been largely unexamined in the developmental literature. Examining such cycles (which would require longitudinal research—a methodology scant in this area of the literature), in combination with the growing body of literature on mediators and moderators of effects of discrimination on child development, may have profound implications for intervention development. A systematic review of interventions for young children aimed at reducing stereotype and

prejudice (Aboud et al., 2012) revealed very inconclusive and mixed effects. It seems that, if a positive influence is to be made in this vital area of child development, new research into processes, settings, and perpetrator–victim cycles of discrimination are warranted.

Race and Ethnicity	382
Summary and Future Directions	384
TRANSITIONS TO EMPLOYMENT	385
Child and Adolescent Predictors of Employment During the Transition to Adulthood	387

Scholars have long regarded full-time employment, marriage, parenthood, independent residential status, and completion of education as hallmarks of adulthood in Western industrialized societies. The transition to adulthood is a bridging period that links childhood experiences to adulthood. It often affords youth increasing autonomy and experiences in new contexts—experiences that may include status and role transitions or advances toward milestones associated with adult status. It is resoundingly clear from an extensive complement of studies that the transition to adulthood in the United States and Western European countries has become less standardized and more prolonged since the 1960s, with new pathways emerging and greater variability in the timing and sequencing of traditional markers of adulthood (Fussell & Furstenberg, 2005; Fussell & Gauthier, 2005; Mouw, 2005; Shanahan, 2000).

In particular, the post-1960s era brought an increase in the median age of marriage and first childbirth, a delay in departure from the natal household, a steep rise in the proportion of young people obtaining higher education after high school, and an increase in the diversity of young people's living arrangements (e.g., nonfamily households,

college dormitories, or other group quarters), school attendance, marital status, and parenthood status. Scholars have linked these demographic changes to myriad factors, including the widespread democratization of education in the 1960s, increased demands and economic returns for high levels of education and training with declines in manufacturing and industrial jobs, invention of the birth control pill, and less stringent standards of sexual morality (Arnett, 2004; Furstenberg, 2008; Fussell & Furstenberg, 2005; Shanahan, 2000).

Study of the transition to adulthood has a long history in the fields of sociology and demography dating back to the 1960s (Hogan & Astone, 1986), and by the 1990s, was a thriving area of research in life course studies (Shanahan, 2000). It has been enriched by a strong international focus, with sociologists and demographers addressing issues such as how transitions to adulthood pertaining to school, work, and family life vary across Western industrialized countries, the role of institutions, policies, and cultural factors in these cross-national differences (e.g., Cook & Furstenberg, 2002; Fussell & Gauthier, 2005; Gauthier & Furstenberg, 2005), the nature of the transition to adulthood in Asian

countries (e.g., Yeung, Alipio, & Furstenberg, 2013), and the relation between youth migration and transitions to adulthood in developing countries (Juarez, LeGrand, Lloyd, Singh, & Hertrich, 2013).

Since 2000, increasing numbers of scholars in developmental science have turned their attention to the transition to adulthood as an area of study, prompted by Arnett's (2000) highly cited article in *American Psychologist* and the intense focus in the popular media on delays in the transition to adulthood. Arnett, a developmental psychologist, posited that the delay and wide variability in the timing and sequencing of traditional markers of adulthood have given rise to a shift in the criteria for what constitutes adulthood. Specifically, he asserted that traditional demographic markers or roles no longer hold sway among young adults in the United States and other Western industrialized societies as prominent signifiers of adult status, having been replaced by a "psychologized" conception of adulthood that emphasizes individualistic indicators of maturity (e.g., making independent decisions, accepting responsibility for oneself).

Arnett concluded that the late teens and early twenties (roughly the ages of 18–25) have become a distinct developmental period in the life course of individuals in Western industrialized societies—one that he termed "emerging adulthood." Psychological hallmarks of this period in Arnett's conception include the subjective perception of "in-betweenness" (the feeling that one has left adolescence but has not completely entered early adulthood), self-focus, and independent explorations of identity in the area of love, work, and worldviews. It is a time when youth expand their range of personal experiences in anticipation of making the more enduring choices of adulthood. Arnett points out that emerging adulthood is not a universal developmental period, but rather "exists only in cultures that allow young people a prolonged period of independent role exploration during the late teens and twenties" (Arnett, 2000, p. 478). He notes that within some highly industrialized countries, members of minority cultures and youth from working- and lower-class backgrounds may experience a truncated period of emerging adulthood or no emerging adulthood at all because of cultural beliefs or opportunity structures that restrict identity exploration.

The concept of emerging adulthood stands out for its deep resonance among scholars in developmental science. This is reflected in part by biennial meetings on the topic that draw developmentalists from North America, Europe, and other locations, the establishment of the Society for the Study of Emerging Adulthood in 2003, and the launching

of an international journal devoted to research on the topic, *Emerging Adulthood*, in 2013. Nonetheless, the concept is not without controversy. Drawing on demographic data from Canada and Britain, Côté and Bynner (Bynner, 2005; Côté, 2006; Côté & Bynner, 2008) pointed out that the prolonged transition to adulthood, the bedrock of Arnett's emerging adulthood model, is fundamentally a product of social and economic conditions that have made it increasingly difficult for young people to gain entry-level, full-time jobs and to make other transitions that historically have marked the transition to adulthood. Data show that contemporary youth in these countries, like youth in the United States, face more challenges in the labor market than earlier cohorts of youth, including an increasing wage gap with older workers, earnings instability, more temporary jobs, fewer job benefits, more instability in employment, and rapid growth of part-time jobs. These challenges appear to be exacerbated by a diminishing of social norms and increasing social anomie in secular institutions and communities that in earlier decades provided structures that guided youth into adult roles.

Viewed against this backdrop, contend Côté and Bynner, Arnett's model of emerging adulthood "overestimates the extent to which young people can exercise choices that are free of constraints" and "mistakes the coping mechanisms among young people, as they agentically struggle against structural obstacles and normative ambiguities, for freely chosen options to delay their entry into adulthood" (Côté & Bynner, 2008, p. 263). Examples of such coping mechanisms include investment in a wider range of competencies and experiences through part-time jobs and seasonal work that may enhance one's employability and building protective mechanisms of peer group solidarity.

Several considerations have prompted scholars to question the legitimacy of defining emerging adulthood as a distinct developmental period. First, they have noted that psychosocial differences between adolescents and emerging adults seem overdrawn in Arnett's model when juxtaposed with findings from empirical studies. Research to date has not found reliable differences between adolescents and emerging adults in the level and progression of identity exploration. It provides no compelling evidence that exploration of identity is uniquely salient during the targeted age period, that identity exploration is normative during this period, or that identity exploration constitutes the typical pathway through which a clear and coherent sense of self is achieved (Côté, 2006; Kroger, 2007; Meeus, Iedema, Helsen, & Vollebergh, 1999; van Hoof, 1999).

Second, critics have asserted that in his attempt to distinguish emerging adulthood as a developmental period, Arnett oversimplifies the transition from adolescence to adulthood, disregarding the fact that the transition is domain-specific, variable, and reversible and that “the search for identity is a process of recurring moratoria and achievements extending over the entire life span” (Henry & Kloep, 2007a, p. 75). Third, scholars are skeptical about designating emerging adulthood as a “developmental stage” because fundamental conceptual and theoretical questions are unresolved—questions such as, in what ways are those who do not go through the stage of emerging adulthood deficient developmentally and what unique psychosocial competencies versus vulnerabilities accrue as a consequence of passing through versus skipping this stage? Offering their view of stage criteria, Côté and Bynner (2008) asserted that “a developmental stage must add something to development beyond simple change; if a set of experiences does not have predictable value-added consequences other than amorphous change over time, it cannot be considered developmental” (p. 253).

A related concern centers on the fact that Arnett’s model of emerging adulthood is culture-specific and is highly limited in its generalizability (e.g., Henry & Kloep, 2010). Henry and Kloep (2007a) argued that Arnett’s model advances neither knowledge nor understanding of human development, but rather is “merely a description limited to a certain age cohort in certain societies at a certain historical time with particular socioeconomic conditions” (p. 76). They cautioned against elevating to the status of theory a model applicable to a very narrow swath of the human population, noting that “We are now in danger of having a psychology of the affluent middle classes in Western societies, with other groups being seen as deviating from that norm” (p. 76). Henry and Kloep (2007a, 2007b) called for going beyond descriptions and abandoning age stage theories altogether in favor of investigating processes and mechanisms of developmental change. In response, Arnett (2007) pointed out that his model gives recognition of the fact that human development occurs within a historical and cultural context and that emerging adulthood as a period of development appears to be proliferating as economically developing societies enter the global economy.

Questions about the cultural-specificity of Arnett’s model are particularly relevant to the central foci of our chapter—how social class, race, and ethnicity shape the transition to adulthood in the United States and other Western industrialized countries. Arnett suggested that, because of educational and occupational barriers, working-class,

low-income, and ethnic minority youth may be less likely to experience the ages of 18–25 as a period of independent exploration of life options. Following Côté and Bynner’s line of reasoning, what unique psychosocial vulnerabilities or competencies accrue among socioeconomically disadvantaged youth who skip this stage as compared with their counterparts who pass through it? Stigma, discrimination, limitations in the opportunity structure, and excessive stress may indeed circumscribe independent exploration of identity issues and life options in socioeconomically disadvantaged young adults. However, there is a paucity of research that examines these presumptions and even less that illuminates the consequences of constrained opportunities for identity exploration among individuals from these or any other groups (Hart, Atkins, & Ford, 1998; Phillips & Pittman, 2003). Because of the more circumscribed nature of the terms “emerging adulthood” and “emerging adults” as Arnett has defined them, we use the terms “early adulthood,” “transition to adulthood,” “youth,” and “young adults” in this chapter.

Several tenets and concepts of life course theory inform this chapter, one of which is that the developmental antecedents and consequences of life transitions and circumstances vary according to their timing and ordering in the life course (Elder & Shanahan, 2006). Elder and Shanahan asserted that the timing and ordering of role and status transitions relative to age is important partly because (a) social timetables, age norms, and age-graded experiences and sanctions influence individuals, and (b) persons in different developmental stages bring different life histories and personal resources to social roles, and hence, experience these social roles differently.

A second tenet of life course theory central to our chapter underscores the interdependence of significant others in regulating and shaping the timing and ordering of life trajectories (Elder & Shanahan, 2006). It is through this network of shared relationships, both those that are nurturing and protective, as well those that are harsh and adversative, that social and contextual influences are expressed. One aspect of these shared relationships that is particularly important for both economically disadvantaged youth and minority youth is the social capital that can accrue within these relationships. The concept of social capital captures valuable resources such as information and assistance that relationships can provide (Lin, 2001). Because social location limits access to these resources (Bourdieu, 1986; Stanton-Salazar, 1997), particularly resources needed as youth transition to post-secondary education and the labor force, we highlight studies that

examine the role social capital plays as youth make these transitions.

The life course concept of cumulative advantage/disadvantage (Dannefer, 2003; Elder, 1998; Elder & Shanahan, 2006) is also highly relevant to our discussion, because as other scholars have emphasized, youth enter late adolescence and early adulthood with a history of cumulative advantage or disadvantage with different capacities and differential access to resources. Adult transitions are embedded in this complicated web of factors, with the added complication that each transition influences the probability of others occurring (Bozick & DeLuca, 2005; Furstenberg, 2008; Fussell & Furstenberg, 2005). Cumulative advantage/disadvantage refers to the “systemic tendency for inter-individual divergence in a given characteristic (e.g., money, health, or status) with the passage of time” (Dannefer, 2003, p. S327), and resonates with popular adages such as “success breeds success” and “the rich get richer—the poor get poorer.” Dannefer (2003) pointed out that “divergence is not a simple extrapolation from the members’ respective positions at the point of origin; it results from the interaction of a complex of forces” (p. S327). In his view, the concept of cumulative advantage/disadvantage does not deny the importance of agency or individual action, but “demonstrates the power of structural realities within which human agency must operate” (p. S328). Much of the work discussed in this chapter underscores how these structural realities impinge on the adult transitions of youth from low-income and disadvantaged ethnic minority backgrounds.

A “social genome model” developed and tested by scholars at the Brookings Center on Children and Families provided an illustration of cumulative advantage/disadvantage over the life course of Americans (Sawhill, Winship, & Grannis, 2012). Analyzing data from the National Longitudinal Survey of Youth and using widely accepted benchmarks of success for each life stage, they found that children born advantaged retained a large advantage at the end of the next stage (i.e., early childhood), with the same pattern prevailing in subsequent stages. In middle childhood, adolescence, and adulthood, those who succeeded in the previous stage were much more likely to succeed in the following stage than those who did not. Importantly, success at each stage varied by race, ethnicity, and family income.

Another exemplar of cumulative advantage processes particularly relevant to our focus on socioeconomic disadvantage is the lasting effects of the Perry Preschool Project. Conducted in Ypsilanti, Michigan, between 1962

and 1967, the Perry Preschool Project (Berrueta-Clement, Schweinhart, Barnett, Epstein, & Weikart, 1984; Schweinhart et al., 1993) was an intensive early childhood education program that provided daily high-quality center-based care and weekly home visits for 2 years to low-socioeconomic status (SES) families. The program randomly assigned 58 families to the treatment group and an additional 65 families to a control group and followed them both from when the children were in the program all the way through mid-adulthood. At the age of 27, program children had higher educational attainment than control children (71% versus 54% completed high school). They also had higher earnings (29% versus 7%, earning more than \$2,000 monthly), received less public welfare as adults and averaged fewer arrests for criminal activity. Because children participated in the program for only 2 years, the lasting program effects likely represent a process of cumulative advantage. The gains in academic skills and social behaviors that the program induced during early childhood likely translated into more successful school experiences, and ultimately, into positive outcomes across multiple domains in early adulthood. Heckman and colleagues frequently referred to the notion that “skill begets skill” (Heckman & Masterov, 2007, p. 447), and argued that these cumulative processes are a primary reason that investment in early childhood programs are likely to produce greater returns than investments later in the life course (Heckman, 2006).

We cite these exemplars of cumulative advantage/disadvantage in this introduction because the concept functions more as a heuristic for our chapter, due to the relative paucity of relevant studies explicitly focused on the transition to adulthood. It is well-documented that social class, race, and ethnic differences in academic skills and experiences promotive of these skills (e.g., school readiness skills, home-based cognitive stimulation, language use, differential access to educational resources), for example, begin very early in life and accumulate through the early and middle childhood years (Arnold & Doctoroff, 2003; Aronson, 2008a; Rouse, Brooks-Gunn, & McLanahan, 2005). Nonetheless, relatively few studies provide evidence of cumulative advantage/disadvantage by empirically linking these very early differences to class, race, and ethnic differences in educational attainment during early adulthood.

Although child and adolescent experiences undoubtedly have consequences for subsequent development, transitions to adulthood also provide opportunities for discontinuities in development. During the transitions, youth experience new levels of autonomy and enter new contexts that

afford different developmental assets and impose different constraints. These changes have the potential to produce dramatic shifts in one's developmental trajectory. Often referred to by life course theorists as "turning points" (Elder & Shanahan, 2006), these changes highlight malleability in development. Although many turning points emphasized in research represent positive changes (e.g., desisting from criminal behavior), it is important to recognize that features of the transition to adulthood, such as the decrease in structure imposed by institutions and growing awareness of one's status in society, may increase the likelihood that the transition to adulthood becomes a negative turning point for some youth, especially those from disadvantaged backgrounds (Schulenberg, Sameroff, & Cicchetti, 2004). Our chapter presents evidence of both continuity and discontinuity as economically disadvantaged and ethnic minority youth transition from adolescence to early adulthood.

While life course theory provides the primary framing for this chapter, insights from other theoretical models also enhance our discussion. The theoretical work on risk and resilience is especially pertinent to understanding how social location, both in terms of economic disadvantage and race/ethnicity, influences development in the transition to adulthood and how certain contextual factors can promote positive outcomes (Masten, 2001). Resilience researchers distinguish between factors that promote positive outcomes for all youth (promotive factors), and factors that promote positive outcomes only for youth who face risk (protective factors) (Sameroff, 1999, 2010). Thus, from an empirical point of view, a promotive factor will likely have a direct effect on an outcome, while the effect of a protective factor will be seen in its interactions with risk factors. Luthar and colleagues (Luthar, Sawyer, & Brown, 2007; Luthar, Crossman, & Small, Chapter 7, this *Handbook*, this volume) have drawn attention to the need to focus on specific processes that promote positive adaptation within populations, regardless of whether or not the factor is promotive in other populations. Although these types of examinations are not sufficient for determining whether a factor is promotive or protective, they do provide important information about how to promote positive development within a specific at-risk population. Although not always explicitly conceptualized as analyses of promotive factors, much of the research reviewed in this chapter, particularly the research on social capital, in essence examines promotive factors among economically disadvantaged or ethnic minority youths.

Our discussion is also shaped by developmental contextualism theory, which highlights the importance of studying youth from diverse backgrounds and emphasizes the multitude of developmental trajectories that youth may take. Furthermore, developmental contextualism recognizes that relations between individuals and their contexts are the critical forces that shape development (Lerner & Castellino, 2002; Lerner & Kauffman, 1985). These principles undergird our discussion of how the social class, race, and ethnicity of youth shape their transitions to adulthood.

The chapter focuses on four domains of functioning pertinent to the transition to adulthood—conceptions of adulthood, mental health, paid employment, and educational attainment. A section of the chapter is devoted to each domain. Links among these domains are briefly noted throughout the chapter, but more refined analyses of how one domain of functioning influences other domains over time in a cascading fashion are not possible. Tests of cascade models predicting outcomes during early adulthood have not given attention to race, ethnicity, or social class or examined how cascade models vary by social location (e.g., Masten, Desjardins, McCormick, Kuo, & Long, 2010). At the beginning of each section, we provide brief overviews of research assessing direct relations between markers of social location and the domain of interest. However, in keeping with developmental contextualism, we focus most of our discussion on studies that illuminate processes that link social location to the development of youth (mediational processes) and examine sources of variation in developmental pathways among economically disadvantaged and ethnic minority youth, with special attention to the positive end of the risk dimension (i.e., promotive factors). We also highlight protective factors, that is, factors and processes that mitigate the negative effects of economic advantage and ethnic minority status on the functioning of youth during the transition to adulthood, but our discussion is limited by the rarity of such investigations (Burt & Paysnick, 2012). Each major section of the chapter concludes with a summary and discussion of important questions and issues that merit future research attention.

The chapter draws heavily on research based on American samples. We incorporate research findings from youth in Canada and Western European countries, but acknowledge the highly selective and modest nature of this synthesis. This is due in large measure to limitations resulting from our background as American researchers who reside in the United States, in combination with the fact that myriad aspects of transitions to adulthood are country-specific, reflecting institutional, cultural, and

social factors unique to respective countries or geographic regions (Cook & Furstenberg, 2002; Douglass, 2007; Walter, 2006).

CONCEPTIONS OF ADULTHOOD

Conceptions of adulthood encompass beliefs about criteria for adult status, beliefs about the optimal timing of transitions that signify adult status, perceptions of one's own status relative to adulthood, and the basis on which individuals perceive themselves as adults. We highlight key findings about each of these issues in relation to ethnicity and social class and review major studies of how experiences during childhood and adolescence shape adult identity. Many of the findings comport with developmental contextualism and the emphasis in life course theory on the developmental consequences of the timing of life transitions.

Social class and ethnicity may influence young adults' conceptions of adulthood through several pathways, including differential economic resources, differences in the timing of adult transitions, and differences in values. Economically disadvantaged individuals may be less likely than more affluent individuals to subscribe to the idea that certain transitions or personal characteristics are what makes one an adult if economic disadvantage increases the difficulty of making certain adult transitions or attaining particular individualistic criteria of adulthood (M. K. Johnson, Berg, & Sirotzki, 2007a). Consider income in relation to the transition to independent living arrangements. Cross-national survey data from the European Community Household Panel study indicate that in the Nordic cluster (Denmark, Finland, and the Netherlands) and the Southern cluster (Greece, Ireland, Italy, Portugal, Spain), young people's own incomes are significantly related to the probability of leaving home to live on their own. In the Northern cluster (Austria, Belgium, France, Germany, and Britain), parents' income is positively related to their adult children's probability of leaving home to live on their own, indicating that parents with more money may be using some of that money to purchase independence for their children (Iacovou, 2011).

In keeping with this general pattern, data from Britain indicate that middle-class youth experience the most protected and privileged pathways to independent living (e.g., affluent parents sometimes buy accommodations for their children's use while the children are in college, and upon graduation, children may continue to live in the property

to save toward a deposit for a house of their own), whereas those from working-class backgrounds often experience the most challenging pathways, reflected in part by an established link between social disadvantage and shared housing among young people in Britain (Heath, 2008).

In the United States, low-income youth and groups of young adults with higher rates of poverty (e.g., African Americans, Latino Americans) tend to have lower rates of residential independence and higher rates of residence in their parents' home than more affluent youths (Cohen, Kasen, Chen, Hartmark, & Gordon, 2003; Hallquist, Cuthbertson, Killeya-Jones, Halpern, & Harris, 2011; Jekielek & Brown, 2005). The racial gap in residential independence has been especially pronounced among males for several decades (Halperin, 1998), and the economic recession in the United States beginning in late 2007 appears to have exacerbated this disparity. In 2011, 30% of African American men aged 25–34 lived in their parents' homes, compared with 11% of European American men (15%). Comparable figures for African American women and European American women were 11% and 9%, respectively (Mather, 2011).

Differences in the timing and sequencing of adult transitions may be another source of ethnic and social class differences in conceptions of adulthood. In the United States and numerous European countries, both ethnic and social class differences exist in the timing and sequencing of transitions that have traditionally signified adult status (e.g., Dennison, 2004; M. K. Johnson et al., 2007a; McCulloch, 2001; UNICEF, 2001). In Britain, for example, Caribbean, Pakistani, and Bangladeshi women have higher teenage birth rates than White women, and young women from lower-class backgrounds are much more likely to become teenage mothers than those from middle- and upper-class families (Dennison, 2004).

In the United States, African Americans and Latino Americans become parents at earlier ages and are more likely to become parents prior to marriage than European Americans and Asian Americans, whereas Asian Americans, compared with non-Hispanic Whites, African Americans, and Hispanics, attend school for longer periods of time and the age at which they leave home, marry, and become parents is higher (Cohen et al., 2003; M. K. Johnson et al., 2007a). American youth from poor families, compared with their counterparts from non-poor families, are more likely to make early family role transitions (e.g., cohabitation, marriage) (Booth, Rustenbach, & McHale, 2008; Cohen et al., 2003), more likely to leave the parental home before the age of 18, but less likely to do so

after the age of 18, and less likely to experience repeated home leaving (Berzin & De Marco, 2010; De Marco & Berzin, 2008). They are also likely to become parents at earlier ages and prior to marriage than youth from more economically advantaged backgrounds (Berzin & De Marco, 2010; Booth et al., 2008; Hamilton, Martin, & Ventura, 2010; M. K. Johnson et al., 2007a; Pew Research Center, 2009).

Research that examines several role transitions jointly further underscores differences in the timing of adult transitions as a function of family income and other markers of social class. Osgood, Ruth, Eccles, Jacobs, and Barber (2005) classified American youth in a predominantly European American, middle- and working-class sample on the basis of the transitions they had made in five role domains by the age of 24: romantic relationships, residence, parenthood, employment, and education. The social class of the natal families of youth (family income, fathers' and mothers' education) was a strong predictor of the paths of youth through the transition to adulthood. Youth who came from families with considerably lower income and education were more likely to be "fast starters" (those who occupied the greatest number of adult roles), more likely to be "parents without careers" (those with extensive commitments in the realm of family and relationships, but limited involvement in employment), and more likely to be "slow starters" (those who had made the fewest transitions to adult roles). Conversely, they were less likely to be "educated partners" (nonparents with higher levels of education, living with romantic partners), or "educated singles" (non-parents with higher levels of education, not living with romantic partners).

Cultural values may be another source of ethnic differences in the conceptions of adulthood that youth hold. Salient among these include the value of *familismo* among Latino Americans, the emphasis on communalism among African Americans, and the collectivistic orientation of Asian Americans and British Asians. *Familismo*, a cultural value frequently shared across Latino American families, emphasizes family unity and loyalty, prioritizing family over individual needs, and reliance on the family for instrumental and emotional support (Calzada, Fernandez, & Cortes, 2010; Cauce & Domenech Rodríguez, 2002; Halgunseth, Ispa, & Rudy, 2006). Communalism among African Americans reflects a commitment to social connectedness whereby social bonds transcend individual privileges and mutual aid is viewed as a moral code (Allen & Boykin, 1992). The collectivistic orientation of Asian Americans and British Asians is reflected in the strong importance on self-sacrifice for the sake of others

and on the well-being of the family and the group, even at the expense of the individual (Brannen & Nilsen, 2002; Fuligni & Pedersen, 2002; Fuligni, Tseng, & Lam, 1999; Phinney, Ong, & Madden, 2000). These values may orient members of these ethnic minority groups to endorse more strongly than members of majority groups criteria for adulthood that reflect obligations and duties to others—that is, completing socially recognized role transitions (e.g., marriage), fulfilling domestic and family roles (e.g., providing financially for family), and interdependence (rather than independence) (Arnett, 2003).

Beliefs About Criteria for Adult Status

Scholarly interest in the beliefs of youth about criteria for adult status is predicated largely on Arnett's assertions that young adults accord more importance to individualistic indicators of maturity than role transitions as criteria for adult status and that this pattern is a psychological response to social change and an important marker of what distinguishes emerging adulthood from adulthood. His work showed that not only do role transitions have little salience in young people's conceptions of the meaning of adulthood (Arnett, 1997, 2001, 2003), but also that their actual role transitions are largely unrelated to their endorsement of corresponding role transitions as criteria for adulthood. For example, youth in their 20s who were employed full-time were no more likely than those who were employed part-time or not employed at all to endorse full-time employment as a criteria for adult status (Arnett, 1997).

Critics have pointed out the absence of empirical research assessing differences in the criteria current versus earlier cohorts of young adults use as criteria for adulthood. Without knowing how young adults living in earlier times in industrial societies would rank role transitions in relation to psychological criteria, they argue, responses from current cohorts cannot be used to make statements about social change (Shanahan, Porfeli, Mortimer, & Erickson, 2005). Skepticism about Arnett's findings and interpretations is based on several additional issues pertaining to research methodology, including reliance on convenience samples, failure to examine individualistic criteria and role transitions simultaneously in a multivariate framework in favor of a univariate data analytic strategy (Shanahan et al., 2005), and use of close-ended survey instruments with a truncated (yes/no) response scheme (Andrew, Eggerling-Boeck, Sandefur, & Smith, 2007). These factors, critics suggest, may have resulted in an

overly simplistic depiction of young people's subjective conceptions of adulthood.

Although the data are not altogether consistent, overall, neither social class nor race/ethnicity appears to have robust, consistent effects on the beliefs of youth about the criteria for adult status. Furstenberg and colleagues' (Furstenberg, Kennedy, McLoyd, Rumbaut, & Settersten, 2003, 2004) analyses of responses from a nationally representative sample of about 1,400 Americans aged 18 to 89 who participated in the 2002 General Social Survey yielded virtually no differences by social class in the importance that respondents attached to various milestones (leaving home, finishing school, getting a full-time job, becoming financially independent from one's parents, being able to support a family, marrying, and becoming a parent) as a criterion of adult status. Ratings also differed little by developmental period (young adults, middle-aged adults, older adults), although older adults placed more importance on marriage and childbearing. Across all ages, the most important milestones were completing school, getting a full-time job, financial independence, and being able to support a family, with 95% of respondents indicating that these markers were at least "somewhat important." Nearly half did not believe it was necessary to marry or to have children to be considered an adult.

Other investigations of American youth, as well as European youth, have reported social class differences in the criteria for adulthood, but caution is warranted because these investigations tend to be less rigorous methodologically than Furstenberg et al.'s (2003) study. Some of the methodological limitations are noted above. Certain role transitions (i.e., completing school), as well as several individualistic characteristics such as ability to support children and family, socioemotional maturity, and norm compliance have been found to be more salient criteria of adulthood among youth from lower SES backgrounds than among youth from higher SES backgrounds (Arnett, 2003; Aronson, 2008b), but these differences were not found in other research with American youth (Arnett, 1997). However, studies of Austrian and Dutch youth have also reported that role transitions (e.g., starting a family, getting a job) are more salient as criteria of adulthood among lower-class youth than middle-class and upper-class youth (Plug, Zeijl, & Du Bois-Reymond, 2003; Sirsch, Dreher, Mayr, & Willinger, 2009).

Very little research has examined ethnic differences in beliefs about criteria for adult status and the findings are conflicting. In Furstenberg et al.'s (2003) study of respondents in the 2002 General Social Survey sample, ratings varied little by race/ethnicity. Arnett's (2003) investigation

of an economically diverse sample of African American, Latino American, Asian American and European American 18- to 29-year-olds indicated that, although ethnic groups do not differ in their endorsement of independence as a criterion for adulthood, ethnic minorities were more likely than European Americans to endorse role transitions and fulfillment of domestic and family roles as criteria for adulthood, even with controls for socioeconomic status, marital status, parenthood status, and other demographic variables. For example, 50% of Latino Americans, 43% of African Americans, and 35% of Asian Americans endorsed "become employed full-time" as a criterion of adulthood, compared with only 19% of European Americans. Even among ethnic minorities, though, role transitions ranked lower in importance as criteria for adulthood status than independence, norm compliance, and fulfillment of domestic and family roles.

Beliefs About Optimal Timing of Adult Transitions

Social class appears more consequential for the ideas youth hold about the optimal timing of adult transitions than their beliefs about the criteria for adult status. Findings from research assessing beliefs about the appropriate or optimal timing of adult transitions comport with earlier entry of low-SES youth into adult roles. In the 2002 General Social Survey, mentioned previously, participants (only those indicating that a particular transition was at least "somewhat important" for adult status) indicated the age by which various "adult" transitions should occur: leaving home, finishing school, getting a full-time job, becoming financially independent from one's parents, being able to support a family, marrying, and becoming a parent (Furstenberg et al., 2003). The most consistent and marked differences in responses were related to social class (responses differed little by race/ethnicity, age, or urban versus rural residence). Less educated and less affluent respondents—those who did not attend college and those in the bottom third of the socioeconomic distribution—were more likely to subscribe to an earlier timetable for all of the transitions. The differences were most pronounced among young adults (as compared with middle-age adults and older adults).

Furstenberg et al. (2003) concluded that "These social class differences in age norms for adult transitions probably stem from the reality that young people with more limited means do not have the luxury of investing in schooling and experimenting in the labor market. They feel they must become economically self-sufficient at an earlier age than youth whose families can afford to help them out

financially while they complete their education and find a good job" (pp. 10–11). The findings appear to be consistent with Arnett's (2000) speculation that youth from lower-class backgrounds may experience a truncated period of exploration before making the more enduring choices of adulthood.

Subjective Adult Identity

Identity theory suggests that commitment to particular roles influences the salience of roles for one's identity, which then influences role performance. It defines identities as internalized sets of role expectations, and links identity to the larger social structure through roles and role performance (Macmillan, 2007). The consequences of embracing an adult identity (i.e., feeling that one has reached adulthood) have not been well-documented, but scholars speculate that an adult identity can be a resource for carrying out adult responsibilities (M. K. Johnson et al., 2007a). Consistent with this speculation, a study of young adults in Belgium found evidence that a stronger sense of adulthood buffered the negative effects of perceived instability in life on work engagement and job burnout (Luyckx, Witte, & Goossens, 2011).

Arnett (2000) does not distinguish analytically between abstract, general conceptions of adulthood and the criteria or standards that youth apply when assessing whether *they* have reached adulthood (i.e., subjective adult identity) (Andrew et al., 2007; Shanahan et al., 2005). This distinction is seen as highly significant on the grounds that the meaning of adult roles varies by whether an individual has acquired that role (Benson & Furstenberg, 2007; Shanahan et al. 2005). Arnett's studies assessed subjective adult identity of youth in relation to demographic factors such as ethnicity and age (Arnett, 2001, 2003), but not in relation to their transition experiences. Arguably, role transitions may have little salience in abstract conceptions of the meaning of adulthood, but nonetheless exert strong influence on the subjective adult identity of youth.

Indeed, there is strong evidence that certain role transitions increase the odds that young people will perceive themselves as adults (Benson & Furstenberg, 2007; Molgat, 2007; Reitzle, 2006; Shanahan et al., 2005). Benson and Furstenberg's (2007) longitudinal study of an American sample composed of predominantly racial minorities from working poor and working-class families found that subjective adult identity changes in response to role transitions. Youth who did not define themselves as adults at Age 19 were more likely to alter their identity and define themselves as fully adult at Age 21 if they had moved out

on their own, become parents, or assumed more financial responsibilities. Transition reversals (e.g., moving back in with one's parents), conversely, reduced the odds of perceiving oneself as an adult at Age 21. Moreover, the effects of some role transitions depended on whether they occurred simultaneously with other roles. Becoming employed full-time increased the odds of acquiring an adult identity, but only if accompanied by establishing an independent household.

Studies of youth from other countries also report evidence of the importance of role transitions in subjective identity. In research with German youth, subjective adult identity was positively correlated with more role transitions (e.g., financial independence, cohabitation, parenthood), controlling for age, education, and other factors (Reitzle, 2006). Molgat's (2007) qualitative interviews with 25–29 year olds residing in Quebec, Canada, echo and extend these findings. Transitions such as finishing school, leaving home, having a "real job," and entering into financial obligations were central to their self-perceptions as adults, but they also perceived themselves as adults because they had met individualistic criteria such as autonomy, financial independence, and responsibility. The emphasis on both role transitions and internal, psychological facets of the transition to adulthood as contributors to the perceptions of youth of being an adult parallels themes in qualitative research focused on conceptions of adulthood (Andrew et al., 2007). It is noteworthy that advancing age per se, at least during the 20s, does not appear sufficient to increase the probability that youth will perceive themselves as adults (Plug et al., 2003).

The documented link between role transitions and subjective adult identity is in line with evidence that young people from less advantaged socioeconomic backgrounds (less highly educated parents, lower family incomes, single-parent homes) are more likely than same-age peers from more privileged backgrounds to define themselves as adults partly because they have experienced more adult role transitions (M. K. Johnson et al., 2007a). Similar findings have been reported in research with German youth (Reitzle, 2006). In terms of ethnicity, contrasts within-study and across-studies indicate that African American and Latino American youth are more likely than their European American and Asian American counterparts to view themselves as adults (Arnett, 2003; Benson & Furstenberg, 2007; M. K. Johnson et al., 2007a; M. K. Johnson & Mollborn, 2009). Similar to findings for social class differences in subjective adult identity, these ethnic differences diminish when role transitions are controlled.

A corresponding pattern of ethnic differences exists in young people's perceptions of their relative age (i.e., how old they feel compared with others of their chronological age; M. K. Johnson, Berg, & Sirotski, 2007b).

Although studies suggest that ethnic minorities in the United States experience earlier role transitions and are more likely than European Americans to endorse role transitions and fulfillment of domestic and family roles as criteria for adulthood (Arnett, 2003; East, 1998; M. K. Johnson et al., 2007a), little evidence has been found in support of the hypothesis that ethnicity moderates the effect of role transitions on subjective adult identity (M. K. Johnson et al., 2007a). This is surprising. If African American youth endorse full-time employment as a criterion of adulthood more strongly than European American youth, for example, it might be expected that the transition to full-time employment would have a stronger effect on the subjective identity of African American youth than European American youth.

It is socioeconomic background, not race/ethnicity, that moderates the relation between role transitions and adult identity among American youth, with the (positive) relation between role transitions and adult identity being much stronger among young adults from advantaged socioeconomic backgrounds than those from disadvantaged backgrounds (M. K. Johnson et al., 2007a). The nature of this moderation effect is contrary to what the researchers predicted, given their assumption that role transitions are more salient to lower-SES youth than middle-SES youth because the former experience many role transitions earlier. Rather, the moderation effect suggests that role transitions are more psychologically meaningful to privileged youth. It is plausible that privileged youth have had fewer opportunities than those from lower socioeconomic backgrounds to behave in ways that foster feelings of being an adult prior to the role transitions examined in the study. However, Reitzle's (2006) study of German youth found the opposite pattern of moderation. Subjective adult identity and accumulated role transitions were positively related among non-college-bound youth, but unrelated among college-bound youth.

Experiences During Childhood and Adolescence as Precursors of Subjective Age and Adult Identity

Life course and identity theorists argue that many of the roles that shape identity are age-graded and that this engenders social expectations and internalized expectations about the appropriate timing of roles (Macmillan, 2007). In keeping with this framework, scholars have posited

that violating age norms for childhood and adolescence challenges one's identity as a child or adolescent and accelerates subjective aging (i.e., individual's subjective sense of their own age; M. K. Johnson et al., 2007b; M. K. Johnson & Mollborn, 2009). M. K. Johnson and Mollborn (2009) hypothesized that various forms of hardship experienced during childhood and adolescence (i.e., economic poverty; exposure to violence as a witness or victim; living in a single-parent family or experiencing a family disruption that resulted in family structures other than married, biological-parent families) accelerate subjective aging and increase self-identification as an adult (i.e., feeling like an adult all or most of the time versus less frequently) among American youth aged 18 to 22 through three types of mediating experiences that violate age norms: (1) transitioning into adult roles earlier than one's age peers, (2) heavy household and paid-work responsibilities during adolescence, and (3) perceiving one's life expectancy as severely curtailed.

They found that each form of hardship increased either subjective age or feeling like an adult. Hardships had a cumulative effect on adult identity—as they compounded, the predicted probability of feeling adult increased substantially. Contrary to expectations, neither intensive paid work (20 or more hours/week during the school year) during adolescence nor anticipating a shorter life span functioned as mediators. Transitioning into adult roles earlier than one's age peers was the only variable that either fully or partially mediated effects of hardship on subjective aging and adult identity.

M. K. Johnson and Mollborn's (2009) study represented an age-graded approach to perceived developmental status seen primarily in sociological research. Psychosocial characteristics or maturation as criteria for adulthood represented another approach to perceived developmental status, one seen largely in developmental research (Arnett, 2000). Benson and Elder (2011) brought these two approaches together in a study of four identity profiles based on subjective age (how often respondents think of themselves as adults; how old youth feel compared with others their age; how fast youth perceived they grew up relative to same-age peers) and psychosocial maturation (self-reports of independence, confidence, and considerateness in early adulthood).

Using a longitudinal sample of young American adults aged 18–22 in the National Longitudinal Study of Health, Benson and Elder (2011) identified two *concordant* profiles—"early adults," that is, those with older subjective ages and higher levels of psychosocial maturity,

and “late adults,” that is, those with younger subjective ages and lower levels of psychosocial maturity. “Early adults” tended to come from the most disadvantaged backgrounds (lower income, single-parent households), with African American youth being the most likely and Asian American youth the least likely to have this type of identity. Race/ethnic differences in “early adult” identity, unlike race/ethnic differences in the other three profiles, were completely explained by adolescent influences (discussed below). “Late adults” tended to be Asian American and individuals who grew up in more advantaged family contexts (i.e., higher income, two-parent families). Benson and Elder (2011) also identified two *discordant* profiles—“pseudo-adults,” that is, those with older subjective ages and lower levels of psychosocial maturity, and “anticipatory adults,” that is, those with younger subjective ages and higher levels of psychosocial maturity. “Pseudo-adults” tended to come from nonintact families, whereas “anticipatory adults” tended to be African American, and to come from intact, two-parent family types.

Experiences during adolescence distinguished the adult identities. Both “early adults” and “pseudo-adults” tended to experience earlier pubertal development, but the latter group as adolescents tended to have lower self-esteem, higher levels of maladaptive and delinquent behavior, and parental relationships marked by a lack of closeness and blurred parent–adolescent generational boundaries as compared with other youth. Both “anticipatory” and “late adults” tended to experience later pubertal development and closer relations with their parents during adolescence than other youth in the sample. However, youth in the anticipatory group were distinct from those in the late group in that they had higher self-esteem and were more likely to take on household responsibilities during adolescence. In addition, compared with those with other profiles, “anticipatory adults” were more subject to generational boundaries as reflected by low levels of peer-like communication with parents. These patterns of relations suggest that a supportive, structured family environment, high self-esteem, and higher levels of responsibilities during adolescence may buffer youth against the potentially adverse effects of delayed pubertal maturation. In contrast, delayed pubertal maturation, coupled with low self-esteem, and a paucity of outlets to develop and practice responsibility appears to lead to late adult identities.

Identity Profiles and Subsequent Attainment

In a follow-up study, Benson, Johnson, and Elder (2012) examined these four identity profiles in young adults aged

18–22 in relation to educational and work attainment at Age 25–29, controlling for adolescent characteristics (i.e., self-esteem), school and work roles at Age 18–22, and a host of status variables (e.g., family income, parental educational attainment, race/ethnicity, family structure, gender, chronological age). By their mid- to late 20s, “late adults” had attained higher levels of educational attainment than youth in the other three profile groups. “Early adults” achieved higher earnings at Age 25–29 than youth in the other three profile groups, even with controls for educational and work patterns at Age 18–22.

“Pseudo-adults,” in general, were faring worse than those with other identity profiles even with controls for prior educational and work patterns. In addition to earning less than early adults, they reported lower subjective attainment and were less likely to hold career-type jobs than anticipatory and early adults, a pattern suggestive of limited psychosocial resources that hindered their ability to make plans and choices associated with successful school-to-work transitions (Benson et al., 2012). “Late adults” reported lower subjective attainment and were less likely to hold career-type jobs than “anticipatory” and “early adults.” In addition, anticipatory adults (younger subjective ages but greater psychosocial maturity), compared with late adults, completed fewer years of postsecondary education, but began their progression toward careers earlier and reported higher levels of subjective attainment.

This study provided two important insights about the significance of psychosocial maturity and subjective age for subsequent educational and work attainment during early adulthood. First, whereas older subjective age among adolescents was associated with self-reported problem behavior (e.g., substance use, antisocial behavior, failure to obey parents) (Galambos, Kolaric, Sears, & Maggs, 1999), the evidence from Benson et al.’s (2012) study suggested that solely having an older subjective age during early adulthood does not deter subsequent attainment; rather, the pivotal issue was *whether an older subjective age was accompanied by high levels of psychosocial maturity*. Second, the findings suggested that lower psychosocial maturity was less consequential when it was accompanied by younger, rather than older, subjective ages. Benson et al. (2012) speculated that the resulting concordant profile may have long-term advantages, noting that “Maintaining a younger identity and taking a slower path to adulthood may facilitate attainment by allowing for key developmental investments and accumulation of experience that will serve young people well” (p. 1756).

Benson et al.'s (2012) study provided an excellent example of the kinds of research needed to advance understanding of when having an older subjective age or adult identity is detrimental and when it is beneficial. Scholars have suggested that some of the adolescent problem behaviors associated with having older subjective ages (e.g., substance use, greater involvement with opposite-sex peers) (e.g., Arbeau, Galambos, & Jansson, 2007) can be thought of as adult behaviors assumed too early (M. K. Johnson & Mollborn, 2009). This perspective, combined with evidence that socioeconomically disadvantaged youth are more likely than their advantaged counterparts to define themselves as adults (M. K. Johnson et al., 2007a), has prompted questions about whether subjective age is one of the mechanisms by which disadvantages from childhood and adolescence are reproduced or maintained into adulthood (M. K. Johnson & Mollborn, 2009). At the same time, it is conceivable that older subjective ages, under certain conditions and in the presence of other psychological characteristics such as initiative and sense of responsibility, may facilitate upward mobility.

In a similar vein, Burton (2007) has discussed the assets and liabilities of childhood adultification in poor families in the United States, a process that may mediate the link between hardships and adult identity/older subjective age. Childhood adultification is distinguished by processes in which youth are prematurely and often inappropriately exposed to adult knowledge and assume extensive adult roles and responsibilities within their family networks. Ethnographic data suggested that this process might engender a high level of independence and a strong sense of agency, on the one hand, but interfere with educational attainment and establishment and maintenance of adult intimate relationships. It is unclear what conditions tip the balance in favor of positive adaptation rather than problematic outcomes. These are intriguing questions that warrant study within longitudinal samples of low-income and ethnic minority youth.

Summary and Future Directions

Evidence from American and European convenience samples indicate that lower-class youth attach more importance to role transitions as criteria for adult status than do youth with higher socioeconomic status, but these social class differences have not been found consistently in small convenience samples and were not evident in research with a nationally representative sample of Americans. Studies are needed that carefully attend to methodological issues

(e.g., sampling procedures, prompts, response categories) that may be sources of these discrepancies. It is noteworthy that extant studies provide no support for the notion that restricted economic resources known to increase the difficulty of making certain adult transitions (e.g., residential independence) diminishes espousal of these transitions as criteria for adult status. However, there is compelling evidence that economically disadvantaged youth subscribe to an earlier timetable for role and status transitions that signify adult status.

It remains unclear whether ethnic minority youth are more likely than majority youth to endorse role transitions and fulfillment of domestic and family roles as criteria for adulthood. Findings based on U.S. samples are sparse and conflicting and, to our knowledge, examination of this issue has not been undertaken with European youth. The value of future studies of ethnic differences in the beliefs of youth about the criteria for adult status would be greatly enhanced by the inclusion of direct measures of cultural values and greater methodological rigor in general.

Subjective adult identity is fluid, changing in response to role transitions. Residential independence, becoming a parent, and assuming more financial responsibilities increase the odds that youth will define themselves as adults, whereas transition reversals reduce the odds. The effects of some role transitions on adult identity depend on whether they occur simultaneously with other roles. African American, Latino American, and lower-SES youth are more likely than European American, Asian American, and higher-SES youth to perceive themselves as adults and these differences are partly mediated by differences in the number and timing of role transitions. However, further research is needed to clarify whether race, ethnicity, and social class moderate the effect of role transitions on subjective adult identity. There is a paucity of work in this area and the sparse findings pertaining to social class as a moderator of the link between role transitions and adult identity among American youth are contrary to theory-based expectations and inconsistent with findings based on German youth.

Transitioning into adult roles earlier than one's age peers appears to be a key pathway through which various forms of hardship during childhood and adolescence accelerate subjective aging and increase the tendency to feel like an adult. More longitudinal research with ethnically and economically diverse samples is needed to better understand the processes through which experiences during childhood and adolescence affect subjective aging and subjective adult identity. The psychological and behavioral

consequences of embracing an adult identity have not been well-documented. Likewise, we know very little about the conditions and circumstances under which older subjective age, earlier adult identity, or a particular age-related identity profile during late adolescence and early adulthood forecast levels of adaptive versus maladaptive functioning in later adulthood. These are among the most compelling questions for future study.

MENTAL HEALTH

Data from the United States reveal countervailing age trends in psychosocial functioning during the transition to adulthood. Between the ages of 18 and 26, mental health (measured as a composite of self-efficacy, self-esteem, and social support) steadily increases, accompanied by steady decreases in depressive affect, anxiety, risk taking, and physical aggression (Schulenberg & Zarrett, 2006)—a trend that has been replicated in longitudinal research conducted in other countries (Galambos & Krahn, 2008; Merikangas et al., 2003). Also, several psychiatric disorders such as clinical depression manifest and increase during this period (Schulenberg & Zarrett, 2006). Explanations for these age trends have emphasized changes in person-context matches that may result from personal, contextual, and social role changes common during the transition to adulthood. With the waning presence of institutional structure and support and easing of role requirements at the end of high school, for example, there is greater potential for individuals to choose activities and paths that reflect personal desires, goals, competencies, and other characteristics. Greater opportunity for self-selection of post-high-school contexts and roles, and hence, greater person–context matches, may improve psychological well-being. For other individuals, the decline in institutional structure, accompanied by attendant changes in social context (e.g., leaving home for college and a subsequent reduction in familial contact and support), can overwhelm coping resources, eroding the person–context match, and setting the stage for psychological maladjustment (Schulenberg & Zarrett, 2006).

Against this backdrop, we review findings from studies of the effects of family-of-origin SES and race/ethnicity on mental health functioning during the transition to adulthood. Disparities exist in mental health across social locations, but the body of research documenting factors and processes that account for these differences is not extensive. Extant studies tend to point to adversities

during childhood and adolescence and early timing of adult transitions as mediators of social class differences, and to a combination of chronic stressors and proximal or concurrent factors operating during the transition to adulthood as mediators of race/ethnic differences. Studies also indicate that family-related adversities (e.g., family violence, low family cohesion, parent-child conflict) and psychological/behavioral problems (e.g., anxiety, depression, delinquency) during childhood and adolescence account for variation in mental health functioning among low-income and ethnic minority young adults (Reinherz, Paradis, Giaconia, Stashwick, & Fitzmaurice, 2003; Wynn, Fite, & Pardini, 2011).

Family-of-Origin SES

Data from community-based and nationally representative samples from the United States and Britain indicate that mental health problems (depressive symptoms, anxiety, psychological distress) are overrepresented among young adults who grew up in lower socioeconomic status families (Costello, Swendsen, Rose, & Dierker, 2008; Harley & Mortimer, 2000; Power & Manor, 1992; Wickrama, Merten, & Elder, 2005). This relation is less likely to be found when the range in socioeconomic levels is highly truncated and the focus is on clinical depression, rather than depressive symptoms (Reinherz, Giaconia, Hauf, Wasserman, & Silverman, 1999). However, investigations of adults that encompass, but do not distinguish young adults, have documented family of origin SES as a risk factor for clinical depression (e.g., Gilman, Kawachi, Fitzmaurice, & Buka, 2002).

A more complicated picture emerges when family-of-origin SES is examined in relation to trajectories of depressive symptoms across the transition to adulthood. Lower SES origin and family-of-origin poverty status have a variable influence on depressive symptoms. In their analysis of data from the American-based National Longitudinal Study of Adolescent Health tracking self-reported depressed mood from Ages 12 to 25, Costello et al. (2008) found that youth from low-SES backgrounds had a greater risk of membership in stable low, early high declining, and late escalating depressed mood trajectory groups than in the no depressed mood group.

In Frye and Liem's (2011) study of an ethnically diverse community sample of American youth, family poverty status in the senior year of high school (Age 18), independent of maternal education, predicted membership in two trajectories of depressive symptoms during a

subsequent 4-year period: (1) higher levels of depressive symptoms that declined steeply and (2) moderate levels that increased steeply (both classes as compared with the low stable symptom class). Their post hoc analyses found no evidence that differential access to employment or postsecondary education influenced the trajectory of depressive symptoms *within* low-income young adults in the sample, leading them to suggest that increasing depressive symptoms among poor youth during the transition to adulthood may be more than structural. Galambos, Barker, and Krahn (2006) identified yet another class-related trajectory in their study of Canadian youth. Between the ages of 18 and 25, depressive symptoms declined less rapidly among those whose parents had lower levels of education, perhaps suggesting that limited socioeconomic resources restricted opportunities to increase person–context match.

Evidence that family-of-origin SES and family-of-origin poverty status are linked to both increasing and decreasing depressive symptoms during the transition to adulthood bears resemblance to the aforementioned countervailing age trends found in U.S. national panel data (Schulenberg & Zarrett, 2006). For some individuals from low-SES family backgrounds, early adulthood may precipitate a decline in depressive symptoms because it is “their first chance to break out of that environment and seek out new opportunities for themselves” (Frye & Liem, 2011, p. 584), perhaps resulting in an improved person–context matches. For others, it may engender increased depressive mood due to stressors engendered by more and earlier adult transitions, less social and institutional support, and fewer skills and competencies that ease adjustment to adult role transitions.

Family-of-Origin SES, Mental Health, and Young Adult Status Attainment

As individuals move through early adulthood, completing school and settling into occupational roles and employment patterns, their achieved social class (i.e., their current occupation, employment status, educational attainment, poverty status) assumes greater potency than their socioeconomic status of origin as a predictor of mental health (Power & Manor, 1992). Clinical depression during young adulthood (Age 26) is more strongly linked to one’s adult socioeconomic status than to childhood socioeconomic status (Poulton et al., 2002), and family-of-origin no longer predicts depressive symptoms among young adults when their present achieved SES is taken into account (Mossakowski, 2008). In Miech, Caspi, Moffitt, Wright, and Silva’s (1999) prospective longitudinal study of the

Dunedin, New Zealand, birth cohort, low parental SES had no significant effect on mental disorders at Age 21, net of the effect of educational attainment and past history of mental disorder of the youth at Age 15. Proximal experiences in adulthood appeared to better account for the association between low SES and depression than did socioeconomic status-of-origin. This is not surprising given that young adults’ achieved SES, as compared to their socioeconomic status of origin, reflects a greater accumulation of class-linked experiences that have implications for mental health, encompassing current or proximal experiences as well as those that transpired during prior developmental periods when SES was based on parental characteristics.

Generally, socioeconomic status differences in mental health have been attributed to either social causation or social selection. A social causation perspective espouses the view that social class differences in mental health are due to stressors and adversities that stem from restricted economic resources and low social status and, conversely, to more favorable conditions that high-status individuals experience. These disadvantages and advantages may be experienced during childhood and/or adulthood. In contrast, a social selection perspective maintains that individuals with preexisting mental health disorders drift down the social scale, while those with better mental health functioning move up the scale (Power, Stansfeld, Matthews, Manor, & Hope, 2002). This perspective also posits an intergenerational link whereby traits and dispositions of future parents lead to variations in socioeconomic status, variations in parents’ relationships with their children, and ultimately variations in children’s development through the endowments and dispositions that parents pass on to their children (Conger, Conger, & Martin, 2010). Proponents of social selection argue that individual-level psychological and cognitive traits are major contributors to low socioeconomic status and that failures to take these characteristics into account results in an overestimation of the environmental effects of stressors and adversities associated with low socioeconomic status (Mayer, 1997; Rowe & Rodgers, 1997).

Meich et al.’s (1999) longitudinal study of selection and causation in the New Zealand birth cohort suggests disorder-specific relations with SES. They found evidence of social selection for externalizing disorders (antisocial behavior, attention deficit disorder), but not for anxiety or depression. By the time adolescents with externalizing disorders reached early adulthood, they appeared to be selected into the lower socioeconomic strata through

restricted educational attainment. Because the study did not replicate the association between SES and depression among adolescents found in other research (e.g., American Psychological Association, 2013; Goodman, Slap, & Guang, 2003), it may not provide an adequate test of SES selection effects for depression.

Data from Britain and the United States suggest that both social causation and social selection processes operate to produce socioeconomic disparities in mental health among young adults. Power and Manor (1992) used data available from birth to early adulthood in the 1958 British birth cohort to estimate the contribution of social selection and social causation on depressive symptoms among 23-year-olds. The odds of poor psychological health (e.g., depressive mood, anxiety, irritability, seeking professional help between the ages of 16 and 23 for a psychological problem) were significantly greater in young adults from lower social classes than those from higher social classes. Health selection was evident (i.e., characteristics and circumstances that existed at birth, including father's occupational class), but inequalities in psychological distress were largely due to an accumulation of diverse factors from birth onward (e.g., unemployment since leaving school) rather than to health selection.

Likewise, Wickrama, Conger, Lorenz, and Jung (2008) found evidence consistent with both social causation and social selection in their longitudinal study of American youth from Iowa. The measure of social status attainment among young adults (Age 25) was a cumulative index encompassing a wide range of variables (educational attainment, full-time employment or full-time college student status, satisfying work situation, independent residence, stable intimate relationship). Consistent with a social causation perspective, early family adversity (e.g., negative life events) predicted an increase in depressive symptoms during adolescence and the early assumption of adult roles during adolescence, which in turn predicted growth in depressive symptoms during the transition to adulthood. Both initial levels of depressive symptoms and growth in depressive symptoms during the adult transition predicted lower social status attainment at Age 25, supporting the social selection hypothesis that earlier personal characteristics predict later socioeconomic circumstances. Depressive symptoms during adolescence and the transition to adulthood presumably diminished young adult social status attainment by interfering in the acquisition of competencies necessary for educational, occupational, and relationship attainment. Lower levels of competence perhaps reduced the amount of social support youth received

and decreased expectations of success in the respective domains of attainment.

Taken as a whole, the study provided evidence of cumulative disadvantage in that adversity in the family of origin was "amplified across the life-course by successively contingent adverse circumstances involving life-transition difficulties and poor mental health" (Wickrama et al., 2008, p. 468), leading the investigators to conclude that many youth from poor families are caught in a self-perpetuating cycle.

Early Timing and Sequencing of Transitions as a Mediator of SES Differences

As discussed in the introduction to this chapter, the timing and temporal ordering of role and status transitions are central analytic constructs in the life course perspective. Although transitions occur at virtually all phases of the life course, Pearlin, Schieman, Fazio, and Meersman (2005) pointed out that certain transitions, such as teenage transition into parenthood, school dropout, and premature entry into the labor force, are especially critical because they lead to consequences that are difficult to reverse or alleviate. The life course penalties of early transitions arise not merely from failure to follow socially valued patterns, they assert, but also from restricted access to vital opportunity structures.

Off-time and out-of-sequence transitions may create demands and conditions that interfere with the achievement and enactment of other roles and statuses such as maintaining stable employment that provides ample financial support. Although this is not inevitable, these kinds of transitions increase the risk of lower occupational and educational attainment that, in turn, place individuals at greater risk for exposure to enduring and myriad occupational, financial, and attendant stressors that can compromise psychological health. In keeping with the notion of cumulative disadvantage, Pearlin et al. (2005) underscore that such transitions occur disproportionately among those of lower socioeconomic status, a link well-established in the research literature (e.g., Booth et al., 2008; Wickrama et al., 2005). It bears mentioning, however, that many early childbearers recover economically in later life (and appear indistinguishable from older childbearers) if they continue their education, control fertility, and marry. Less is known about their psychological health over the longer run (Coley & Chase-Lansdale, 1998; Furstenberg, 2003; Furstenberg, Brooks-Gunn, & Chase-Lansdale, 1989).

Tests of early timing of transition events as a mediator of social class disparities in young adults' mental health

functioning affirm Pearlin et al.'s observations. Harley and Mortimer (2000) found a social class (family-of-origin) gradient in depressive affect among American youth 4 years after high school (Age 22) in their panel study of adolescents followed since ninth grade (Age 12). Neither timing nor sequencing of three family-related transitions (i.e., independence from the parental home, marriage/cohabitation, parenthood) alone accounted for the social class effect. Rather, the social class effect was mediated by early timing of transition events in combination with a pile-up of transitions, that is, a higher number of transitions occurring in a single year. The findings suggested that young adults from lower socioeconomic backgrounds might be at greater risk of experiencing dysphoria as a consequence of assuming new responsibilities and attendant stressors without sufficient time to adapt to them.

In Wickrama et al.'s (2008) longitudinal analysis of American youth from Iowa, early timing of transitional events during adolescence explained variation in the slope of depressive symptoms during the transition to adulthood. Early timing was indexed by several events: sexual intercourse by 14 years of age, and pregnancy, cohabitation, marriage, parenthood, or leaving the parental home by 17 years of age. Lower parental education predicted early timing of transitional events, partly through increasing the occurrence of negative life events experienced by parents or the family (e.g., getting laid off, taking wage cuts, moving to worse residences or neighborhoods, death of family members). Early timing of transition events, in turn, predicted growth in depressive symptoms during the transition to adulthood (roughly the ages of 18–24). In a similar vein, Wickrama et al.'s (2005) longitudinal analyses of Add Health data from a nationally representative sample of American youth indicated that family poverty and lower maternal education increased the risk of early timing of transition events (i.e., sexual intercourse before Age 16 and pregnancy, marriage or cohabitation, leaving home, or full-time employment at or before Age 19), which in turn predicted a growth in depressive symptoms among youth in late adolescence and early adulthood.

A discordant note comes from Booth et al.'s (2008) study of early family transitions as predictors of changes in depressive symptoms from adolescence to early adulthood (Ages 17–23). Analysis of data from the Add Health Study indicated that individuals who made early family transitions (i.e., cohabitation, marriage, parenthood) generally were no more likely to experience increases in

depressive symptoms than individuals who made no family transitions, even without controls for family background and risk and protective variables (e.g., school attachment). For example, women who became parents were no more likely to experience changes in depressive symptoms than women who did not transition to parenthood, regardless of whether births were inside or outside unions.

Differences in foci and samples may partly explain the discrepancy between Booth et al.'s (2008) findings and those of other studies showing elevated mental health problems among youth who made early status and role transitions. Booth et al. focused solely on family transitions, whereas other studies focused on a broader range of transitions (e.g., full-time employment, leaving the parental home, sexual intercourse, pregnancy irrespective of the outcome of the pregnancy) that collectively could have greater implications for mental health functioning than family transitions alone. Relatedly, whereas Booth et al. examined each transition separately, Wickrama et al. (2005, 2008) created a cumulative risk index by summing across multiple early transitions. Inclusionary criteria for the samples may also have been a factor. For the analysis of each transition, Booth et al. eliminated from the sample individuals who were close in age to those who typically make the transition (for example, in the analysis of the transition to marriage and parenthood, 23- to 25-year-olds were eliminated) so that, for comparison purposes, those making early transitions were in the same age range as those who did not. The resulting sample included individuals whose average age of making family transitions was below national averages. This procedure may have introduced biases that resulted in an underestimation of the effects of early family role transitions. In other investigations, early timing was defined with reference to national normative ages, but the age ranges of the youth were more truncated than was the case in Booth et al.'s original sample and chronological age was not confounded with the age of early transitions.

Booth et al.'s (2008) findings are especially important to the extent that they prompt more careful study of early family formation in context and clarification of the contexts within which early family transitions represent positive choices. As Booth et al. pointed out, the option to treat early adulthood as a time of exploration is not open to all individuals given their personal, social, and economic resources. In these circumstances, the consequences for mental health of early family transitions may be less negative or more benign than in more economically and socially advantaged contexts.

Race and Ethnicity

There is considerable evidence that during the transition to adulthood, African Americans have higher levels of depressive symptoms and greater increases in depressive symptoms than European Americans (or an increasing trajectory reverse that of European Americans), even when social class (Brown, Meadows, & Elder, 2007; Costello et al., 2008; Gore & Aseltine, 2003; Jager, 2011) and family-of-origin poverty status (Frye & Liem, 2011; Turner, Taylor, & Gundy, 2004; Walsemann, Gee, & Geronimus, 2009; Wickrama et al., 2005) are controlled. Latino ethnicity is also a risk factor for depressive symptoms during early adulthood, controlling for parent education and duration of poverty (Brown et al., 2007; Costello et al., 2008; Mossakowski, 2008; Walsemann et al., 2009; Wickrama et al., 2005). In Gore and Aseltine's (2003) study following an ethnically diverse, urban sample of young adults over a 2-year period, average levels of depressed mood increased among African Americans and Latino Americans, whereas they decreased among European Americans and Asian Americans, independent of socioeconomic background factors. Costello et al.'s (2008) longitudinal analysis tracking self-reported depressed mood from Ages 12 to 25 (based on data from the National Longitudinal Study of Adolescent Health) indicated that African Americans had a greater likelihood of membership in depressed mood trajectory groups than membership in the no depressed mood group. Similarly, being African American predicted membership in the increasing depressive symptom class in Frey and Liem's (2011) longitudinal study conducted over a 4-year period following high school, even with controls for family poverty.

It is notable that persons of African descent living in Britain are also at increased risk of poorer mental health. In the 2011–2012 Subjective Well-Being Annual Population Survey of individuals aged 16 and over residing in Britain, those who identified as Black/African/Caribbean/Black British reported the lowest average rating of happiness and life satisfaction of all the ethnic groups represented in the survey (White, Indian, Pakistani, Bangladeshi, Chinese, Arab, etc.) (Office for National Statistics, 2012b). Ethnic group comparisons within age or developmental groups were not conducted, but it is likely that the pattern for young adults parallels that found in the general population.

Mediating Influence of Stressors

Chronic poverty has been found to mediate race and ethnic differences in depressive symptoms among Americans

during the transition to adulthood. In Mossakowski's (2008) longitudinal study based on data from the NLSY, duration of poverty across a 13-year period accounted for the higher levels of depressive symptoms among African American and Latino American young adults, as compared with European American young adults. The depressive effect of poverty duration was very robust, as it was independent of family background (parental education and occupation), present poverty status, and other indicators of present SES (education, occupation, net worth, not a homeowner).

Mossakowski's (2008) findings raise questions about whether Frey and Liem (2011) found race effects on depressive symptoms even after controlling for family poverty because they measured family poverty at a single time point, rather than assessing the duration of family poverty. A measure of poverty duration, rather than current poverty status, would likely yield a more valid estimate of the unique contribution of race to depressive symptoms, given (a) the vast differences between African Americans and European Americans in the duration of childhood poverty, (b) much larger race differences in the duration of childhood poverty than annual poverty rates, and (c) the more detrimental effects of persistent childhood poverty, as compared with transitory or short-term poverty, on developmental outcomes and contexts of development (Duncan & Brooks-Gunn, 1997; Duncan, Brooks-Gunn, & Klebanov, 1994; Duncan & Rodgers, 1988).

Longitudinal research suggests that African Americans experience higher levels of depressive symptoms during early adulthood than European Americans (controlling for poverty and socioeconomic status) partly because of their greater exposure to social stress (i.e., stressful life events, chronic strain related to employment, neighborhood and living conditions, interpersonal relations) (Brown et al., 2007; Taylor & Turner, 2002; Turner et al., 2004)—a factor highly associated with poverty. Evidence that African American status predicts membership in an increasing depression class, but not a high stable depression class (Frye & Liem, 2011) suggests that transitions to adulthood engender a surfeit of social stresses for African Americans that elevate their risk for mental health problems.

Jager's (2011) longitudinal study of race differences in depressive affect is unique in that it focused on social roles and attendant stressors particularly pertinent to early adulthood (i.e., living arrangements, college/work status, single-parenthood). Race differences in the growth of depressive affect (spanning Ages 13 to 22) were not explained by the distribution of early adult social roles,

though they were reduced when family SES was controlled. Race moderated the relation between growth in depressive affect and “challenging” social roles (i.e., living with parent/relatives, under/unemployment, being a single parent), with the relation being stronger for African Americans than European Americans. Race was unrelated to growth in depressive affect among those not experiencing challenging social roles. However, as the number of challenging social roles increased—under/unemployment in particular—the risk (relative to European American youth) of elevated growth among African American youth increased. After controlling for family SES, though, race was unrelated to differences in vulnerability to challenging social roles.

There is increasing empirical study of racial discrimination as a stressor among youth. African American youth are more likely to report experiences with discrimination than European American youth and youth from other ethnic minority backgrounds. Several studies have documented links between experiences of interpersonal racism and problematic functioning among African American youth (mostly adolescents, rather than young adults), including lower self-esteem, increased depressive symptomatology, psychological distress, anxiety, and lower life satisfaction (for a review, see Cooper, McLoyd, Wood, & Hardaway, 2008). It is conceivable that experiences of interpersonal racism partly explain why African American young adults experience more depressive symptoms than their European American counterparts. As African American young adults extend their focus beyond familiar neighborhoods and school settings and enter new educational and employment venues in search of adult employment and educational opportunities, it is plausible that they are exposed to more or new sources of racism, that racism is experienced as more pernicious, and/or that they gain new understandings of the barriers that racism poses, leading to increases in depressed mood (Frye & Liem, 2011).

However, while there is research linking experiences of interpersonal racism and psychological distress among African Americans during the transition to adulthood, these experiences have not been found to mediate racial/ethnic differences in depression among young adults (Taylor & Turner, 2002). In their study of African Americans and European Americans, differences in lifetime adversity (assessed retrospectively when respondents were 19–21 years old using yes/no checklist) and exposure to more general forms of chronic social stressors, but not experiences of interpersonal racism, accounted for race differences in depressive symptomatology. Experiences of interpersonal racism have been linked to poorer physical and mental

health among ethnic minority groups in Britain as well, though these studies focus on individuals in the general population rather than young adults specifically (e.g., Bhui et al., 2005; Karlsen & Nazroo, 2002).

Mediating Influence of Social and Institutional Support

Less supportive relationships subsequent to the high school years appear to be important mediators of race/ethnic differences in depressive mood trajectories. Peer and familial relationships typically improve during early adulthood. This pattern generally held across all of the race/ethnic groups in Gore and Aseltine’s (2003) community sample. However, race/ethnic disparities existed in the degree of change in the quality of these relationships and these differences partially accounted for differences between the trajectories of depressive mood among African American and Latino American youth (depression increased across time) and the trajectories of depressive mood among European American and Asian American youth (depression decreased across time). The inclusion of several control variables (e.g., parental education, standard of living, living with parent or other living arrangements) had only a trivial effect on these race/ethnic disparities. Following the transition from high school, the relationships of European American youth with their parents improved (more support, less conflict), while those of Latino American youth did not. Peer support mediated the race difference in depression trajectories, with African American youth reporting lower levels of peer support after high school than European American youth.

Finally, poorer prospects for educational advancement, specifically lower rates of enrollment in 4-year colleges among African American and Latino American youth, has been documented as a mediator of differences in depressed mood between members of these groups and European Americans. Only 20% of the African Americans and 15% of the Latino Americans in Gore and Aseltine’s (2003) sample were enrolled in a 4-year college at Time 2 of the study, compared with 46% of European Americans and 68% of Asian Americans. Not only did relatively more African American and Latino American youth lack the institutional and psychological support that 4-year colleges provide, a larger percentage of them, relative to European American youths, were non-students who were not working (14%, 16%, 5% of African Americans, Latino Americans, and European Americans, respectively), a status highly promotive of depressive symptoms (Dooley, Prause, & Ham-Rawbottom, 2000; Galambos & Krahm, 2008; Power & Manor, 1992).

Summary and Future Directions

During the transition to adulthood, youth from lower socioeconomic backgrounds experience more mental health problems and their depressive symptoms decline less rapidly compared with their middle-class counterparts. Socioeconomically disadvantaged youth show divergent trajectories in depressive symptoms across the transition to adulthood, but very little is known about the factors and processes that account for these divergent trajectories. Findings from multiple longitudinal studies indicate that early timing of transition events mediates social class disparities in young adults' mental health functioning, but there is evidence pertaining to early family transitions in particular that contradicts this pattern. This is a particularly fertile area for further research. Studies are needed to better understand individual and contextual factors that influence the mental health consequences of early family transitions and early transition events.

Scholars have employed various strategies to estimate the unique contributions of stressors and adversities to psychological and mental health outcomes in offspring over and above family-of-origin SES and parental characteristics. Existing studies based on biologically related individuals suggest that both social selection and social causation processes contribute to the social class differences in mental health. However, critics dismiss such investigations on the grounds that they completely confound genetic and environmental effects and argue that behavioral genetic studies provide the only valid tests of environmental influences (Rowe & Rodgers, 1997)—positions that have been challenged (Huston, McLoyd, & García Coll, 1997). Resolution of this controversy does not seem close at hand. There is still considerable distance to travel toward truly integrative research that incorporates strong assessment of genetic and biological constructs with a sophisticated view and appraisal of the environment at both the individual and social structural levels.

More work is needed to understand the unique effects of out-of-sequence transitions on mental health during and subsequent to early adulthood, though this is challenging because timing and sequencing of certain roles are highly confounded (e.g., parenthood, marriage). Extant longitudinal research examining the ordering of social roles across the life course suggests that the type of role sequencing patterns that are conducive to positive mental health depends on social location and cohort status (Jackson, 2004). This work, while not focused on young adults or the transition

to adulthood, underscores the importance of taking into account cultural and economic context in future inquiries.

Future study of the effects of early timing of transitions should attempt to address selection effects by taking into account the antecedents of early timing of transitions. Besides socioeconomic disadvantage, several circumstances and characteristics during adolescence increase the odds of early family transitions for women, including poor relationships with mothers (increases odds of early cohabitation), poor vocabulary skills, low school attachment, high levels of delinquency (increases odds of early cohabitation and early parenthood) (Booth et al., 2008), negative life events, and depressive symptoms (Wickrama et al., 2008).

During early adulthood, African American and Latino American youth have elevated depressive symptoms and experience increases in depressive symptoms, compared with European American and Asian American youth. Mental health risks appear to be particularly acute among African Americans during this period, though longitudinal research indicates that by middle age, race differences (and differences between Latino Americans and European Americans) in depressive symptoms are eliminated (Walseman et al., 2009). In general, there are relatively few studies that examine mediators of race/ethnic disparities in mental health among young adults, and most focus on chronic adversities and proximal variables. This makes it difficult to gauge if these mediating variables account for race/ethnic disparities in depressive mood above and beyond the influence of childhood experiences and prior psychological characteristics.

Factors that partially account for higher depressive symptomatology among African Americans and Latino Americans as compared with European Americans during early adulthood include increased exposure to social stresses, chronic poverty, less supportive family and peer relationships, and poorer prospects for educational advancement and employment. In essence, the ethnic/racial disparity in depressive symptoms seems to reflect growing adversity among African American and Latino American youth as they seek to negotiate new contexts and new demands as social and institutional supports diminish. Unemployment in combination with no or lower levels of involvement in post-secondary schooling—a status customarily labeled “NEET” (not in education, employment, or training) in Britain (Bynner & Parsons, 2002)—appears particularly conducive to depressive mood. Youth in these circumstances are less involved than others in instrumental activities that foster human and social capital,

the consequences of which can accumulate over time and have rippling effects across multiple domains of functioning. In addition to increased focus on experiences during childhood and adolescence as potential mediators of race/ethnic differences in mental health functioning, more systematic attention needs to be given to trajectories of functioning across a wide range of adult roles and transitions (e.g., independent residential status, financial independence, romantic involvement) as mediators (Cohen et al., 2003), in light of research documenting links between these factors and psychological well-being (e.g., Galambos & Krahn, 2008).

Further study is needed to understand why social relations are not as positive for African American and Latino American youth, compared with European American youth, and the significance of gender in this pattern. It is notable that there is no evidence that early timing of transition events mediates the link between race/ethnicity and depressive symptoms. Although African Americans and Latino Americans make certain transitions earlier than their European American counterparts, these differences are driven largely by social class and family income differences and appear to play little if any role in elevated depressive mood among the two groups (Wickrama et al., 2005). However, too few studies have examined this issue to warrant a firm conclusion.

Scholars have hypothesized that racial/ethnic discrimination is among the social stresses that account for racial/ethnic differences in mental health among young adults. Quantitative research has found no support for this hypothesis but further study is warranted because available research is very sparse. Although there is evidence of racial/ethnic disparities in the mental health of individuals living in Britain and studies have linked experiences of interpersonal racism to poorer physical and mental health among ethnic minority groups in Britain, little attention has been devoted to the study of these issues among young adults as a targeted group. In general, our review suggests that issues pertaining to the psychological functioning of young adults from racial and ethnic minority groups have received less scholarly attention in Britain and other European countries than in the United States.

Vigorous study of sources of within-group (race, ethnicity, low-SES) variation in mental health functioning and patterns of developmental transitions across the transition to adulthood needs to proceed alongside further study of race, ethnic, and social class differences and the factors and processes that mediate these between-group differences. Variables that best explain within-group differences

may be different than those that best explain differences between youth from different racial, ethnic, and social class backgrounds. Work is also needed to determine under what conditions and for what psychological outcomes ethnic minority youth are affected more strongly by low SES than are majority youth, and how gender intersects with these statuses. In studies of race/ethnic differences in young adult outcomes, SES typically is controlled rather than examined as a moderator of the strength of race/ethnic differences. It is essential to develop a knowledge base about identity development and the existence, nature, contextual correlates, and consequences of identity exploration among low-income and ethnic minority youth. Research examining patterns of growth in dimensions of racial identity across the transition to adulthood among African Americans may be a harbinger of programmatic efforts in this area (Hurd, Sellers, Cogburn, Butler-Barnes, & Zimmerman, 2013). Increasing focus on identify processes among European youth also holds promise for expanding knowledge about identity processes in ethnic minority and low SES youths (e.g., Schwartz, 2012; Seiffge-Krenke & Haid, 2012). Knowledge about the predictors and consequences of constrained opportunities for exploration of identity issues and pathways to successful resolution of identity issues in these populations is critical to the advancement and longer-term viability of the field of “emerging adulthood.”

TRANSITIONS TO EMPLOYMENT

Employment is a central role of adulthood, and work experiences in early adulthood have influences throughout the life course (Shanahan, 2000). In current American society, youth often combine schooling and work roles before moving into an “employment-only” role (Bozick, 2007), an issue discussed in more detail in the next section of the chapter focusing on transitions to higher education. Data indicate that 77% of 25-year-olds in America who were not in school reported working (Bureau of Labor Statistics, 2013). However, these employment rates vary both by race/ethnicity and educational attainment. In 2005, only 68% of African American youth reported being employed, as compared with 79% of European American youth and 77% of Latino American youth. Importantly, there appears to be a narrowing of the employment gap between African American and European American youth at higher levels of education. In 2005, among high school dropouts, only 43% of African American youth were employed, compared with

66% of their European American counterparts. However, the racial disparity is reversed among those with a 4-year college degree. Among 25-year olds with a Bachelor's degree, 94% of African Americans reported employment compared with only 91% of Whites. However, the employment rate for Latino Americans with a Bachelor's degree lagged behind at 88%.

Although race differences in employment rates vary by education, there are race disparities in earnings across educational levels. Earnings is an important employment indicator because it shows differentials that go above and beyond whether or not individuals are employable and taps into a quality indicator, namely how much the jobs pay. The National Center for Educational Statistics examined earnings among young adults aged 25–34 who were employed full-time throughout 2010. The mean earnings of European Americans was \$40,000, while average earnings totaled only \$31,600 for African Americans and \$30,000 for Latino Americans. Moreover, earning differences across race/ethnic groups persist at all education levels. For example, on average, employed European American young adults who have less than a high school degree earn \$25,000, while their African American counterparts earned only \$20,300 on average. Employed Latino American young adults with less than a high school degree earned even less, with the average being \$19,900. Among full-time employed young adults with at least a Bachelor's degree, differences of similar magnitude exist, with European American young adults earning \$49,500, compared with \$41,000 and \$44,100 for African American and Latino American young adults, respectively.

In Europe, there is considerable variation in youth unemployment disparities by ethnic minority status. Overall, youth unemployment rates are quite high, but there is variation across countries; furthermore, there is variation in the proportion of youth who are members of ethnic minority groups. Although statistics available on ethnic minority groups vary across country, statistics on the percentages of foreign-born residents exemplify these differences. For example, in 2004, Finland's foreign population accounted for only 2% of the total population, compared with 8.48% for Germany and approximately 8% for Spain (Morch, Jensen, Stokholm, & Hansen, 2008). Within each country, the composition of ethnic minority groups varies as well. For example, most foreign-born Germans are of Turkish descent, while Portugal has a large proportion of Ukrainians. Foreigners and ethnic minority youth in Europe often have higher unemployment rates than native and majority-group youth and are often overrepresented in

low-wage sectors of the labor market (Morch et al., 2008). However, there is marked variation within foreign and ethnic minority youth. For example, in Norway, Eastern European immigrants, have higher employment rates than immigrants from the Middle East and Africa (Fangen & Paasche, 2013). In the United Kingdom, in 2005, Indian adults had an unemployment rate of 6.4%, while Black Caribbeans and Black Africans had rates around 11%. Faring worst were adults from Pakistani and Bangladeshi backgrounds who had unemployment rates of 12.8% and 19.4%, respectively (Kahenec, Zaiceva, & Zimmerman, 2010).

Striking disparities in youth unemployment exist in London, the most ethnically diverse area of Britain (Office for National Statistics, 2012a). In 2012, overall rates of unemployment among youth between the ages of 16 and 24 were high, with an average of 25.4%. However, the unemployment rate of White youth was only 19.4%. Youth of Indian (24.4%) and mixed (26.8%) backgrounds had higher rates, but were close to the overall average. Most troubling are the unemployment rates of Bangladeshi (37.6%), Pakistani (44%), and Black/African/Caribbean youth (44.3%). Overall, these rates highlight the significant ethnic disparities in youth employment and the need to examine rates by specific ethnic groups to understand the patterns within a given country (Office for National Statistics, 2012c).

Work with U.S. samples has assessed the relation between family income during childhood and employment during early adulthood. Using data from the longitudinal, nationally representative Panel Study of Income Dynamics, Duncan, Zirol-Guest, and Kalil (2010) examined family income during different developmental periods as predictors of annual hours worked and annual earnings throughout individuals' late 20s and early 30s. They found that, when entered in the same model, family income in early childhood (Ages 0–5) was predictive of both hours worked and earnings, whereas middle-childhood family income (Ages 6–10) and late-childhood family income (Ages 11–15) were not. These results highlighted the importance of early life experience to employment outcomes in early adulthood. Interestingly, most of the association between early childhood income and adult earnings operated through hours worked. Youth whose families reported more income during early childhood were able to work more hours in early adulthood which produced earning differentials, but they were not earning significantly more per hour. Further research is needed to understand the processes through which childhood family

income at different developmental periods influences multiple aspects of employment throughout the transition to adulthood, and how these aspects are interrelated (Duncan et al., 2010).

A critical question is what underlies these disparities across race/ethnicity and socioeconomic status. One perspective highlights the importance of childhood and adolescent experiences to successful transitions and how these experiences are stratified by race and social class. Another body of research focuses on how concurrent factors during the transition to employment enhance or limit individuals' success. In the next sections, we review findings from both of these perspectives and discuss the intersections between these two bodies of work. We begin with a discussion of contextual factors that influence employment outcomes during early adulthood. This is followed by a discussion of adolescent attributes and how they interact with contextual factors to influence employment outcomes. The section concludes with a discussion of proximal factors related to social location that influence the employment prospects of low-income and ethnic minority youth.

Child and Adolescent Predictors of Employment During the Transition to Adulthood

Throughout childhood and adolescence, youth are developing skills, attitudes, and behaviors that have lasting consequences for multiple facets of their adult life, including their career success. These attributes are shaped through interactions across a number of contexts, including home and school. However, a wealth of research has shown that children and adolescents' contextual experiences are shaped by both their family socioeconomic status and their race/ethnicity (Evans, 2004; Hardaway & McLoyd, 2009; McLoyd et al., 2009). In the following sections, we discuss research pertaining to contextual experiences as well as individual attributes as processes through which social location during childhood and adolescence influence employment in early adulthood.

Developmental Contexts

In this section we discuss the family and school as institutional contexts that influence employment outcomes during early adulthood. We also include adolescent employment as an important context, on the grounds that experiences of adolescent employment or unemployment are shaped in part by societal opportunity structures that result in socially structured experiences reflecting

membership in ethnic minority groups and socioeconomic status.

Family. The family is an important context for many aspects of development and this includes the occupational development of youth (Porfeli, Wang, & Hartung, 2008). Race/ethnicity and socioeconomic status shape parents' own occupational success and their parenting, both of which have the potential to influence the transition to employment of youth. For example, in their sample of inner-city males, DiRago and Vaillant (2007) found that low family socioeconomic status during adolescence predicted low occupational status at Age 25. Protective environmental factors, operationalized as positive relations with parents and positive home environments, predicted higher occupational status, but the study did not cast light on how socioeconomic status and the family context operated in conjunction with one another to influence occupational outcomes. That is, because moderation was not examined, it is unclear whether these positive aspects of the family environment represented protective factors for socioeconomically disadvantaged youth, or were promotive factors that were important for occupational success for youth of all backgrounds.

Parallel work in Britain has focused on the concept of NEET, a term we mentioned previously that refers to youth who are not in education, employment, or training. Using longitudinal birth cohort data, Bynner and Parsons (2002) showed that youth who received free lunch benefits and youth whose families resided in an inner-city neighborhood, both at Age 10, were more likely to spend at least 6 months in NEET during the 2 years immediately following the end of formal schooling (Ages 16–18). However, the influence of family poverty, as indicated by free lunch status, was concentrated among girls, while the influence of neighborhood disadvantage, as indicated by residing in an inner-city neighborhood was concentrated among boys (Bynner & Parsons, 2002). Importantly, these relations were maintained even when educational qualifications at Age 16 were included in the statistical models, indicating that educational achievement is not the sole mechanism linking earlier disadvantage to NEET status. While the concept of NEET is useful to our discussion of transitions to employment, Roberts (2011) pointed out that there are many youth who are not in NEET but are also not gaining the skills and experiences needed to have a productive career. For example, many youth he interviewed were not in school and were working in retail jobs with little room for advancement. Further conceptualization of the

many pathways socioeconomically disadvantaged youth experience is an important direction for future work.

Additionally, there is a need for more examinations of the pathways through which social class influence the transition to employment of youth. Although there is a dearth of research that examines how families influence actual employment outcomes in the transition to adulthood, there is evidence that family economics influence the attitudes and beliefs of youth about their own occupational futures. For example, research indicates that adolescents are more optimistic about their economic and occupational futures if their parents are employed (Quane & Rankin, 1998), if they perceive their families as experiencing less financial strain (Flanagan, 1990; Larson, 1984; McLoyd & Jozefowicz, 1996), and if they perceive their parents as having more favorable work experiences (Neblett & Cortina, 2006). Future work needs to examine whether these occupation-related attitudes influence actual occupational outcomes as youth transition to adulthood.

School. Although there is a well-established process by which family socioeconomic origins influence adult employment outcomes through educational attainment (Sewell & Hauser, 1975), there have been relatively few studies that link aspects of the school context to employment-related outcomes. A “college for all” mentality prevails in the United States, a side effect being that secondary schools do not actively prepare youth for the transition to careers (Rosenbaum, 2001). This is especially problematic for youth from economically disadvantaged families because they have fewer financial sources for post-secondary schooling than their economically advantaged counterparts.

Research on alternate school models suggests that emphasizing careers during high school may benefit youth as they negotiate the transition to adulthood. Some of the most promising evidence comes from a rigorous, longitudinal random assignment evaluation of Career Academies (Kemple, 2008). Career Academies are high schools that focus curricula around both academic and technical themes, and provide work-based learning activities through partnerships with local employers. Youth who were assigned to the Career Academies treatment group had higher earnings across the first 8 years after high school and were averaging more hours worked per week (Kemple, 2008). These findings were concentrated among minority men, who are typically the most disadvantaged group of youth in the transition to employment (Edelman, Holzer, & Offner, 2006). Importantly, educational attainment was

not lower for students who attended Career Academies, as compared with students in the control group, indicating that the increases in employment-related outcomes did not come at the expense of educational attainment (Kemple, 2008).

Many countries have vocational training models that provide youth with practical job skills and experience. For example, in Germany, youth are tracked at the end of elementary school (approximately 4th grade in the American system) into different types of training. Two of these tracks, *Hauptshulen* and *Realschulen*, focus on providing schooling in combination with vocational preparation. Importantly, these tracks provide adolescents with apprenticeships, which allow youth to gain real employment experience and begin to make connections in the labor market (Cook & Furstenberg, 2002). An advantage of the German system is that youth from these tracks leave secondary schooling with job skills and experience. Because of the lack of attention paid to vocational training in the United States, students who do not attend college have to start gaining these skills and experiences on their own, and have few qualifications for employment beyond the low-wage service sector (Rosenbaum, 2001). Additionally, scholars have argued that vocational training provides youth with the opportunity to be mentored in a meaningful way (Hamilton & Hamilton, 2004).

However, there are downsides to the German system as well. In particular, tracking youth from such an early age is likely to intensify reproduction of existing social class and ethnic disparities. For example, youth from Turkish families are less likely to obtain apprenticeships and are more likely to receive training for menial jobs than youth from German families (Cook & Furstenberg, 2002). Other European countries, such as Sweden, provide vocational training to youth during high school, but the decision to enter this track is made at the start of high school, much later than in German system. This may provide opportunities for more mobility for youth from disadvantaged social locations (Cook & Furstenberg, 2002).

Adolescent Employment. For many youth, employment begins during the adolescent years. These early employment experiences shape later occupational outcomes, particularly for youth from socioeconomically disadvantaged families. While national studies tend to find small or nonexistent relations between adolescent employment and employment in early adulthood (Light, 1999), studies that focus on youth from economically disadvantaged families point to employment during adolescence as

an experience that promotes positive outcomes during the transition to adulthood. For example, Staff and Mortimer (2008) used detailed, longitudinal data to examine how patterns of employment during high school predicted wages during the transition to adulthood and early adulthood. Adolescent employment experience predicted higher wages in adulthood for youth whose parents did not attend college. Among this group of youth, intense adolescent employment (i.e., working more than 20 hours per week), predicted higher wages when youth were in their early 20s, but this relation faded by Age 31. In part, this fade-out occurred because the high levels of employment reduced the educational attainment of youth. However, low-SES youth who had steady, low-intensity work throughout adolescence had higher wages in their 20s and 30s than low-SES youth who had less steady work or no work during adolescence. Moreover, multiple studies have shown that stable, low-intensity adolescent employment is related to an increased likelihood of college attendance and completion for youth from socioeconomically disadvantaged backgrounds (Leventhal, Gruber, & Brooks-Gunn, 2001; Staff & Mortimer, 2008).

Adolescent employment may matter more or differently in the long term for youth from socioeconomically disadvantaged families than more advantaged youth for several reasons. First, youth from low-SES families are more likely to be living in economically depressed areas, where jobs are difficult to obtain. Consequently, youth who are successful at securing and maintaining jobs may already have higher levels of work-related skills and personal characteristics such as autonomy (Purtell & McLoyd, 2013). Second, low-SES youth are more likely to be working so they can contribute earnings to the family or to save for college (Entwistle, Alexander, & Olson, 2000; D. S. Johnson & Lino, 2000; Lerman, 2000). In contrast, more affluent youth often spend their earnings on leisure purchases and activities (D. S. Johnson & Lino, 2000). These differential spending patterns may indicate that the meaning of work experience and the importance given to it varies by socioeconomic backgrounds. Lastly, because low-SES youth are less likely to attend college than high-SES youth, their connections and experiences on the job, more than those of high SES youth, may directly connect them to future employment (Ruhm, 1997).

African American and Latino American youth are less likely to be employed during adolescence than European American youth regardless of socioeconomic background (Gardecki, 2001; Lerman, 2000). Furthermore, Entwistle and colleagues (2000) documented that, among

low-income youth in Baltimore, African American youth put more effort into finding jobs, but were less likely to secure employment and were more likely to experience spells of unemployment than European American youth in the sample. Other longitudinal research, using an elaborate sibling fixed-effect methodology that compared outcomes between brothers in the same family, found that employment during adolescence predicted earnings in early adulthood. However, this relation did not hold for poor, African American males (Foster, 1995). Follow-up analyses suggested that a primary reason for this was that African American males did not work as much as other youth, and this may have prevented them from accruing the skills, experience, and connections that other youth in the sample developed (Foster, 1995). Taken together, these studies suggest that the challenges ethnic minority youth face in the adolescent labor market may further disadvantage them when they seek employment during the transition to adulthood.

Individual Attributes as Predictors

Research indicates that adolescents' cognitive and behavioral skills, as well as their occupational aspirations and expectations, forecast employment outcomes in early adulthood.

Skills and Behaviors. Caspi, Wright, Moffitt, and Silva's (1998) analysis of data from a birth cohort in New Zealand showed that reading scores and delinquency during adolescence were independent predictors of the employment status of youth between the ages of 15 and 21 (compulsory education ends at the age of 15 in New Zealand), above and beyond their educational attainment during that time period. These analyses also showed that parents' occupational status significantly predicted unemployment of youth, but the researchers did not test for mediation so it is unclear whether any of the personal characteristics mediated the relations between family socioeconomic status and unemployment during the transition to adulthood. Similarly, DiRago and Valliant (2007) did not test for mediation in their longitudinal study but did find that IQ during middle school predicted occupational status at the age of 25; however, this relation dissipated once educational attainment was included in the model. Other research has examined social skills as a predictor of employment success. In their long-term examination of a sample of youth in poverty, Collins and van Dulmen (2006) found social competence to be a strong predictor of work success during the transition to adulthood.

Aspirations and Expectations. Aspirations and expectations have long been studied as potential mediators through which social class is replicated across generations, a focus also evident in the research literature on educational attainment (see the “Educational Attainment” section). In their formative work on status attainment, Sewell and Hauser (1975) found that much of the relation between parental income and occupational status among males in the transition to adulthood was mediated through adolescent occupational aspirations and plans for the future. Ashby and Schoon (2010) used British birth cohort data to test an elaborate model of processes linking family social class and income to young adult (Age 34) earnings and social status. Their results showed that family income directly influenced adolescents’ ambition value (i.e., the importance they placed on being challenged in a job and moving up and getting ahead; career aspirations; educational performance). Income also influenced these adolescent characteristics indirectly through parents’ education aspirations for their children. In turn, each of these adolescent characteristics predicted later earnings and social standing, although some relations only held for males or females (Ashby & Schoon, 2010). Longitudinal analyses of this nature provide important insights into the processes through which family socioeconomic status operates to influence occupational outcomes during the transition to adulthood and beyond.

Other longitudinal work with the British Cohort Study has shown that the importance of occupational aspirations for future success varies by the social class of youth (Yates, Harris, Sabates, & Staff, 2011). In particular, having misaligned aspirations, where youth aspire to a career that requires more education than they expect to receive, and having uncertain expectations, where youth report not knowing what they want to be, at the age of 16 were both predictive of a higher likelihood of not being employed or enrolled in school or training (NEET) for at least 6 months between the ages of 16 and 18. Interestingly, when these ambitions were interacted with social classes, results indicated that the relations between misaligned and uncertain expectations and NEET were stronger for youth from lower socioeconomic backgrounds. This moderating effect was only found for boys, although the authors suspected that teenage pregnancy, which is very predictive of NEET among girls, may be confounding the effect of socioeconomic status. These results suggest that higher SES-youth in the United Kingdom may have additional resources to prevent them from falling into NEET status, even when they have misaligned or uncertain

aspirations, that low-SES youth cannot access (Yates et al., 2011).

Interactions Between Contexts and Individual Attributes

Longitudinal models that examine the interplay between socioeconomic status, contextual experiences, and individual characteristics are necessary to fully examine the processes through which family socioeconomic status affects transitions to employment of youth. Although some longitudinal studies included these constructs in their models simultaneously, they often did not directly test mediating and moderating influences (Caspi et al., 1998; DiRago & Vaillant, 2007; Wiesner, Vondracek, Capaldi, & Porfeli, 2003), and hence, provide no information about protective processes or the processes through which social location influences developmental outcomes. A notable exception is research using a British birth cohort sample. In addition to the study described above (Ashby & Schoon, 2010), Schoon and colleagues (2002) created a developmental-contextual model to examine how parent social class influenced an individual characteristic (i.e., academic attainment) and a contextual characteristic (i.e., cumulative risk). They extended this model to examine how academic attainment and cumulative risk were related at multiple time points throughout childhood and adolescence and how they each predicted social position (a measure that taps into occupational status) at the age of 30 or 33.

Their results clearly showed that: (a) parental social class predicted the cumulative risk and academic attainment of youth; (b) cumulative risk and academic attainment were correlated throughout childhood and adolescence; (c) cumulative risk at one time in childhood predicted the academic attainment of youth at the next time point; and (d) while academic attainment was a stronger predictor of social position in adulthood, some of that relation reflected the fact that risk indirectly influenced social position through academic attainment. Because they used two different birth cohorts (i.e., 1958, 1970), the authors were also able to document an increase across historical time in the importance of cumulative risk during adolescence to social position in adulthood (Schoon et al., 2002). By examining the influence of contextual risks and individual development at multiple times, these results showed one way in which disadvantage could accrue over time. Research from a resilience perspective has shown that both individual attributes (childhood IQ) and contextual characteristics (parenting support) predict work success at Age 30 (Masten et al., 2004). Interestingly, these influences

dissipated once competencies at Age 20 were included in the model.

Although the requisites for this type of research are high, more studies of this complexity are needed to document the processes that link social location of youth to childhood and adolescent characteristics and experiences and the transition to employment. Not only will they fill a gap in current research, but a more nuanced understanding of these processes can provide information about potential targets for future policies and programs seeking to enhance the outcomes of disadvantaged youth during the transition to adulthood. Next, we turn to examinations of how social location shapes processes during the transition to adulthood and their consequences for employment-related outcomes.

Proximal, Social Location Influences During the Transition to Adulthood

Although childhood and adolescent experiences certainly explain some of the influence of both race/ethnicity and socioeconomic status during the transition to employment, these social locations are associated with differential outcomes during the transition to adulthood above and beyond the influence of earlier experiences. For example, when Kmec and Furstenberg (2002) examined a sample of urban youth in Philadelphia in adolescence and later during the transition to adulthood, they found that minority men were more likely to be “off track” in terms of employment than minority women and both European American men and women. A finding of particular importance was that the inclusion of adolescent experiences and skills in their regression analysis did not reduce the discrepancies between minority men and the other youth in the sample. In short, the African American and Puerto Rican men were doing worse than might have been expected from their status in early adolescence. They were having greater difficulty than the other race/gender groups sustaining their status from early to later adolescence or translating their early educational attainment into further schooling or labor market experiences. These results suggested that processes driven by social location occur during the transitions to employment that contribute to the increased employment difficulties that ethnic minority men encounter during the transition to adulthood.

MacLeod’s seminal ethnographic work (1987, 2008) with two groups of males living in an urban neighborhood exemplifies the employment-related struggles that male youth from low-SES families face during the transition

to adulthood. The work documented how race, social class, and life events shaped aspirations and high school behaviors and attitudes. Seven years later, MacLeod reinterviewed these men to examine how they were faring, and whether their aspirations were actualized. Disheartening as they were, the follow-ups illuminated a number of pivotal processes that occur during the transition to employment. One group, labeled the “Brothers” because members were primarily African American, although on the “right track” academically in high school and strongly committed to the Protestant work ethic, were floundering as adults. They struggled to maintain steady employment, and primarily held jobs in the service sector that had minimal opportunities for advancement and increases in earnings. The other group, labeled “Hallway Hangers,” were primarily European American. Compared with the “Brothers,” they had higher levels of family stress during childhood and markedly lower levels of engagement in academics during high school. They too were struggling to maintain employment, but were also more engaged than the “Brothers” in detrimental behaviors such as drug use and crime. As discussed further on, the interviews with these young men pointed to both social capital and cultural capital as critical factors in their journey toward employment.

Social Capital

Social capital can be described as relationships and networks that are capable of transmitting valuable resources (e.g., information and assistance) (Lin, 2001). Networks of people have stores of resources at their disposal, and these resources are exchanged through social interactions (Ream, 2005). Social capital that inheres in relationships can be used to generate other forms of capital, including human and cultural capital (Ream, 2005). Social stratification is inherent in social capital, such that networks comprised of middle class and wealthy individuals typically have access to more valuable resources than do networks comprising working class and poor individuals (Bourdieu, 1986; Stanton-Salazar, 1997).

Multiple qualitative studies (Blustein et al., 2002; MacLeod, 2008; Newman 1999) have documented that knowing adults with connections to specific employment opportunities is the most common route to obtaining a job for low-SES young adults. For example, in her ethnographic study of young fast food workers in Harlem, Newman (1999) noted that youth who had employed family members or family members who were well connected within the community often utilized these connections to

obtain jobs. Although personal connections are advantageous at all levels of the labor market, they are particularly useful in the low-wage service market where there is often a large supply of workers who are qualified for the jobs in question (Newman, 1999). The importance of these connections is magnified even further for young workers, who are competing with older, more experienced job applicants.

Research in Britain has documented similar processes for young adults from disadvantaged neighborhoods. In their in-depth study of these processes, MacDonald, Shildrick, Webster, and Simpson (2005) found that these young adults relied on family members, friends, and neighbors for connections to jobs, but the jobs that these networks provided were often in the service industry and routine factory production industry. Consequently, the jobs had little room for mobility and were harder to maintain employment in because the large pool of adults trying to secure these jobs made employees highly replaceable. A critical insight that this work points to is the paradox of “the weakness of strong ties” (MacDonald et al., 2005, p. 884). When young adults reside in neighborhoods with diminished employment opportunities, strong ties to the neighborhood and community may actually be detrimental to their employment prospects, as the ties do not provide needed opportunities, and importantly, may actually limit young adults from forming connections outside the neighborhood that would potentially be more conducive to employment mobility (MacDonald et al., 2005). As will be discussed in the section of our chapter focusing on barriers to building social capital, a similar point has been made about the ways in which low-SES parents’ social capital and networks may limit the educational attainment of youth (Fasang, Mangino, & Brückner, 2010; Horvat, Weininger, & Lareau, 2003; D. H. Kim & Schneider, 2005).

The occupational success of the young men in MacLeod’s (2008) study was also heavily influenced by their social capital. Almost all of the men found jobs through people they knew, whether it was office jobs such as computer work, or blue-collar jobs such as roofing. Even the young men who were able to obtain educational credentials beyond their high school degree were still dependent on personal connections to obtain jobs. Another important theme that emerged from MacLeod’s work concerned the race disparity in social capital as it related to jobs. Although all of the “Brothers” had earned high school degrees, they struggled to obtain employment, in large part because they lacked connections to adults who could help them get hired. Although they had positive

adult figures in their life, these individuals were often not in position to help them get jobs. In short, the “Brothers” were not rewarded for their academic commitment with additional social capital related to employment. In contrast, several of the European American members of the “Hallway Hangers” were able to use their personal connections to obtain employment in spite of their academic and behavioral problems during adolescence and the transition to adulthood. This research exemplified one of the key challenges that African American men face when trying to break into the job market.

Detailed research in high schools and community colleges has shown that these institutions often have no direct connections to employers in the community (Rosenbaum, 2001; Rosenbaum, Deil-Amen, & Person, 2007). Establishing these connections is an important step toward linking employers to youth who are trying to make the transition to employment. Youth who work hard and do well in school, but are from families and neighborhoods where connections to employment are weaker, stand to benefit from these potential pathways to jobs. A more extensive discussion of the functional importance of social capital is presented in the section on transitions to higher education. Many of the processes discussed there have implications for the employment experiences and occupational attainment of low-income and ethnic minority young adults.

Cultural Capital

In MacLeod’s (1987, 2008) work, a key characteristic that differentiated the African American men who were successful in their jobs and those who were not was their ability to “fit in” with their bosses, coworkers, and in some cases, customers. Fitting in encompassed many things, including acting professionally, dressing a certain way, and communicating in ways that made others feel at ease. Cultural capital, originally proposed by Bourdieu (1977), is a resource that is defined by a dominant group that enables them to maintain their status in society. It encompasses linguistic styles such as ways of speaking, and outward cultural styles such as how one dresses (Dumais, 2002). In employment settings in the United States and other countries, cultural capital is primarily determined by middle-class, nonminority groups. Given the widespread racial and class segregation in the United States, it is not surprising that youth from ethnic minority and low-SES groups possess less cultural capital than European American, middle-class youth and that this can hurt them in the world of work. For example, they may know relatively little about appropriate dress and

self-presentation for job interviews. In MacLeod's work, the African American men who were most successful modified the way they spoke and dressed at work. Although this was advantageous to them in terms of employment, it sometimes led to problems in their social life as some of the young men were accused by friends and family of "acting White." Some of the men were able to successfully navigate the cultures of their workplace, family, and community by becoming "bicultural."

In a seminal study of Chicago employers, W. J. Wilson (1996) found that employers often held negative stereotypes about African American men. Many of these stereotypes were related to cultural capital. For example, employers reported that African American men "use street talk" instead of proper grammar and that this hurt them in job interviews (W. J. Wilson, 1996). In addition, they often observed that African American men lacked "soft skills" such as dependability and the desire to work hard. Although employers consistently reported negative opinions about the employability of African American men, they were much more favorable in their perceptions of African American women and their job-related skills and attitudes. As the low-wage job market continues to become more service-based, as opposed to labor-based, the importance of communication and customer relation skills increases (MacLeod, 2008) and individuals who have limited cultural capital and soft skills are likely to struggle when looking for jobs. Indeed, quantitative data indicates that African American males are much less likely than either European American men or African American women to be employed in "noncollege jobs" that involve interacting with customers (Holzer, 1996). Although much less studied, Hispanic males and females are also underrepresented in these types of jobs, perhaps due in part to language barriers (Holzer, 1996).

Discrimination

Other factors that shape the transition to employment are discriminatory hiring practices. While employers' unfavorable perceptions of young African American men appear to be based partly on their experiences with prior employees, they may unfairly disadvantage the job prospects of new workers looking for jobs. Many employers report utilizing tactics to deliberately exclude African American men from the process. These tactics include not calling applicants who reside in certain neighborhoods and placing advertisements only in suburban newspapers (Neckerman & Kirschenman, 1991; W. J. Wilson, 1996). In their study of low-skill employment in a poor neighborhood in Brooklyn,

Kasinitz and Rosenberg (1996) found that employers held similarly negative views about hiring African American men and were biased against hiring individuals from the local neighborhood, believing that such individuals were less reliable and more likely to engage in criminal activity. Thus, minority men from impoverished neighborhoods may experience multiple barriers when trying to enter the job market.

Another line of research has utilized audit studies to document how race shapes hiring processes (Bertrand & Mullainathan; 2004; Pager, 2007; Turner, Fix, & Struyk, 1991). In these studies, resumes are created with matched levels of education, experience, and other characteristics related to hiring—the only difference is whether the name on the resume sounds like the name of a European American or an African American person. The matched resumes are sent out as responses to the same job advertisement and responses from the employer, such as requests for interviews are tracked. In Bertrand and Mullainathan's (2004) audit study, the "White" resumes had a 50% higher callback rate than the "African American" resumes. On average, there was 1 request for an interview for every 10 "White" resumes, but only 1 request for every 15 "African American" resumes. Furthermore, living in a wealthy neighborhood provided an increase in the likelihood of callbacks for both groups of resumes. This again indicated that both socioeconomic status, as measured by neighborhood location, and race/ethnicity influenced the process of job attainment in adulthood.

Other audit studies have found that resumes with "White" names also receive more callbacks than resumes with Latino-sounding names (Kenney & Wissoker, 1994). Audit studies have also examined how race and educational prestige, in terms of the college at which one earned a bachelor's degree, influences one's early success on the job market (Gaddis, 2014). Results indicated that in terms of callbacks, resumes of African American youth who attended highly prestigious universities, such as Harvard, were about as successful as the resumes of European American youth who attended much less prestigious universities. Although education can help reduce race disparities in employment, this research suggested that education does not create a completely equal opportunity structure (Gaddis, 2014).

Audit studies often find low rates of callbacks across all of the resumes submitted, regardless of the names on the resumes. This is likely due in part to the fact that many employers hire people they know or are recommended by someone they know, reiterating the importance of social

capital in the transition to employment (DiTomaso, 2012; Gaddis, 2013; Kasinitz & Rosenberg, 1996; MacLeod, 2008). DiTomaso (2012) has explored the ways in which employed European American adults make it more difficult for minority adults to obtain job success, without holding discriminatory views. The insights from her interviews with adults in various types of jobs and social classes illuminated the role of social capital in reproducing racial employment disparities. European American adults are more likely to be in employment roles that have power and a say in hiring practices, and they are more likely to hire relatives, friends, or other members of their social networks. Because of this preference, African American adults have much lower odds of being hired, even though it is not directly related to their race, a process DiTomaso refers to as “in-group favoritism.” Her work made a compelling case that future research needs to focus on these processes to better understand why racial inequality is so persistent in the United States and other countries such as Britain.

Discrimination in hiring is *not* unique to the United States. For example, Fangen and Paasche (2013) summarize evidence indicating that very similar processes occur in Norway. Audit studies have shown that ethnic minority youth struggle to obtain job interviews when their names indicate that they are probably members of a minority group. Furthermore, qualitative research revealed that when ethnic minority youth received interviews, they were frequently told that they were not good fits for the jobs they applied for, even when they were highly qualified. It is unclear if these interview issues are due to cultural capital challenges or further discriminatory hiring practices, but either way, they present a serious employment challenge for ethnic minority youth. It is important to note that different ethnic minority groups within Norway reported different experiences with labor market discrimination. African-origin youth commonly reported discrimination while some youth from Asian backgrounds recognized that their minority group fared better in the labor market. Youth from other areas of Europe, such as Bosnia, recognized that their relative similarity to nonminority adults was advantageous to them in their job searches (Fangen & Paasche, 2013).

These labor market disadvantages, whether due to lower levels of social or cultural capital or experiences with discrimination, have lasting consequences. Early career experiences, such as time spent looking for jobs and the accumulation of job experiences, contribute to racial earnings gaps later in the life course, above and

beyond educational and early cognitive skill differences (Tomaskovic-Devey, Thomas, & Johnson, 2005). Early job market struggles inhibit the growth of human capital, most notably, skills that are needed in one’s specific field, and this contributes to racial inequalities in earnings later across adulthood. Understanding the processes that shape the transition to employment can also provide important insights into how careers and earnings unfold later in life.

Role Conflicts

Other life roles influence one’s ability to successfully navigate the transition to adult employment and these roles are also shaped by social location. For example, as discussed in more detail in the next section of the chapter on educational attainment, low-SES youth are more likely to be enrolled in higher education while transitioning to employment (National Center for Educational Statistics, 2010). Balancing schoolwork and employment is difficult and employers are not always able or willing to adjust work schedules to accommodate employees who have school demands (Newman, 1999). Furthermore, young adults from low-SES families are more likely to be using their earnings to contribute to family finances or to pay for their education than youth from more affluent families. Because their earnings are used for necessities as opposed to luxuries, young adults from low-SES families may be more likely to continue to work at jobs that have unfavorable work conditions. In particular, ethnographic work indicates that they may be more likely to stay in jobs where they experience harassment (McLaughlin, Uggen, & Blackstone, 2008). Future work is needed to further elucidate how social location influences experiences on the job, and employees’ tolerance of varying working conditions.

For young adults with children, particularly women, securing childcare is another challenge to maintaining consistent employment. As noted previously, African American, Latina American, and low-income women are more likely than middle-class European American women to have children during their late teens and early 20s (Martinez, Daniels, & Chandra, 2012; Mathews & Hamilton, 2009). In their longitudinal, mixed-methods work with low-income mothers—many who were in their 20s—Lowe and Weisner (2006) found that lack of childcare was a significant barrier to employment for many women. Even with state subsidies, women often found that childcare was too expensive to afford on their current wages. As an alternative, many working mothers relied on informal childcare, often from family members

and friends. These arrangements were sometimes unreliable, interfering with their ability to maintain their work schedules. These challenges increased the likelihood of job loss and “rapid job cycling,” where women frequently entered and exited employment. This rapid job cycling was associated with problematic job transitions, such as being fired and stagnant wage growth (Yoshikawa et al., 2006). Demographic research in Africa has documented detrimental effects of early childbearing on young women’s ability to obtain employment; however, further research is needed to elucidate how these processes unfold in developing economies (World Bank, 2009). Taken as a whole, these findings highlighted the consequences that motherhood can have for women’s transition to employment and their ability to maintain employment and achieve growth in their wages.

Although concern over challenges to the transition to employment have largely centered on African American and Latino American men (see Edelman et al., 2006), there is a need to study these processes in ethnic minority women as well. Evidence exists that African American women’s attachment to work values, including extrinsic, intrinsic, and social rewards, decreases throughout the young adult years at a rate significantly steeper than that of African American men or European American men and women (M. K. Johnson, 2002). Explanations for this disparity center on experiences distinctive to African American women. Specifically, M. K. Johnson (2002) noted that African American women were more likely than women in other demographic groups to be socialized to both family and worker roles, but subsequently have to contend with both gender and racial discrimination in the labor market. It is this confluence of factors, Johnson speculates, that prompts decreases in the value of work. Clearly, these important ideas warrant further examination. More generally, employment experiences among ethnic minority and low-SES women during early adulthood are a fertile area for future study.

Summary and Future Directions

It is clear that both race/ethnicity and socioeconomic status are linked to processes that lead to challenging transitions to employment in early adulthood. Although some scholars have concluded that socioeconomic constructs largely account for race and ethnic differences in the transition (Shanahan, 2000), we believe that race/ethnicity and socioeconomic status are both linked to processes that influence employment outcomes, although we recognize

that, in many cases, the processes associated with both overlap. Furthermore, it is clear from existing research that race/ethnicity, socioeconomic background, and gender all interact to influence the transition to employment. Quantitative and qualitative research suggests that African American men from economically disadvantaged backgrounds face the most challenges when trying to secure employment in early adulthood (Edelman et al., 2006; Kmec & Furstenberg, 2002; W. J. Wilson, 1996).

It is also apparent that these disparities are grounded in early experiences, during both childhood and adolescence. In particular, socioeconomic disadvantage shapes the contextual experiences of youth and their skills, behaviors, and aspirations. Although there is still much to be explored concerning the linkages between socioeconomic disadvantage, contexts, individual-level characteristics and later employment outcomes, it is clear that increasing the academic skills and social competence of socioeconomically disadvantaged youth, increasing their cultural and social capital, and reducing discrimination in hiring would improve the ability of socioeconomically disadvantaged youth to secure and maintain employment as they exit school and enter adulthood (Ashby & Schoon, 2010; DiRago & Vaillant, 2007). Evidence about how individual attributes interact with social and cultural capital across contexts and reliable findings about the characteristics of institutions that foster social and cultural capital among socioeconomically disadvantaged youth could inform the design of interventions to test the effects of policies and programs on the employment status, transitions, and experiences of at-risk young adults.

EDUCATIONAL ATTAINMENT

Our discussion of postsecondary educational attainment in relation to social class, race, and ethnicity begins with a demographic overview. Detailed attention is given to the demographics of postsecondary educational attainment in the United States. Against this backdrop, we examine interpersonal and institutional operating during middle-school and high-school that appear to influence post-secondary educational attainment among low-income and disadvantaged ethnic minority youth. We discuss race/ethnic disparities in resources that undermine educational attainment among low-income and disadvantaged ethnic minority youth, as well as factors promotive of educational attainment in these groups. We then turn to a brief discussion of concurrent or proximal factors related

to social location that shape experiences within the college context. Social capital is a central theme throughout the discussions of parental, extrafamilial, and institutional factors. Because social capital appears to be pivotal in the educational and occupation trajectories of low-income and racial and ethnic minority youth, we present a discussion of barriers to building social capital. Our discussion centers on research conducted with American youth, but we bring in research based on European youth selectively to illustrate cross-national generalization of certain findings. We conclude with a discussion of limitations in the current research literature and important areas for future research.

Demographics of Postsecondary Education

We focus on several indicators of postsecondary educational attainment, including timing of enrollment, college participation rates (i.e., the percentage of 18- to 24-year-olds enrolled in 2- or 4-year institutions), college persistence, and college graduation rates. Timing of enrollment—that is, whether high school completers enroll immediately or delay enrollment, is an important variable because those who delay are much less likely to attain a bachelor's degree in 6 years than those who begin immediately after high school completion (Bozick & DeLuca, 2005).

Socioeconomic Status

In the United States, as in Britain, lower social class is a strong predictor of lower levels of attainment in postsecondary education. In Britain, young people from manual social classes are underrepresented in higher education and this gap has increased over the past four decades (Connor, 2001; Summerfield & Gill, 2005). In the United States, youth from low-SES families, compared with youth from more economically advantaged families, are more likely to delay enrollment (controlling for race, gender, financial resources, academic achievement and preparation, etc.), less likely to enroll immediately (i.e., enrollment in the fall immediately after completing high school) or within 8 years of graduating from high school (Aud et al., 2013; Rowan-Kenyon, 2007), more likely to drop out (Walpole, 2003), less likely to return after dropping out, and less likely to attain a postsecondary degree (Diemer & Li, 2011). Analysis by quartiles of family income indicates that in 2010, the college participation rate among American youth was approximately 47% for those from the bottom quartile, compared with 82% for those from families with

income in the top quartile. In the same year, among 18- to 24-year-olds, about 11% from the bottom quartile of family income had completed bachelor's degrees by age 24, compared with 79% from families with income in the top quartile. The increase in bachelor's degree completion rates between 1970 and 2010 has occurred almost entirely among students from the top half of the family income distribution (Mortenson, Stocker, & Brunt, 2012).

Longitudinal research has provided estimates of the independent effects of parental economic resources available during adolescence on the educational outcomes of youth. Teachman, Paasch, Day, and Carver (1997) found that children who spent 4 years of their adolescence living in families below the poverty line were about 60% less likely to attend college (conditioned on high school graduation). With controls for welfare receipt, race, IQ, parental education, and other factors, the number of years spent below the poverty line was no longer significant. However, the difference in average income-to-needs ratio for the 4-year period remained statistically significant, with adolescents in families with lower income-to-needs ratios being less likely to attend college and obtaining fewer years of schooling.

Researchers have sought to identify distinctive roles of parental economic assets—not just income—in accounting for the educational attainment of youth. Y. Kim and Sherraden's (2011) investigation—based on a sample drawn from the Child and Young Adult data supplement to the National Longitudinal Study of Youth 1979—indicated that both family income and parental economic assets during the period when youth moved from 5th/6th grade (aged 10) to 9th/10th grade (aged 13) were associated with college attendance and college degree attainment. However, liquid assets (e.g., bank accounts, CDs) during this period were more important for college attendance (i.e., they accounted for the effects of income on college attendance), while stable income and more solid types of assets (e.g., values of residential and non-residential properties) were more important for college degree attainment. These relationships did not change substantially when noneconomic characteristics of parents and children were taken into account (e.g., race, child's cognitive ability, parental involvement in education).

Although low-income students' enrollment in college after high school represents a degree of success in overcoming obstacles, they are less likely to persist through graduation and "often enroll in institutions positioned lower in the stratified higher education system, instead of enrolling in institutions which have been found to

positively influence aspirations and persistence" (Walpole, 2003). They are overrepresented in 2-year colleges, as are African American, Latino American, and first-generation college youth. Community colleges are an especially important source of postsecondary opportunity for these students because of their affordability, physical accessibility (their geographic distribution increases the likelihood that youth can find a school within commuting distance of home and jobs), and open admissions policies, compared with 4-year institutions (Costello, 2012). Students who begin their higher education at 2-year colleges are much less likely to earn bachelor's degrees than are their counterparts who begin at 4-year institutions (National Science Board, 2002).

Race and Ethnicity

Although many racial and ethnic differences in postsecondary educational attainment among American youth have narrowed over the past three decades, for virtually all indicators, racial and ethnic differences continue to favor Asian Americans and European Americans, as compared with African Americans and Latino Americans. In 2010, the immediate college enrollment rate was 88% and 70% for Asian/Pacific Islander and European American high school completers, as compared with 66% and 60%, for African American and Latino Americans, respectively (U.S. Department of Education, 2012). Conversely, African Americans and Latino Americans were more likely to delay enrollment than Asian/Pacific Islanders and European Americans (Rowan-Kenyon, 2007).

Delayers, compared with on-time enrollees, had weaker academic credentials, came from families with fewer socioeconomic resources, and were more likely to attend non-4-year institutions (community colleges, technical/vocational colleges, junior colleges) and to transition to other roles such as spouse or parent before entering college (Bozick & DeLuca, 2005; James, 2012). Even after controlling for these differences, students who delay postsecondary enrollment have lower odds of bachelor degree completion. Scholars have speculated that the delayed enrollment effect may be due to lower levels of social integration resulting from reduced contact with students and faculty, fewer institutional supports, and more negative experiences as a consequence of being off-time with respect to their birth cohort's age-grade progression through the education system (Bozick & DeLuca, 2005).

Racial/ethnic disparities in college participation rates and college graduation rates parallel rates of immediate college enrollment. In 2008, the college participation

rates for Asians/Pacific Islanders and European Americans were 58% and 44%, respectively, while rates for African Americans and Latino Americans were 32% and 26%, respectively (Aud, Fox, & KewalRamani, 2010). There are different measures of graduation rates, but the most common is the proportion of first-time, full-time bachelor's degree-seeking students who graduate within 6 years. Based on this measure, Asian Americans have the highest graduation rate (69% in 2010), followed by non-Hispanic Whites (62%), Latino Americans (51%), Native Americans (40%), and African Americans (40%) (College Board Advocacy and Policy Center, 2013). In 2012, the percentage of 25- to 29-year olds with bachelor's degrees or higher stood at 60% for Asians/Pacific Islanders, 40% for European Americans, 23% for African Americans, and 15% for Latino Americans (educational attainment rates) (Aud et al., 2013). For most racial/ethnic groups, the college participation rate is higher for females than males, a trend that began in the 1990s. In 2008, the gender gap was largest for African Americans (African American undergraduate fall enrollment was 64% female; comparable figures for Latino American and non-Hispanic White undergraduate fall enrollment were 58% and 55%, respectively) (Aud et al., 2010).

In Britain, ethnic minorities are *more* likely than Whites to progress to higher education. Nonetheless, compared with White British students, on average, they have lower entry qualifications, are more likely to come into higher education from further education colleges (not dissimilar to continuing education in the United States), less likely to take the traditional "A" level route (academic, rather than vocational route), and exhibit lower levels of degree performance. However, these overall differences mask divergences between groups of ethnic minority students. In general, Black (Black Caribbean, Black African) students exhibit the most disadvantaged profile, with Indian and Chinese students exhibiting the most advantaged profiles. Compared with other ethnic minority students in Britain, Black students are older on entry, more likely to have vocational entry qualifications, and more likely to leave early from degree courses (Connor, Tyers, Modood, & Hillage, 2004).

In Belgium, Moroccan and Turkish youth (mostly Belgium citizens—local-born children of migrant parents who entered Belgium post-1950 in response to recruitment of foreign labor) are underrepresented in university education and overrepresented in vocational training. Italian youth in Belgium (mostly Belgium citizens whose descendants came to Belgium during a wave of immigration in the

1920s and a second wave in the 1960s) are less disadvantaged than Moroccan and Turkish youth in terms of university education, but are still at a disadvantage compared with their nonminority peers (Phalet, Deboosere, & Bastiaenssen, 2007).

Antecedents of Educational Attainment Among Low-Income and Ethnic Minority Youth

This section presents an examination of parental and peer factors operating during middle school and high school that appear to influence education attainment among low-income and disadvantaged ethnic minority youth during the transition to adulthood. Attention is also given to the role of mentoring relationships, relationships with institutional agents such as school personnel, and school structures. It is reasonable to assume that many of the factors and processes discussed below mediate social class, racial, and ethnic differences in educational attainment during the transition to adulthood. However, longitudinal studies that directly test these presumed processes are surprisingly sparse. A vast research literature exists on contributors to postsecondary education outcomes, but researchers often control for social class differences and racial/ethnic differences rather than assess how these differences may shape the experiences and outcomes of youth (Walpole, 2003).

Parental Factors

Research examining linkages between parental factors and educational attainment among low-income and ethnic minority youth coalesces around two types of parental factors—parents' educational expectancies for the child and their involvement in the child's schooling. We discuss each of these factors in turn.

Educational Expectancies. In keeping with the Eccles et al. (1983) expectancy-value model, numerous longitudinal studies based on U.S. and British samples point to the educational expectations of parents and youth during middle school and high school as important variables in the mediated chain of constructs that influence postsecondary educational outcomes among low-income and disadvantaged ethnic minority youth (Cardoza, 1991; Charles, Roscigno, & Torres, 2007; Chowdry, Crawford, & Goodman, 2009; Connor et al., 2004; Horn & Chen, 1998; Y. Kim & Sherraden, 2011; Rowan-Kenyon, 2007; Sandefur, Meier, & Campbell, 2006; Wood, Kurtz-Costes, & Copping, 2011; Zarate & Gallimore, 2005). The

longitudinal relationships between expectations and postsecondary educational outcomes are highly robust, as they typically hold with controls for financial resources, academic achievement of youth, and various demographic and background characteristics.

Parental expectations are an important source of variation in educational attainment within low-income and ethnic minority youth and a mediator of social class disparity in educational attainment. Low-SES parents are less likely than higher-SES parents to expect their children to attain bachelor's or advanced degrees. They are also less likely to tie their definition of success to 4 years of college attendance (Gutman, Schoon, & Sabates, 2012; Walpole, 2003). Research based on data from the Longitudinal Study of Young People in England shows that socioeconomic differences in college plans of youth, uncertainty regarding their aspirations for postsecondary education (responding "don't know" when asked whether they want to continue school after compulsory education), and college enrollment are partly mediated through parents' educational expectations (Gutman et al., 2012).

Early parental expectations are strong correlates of college attendance of youth because they reflect commitments that parents will follow through later on in the children's schooling. In Charles et al.'s (2007) study following an ethnically diverse national sample of youth, parents' expectations at 8th grade (Age 13) about how far the children will go in school was positively related to various investments in children's education 4 years later (12th grade). These investments included involvement in high school programs (discussing school courses, activities, etc.), amount of money saved for college, and knowledge about grants, loans, and scholarships for college attendance. Controlling for prior student achievement, all of these investments were significant predictors of both 2-year and 4-year college attendance 2 years later (with the exception that amount of money saved was unrelated to 2-year college attendance).

Parental expectations were closely aligned with subsequent college enrollment of male youth in Zarate and Gallimore's (2005) 15-year study of low-SES Latino American families (primarily Mexican Americans). In this study, the last interview was conducted 1 year after high school, when the majority of the participants were 19 years old. Throughout their children's schooling (kindergarten through 10th grade), parents of boys who eventually attended college consistently had higher expectations for boys' college attendance than boys who did not enroll in college. It was only in high school, however, that parents' expectations of girls distinguished between those who later

went to college and those who did not. Zarate and Gal-limore speculated that girls' college-enrollment outcomes might be less influenced by parental expectations because of acculturation, citing evidence that acculturated girls relied less on family than on school agents for emotional support.

In Diemer and Li's (2011) study of postsecondary persistence among low-income youth, mothers' expectations about how far their children would go in school indirectly affected postsecondary persistence (i.e., progress toward degree) 3 and 5 years later by fostering educational expectancies of youth for success in college. Expectancies of youth also mediated the effects of contextual support (i.e., how frequently youth discussed their future plans with their family and friends) on postsecondary persistence, but maternal expectations played a more significant role in expectancies of youth than contextual support. Wood et al.'s (2011) examination of on-time postsecondary educational progress among African American youth indicated that parents' expectations (when youth were in Grade 11, aged about 17) about how far their children would go in school were positively related to adolescents' educational aspirations and expectations, controlling for SES and academic achievement. Relations between parents' expectations and the aspirations and expectations of youth were mediated by the perceptions youth held of their parents' expectations. For boys, Grade 11 educational expectations and utility values each uniquely predicted college attendance one year after high school graduation.

Maternal expectations for educational attainment of youth also predict the timing of college enrollment. The odds of youth enrolling in college immediately after high school graduation, rather than delaying enrollment, are higher when mothers' educational expectations are higher during the child's senior year (aged 18), controlling for background factors, financial resources, academic achievement and preparation, and other factors. In addition, when mothers had no postsecondary expectations for the children, rather than expectations for graduate school attendance, high school completers were substantially more likely not to enroll within 8 years of high school graduation than to delay enrollment (Rowan-Kenyon, 2007).

Educational expectations of youth have been found to be associated with parents' economic assets (Y. Kim & Sherraden, 2011). There is growing interest in child developmental accounts (CDAs) as a strategy to encourage families to invest in a savings account specifically for their children's future postsecondary education. In addition

to their instrumental function, CDAs are hypothesized to increase educational expectations among low- and moderate-income parents and their children (Y. Kim & Sherraden, 2011). Destin and Oyserman (2009) designed an experiment to investigate the notion that children from families with fewer economic assets lower their expectations for college because they perceive it to be cost-prohibitive, and as a consequence, engage in less effort in school. The researchers experimentally primed low-income seventh-grade Latino American students to view college as closed (expensive) or open (college can be paid for with need-based financial aid). As predicted, students in the open condition, compared with those in the closed condition, had higher academic goals (as indicated by the grade they thought they would get in math and English classes). Among girls, those in the open condition, compared with those in the closed condition, planned to spend more time reading/studying and doing homework. In a follow-up experiment with low-income African American 12-year-olds, planned effort was higher in the open condition than in the control condition where children were not given any college information (controlling for student GPA).

Parental Involvement. A number of studies have found that parental involvement in school is related to children's school success, including college attendance (Sandefur et al., 2006). Parents' involvement in parent teacher associations (PTAs) is associated with greater educational attainment for children (Erickson, McDonald, & Elder, 2009). Parents' contact with school regarding high school and postsecondary planning increased the likelihood that students would see their school counselors about college information (Bryan, Holcomb-McCoy, Moore-Thomas, & Day-Vines, 2009). Parents who discussed education-related issues with their children and who initiated contact with the school about volunteering and academic matters increased the chance that their children would enroll in 2- or 4-year colleges, controlling for other forms of capital (financial, cultural, and human capital) (Perna & Titus, 2005; Sandefur et al., 2006). The relation of parents' education and income to postsecondary education outcomes decreased when social capital variables were taken into account, which suggested that parents' income and education was indirectly related to children's educational outcomes through social capital. Interestingly, in terms of magnitude of effects, the effects of some aspects of social capital on educational outcomes rivaled those of the parents' income and education (Sandefur et al., 2006).

Social capital variables also play a role in the timing of college enrollment. One study showed that students who delayed first-time college enrollment experienced considerably less parental involvement in their education during high school. These students also had weaker network support, in that they had fewer financial aid contacts, their parents were less connected to other parents, they had less positive student-teacher relationships, and they received less support from their high schools. Of the social capital variables examined, parental involvement in the children's education and high levels of school support increased the likelihood of enrolling in college immediately (Rowan-Kenyon, 2007).

Part of parental involvement includes parents' skill at garnering resources for their children. D. H. Kim and Schneider (2005) use the term "aligned action" to describe "goal-specific action through which parents channel information and resources outside the family and appropriate them for the purpose of helping their children achieve their goals" (p. 1184). They found that parental participation in programs designed to inform them about postsecondary education and financial aid programs increased the likelihood that their children would enroll in 4-year versus 2-year colleges. Other work has shown that the help parents provided to students and visits parents made to school were associated with better track placement (Ream & Palardy, 2008).

In addition to parents' direct involvement with their children and schools, the support parents receive from their networks also appears to promote positive outcomes among youth. In a longitudinal investigation of teenage mothers and their offspring, Furstenberg and Hughes (1995) found that social capital during adolescence predicted socioeconomic outcomes (i.e., college enrollment, labor force participation) in early adulthood, even when family human capital and the adolescents' early academic achievement and behavior were taken into account. Although this study focused on various aspects of social capital, the support mothers received from their social networks stood out as being related to each of the young adult outcomes. In addition to mothers' social support, parent-child activities, mothers' attendance at the children's schools, and the number of the children's friends the mothers reported knowing were uniquely associated with college enrollment.

Friendships

There is a surprising dearth of longitudinal research examining whether and how adolescent friendships during high

school influence the decisions of ethnic minority and low-income youth to go to college and their persistence once enrolled. The few extant studies generally report positive associations, but for reasons discussed below, the findings warrant caution. Horn and Chen (1998) identified eighth graders (12-year-olds) in the National Educational Longitudinal Study (NELS) who were at moderate or high risk of educational failure (i.e., they had two or more of the following risks—low SES, single-parent family, older sibling dropped out of high school, changed school two or more times from first to eighth grade, and average grades of C or lower from sixth to eighth grade, repeated an earlier grade from 1st to 8th grade). These students, compared with low-risk students, were more likely to be African American or Latino American and had less educated parents.

Two measures of peer engagement were assessed 2 years later, both based on reports from the focal students: (1) how important they thought their friends considered attending classes, studying, getting good grades, finishing high school, and continuing education past high school, and (2) how many of the students' friends had plans to attend 4-year colleges. The findings indicated positive effects of peer engagement on postsecondary and college enrollment, even with controls for parental school involvement, parents' educational expectations, students' school engagement, and college preparation activities. Compared with students whose friends did not have college plans, students who reported that most or all of their high school friends had plans for enrolling in 4-year colleges were far more likely to enroll in 4-year colleges themselves within 2 years of high school graduation. In addition, the importance that friends reportedly attached to learning activities such as studying and getting good grades increased the likelihood that the focal students would enroll in some form of postsecondary education (from short-term vocational programs to bachelor's degree programs), but not whether they would enroll in 4-year colleges. However, these peer factors were unrelated to students' persistence in postsecondary education (i.e., enrollment in postsecondary education full-time within a year after high school graduation and continuous attendance).

Sokatch (2006), also using data from the NELS but employing less restrictive sample selection criteria, reported similar findings. In his study of a sample of low-income African American and Latino American youth who attended public urban high schools, the best predictors of enrolling in 4-year colleges at least half-time in the fall following high school graduation were having more

friends who planned to go to 4-year colleges and having friends who wished to go to college after high school. This relation held with controls for academic achievement, financial aid information, parenting behavior, maternal school involvement, and students' perceptions of whether their mothers wished them to enroll in college immediately after high school.

In qualitative interviews with African American and Latino American college students about how peers in high school influenced their preparation for, decisions about, and adjustment to postsecondary education, many credited their friends for getting them to consider college as an option. They described their friends as advocates and monitors of academic engagement, as sources of academic and social support that were critical in keeping them on track academically, and as college advisors (e.g., introducing them to programs that sponsor student visits to college campuses and universities around the country, encouraging involvement in college preparatory programs, helping with applications to college; Holland, 2011). In addition, friendships with majority-group peers might allow ethnic minority youth to garner cultural and social capital that enhances education attainment of ethnic minority youth. Baysu and de Valk (2012) investigated the educational trajectories of Turkish and Moroccan second-generation ethnic minority youth living in four Western European countries (Sweden, Belgium, Austria, Germany). Across school systems, having more majority group friends (i.e., friends of Swedish/Belgian/Austrian/German origin) was associated with increased chances that the Turkish and Moroccan youth followed academic trajectories that ended with university attendance, net of school-level ethnic segregation. Having friends who left school without a diploma was associated with being in nonacademic trajectories (e.g., vocational).

Although studies of this genre are a needed counterweight to the emphasis in the research literature on the negative influences of young peers and friends, they do not provide compelling evidence of positive peer/friend influences, largely because they fail to address selection issues. Linkages between the behavior/attitudes of youth and that of their friends may reflect *influence* whereby friends socialize each other through modeling, support, reinforcement, and other processes, but they also may reflect *selection* whereby individuals interested in postsecondary education, for example, seek out peers with similar values (Crosnoe, Cavanaugh, & Elder, 2003). Both processes may occur within the same dyadic relationships, but efforts to parcel out the relative importance of these

two processes suggest that selection may be stronger in explaining associations between friends' behavior (e.g., Matsueda & Anderson, 1998). Without controlling for selection, overestimation of effects is likely.

One strategy to control selection effects in quantitative studies involves estimating cross-lagged models that measure the association between behavior/attitudes of youth and friends' behavior across three or more time-points (Matsueda & Anderson, 1998). Another is to examine the longitudinal association between behavior/attitudes of youth and friends' behavior at one time point, controlling for earlier behavior/attitudes (e.g., Crosnoe et al., 2003). Studies seeking to determine whether and how adolescent friendships during high school influence the decisions of ethnic minority and low-income youth to go to college and their persistence once enrolled have not used either of these strategies. A second limitation of these studies, and one that precludes use of the aforementioned strategies, is reliance on youths' perceptions of their friends in the absence of data directly from friends. This is problematic because adolescents tend to overestimate the extent to which their friends are similar to them (Crosnoe et al., 2003). Research that overcomes this limitation and employs sophisticated strategies to control selection effects will advance this area of study.

A longitudinal investigation by Cherng, Calarco, and Kao (2013), using data from the National Longitudinal Study of Adolescent Health, represents an important step in this direction. Direct measures of the characteristics and resources of both adolescents and their same-sex best friends permitted Cherng et al. to control several variables that might influence friend selection (e.g., GPA). They found that having a best friend with a college-educated mother significantly increased the likelihood of college completion, but having a best friend whose parents were high income did not. The effect held even after controlling for adolescents' family resources and for other factors (e.g., adolescents' and friends' academic achievement and expectations, parental expectations, school characteristics) that might influence both friend selection and educational attainment. Importantly, adolescents of different racial/ethnic backgrounds, socioeconomic statuses, and achievement levels appeared to benefit similarly from having best friends with a college-educated mother, and the benefits were evident regardless of whether friendships were reciprocated. Cherng et al.'s findings suggest that adolescent friendships can be an important source of social capital by providing access to college-educated adult role models, some of whom may adopt a direct mentoring role.

Mentoring Relationships

Mentoring relationships that develop outside of school naturally or through formal programs are also associated with positive education-related outcomes. An analysis of youth participating in the Big Brothers/Big Sisters of America program found that time spent with mentors and mentees' trust in the mentors were positively associated with increases in grade point average over time. Time spent with mentors was also associated with increases in time spent on homework (Gaddis, 2012). A study that used data from the National Longitudinal Study of Adolescent Health examined the effects of having natural mentors during adolescence and on outcomes from the ages of 18 to 26. After controlling for earlier levels of functioning, youth who reported having mentors were more likely to have finished high school and attended college. Moreover youth who did not attend college were more likely to work 10 or more hours a week if they reported having mentors (DuBois & Silverthorn, 2005).

Organized youth programs can put young people in contact with institutional agents. Research shows that youth involvement in extracurricular activities is associated with greater educational attainment (Erickson et al., 2009), and one of the mechanisms underlying this link may be the social capital youth develop through relationships with institutional agents. Involvement in extracurricular activities and organized youth programs can expose youth to adults who provide guidance and resources. Jarrett, Sullivan, and Watkins (2005) found that adults participating in organized youth programs provided youth with resources, including information, assistance, exposure to adult worlds, support, and encouragement. Youth also build relationships with institutional agents through programs designed to prepare them for work or college. Hemmings (2007) studied a program in which youth advocates, who were recent college graduates, help set up low-income high school students with internships in order to prepare them for the world of work. The youth advocates went beyond the stated goals of the program by helping youth build social and cultural capital that help in navigating college and middle-class society. They tried to help students develop a cultural repertoire that would enable them to be facile in disparate environments. In addition to addressing students' individual needs, they took students on college campus visits, helped them with college applications, and exposed youth to middle-class social networks. Youth advocates acted as bridges to resources and services to which the participants in the program would not normally have access.

Similarly, "I Have a Dream" programs that provide comprehensive and individualized support to help low-income youth graduate from high school and guarantee college scholarships to those who do graduate have been successful in large part because of the relationships students establish with program staff. Studies of these programs indicate that program staff provided students with various resources, including tutoring, tuition for private schools, and emotional support. Participants in two "I Have a Dream" programs graduated from high school at almost twice the rate of a control group of students who were a year older. Participants in the program also attended college at higher rates than similar students not in "I Have a Dream" programs (Kahne & Bailey, 1999).

Natural mentors can provide multiple forms of capital that keep motivated low-income students on track academically and help them get back on track if they digress. Abelev (2009) conducted life-history interviews with 50 adults (mostly African American) who were first-generation college students. Half were currently enrolled in universities and the other half were middle-class professionals already established in their careers. In discussing factors that contributed to their educational attainment and socioeconomic advancement, over half of the respondents mentioned a mentor who helped them transfer from low-performing public schools to high-performing public schools (typically magnet or charter schools) or private schools. The mentors often paid for the tuition, or arranged to have the fees waived for the students (direct financial assistance was the second most often mentioned factor/resource). A third type of resource that mentors provided was a customized education plan to ensure that "at-risk" behaviors such as teen pregnancies did not derail the educational trajectories of youth. In instances where adolescents gave birth, these plans helped them fulfill their family responsibilities while continuing to advance educationally. The mentors were also important sources of cultural capital, helping youth learn middle-class "habitus" (Bourdieu, 1977), including how to successfully navigate and maneuver within various "mainstream" social contexts.

Relationships With Institutional Agents

Along with the social capital that comes from parents, important nonparental adults—termed institutional agents—can also be key sources of social capital for young people. Institutional agents are "individuals who have the capacity and commitment to transmit directly, or negotiate the transmission of, institutional resources and opportunities" (Stanton-Salazar, 1997, p. 6). Institutional agents

help youth navigate institutions by providing knowledge, teaching skills, and helping socialize youth around the norms of mainstream institutions. Institutional agents are not merely supporters and role models—they actually pass on resources and provide children with access to various opportunities (Stanton-Salazar & Dornbusch, 1995). Institutional agents can also act as bridges to important people, networks, and opportunities (Stanton-Salazar, 1997). School counselors, coaches, program staff, and mentors can act as institutional agents (DuBois & Silverthorn, 2005).

School personnel are some of the most important institutional agents for low-income youth. Erickson et al. (2009) found that having teacher mentors rather than other types of mentors was most strongly related to educational attainment. Youth with more parental resources were more likely to have mentors, especially teacher mentors, but teacher mentors increased the probability of attending college more for youth with fewer resources than for youth with more resources. On the other hand, naming relatives as mentors seemed to be more beneficial for youth with more resources. Youth who named relatives as mentors were more likely to attend college. This increase in probability was greater for youth with more resources compared with youth with fewer resources. The findings suggested that relatives as mentors have complementary effects, increasing the likelihood of college attendance more for youth who are advantaged, whereas teachers as mentors have compensatory effects, increasing the likelihood of college attendance more for youth who are more disadvantaged (Erickson et al., 2009).

González, Stoner, and Jovel's (2003) qualitative study contrasted the prior school experiences of Latina American students who were in community colleges with those who were in 4-year colleges. Almost all of the students in 4-year colleges participated in gifted and talented education programs in which teachers encouraged them and were invested in their school success. Many of the students described getting glowing recommendations for college from their teachers. Moreover, participating in the gifted and talented education programs opened the door to other college preparatory programs that provided SAT-taking skills, college visits, and help with college essays. For these students, social capital accumulated throughout their K–12 education. On the other hand, a group of students who attended community college described mostly negative school experiences. They explained how tracking, English as a second language placement, and unsupportive school personnel essentially thwarted their chances of attending 4-year colleges. Access to institutional agents and social

capital seemed to differentially shape the trajectories of these two groups of students.

School counselors can also be institutional agents and critical sources of social capital. For low-income students, in particular, school counselors may be one of the most important resources for information about college, especially because low-income parents may lack knowledge about the college application process. African American students and low-SES students are more likely to go to their school counselors for information about college than non–African American students and high-SES students (Bryan et al., 2009). Contact with school counselors for college information by Age 16 increases the odds that low-income high school students would apply to two or more colleges (Bryan, Moore-Thomas, Day-Vines, & Holcomb-McCoy, 2011).

School Structures

High school graduates from low-income, African American, and Latino American families enter 4-year institutions at lower rates than those from higher-income, European American and Asian American families partly because of financial barriers, but also because, on average, they are less qualified academically. For example, the U.S. National Center for Education Statistics constructed a 4-year college qualification index based on high school grade point average, senior class rank, aptitude test scores from the National Educational Longitudinal Study, SAT or ACT scores, and a measure of curricular rigor. On this index, 86% of high school graduates in 1992 from families with high incomes were at least minimally academically qualified for admission to 4-year institutions, as compared with 68% of those from middle-income and 53% of those from low-income families. The proportion of college-qualified students was also directly related to their parents' educational attainments (National Science Board, 2002).

Score gaps among demographic groups in performance on the U.S. National Assessment of Educational Progress (NAEP), a congressionally mandated program, narrowed between 1990 and 2009, but remain substantial. In 2009, at Ages 10, 14, and 18, European and Asian American students scored significantly higher than their African American and Latino American counterparts (National Science Foundation, 2012). In 2005, at Age 18, a higher percentage of Asian American students (35%) scored at or above “proficient” on the NAEP mathematics assessment measures than did European American (29%), Latino American (8%), and African American (6%) students (Aud et al., 2010).

These demographic disparities parallel numerous inequalities in education. For example, U.S. national data collected from public high school teachers in 2007–2008 indicated that the racial/ethnic concentration of schools was related to teacher qualifications and teacher experience, both indicators of teacher quality (Aud et al., 2010). In schools with at least half African American enrollment, 25% of mathematics teachers had neither majored in mathematics in college nor been certified to teach mathematics—a rate that was almost 3 times higher than the rate for schools with at least half European American enrollment (8%). Schools that were more than half African American and schools that were at least half Latino American had a larger percentage of new teachers (i.e., less than 3 years of experience) than schools with at least half European American enrollment (13%, 15%, 10%, respectively; though it should be noted that in schools that were 50% or more Asian American, 16% of the teachers had less than 3 years of experience) (Aud et al., 2010).

Another challenge facing low-income and disadvantaged racial/ethnic minority youth is the lack of advanced placement classes. These classes provide opportunities for higher learning and enable students to begin earning college credits. Research has shown that low-income and disadvantaged ethnic minority students are less likely to attend schools that offer a wide variety of advanced placement classes and that within the schools that do offer them, low-income and ethnic minority students are disproportionately underrepresented in them (Solorzano & Ornelas, 2002).

The resources high schools dedicate to postsecondary planning and the extent to which school personnel are active in promoting college attendance shape college enrollment and college choice. As noted previously, these resources are particularly important for low-income and disadvantaged ethnic minority students who come from families without college-going histories. These students are especially dependent on teachers, counselors, and other nonfamilial adults to help them make educational plans and decisions (Roderick, Coca, & Nagaoka, 2011). Nonetheless, this is another domain in which low-SES and ethnic minority youth are at a disadvantage. Relying on data from the National Educational Longitudinal Study, Hill (2008) used surveys from school administrators to characterize school practices related to college attendance. Schools were grouped into three types of college-linking strategies. *Traditional schools* encouraged college visits and assisted students with college applications, but were limited in their outreach to parents. *Clearinghouse schools*

devoted substantial resources to college planning, assisted students with college applications, and conducted outreach to college representatives but little to parents. *Brokerizing schools* exemplified all of these characteristics, but also conducted considerable outreach to parents. Hill found that, controlling for student characteristics, students in brokering schools were more likely to enroll in college and in 4-year colleges rather than 2-year colleges. Brokering schools were less likely to serve minority and low-SES student populations, a factor that may partly explain why the vast majority of high-achieving, low-income students do not apply to highly selective colleges (Hoxby & Avery, 2013).

In a study of the 2005 high school graduates of the Chicago Public School System, which serves a predominantly low-income ethnic minority population, Roderick et al. (2011) demonstrated that urban students who aspire to 4-year degrees are more likely to plan to attend, apply to, be accepted into, and enroll in 4-year colleges that match their qualifications if they attend high schools where (a) a strong history of 4-year college-going exists, (b) teachers report high expectations and strong supports for college attendance, and (c) a high percentage of students complete the college financial aid application. Because the financial aid application is complex and requires technical support, its completion is a good indicator of the extent to which the schools are organizing students and providing concrete support around college application.

Poor schools appear to be an important contributor to the pre-college disparity in educational attainment between Black Caribbean students and White British students. Research based on national longitudinal data indicates that family-level socioeconomic variables do not account for the racial gap. Nor do parental and student attitudes (e.g., academic self-concept, educational aspirations), educational expectations, or achievement-related behaviors (e.g., parental supervision, parental involvement), as Black Caribbean students and their parents on average are *more* advantaged on these measures than White British students (Strand, 2007, 2011).

Proximal, Social Location Influences Within the College Context

Just as social location differences are reflected in the demographics of postsecondary education, they are also mirrored in the college experience itself. In addition to juggling increasing independence with the academic and

social demands in the college environment, the transition to college of low-income and racial/ethnic minority youth may be complicated by negative stigma, social class bias, and discriminatory treatment (Huynh & Fuligni, 2012). Low-income and racial/ethnic minority youth may experience feelings of isolation, alienation, and marginality, especially if norms in the college context (e.g., independence) are incongruent with norms in their natal family and community (e.g., interdependence) (Connor et al., 2004; Garcia, Hallahan, & Rosenthal, 2007; Stephens, Fryberg, Markus, Johnson, & Covarrubias, 2012; Stuber, 2011). Such experiences can undermine psychological adjustment, academic performance, and academic persistence (Connor et al., 2004; Huynh & Fuligni, 2012; Stephens et al., 2012), although some research indicates that perceived discrimination during college is associated with enhanced academic motivation among African American students (Levin, Van Laar, & Foote, 2006). The latter finding has been interpreted as a challenge response (coping resources outweigh task requirements) in distinction to a threat response (task requirements outweigh coping resources) and consistent with the notion that awareness of racism and structural barriers, in combination with connection to other African American students, are important elements of achievement strategies among African American students (Levin et al., 2006). It has also been pointed out that African Americans' ability to attribute negative experiences and outcomes to external causes enables them to maintain high academic commitment and motivation in the face of perceived discrimination (Levin et al., 2006; Oliver, Rodriguez, & Mickelson, 1985).

For low-income and working-class students in the United States and Britain, college attendance often means high-intensity employment and living off-campus. Compared with students from higher-income families, students from low-income families are more likely to work to earn money to support themselves while in college and are more likely to live at home during the first year of college (Bozick, 2007; Connor & Dewson, 2001; Heath, 2008; Walpole, 2003). Similarly, among those attending college in Britain, Black (Black Caribbean and Black African) students spend more time working than White and Indian students (Connor et al., 2004). These economic strategies can put students at a disadvantage in terms of persistence; accrual of human, social, and cultural capital; and post-college earnings (Bozick, 2007; Humphrey, 2006). Students who work more than 20 hours per week are more likely to drop out during or at the end of the first year of

college, controlling for socio-demographic characteristics, academic preparation, and a host of other background factors. This relation is attenuated when students live on campus, but intensified when students live at home. Students with the fewest economic resources tend to live at home and work at high levels of intensity, further impeding their ability to persist (Bozick, 2007).

In addition to making it difficult to keep up with course work, working can hamper involvement in student activities (Humphrey, 2006; Walpole, 2003). Longitudinal data from Walpole's (2003) national study of college students attending 4-year institutions indicated that low-SES students spent less time than their higher-SES counterparts engaging in activities that provided opportunities to accumulate social and cultural capital especially useful for educational attainment (e.g., visiting faculty members at home occasionally or frequently; spending time in study clubs or groups). They also spent less time studying than their higher-SES counterparts. Low-SES students appear to be less able than advantaged students to convert whatever social and cultural capital they accumulate during college to economic capital upon leaving college. Walpole (2003) found that, 9 years after entering college, students from low-SES backgrounds had lower levels of income, lower rates of graduate school attendance, and lower educational attainment than their peers from high-SES backgrounds. Low-SES students converted their capital into membership in the workforce at higher rates, but secured lower-paying positions than their high-SES peers.

Barriers to Building Social Capital

Several barriers preclude the accumulation of social capital by poor and working-class minority adolescents, including trust, race- and class-based stigma, economic constraints, and structural constraints. Understanding these barriers is a precondition to overcoming them in order to transmit the kinds of social capital that will facilitate educational attainment among socioeconomically disadvantaged youth.

Trust

One of the ways that social capital is created is through trusting relationships (Coleman, 1988). Abada and Tenkorang (2009) found that having trusting relationships with family members, neighbors, and people at work was particularly important in predicting enrollment in postsecondary education for Black youth in Canada, as compared with

other children of immigrants. Having trusting relationships helped explain the disparities in educational outcomes between Blacks and other groups. Similarly, Gaddis (2012) found that the level of trust between mentees and mentors is positively related to better grades for mentees.

Trust established in these types of relationships can provide a foundation for information and resources instrumental in promoting academic achievement and the pursuit of postsecondary education. For poor and working-class youth, differences in race and class and accompanying social distance, may make establishing trusting relationships with institutional agents particularly difficult. Youth may encounter mistreatment and experience alienation when they reach out for help (Kahne & Bailey, 1999). Minority students perceive more barriers to developing genuine and trusting relationships with school personnel, with the most frequently cited barrier being the authority/status of school personnel (Markward, McMillan, & Markward, 2003).

Stigma

Awareness and internalization of stigma associated with poverty or low-income may also act as a barrier that impedes youth from forming relationships with institutional agents. Research shows that individuals become aware of socioeconomic status and endorse stereotypes about the poor very early in childhood (Chafel, 1997; Weinger, 1998). Internalized class stigma can affect the way people behave and perform under pressure (Croizet & Claire, 1998) and can shape the way they interact with individuals who are of higher status. In their experiment examining cross-class interactions among college students, Garcia et al. (2007) found that low-income college students were less expressive (i.e., more difficult to read) when interacting with high-income peers. They concluded that, because lower-class status is stigmatized, low-income individuals attempted to conceal their class identity in these interactions by being less expressive. In a companion study, students who reported being from blue-collar backgrounds reported that they would change their behavior more when interacting with wealthy individuals than when interacting with working-class individuals. The findings from both of these studies imply that social class stigma is salient when lower-class individuals are interacting with individuals from higher-class backgrounds (Garcia et al., 2007). Awareness of stigma (whether conscious or subconscious) may make initiating cross-class relationships with institutional agents difficult for lower-class individuals and perhaps may make these interactions more stressful. Lack

of expressivity on the part of lower-class individuals may make it more difficult for a shared understanding to be reached during these interactions. Stigma may keep youth from accessing or tapping into resources and networks.

Furthermore, biases, stereotypes, and stigma likely shape who institutional agents choose to sponsor. Youth are valued differently based on race, class, culture, and language. Latino American students in one study described more negative than positive experiences with teachers and counselors. School personnel had low expectations and provided little encouragement to pursue postsecondary education (González et al., 2003). Likewise, a study of Aboriginal and Anglo-Australian girls living in public housing in Glebe, Australia, described how school personnel stigmatized them based on their neighborhood. As a result, these girls did not feel encouraged in their educational pursuits and turned to relationships with friends, instead of school-based institutional agents, for help dealing with problems at home or for assistance with meeting everyday needs (Bottrell, 2009). Young, ethnic minority Britons from working-class backgrounds also describe similar experiences as barriers to completing higher education (Basit, 2012).

Gaining access to high-status or privileged social capital may require certain types of cultural capital, as institutional agents may recruit mentees who display middle-class cultural capital (Stanton-Salazar, 1997; Stanton-Salazar & Dornbusch, 1995). In addition to issues of stigma and discrimination, low-SES youth may have fewer opportunities to build relationships with institutional agents because of financial constraints. As mentioned earlier in the chapter, low-income students work more during college and are more likely to live at home, instead of on campus, than other students. These circumstances increase the likelihood that low-income students will leave school during their first year of college (Bozick, 2007) and spend less time than more economically advantaged students in activities that potentially build social capital (e.g., attending social events at faculty members' home, participating in student clubs and groups) (Walpole, 2003).

Structural Constraints and Network Composition

Broader systems of social stratification influence how networks are formed and who is included and excluded (Hampton & Duncan, 2011; Stanton-Salazar, 1997, 2011). Social networks tend to be largely homogeneous in terms of demographic characteristics such as race and class (McPherson, Smith-Lovin, & Cook, 2001). Factors such as homophily in social networks and neighborhoods, as

well as racial and economic segregation in neighborhoods, schools, and other contexts, may act as barriers that block access to networks that would open up educational opportunities for minority youth and youth from poor and working-class backgrounds (Quillian & Redd, 2008). Exclusion inherent in some social networks likely contributes to inequality in educational opportunities (Stanton-Salazar, 1997).

Racial and economic segregation are structural constraints that influence the contexts in which children are developing and the resources available to them within these contexts. Poor and working-class youth lack access to high-status institutional agents and networks, in part because of where they live (Coll et al., 1996; Quillian & Redd, 2008). Neighborhoods that have greater proportions of residents with higher levels of income and education are associated with better educational achievement and attainment outcomes among youth, even accounting for school-level variables (Ainsworth, 2002; K. Wilson, 2001). Goldsmith (2009) examined the long-term effects of school and neighborhood racial segregation during high school on educational attainment at Age 26. After accounting for early student and family characteristics, the concentration of African American and Latino American students in a school was associated with less educational attainment by Age 26. This research suggests that students with similar characteristics and backgrounds have different odds of educational attainment depending on the racial and ethnic makeup of their schools. Goldsmith hypothesized that part of the reason for this disparity is that African Americans and Latino Americans in segregated neighborhoods and schools have limited access to high-status networks that provide information and resources important for accruing high levels of education.

Other work has shown that human and social capital at the school level, as measured by the number of parents who contact the school about academic matters, average family income, average parental education, and average parental educational expectations within the school, is positively associated with college enrollment (Perna & Titus, 2005). African American and Latino American families not only had less family income, parental education, and math coursework than European American and Asian American families, but the African American and Latino American youth were much more likely to be in schools with the lowest average family income and parental education (Perna & Titus, 2005).

Several studies have reported that the networks of poor and working-class youth consist of individuals with

lower levels of human capital (e.g., education, income, and occupational prestige) and less middle-class social capital (Ream & Palardy, 2008). In terms of human capital, Haddad, Chen, and Greenberger (2011) found that the nonparental adults who were important in the lives of Latino American youth had lower levels of education than those of Asian American or European American youth. Important nonparental adults in the lives of Asian American youth had higher occupational prestige than the nonparental adults named by European American and Latino American youth. A similar pattern was shown among Mexican-origin high school students where the networks of high-SES students had an overall higher SES, based on the combined status of the members of the network (Stanton-Salazar & Dornbusch, 1995). The networks of poor and working-class youth and their parents also tended to include fewer school personnel and professionals (Horvat et al., 2003; Stanton-Salazar & Dornbusch, 1995).

Horvat et al.'s (2003) qualitative study of parents of elementary school students indicated that the networks of poor and working-class parents were distinctly less adept at navigating the school environment than those of middle-class parents. The networks of poor and working-class parents were comprised mostly of family members, whereas the networks of middle-class families were comprised of a wider array of adults, including other parents, school personnel, and extracurricular activity leaders. Middle-class parents had larger networks, in part because their children participated in organized activities at greater rates than other children; parents were able to meet other adults who were affiliated with the organized activities in which their children participated. Parental networks enabled middle-class parents to band together to address problems at school, advocate for their children individually and collectively, and secure special services and resources for their children. Although the networks of working-class parents were helpful in many other areas (e.g., childcare, transportation, emotional support), network members tended not to be useful when it came to school-related matters (Horvat et al., 2003).

Thus, although low-SES parents have social capital, the status of the network members is generally what makes some aspects of social capital more valuable than others. To illustrate this point, Portes and Landolt (1996) stated that "there is considerable social capital in the ghetto areas but the assets obtainable through it seldom allow participants to rise above their poverty" (p. 20). D. H. Kim and Schneider (2005) made a similar point when discussing network closure (i.e., when members of a network know

each other; Coleman, 1988). They explain that “network closure among parents with limited education and few social resources could result in a network that provides few resources for helping students gain access to information necessary for college applications” (p. 1183). Illustrating this point, findings from an empirical study suggested that social closure in parental networks may only promote high school graduation in low-poverty schools and that it may in fact be detrimental to high school graduation in high-poverty schools (Fasang et al., 2010).

Networks that are dense with individuals with high levels of education, high-paying jobs, elite careers, or wealth are likely better able to provide information, resources, and opportunities than networks comprised of poor and working-class individuals. As a result, working-class and minority youth may be more dependent on nonfamilial sources of social capital (e.g., institutional agents) for education-related issues and opportunities. In middle-class families, parents can often act as institutional agents (Stanton-Salazar & Dornbusch, 1995). However, in poor and working-class families, parents and other family members may be incapable of acting as institutional agents because they lack power and influence and do not have personal experience successfully navigating educational institutions (Stanton-Salazar, 1997).

Even when parents lack middle-class social capital, they may still be able to connect children with institutional agents (Stanton-Salazar & Dornbusch, 1995). Wuthnow (2002) referred to connections made between people of different social classes as “status-bridging social capital.” Through status-bridging social capital, people with less influence acquire resources through their social ties to individuals with higher status. Indeed, connections with high-status individuals or individuals in elite careers may help compensate for the shortcomings and lack of resources within low-income parents’ networks. For example, Jarrett (1995) reviewed existing qualitative studies of poor African American families, focusing on family factors related to upward mobility. Parents of socially mobile children were effective at developing networks of adults, including friends and relatives who provided support and resources to children. Sometimes these adults were middle class and could provide exposure to mainstream institutions and resources not available in the neighborhood. Another strategy used by parents of upwardly mobile children was building strategic alliances with mobility-enhancing institutions and organizations that underscore the values parents want to instill in their children. One way parents built these alliances was by making sure their children

were actively involved in church and school. These parents sought out programs and activities that help their children develop skills and build relationships. Parents of socially mobile children also encouraged adult-sponsored development, whereby children develop skills and competencies under the guidance of adults.

Summary and Future Directions

Parental expectations during middle school and high school are an important source of variation in postsecondary educational attainment among low-income and ethnic minority youth and there is a modest amount of evidence that they mediate social class disparity in the college plans and college enrollment of youth. Parental expectations influence educational attainment because they forecast the investments that parents will make in their children’s education and because they shape children’s educational aspirations and expectations. Parental involvement is also highly related to enrollment of youth in postsecondary education. In general, the link between parental expectations/involvement and educational attainment of youth is quite robust, as it holds after taking account of academic achievement of youth and various economic and demographic factors.

Further research is needed to assess the effects of educational aspirations and expectations on specific achievement-related behaviors in low-income and ethnic minority youth during high school and to determine whether the strength of these relations varies significantly by race, ethnicity, and race/gender subgroups. Research conducted two decades prior to the time of this writing indicated that the extent to which students believed that there were *negative* employment consequences of poor school performance was a better predictor of students’ academic achievement and engagement than the extent to which they believed that there were *positive* employment consequences of school success. African American and Latino American youth, as compared with Asian American youth, were overly optimistic that they could get a “good” job without getting a good education (Steinberg, Dornbusch, & Brown, 1992). During the past two decades, these beliefs may well have shifted and the ethnic/race differences may have dissipated, in response to increased demands and economic returns for high levels of education and training and continued declines in manufacturing and industrial jobs. Given increasing globalization and the major structural changes that have occurred in the U.S. economy during this period, there is merit in reassessing

these beliefs in relation to social location, and documenting the extent to which beliefs mediate and moderate links among achievement-related behaviors, parental educational expectations, and postsecondary educational attainment

There is a dearth of longitudinal research examining whether and how adolescent friendships during high school influence the decisions of ethnic minority and low-income youth to go to college and their persistence once enrolled. The few extant studies report positive effects of adolescent friendships on college-going, but these findings warrant caution because of potential selection bias. Studies are needed that use sophisticated strategies to control selection effects, as they would provide more valid estimates of the unique contribution of friendships to the postsecondary education outcomes of low-income and ethnic minority youth. Some research suggests that, in comparison with European American students in middle and high school, African American and Latino American students are more influenced by their peers and less by their parents in matters of academic achievement (Ogbu, 2003; Steinberg et al., 1992). Knowing whether this race/ethnic disparity exists with respect to college plans and college enrollment, in conjunction with knowledge about the educational plans of the mentees' friends, could be useful to high school counselors and mentors in shaping the messages they transmit to mentees.

Although researchers have made substantial strides in understanding the link between social capital and educational outcomes, there are several notable limitations that need to be addressed in future work. One of the main limitations is that most studies rely on secondary analysis of indicators that were not intended to measure social capital (Dika & Singh, 2002; Furstenberg, 2005). As a result, there are major discrepancies between how social capital is discussed theoretically and how it is assessed empirically. Theoretically informed, well-validated measures of social capital are needed to replace these crude, proxy indicators, as are systematic studies specifically designed to understand social capital (Dika & Singh, 2002). Measures of social capital should assess the status of network members, quality of relationships between network members, and the resources that are transmitted in these relationships.

In addition to measurement problems and the lack of in-depth studies, there is a paucity of research focusing on social capital during the transition to adulthood. Most studies have investigated the role of social capital during childhood and adolescence. Future studies that explore how parents use their networks to garner resources for

their children during the transition to adulthood would be valuable. Some noteworthy research has been conducted on the role of social capital among first-generation college students. More work examining how noncollege youth access, accumulate, and utilize social capital would be valuable. Likewise, more work should be directed toward understanding the role of race and discrimination in the ability of ethnic minority youth to access and convert social capital (Parcel & Dufur, 2001). How young adults acquire and use their own social capital through relationships with institutional agents is another important area for future research.

Few studies have focused on mentoring relationships during the transition to adulthood, and questions remain about what characteristics predict having a mentor and what characteristics of mentoring help connect young adults to jobs and educational opportunities. As with mentors, same-age peers may play a role in promoting or enhancing opportunities during the transition to adulthood. Thus attention should be paid to the extent to which friends transmit information and resources, as well as young adults' involvement in social and professional organizations as a source of social capital. Social capital studies focusing on the transition to adulthood need to expand the range of outcomes that are assessed. Examining how social capital affects the employment opportunities, labor force participation, and occupational prestige of youth is particularly important.

The gender gap in educational achievement, college participation, and college graduation rates among African Americans is alarming. The gap is substantially larger than what exists among other racial/ethnic groups and has increased markedly since the mid-1970s. This pattern has crucial implications for individual-level mental health functioning, economic well-being, family formation and stability, and performance of paternal roles. It also exacts a high societal cost linked to myriad social problems resulting from low educational attainment. Undoubtedly, the causes of this gender gap and the racial disparity in the gender gap are multifaceted. In light of these considerations, there is a clear need to document processes that promote postsecondary attainment among highly vulnerable groups, mediate differences among race/gender groups in educational outcomes, and processes that mitigate these disparities.

INTRODUCTION

Since the latter part of the 20th century, dramatic changes have taken place to the structure of the family, such that the traditional nuclear family headed by a heterosexual married couple is now in the minority. A number of factors have contributed to the diversity of family forms in which children are reared today; the increasing numbers of women employed outside the home, women’s enhanced educational and career opportunities, the introduction of the contraceptive pill, the rise of the women’s and gay liberation movements, greater involvement of fathers in the day-to-day lives of their children, and the advent of assisted reproductive technologies are just some of the factors that have increased the complexity of contemporary family life. As a result, a growing number of children are being raised by cohabiting, rather than married, parents, by single parents, by stepparents, and by same-sex parents,

with many children moving in and out of different family structures as they grow up. More remarkably, it is now possible for a child to have up to five “parents” instead of the usual two; these may include an egg donor, a sperm donor, a surrogate mother who hosts the pregnancy, and the two social parents whom the child knows as mom and dad, or mom and mom in the case of lesbian mothers and dad and dad when the parents are gay fathers.

In spite of the rise in the numbers of these nontraditional family forms, the nuclear family is still generally considered the optimal environment in which to rear children, and remains the gold standard against which all other family types are assessed. This view is rooted in the theories of children’s socioemotional development that were in vogue in the early 1970s, including psychoanalytic theory, social learning theory, and, to a lesser extent, attachment theory. Central to psychoanalytic theory was the belief that a mother and a father were necessary for boys and

girls to identify with the parent of the same gender as themselves, and thus to achieve healthy psychological functioning (Freud, 1925). An underlying assumption of classic social learning theory was also that mothers and fathers were influential in children's development and well-being, by providing role models for their daughters and sons (Bandura, 1977). Whereas attachment theory, at that time, stressed the importance of the child's relationship with one parent (the mother, with the father playing an essential supporting role) (Bowlby, 1969), this view was challenged by Rutter (1972), who showed that children could form attachments to more than one parent, and that the primary parent need not be the mother; this position was later accepted by Bowlby (Bowlby, 1988).

Contemporary theories have drawn from a developmental systems approach (Lerner, 2006; Lerner, Lewin-Bizan, & Warren, 2011), whereby bidirectional relations between individuals, the family, and the wider social world, including historical time and place, are viewed as influences on child development. This perspective places less emphasis on the presence of two married opposite-sex parents in the family home and instead focuses on the quality of family relationships, including parenting processes such as warmth and control, child effects on parenting such as temperament, and wider social and cultural influences (Lamb, 2012). Thus, there has been a shift in thinking, such that family processes are coming to be viewed as more important than family structure for children's psychological well-being, although it is acknowledged that each may influence the other.

Research on children's socioemotional development has also been enhanced by a life-span perspective, which views development as a process from conception onward (Freund & Lamb, 2010). This approach has been used to good effect in relation to nontraditional families by Hetherington and Stanley-Hagan (2002) who conceptualized divorce, single-parenthood, and remarriage as a series of transitions, each of which may affect parenting and child adjustment and may have a greater impact in the years immediately following a transition or when a family transition coincides with a developmental transition. In the present chapter, we examine the impact of changing family contexts on socioemotional development from infancy to early adulthood, where such data are available, with particular attention to the developmental stages that are of greatest relevance to the different family types.

Studies of the socioemotional development of children in changing family contexts are not simply of interest in their own right, but also provide "natural experiments,"

whereby factors that usually go together can be examined independently (Rutter, 2007). Thus, studies of emerging family forms can shed light on the influence of the number, gender, sexual orientation, and genetic relatedness of parents on child development (Golombok, 2000, 2005). This chapter examines the nontraditional family contexts in which children are being raised at the beginning of the 21st century: families headed by single parents, step-parents, cohabiting parents, parents whose children have been born through assisted reproductive technologies, and same-sex parents. The specific issues and concerns raised by each family type are outlined, followed by a discussion of the empirical findings on parenting and child adjustment, with particular attention to the relative importance of family structure and family processes for children's socioemotional development. Each section ends with a short conclusion. The general conclusion revisits the contribution that research on changing family contexts has made to our theoretical understanding of family influences on children's socioemotional development.

SINGLE-PARENT FAMILIES

Since the 1970s there has been a striking increase in the numbers of single-parent families. In the United States in 2008 (U.S. Census Bureau, 2012a) and the United Kingdom in 2007 (Lloyd & Lacey, 2012), around 30% of households with children were headed by single parents. This compares with less than 10% at the beginning of the 1970s. However, there is considerable variation from one country to another, with data reported by the U.S. Census Bureau (2012a) showing that the proportion of single-parent families in Japan, today, is similar to that of the United States and United Kingdom in the early 1970s.

Although often viewed as a homogenous group, single-parent families are formed in a number of ways, each with different implications for children. Parental divorce or separation is the most common reason for children to be raised by a single parent, who is usually their mother. However, there has also been a rise in the number of mothers who have been single from the time of the child's birth. Whereas the large majority of these mothers had unplanned pregnancies, a small but growing number of women have actively chosen to become single mothers. The studies that follow have focused almost entirely on families headed by single mothers, rather than single fathers. However, the limited body of research on single-father families is also discussed.

Divorced Single Mothers

Each year, around 5% of U.S. marriages end in divorce (U.S. Census Bureau, 2012b). Divorce statistics do not give the whole picture, however, as there are no official registries of relationship breakdown among cohabiting couples, and thus of the number of children affected by the separation of cohabiting parents (Amato, 2000). The numerous studies of the psychological consequences of divorce for children have consistently shown that children whose parents divorce are more likely to exhibit emotional and behavioral problems, and are less likely to perform well at school, than are children in intact families (for reviews see Amato, 2000, 2001, 2005; Amato & Keith, 1991; Coleman & Glenn, 2009; Hetherington & Stanley-Hagan, 1999; Pryor & Rodgers, 2001; Rodgers & Pryor, 1998). For example, a landmark study that followed 4-year-old children from the time of their parents' divorce was conducted in the United States (Hetherington, Cox, & Cox, 1982; Hetherington, 1988). These children were compared with children whose parents were happily married, and also with children whose parents remained together in spite of marital problems. The children's behavior was assessed over a period of 6 years. In the first year, children from divorced families showed higher levels of conduct problems both at home and at school than did children from two-parent families, and higher even than those whose parents were in conflict but remained together. By the end of the second year, children's difficulties had declined, although the sons of divorced parents still showed higher levels of conduct problems than did boys from harmonious two-parent homes (Hetherington, Cox, & Cox, 1982). A similar pattern of findings was found at 6 years following the divorce. Compared with children in nondivorced families, daughters whose mothers had not remarried remained well-adjusted. Sons also exhibited more positive adjustment, but still showed a tendency toward increased rates of conduct problems (Hetherington, 1988).

As the majority of studies of single-parent families have focused on families formed by divorce, the question is raised of whether having only one parent is, in itself, psychologically harmful for children, or whether other aspects of single-parenthood are implicated. One such factor that has consistently been shown to be related to children's adjustment problems is conflict between parents (Amato, 2000, 2005; Pryor & Rodgers, 2001; Rodgers & Pryor, 1998). Interestingly, longitudinal studies have shown that children can develop psychological problems years before their parents' divorce, sometimes even before the

parents have considered separation (Cherlin et al., 1991), suggesting that the psychological problems shown by children in single-parent families may not simply result from the absence of a parent, but instead may arise from hostility between parents beginning before the divorce took place.

The financial hardship that commonly accompanies the transition into a single-parent family following divorce is another key factor associated with children's psychological problems (Amato, 2000, 2005; Hetherington & Stanley-Hagan, 2002; Pryor & Rodgers, 2001; Rodgers & Pryor, 1998). From their detailed examination of four large, nationally representative samples in the United States, McLanahan and Sandefur (1994) concluded that the lower income and sudden drop in income that results from single-parenthood is the most important factor in the underachievement of young people from single-parent homes. They found that adolescents who had lived apart from one parent during some period of their childhood were twice as likely to drop out of high school, twice as likely to have a child before the age of 20, and one and a half times more likely to be out of work in their late teens or early 20s than were those from comparable backgrounds who grew up with two parents at home. Similar findings arose from an earlier study of 16,000 children born in the United Kingdom in 1 week in March 1958 (Elliot & Vaitilingam, 2008; Ferri, 1976). A comparison of children in single-parent families and children in two-parent families around the time of their 11th birthday showed that those in single-parent families were more likely to show emotional and behavioral problems, as well as poorer academic achievement. However, the difficulties experienced by children in single-parent families were explained almost entirely by the low income associated with single-parenthood, rather than the absence of a parent. When family income was controlled for, children with single parents did not differ from children with two parents in the family home. From their review of more than 200 studies, Rodgers and Pryor (1998) concluded that the low socioeconomic status of single-parent families is largely responsible for the lower educational achievement of children whose parents have divorced. In addition to the direct effects of low income, the financial hardship experienced by many single-parent families following divorce often necessitates a move to a poorer neighborhood and a change of school, each of which is associated with negative outcomes for children (Amato, 2000, 2005).

It is not only financial support, but also social and emotional support that are often lacking for single mothers. As

Hetherington and Stanley-Hagan (2002) pointed out, it is not unusual for mothers to feel anxious, depressed, lonely, and lacking in confidence when they divorce. At the same time, children become more demanding, less compliant, more aggressive, and more withdrawn. For newly single mothers, the demands of looking after difficult children while in a poor emotional state can impair their ability to function as effective parents. They may be less affectionate, less communicative, less consistent, more irritable, and more punitive in disciplining their children than before, which may exacerbate their children's difficulties (Hetherington & Clingempeel, 1992). A number of studies have demonstrated a link between parental depression, poor parenting, and negative child outcomes in single-parent families following divorce (Amato, 2000; Dunn et al., 1998; Hetherington & Stanley-Hagan, 2002), with improvement in mothers' emotional well-being associated with improvement in children's adjustment. Hetherington and Stanley-Hagan (2002) found that, 2 years following divorce, three-quarters of divorced women reported that they were happier in their new situation than they had been in their final year of marriage, and most felt that it was easier to raise their children alone than with a disengaged, undermining, or acrimonious husband.

Although negative effects of divorce for children's functioning have consistently been reported, the differences found between children in divorced and intact families have been relatively small (Amato, 2000, 2001, 2005; Amato & Keith, 1991). Not all children whose parents divorce develop problems, and some show improved functioning. Of those who do exhibit problems, some experience short-term distress (which may last from a few months to 2–3 years), whereas others face long-term difficulties (Amato, 2001; Hetherington, 1989). Whether or not children develop problems, and how quickly they recover, depends on a number of factors, the most significant of which appears to be the effect of divorce on the relationship between parents (Amato, 2000, 2001, 2005; Amato & Keith, 1991; Coleman & Glenn, 2009; Hetherington & Stanley-Hagan, 1999; Rodgers & Pryor, 1998). When couples remain in conflict after divorce, children are more likely to continue to have problems, especially if they are drawn into their parents' disputes. If parents are able to cooperate over parenting, children are more able to cope. The quality of the relationship between children and their parents postdivorce has also been found to be influential—with a warm and supportive relationship with at least one parent acting as a protective factor for the child—and there is growing evidence for the importance of a positive

relationship with the noncustodial father (Amato, 2000; Amato & Gilbreth, 1999).

Whether or not the gender of the child, or the age at which the child makes the transition into a single-parent family, makes a difference to the impact of divorce on children remains inconclusive (Amato, 2000, 2001; Amato & Keith, 1991; Hetherington & Stanley-Hagan, 1999; Rodgers & Pryor, 1998). Although boys seem to be more vulnerable than girls, it has been suggested that girls may show distress in different ways. In terms of children's age at divorce, adolescence is often considered to be an especially difficult time. However, few studies have identified a clear link between children's age at divorce and psychological outcomes (Amato, 2000).

An important question is whether the difficulties experienced by children in single-parent families following divorce result from selection effects rather than the divorce itself. Individuals with psychological problems may be more likely to marry each other and to have children with psychological problems, transmitted through inheritance or poor parenting. The parents' psychological problems may also contribute to marital breakdown. Thus, the difficulties shown by their children may not be directly related to divorce. Amato (2000) concluded from his review that the negative outcomes for children whose parents had divorced had resulted largely from marital breakdown rather than selection effects, and to the extent that pre-existing factors were involved, the divorce had exacerbated these difficulties.

Unmarried Single Mothers

In addition to the increasing number of children raised by divorced single mothers, there has been a sharp rise in the number of children raised by unmarried single mothers. Today, around 20% of babies in the United States (McLanahan, 2012) and 15% of babies in the United Kingdom (Kiernan, 2006) are born into single-mother families. Before the 1970s, the proportion of children born to single mothers was less than 5%. Currently, in the United States, the rates are highest for children born to African American mothers. However, there has been an increase in single-mother families across many ethnic-racial groups. In the United Kingdom, the large majority of unmarried single mothers are White, although a higher proportion of Black Caribbean mothers are single at the time of the birth, as compared with mothers from other ethnic groups (Kiernan & Mensah, 2010). Rather than race or ethnicity, the factor most associated with the rise in single unmarried

mothers is social disadvantage. Whereas college-educated women continue to have children in the context of marriage, women who have not received an education beyond secondary school are much more likely to have children as single unmarried mothers (Kiernan, 2006; McLanahan, 2012). Although single at the time of birth, many unmarried mothers experience transitions in and out of cohabiting relationships, rather than remaining stably single (Kiernan & Mensah, 2010; McLanahan, 2012).

An influential study of the consequences of unmarried single-motherhood for children is the Fragile Families and Child Wellbeing Study (FFCWS), a longitudinal investigation of approximately 5,000 children born between 1998 and 2000 in the United States. The study recruited participants in medium to large cities, and included an oversample of births to single as well as cohabiting unmarried mothers (Reichman, Teitler, & McLanahan, 2001). In-depth data were obtained on children's cognitive development and behavioral problems. More negative cognitive and mental health outcomes were found for children born to single unmarried mothers than to married parents, even after differences in parental resources were adjusted for (Waldfogel, Craigie, & Brooks-Gunn, 2010). The more negative cognitive outcomes appeared to have resulted from a high level of family instability rather than single-motherhood in itself. However, growing up with a single unmarried mother seemed to have mattered more than family instability for children's emotional and behavioral problems. As with single-mother families formed by divorce, economic hardship, parental mental health problems, and poor parenting quality were associated with more negative outcomes for children of unmarried single mothers. Again, selection effects may have also been operating in this study, such that the preexisting characteristics of parents might have led to poorer outcomes for children of unmarried single mothers (Waldfogel et al., 2010).

The Millennium Cohort Study (MCS) in the UK (Hansen et al., 2008), a longitudinal investigation of a nationally representative sample of approximately 18,000 children born at the turn of the century, also provided data on children of unmarried single mothers. The study oversampled disadvantaged families, and 15% of the children had been born to unmarried single mothers. In a comparison between children born to single mothers, cohabiting mothers, and married mothers over the first 5 years of life, children born to single mothers who did not marry the child's biological father and children born into cohabiting families where the parents had separated showed the highest rates of externalizing and internalizing problems

(Kiernan & Mensah, 2010). The single mothers also experienced the highest levels of economic disadvantage and poorest mental health. After taking account of whether the family lived in poverty or the mother was depressed, no significant differences were found across family types for children's internalizing problems. However, although reduced, higher levels of externalizing problems remained for the children of single unmarried mothers.

Single Mothers by Choice

The term "single mother by choice" refers to a woman who has actively chosen to parent a child without a partner. Such women are generally, but not always, well-educated and financially secure, and in their late 30s or early 40s when they become mothers (Bock, 2000; Jadv, Badger, Morrisette, & Golombok, 2009; Murray & Golombok, 2005a). The different routes to single-motherhood by choice include sexual intercourse with a man who will not act as a father to the child, donor insemination (DI) at a fertility clinic, self-insemination with a known or anonymous donor, and adoption (Bock, 2000; Hertz, 2006; Jadv, Badger, et al., 2009; Weinraub, Horvath, & Gringlas, 2002). Although women opt for different routes according to their circumstances and beliefs, donor insemination at a clinic appears to be the most popular method, with donor insemination favored over adoption by those who wish to experience pregnancy and have a genetically related child (Hertz, 2006; Jadv, Badger, et al., 2009). Contrary to the notion of "choice," the majority of women who decide to go it alone as mothers do so not from choice, but because they do not have a current partner and feel that time is running out for them to have a child (Hertz, 2006; Jadv, Badger, et al., 2009; Murray & Golombok, 2005a).

Concerns about single mothers by choice stem from studies of single-mother families created by divorce or unplanned pregnancy, which show that children are at risk for psychological problems. However, as discussed above, the adverse outcomes for children in these single-parent families appear to be largely associated with parental conflict, socioeconomic disadvantage, maternal depression, and lack of social support, none of which is characteristic of families formed by single mothers by choice. Children of single mothers by choice are not exposed to parental conflict or separation from a father with whom they share their daily lives. Neither do they generally experience the economic disadvantage, lack of social support, or maternal psychological problems that commonly accompany marital breakdown or unplanned parenthood (Hertz, 2006;

Jadva, Freeman, Kramer, & Golombok, 2009; Murray & Golombok, 2005a). Nevertheless, they grow up without a father from the start and, perhaps more significantly, do not know his identity. This makes them distinct from most other children of single mothers, whose fathers may be absent but whose identity is known.

There is, as yet, little research on the development and well-being of children raised by single mothers by choice. The two controlled studies that exist have focused on single-mother families created by donor insemination. In one, a comparison was conducted between 27 single heterosexual mother families and 50 married heterosexual parent families, all with 6- to 12-month-old infants (Murray & Golombok, 2005a). There were no differences between the two family types, either in terms of maternal psychological well-being and adaptation to motherhood, or in expressed warmth and bonding between mother and infant. However, single mothers showed lower levels of interaction with and lower levels of sensitive responding to their infants than did married mothers, possibly because the presence of a partner allowed the married mothers more time with their babies. When followed up at the child's second birthday, the single mothers showed greater pleasure and less anger toward their children, and their children showed fewer emotional and behavioral problems (Murray & Golombok, 2005b). Nevertheless, at Age 2, the children of single mothers were too young to understand the meaning of their nontraditional family structure.

In a study of older children conceived by donor insemination, 30 single heterosexual and lesbian mother families were compared with 50 two-parent heterosexual and lesbian mother families (Chan, Raboy, & Patterson, 1998). The average age of the children was 7 years. The children were found to be well-adjusted, with no differences between children of single and partnered mothers in externalizing or internalizing problems, social competence, or adaptive functioning. Instead, behavioral problems were associated with greater parenting stress, greater interparental conflict, and less interparental love, irrespective of family type.

A key question regarding children born to single mothers by donor insemination is how they will feel about not knowing the identity of their biological fathers. How best to respond to children's questions about their fathers is a major concern of single mothers by choice (Jadva, Badger, et al., 2009; Mattes, 1997). Single mothers are more likely than heterosexual parents to be open with their children about their use of donor insemination, not least because they have to explain the absence of fathers to their children

(Murray & Golombok, 2005a, 2005b; Jadva, Freeman, et al., 2009). In a study of 35 single mothers with children aged between 4 and 8 years, mothers reported that their children began to ask about their fathers from Age 2 to 3 onward (Zadeh, personal communication, June 8, 2013). The extent to which children of single mothers by choice will feel the need to know the identity of, have information about, or even form a relationship with, their donors as they grow older is, as yet, unknown. However, a small study of adolescents with identity-release donors in the United States found that those from single-mother families were more likely than their counterparts from two-parent families to plan to request the identity of their donors when they reached Age 18 (Scheib, Riordan, & Rubin, 2005). Jadva, Freeman, Kramer, and Golombok (2010) found that the majority of adolescents who searched for, and made contact with, their donors through the Donor Sibling Registry, a website designed to help donor-conceived people find their donors and donor siblings (half-siblings born from the same donor but living in different families), were from single-mother homes. This suggests that finding out about their donors was more important to adolescents from single-mother families than to those with two parents. However, the large majority searched because they were curious about their donors, and not because they wanted father-child relationships (Jadva et al., 2010). Interestingly, studies have found that the majority of single mothers believe it is important for children to have male role models to compensate for the absence of fathers, and most ensure that their children have male figures in their lives (Jadva, Badger, et al., 2009; Murray & Golombok, 2005a). Whether or not this makes a difference to the development and well-being of children of single mothers by choice remains to be seen. However, as highlighted by Lamb (2012), there is no empirical evidence from other family types to suggest that male role models in the home enhance the adjustment of children and adolescents.

Single Fathers

Although far less common than single-mother families, single-father families are increasing in number. Around 8% of households with children in the United States are headed by a single father, up from 1% in 1960 (Pew Research Center, 2013). Single-father families are most likely to be formed following parental separation or divorce, or, less commonly, when the mothers have died (Weinraub et al., 2002). Although it is unusual for fathers to be awarded sole custody of the children following divorce, this is becoming

more widespread, often because the mothers are unable to care for the children, themselves. There are also a small but growing number of unmarried single-father families. In addition, single fathers by choice are beginning to emerge. Like their female counterparts, these men actively choose to parent alone. The most common route is through adoption. Although inconceivable just a few years prior to the time of this writing, single men are also beginning to have children through surrogacy and egg donation.

There has been little research on the quality of parenting shown by single fathers or on the consequences of single-fatherhood for children's psychological adjustment. As Biblarz and Stacey (2010) pointed out in their review of existing studies, comparisons between single father and single mother families have been confounded by the very different processes that select men and women into single parenthood. Studies have shown that single-father households are more likely to have been recently formed through children switching custody arrangements due to difficulties in their relationships with their mothers or their new partners. Moreover, children in this situation are more likely to be boys, to be older, and to have behavioral problems. Single mothers are more likely to lack social support, to be younger, and to be economically disadvantaged. The few existing studies of single fathers have shown that most are committed and competent parents. However, where differences have been identified, single mothers have tended to show more positive parenting than have single fathers, in terms of closeness, involvement, communication, supervision and control, and their children have shown more positive outcomes in terms of behavior and achievement (Biblarz & Stacey, 2010). The different pathways to single-parenthood for men and women are likely to have influenced these findings, but the extent to which they have done so is unclear.

Conclusions

Although children in single-parent families formed by divorce are more likely to show poorer outcomes in terms of psychological well-being and academic achievement than are their counterparts in two-parent families, their difficulties appear to be largely associated with aspects of the divorce, rather than single-parenthood in itself. Several factors have been shown to be involved, including parental conflict, financial hardship, maternal depression, and poor parenting, all of which may interact with and exacerbate each other. Although some children are adversely affected by divorce, most recover over time, especially where

divorce improves family relationships. Similar processes appear to be at play in families headed by unmarried single mothers. The elevated levels of behavioral and emotional difficulties, and poorer cognitive development, of children raised by single mothers from birth appear to be largely associated with socioeconomic disadvantage, mothers' mental health problems, and poor parenting, with each adversely influencing the other. Studies of single mothers by choice provide an opportunity for researchers to examine the impact of single-parenthood on children in the absence of these risk factors, and will be informative in the future in addressing the question of whether being raised by single mothers *per se* has negative consequences for children. However, a potential risk factor for this latter group of children is not knowing the identity of their fathers.

STEPFAMILIES

Stepfamilies are a common family form in many Western societies. Around half of the adults younger than 30 years old in the U.S. Survey of Income and Program Participation (SIPP) in 2009 reported having at least one step-relative (Pew Research Center, 2011). Data from the SIPP also revealed that approximately 10% of children under 18 years old were living with a biological parent and a married or cohabiting stepparent, with the majority living with their biological mother and stepfather (Kreider & Ellis, 2011).

Stepfamilies vary considerably in terms of prior family context, producing a diversity of immediate and wider family networks. Stepfamilies may form when divorced or bereaved parents remarry; they may also be formed when divorced or bereaved parents cohabit with new partners. Just as the shadow of separation and divorce may continue to extend over stepfamily living, the legacy left by bereavement cannot be ignored. However, widows and widowers are often in a better financial position than are divorcees, and extended family are more likely to rally to support the remaining parents and the children after bereavement than after divorce (McGoldrick & Carter, 2011). Surprisingly little work has empirically investigated how the legacy of bereavement affects children's developmental outcomes in stepfamilies, and the evidence reviewed in this chapter concentrates on stepfamilies formed after parental separation.

Stepfamily membership can span multiple households. Sometimes children will live in a stepfamily with their parent and stepparent and, at other times, they will be

visitors to their nonresident parent and partner's household. In addition, Stewart, Manning, and Smock (2003) indicated that over half of the residential stepparents in their sample also had children living elsewhere. Sometimes more than one set of children is involved in a stepfamily. Simple stepfamilies are formed when only one of the repartnering adults has children from a prior relationship. In complex, or blended, stepfamilies, both partners are parents to children from preceding unions and both become stepparents in the new stepfamily formations. Children in these families become stepsiblings to each other. Complex stepfamilies may also arise when children are born (or adopted) within stepfamilies, making children within the stepfamilies half-siblings to each other.

Stepfather Stepfamilies

Much of the knowledge concerning the socioemotional well-being of children in stepfamilies has derived from studies of children living with their mothers and their stepfathers. Many of the important initial findings came from carefully designed longitudinal controlled studies of European American middle-class families in the United States, such as the Developmental Issues in Stepfamilies study (DIS; Bray & Berger, 1993) and the work of Hetherington and colleagues on the Virginia Longitudinal Study of Divorce and Remarriage (VLS; Hetherington, 1993; Hetherington et al., 1982), the Hetherington and Clingempeel Study of Divorce and Remarriage (HCSDR; Hetherington & Clingempeel, 1992) and the Nonshared Environment in Adolescent Development (NEAD) study (Reiss et al., 1994). Initial data from both the DIS and Hetherington's studies generally indicates that the children in stepfamilies displayed more externalizing problems and lower social competency than the children in either mother-father families or single-mother households on the Child Behavior Checklist (CBCL) and associated Teacher Report Form (TRF) (Achenbach & Edelbrock, 1983). However, other findings have presented a more nuanced picture, and suggest wider variance in developmental outcomes among the children who live in stepfamilies, compared with other family types.

Data from the VLS highlighted the importance of both the timing of maternal remarriage in relation to the child's gender and life-cycle development, and the recency of the remarriage, for the child's adjustment. Earlier data from the VLS seem to indicate that, while boys had a more difficult time adjusting to parental divorce (Hetherington et al., 1982), girls had more difficulty later in childhood

if their mother remarried (Hetherington, 1993). However, Skaggs and Jodl (1999), examining data from a 3-year follow-up wave of the stepfamilies in the NEAD study, found no differences between the adolescent boys and girls, and the adolescents in stable, simple stepfather families did not differ from the adolescents in the nonstepfamily comparison group on CBCL-derived measures of adolescent adjustment.

Findings from other studies of nationally representative samples have been inconsistent with respect to gender differences in children's adjustment. Aughinbaugh, Pierret, and Rothstein (2005), using data on the marital transitions of young women recruited to the U.S. National Longitudinal Survey of Youth in 1979 (NLSY79) and subsequent data on their children's developmental outcomes, found a more substantial increase in behavioral problems following mothers' remarriages for girls than for boys. However, data from the Avon Longitudinal Study of Parents and Childhood (ALSPAC), an epidemiological study of 14,000 families in the United Kingdom, showed that, at Age 4, boys, rather than girls, in stepfather family settings displayed greater emotional and behavioral problems and less prosocial behavior, even after the quality of parent-child relationships, maternal history, and current socioeconomic status were controlled for (Dunn et al., 1998).

Other studies have focused on educational outcomes and socioemotional problems among children in stepfather families. For example, Zill (1994) examined data from the National Household Education Survey (NHES) and found that, even after sociodemographic factors were controlled for, adolescents from stepfather families were more likely to have been excluded from school or to have had problems progressing through school, than those from mother-father families. Nevertheless, most adolescents from all types of families completed high school. Other data from the NHES indicated that levels of involvement of one or both parents in school were lower for students in stepfather families, than in mother-father families. And although greater parental involvement in school was associated with better student progression through school for those from stepfather families, this did not cancel out the effect of stepfamily status. However, Thomson, Hanson, and McLanahan (1994) examined parental reports of children's academic grades as gathered in the National Survey of Families and Households (NSFH) and found no significant differences between the academic performance of children in stepfather families and those in mother-father homes, but did find that parents reported stepchildren to display

more socioemotional problems. Thomson and colleagues found that poorer economic resources accounted for some, but not all, of the detrimental effects of family structure on stepchildren's academic grades and socioemotional behavior. Race/ethnicity effects were also found in longitudinal analyses of the NLSY79 dataset (Aughinbaugh et al., 2005). For Latino American children, behavioral problems increased subsequent to the mothers' marriages, whereas this was not the case for European American or African American children.

Research has indicated that parental divorce and remarriage might also have an effect on children's pubertal development, and might influence psychological outcomes via either adolescent hormones or self and others' perceptions of maturity. In the VLS, both the absence of biological fathers and the presence of stepfathers in the home were associated with the early onset of puberty for girls, but not for boys (Hetherington, 1993). Furthermore, adolescent girls who matured early were more likely than girls who matured later to become involved with older peers, including those involved in antisocial behavior; this difference was more pronounced in early maturing girls from remarried, as compared with married, mother families. Adolescents in remarried mother families were more susceptible to negative peer group influences than were children in nondivorced families (Hetherington, 1993).

Some researchers have examined whether growing up in stepfamilies is associated with differences in the young adults' attachment styles. An investigation of Australian university students found partial evidence that the students from stepfamily backgrounds were less likely than those from mother-father backgrounds to be securely attached (Planitz, Feeney, & Peterson, 2009). Further analyses revealed that satisfaction with the quality of their relationships with their biological fathers mediated the link between stepfamily background and negative attachment models. Students from stepfamily backgrounds also depended more on romantic partners as attachment figures than did participants from mother-father families. Hayashi and Strickland (1998) found that parental divorce disrupted young adults' feelings of security in their current romantic relationship. However, students from a background of parental divorce who rated at least one of their parental figures as accepting of them were more likely than others to feel secure in their romantic relationships.

Other studies have focused on the effects of family background on transitions into adulthood. Stepchildren tend to leave home earlier than children raised in mother-father families. Aquilino (1991) reported that 65%

of the stepchildren in his sample left home before 19 years of age, compared with 50% of the children brought up in mother-father families; this effect was stronger for stepdaughters than for stepsons, and also more noticeable if the stepchild had one or more stepsiblings living at home. The UK National Child Development Study (NCDS) also demonstrated that both stepsons and stepdaughters were more likely to leave home earlier than their peers in either mother-father or single-mother families, and left for college less often (Kiernan, 1992). In the NCDS, stepchildren were more likely than their peers to cite family conflict as a reason for leaving home. Data from the NCDS on young adult transitions also indicated that young people from stepfamily homes were more likely than those in single-mother families to leave school early and enter the labor force early. Goldscheider and Goldscheider (1993) found that the effect of stepfamily status on leaving home was stronger for young women than for young men, and that stepfamily status had a greater effect on the leaving-home patterns of European Americans and Asian Americans than it did for either Latino Americans or, especially, African Americans. McLanahan and Sandefur (1994) also identified differential effects of stepfamily living according to gender and race-ethnicity; young African American men in stepfamilies were at no greater risk of dropping out of school and young African American women were at no greater risk of teenage parenthood than were those in mother-father families. For European American youth, growing up in stepfamilies put them at greater risk of these outcomes, as compared with youth from mother-father families.

Nevertheless, some investigations have found no evidence that growing up in stepfamilies in itself influences long-term developmental outcomes for children. Longitudinal data from the Christchurch Health and Development Study in New Zealand initially indicated that growing up in stepfamilies increased the risk of various developmental outcomes at Age 18, including early onset of sexual activity and multiple sexual partners, a criminal record, substance misuse, and leaving school without educational qualifications (Nicholson, Fergusson, & Horwood, 1999). But additional analyses controlling for concomitant sociodemographic and individual risk factors that were present prior to stepfamily formation in middle childhood effectively nullified associations between stepfamily background and adolescent outcomes.

Regarding the influence of a stepfamily upbringing on young adults' family formation patterns, Goldscheider and Goldscheider (1993) found that stepchildren were

significantly more likely than their peers from mother-father families to marry early. Other reports, such as that by McLanahan and Bumpass (1988) using data from the U.S. National Survey of Family Growth, have found that children brought up in stepfamilies are more likely than those from mother-father family backgrounds to marry and have babies either early in marriage or before marriage. Adults from stepfamily or single-parent family backgrounds are also more likely to have their own marriages end in divorce than those from mother-father families.

Amato and Kane (2011) used longitudinal data from nearly 2,500 young women aged 16 years and older at the beginning of the Add Health study to examine the effects of parental marital status and relationship distress on daughters' family formation. Daughters from remarried-parent families were more likely than those with continuously married parents to have had either a nonmarital birth and/or to have cohabited by the third wave of the study 7 years later. Low self-esteem, symptoms of depression, poor school grades, and less traditional attitudes toward sex and pregnancy often mediated the association between family type and nonmarital births and cohabitations. Parental divorce, itself, did not increase the risk of an early marriage or a marital birth in this cohort, except for daughters whose resident parents reported unhappy remarriages. Levels of marital distress recorded for the continuously married parents group were not associated with daughters' family formation, thus suggesting that parental marital dissatisfaction was only influential against a background of prior parental divorce and subsequent remarriage.

In terms of social support over the life course, it seems that stepfamily support networks are weaker than those of biological kin (Harknett & Knab, 2007; White, 1994). Neither relationship quality nor level of contact between adult stepchildren and their stepparents were as high as for their counterparts from nondivorced families in White's (1994) analysis of data from the U.S. National Survey of Families and Households (NSFH). Adult stepchildren were also less likely to perceive their parents as available to offer emergency help if they needed it, or indeed to give help to their parents and stepfathers if requested. Nevertheless, current relationships with residential stepfathers were rated more highly on relationship quality than were relationships with nonresidential fathers. But if parental remarriages had ended in divorce, then contact had been lost with over half of the stepfathers involved. Other analyses of NSFH data indicated that stepsibling relationships were also weaker than full sibling relationships in adulthood; for example, stepsiblings were less likely than siblings to be called upon

for emergency assistance or to be listed as a "best friend" (White & Riedmann, 1992).

The evidence above seemingly indicates that children in stepfamilies have greater difficulties than do children in mother-father families in childhood, adolescence, and adulthood. However, it is important to frame the risk of problematic behavior within a picture of the general well-being of the majority of children growing up in stepfamilies, and of considerable within-group variation. As both Hetherington and Jodl (1994) and Bray (1999) have pointed out, most children living in stepfamilies (between two-thirds and three-quarters) score within the nonclinical range on standardized measures such as the CBCL.

Stepfamily Processes

Next we consider evidence on how family processes can influence the socioemotional well-being of children in stepfamilies. Given the wide variation in social developmental outcomes among children growing up in stepfamilies, it is crucial to consider how differences in the quality of family relationships within stepfamilies might sway the likelihood of different outcomes.

Family Instability

One perspective on the reasons for children's problems in stepfamilies is that children experience difficulties as part of family instability: a cycle of multiple family transitions from parental separation and repartnership and back again. Remarriages are more vulnerable to divorce, and end in divorce more quickly, than do first marriages (Bumpass & Raley, 2007; Cherlin, 2010). Remarriages also seem to be particularly vulnerable to divorce if mothers have children from previous relationships living in the households (Teachman, 2008; White & Booth, 1985). Findings from several studies point to a link between children's experiences of family instability and problematic behavior. For example, the most frequent and serious adjustment problems (hyperactivity, peer relationship problems, and conduct disorder) shown by the 4- and 7-year-old siblings in the ALSPAC study were more likely to have been displayed by children with family histories involving multiple transitions (Dunn et al., 1998). Capaldi and Patterson (1991) examined the relation between family transitions and children's adjustment problems in more than 200 boys aged 9 to 10 years from predominantly European American low-income families in the Oregon Youth Study, finding that boys who had experienced multiple transitions showed the poorest adjustment, even when

controls for family income were introduced. Likewise, studies using representative samples of 11- to 13-year-olds in New Zealand (Fergusson, Horwood, & Lynskey, 1992) and 12-year-olds in the United States (Kurdek, Fine, & Sinclair, 1995), respectively, found higher rates of juvenile offending and disruptive behavior among children who had experienced multiple changes in family structure. Some evidence from the NLSY79 indicates that the effects of transitions into new family forms might be even more disruptive for children than the ending of parental partnerships (Aughinbaugh et al., 2005; Fomby & Cherlin, 2007).

Longitudinal studies have indicated that the length of time stepfamilies have been together is an important factor influencing both stepfamily relationships and the quality of children's adjustment. Results from follow-up waves of both the DIS (Bray & Kelly, 1998) and Hetherington's longitudinal studies (Hetherington, Henderson, & Reiss, 1999) have demonstrated that, in long-term stable stepfamilies, good marital relationships, authoritative parenting, and positive sibling relationships are all associated with positive outcomes for adolescents.

A key element underlying the instability of remarriage is likely to be couple conflict. For children growing up in mother–father families, associations between the quality of the couple relationship and child adjustment are strong (Jenkins, Simpson, Dunn, Rasbash, & O'Connor, 2005). One question of interest has been whether the quality of couple relationships in repartnerships is positively associated with children's psychological adjustment in the same way as in mother–father families. Data from the VLS indicate that closer couple relationships for recently remarried mothers was associated with preadolescent girls displaying more internalizing and externalizing behaviors and more negative behavior toward their mothers and stepfathers in the early stages of remarriage (Hetherington, 1993). However, levels of couple satisfaction with remarriage were associated with lower levels of externalizing behaviors in preadolescent stepsons. And if maternal remarriage occurred when children were safely into their adolescent years, then close couple relationships were associated with greater acceptance of remarriage and less discordant parent–child relationships for stepchildren.

Other studies have also tended to support the view that positive couple relationships benefit stepchild adjustment. In the NEAD sample, remarried couples who disagreed less about childrearing were more likely to indicate satisfaction with their relationships (O'Connor & Insabella, 1999). Furthermore, greater relationship satisfaction for remarried

couples was associated with stepchildren exhibiting fewer externalizing behaviors. Similarly, the ALSPAC study found that positive relationships between mothers and stepfathers predicted positive family relationships, just as they did in non-stepfamilies (Dunn, Deater-Deckard, Pickering, Golding, & the ALSPAC Study Team, 1999). In addition, the DIS found that mothers and stepfathers who reported, and were observed to display, more positive family cohesion and communication also showed more positive mother–child and stepfather–child interactions (Bray & Berger, 1993). In particular, stepfathers' ratings of marital adjustment were strongly associated with both stepfathers' and mothers' relationships with the children.

In contrast, findings have been inconclusive with respect to the effects of negative couple relationships on stepchildren. Dunn et al. (1999) found that, in contrast to findings about mother–father families, levels of mother–stepfather hostility did not predict either parent–child or sibling relationship negativity for the older stepsiblings of the children in the ALSPAC sample. However, involvement in mother–stepfather conflict was associated with children aged 10 years and older displaying greater socioemotional problems on the CBCL, and the children themselves indicated that they were more likely to side with their biological parents than with their stepparents (Dunn, O'Connor, & Cheng, 2005). Findings from later waves of the DIS indicate that, while general levels of family conflict were similar in long-term stepfamilies and non-stepfamilies, associations between family conflict and poor adolescent adjustment were stronger in stepfamilies than in non-stepfamilies (Bray, 1999). Bray suggested that the meaning of conflict may be different for adolescents with stepfamily backgrounds, perhaps because it resonates with prior experience of parental separation.

Mother-Child Relationships in Stepfather Stepfamilies

Another reason for the variability in developmental outcomes for stepchildren is the range of different parent–child and stepparent–child relationships within these families. Dunn (2002) highlighted the mediating role that biological parent–child relationship quality plays in transmitting, or buffering, the effects of other stepfamily dynamics on children. This appears to be the case whether data are obtained from parents (Dunn et al., 1998) or children (Dunn, Davies, O'Connor, & Sturgess, 2001). Much of the variation in children's behavioral and emotional problems is explained by the quality of parent–child relationships, parental depression, and socioeconomic adversity (O'Connor, Dunn, Jenkins, Pickering, & Rasbash, 2001).

Across all three studies conducted by Hetherington and colleagues (the VLS, the HCSDR, and the NEAD) stepchildren reported closer relationships with their resident mothers than with their stepfathers (Hetherington & Jodl, 1994). In the early period after remarriage, just as after parental separation, parent-child relationships were less positive and more conflicted, and residential parents were less likely to display authoritative parenting styles. However, residential parents generally reestablished authoritative parenting over time and, in stabilized stepfamilies, few differences in parenting quality between mothers in remarried stepfather families and in nondivorced families were apparent.

Stepfather-Child Relationships

From the perspective of many stepchildren, stepfathers play a far more peripheral domestic role in contrast to the central role played by mothers. Hetherington and Jodl (1994) found that, compared with the majority of mothers in stabilized stepfamilies, stepfathers were more likely to have disengaged from parenting and less likely to have established an authoritative parenting style with their stepchildren. In stabilized stepfamilies with adolescent stepchildren, stepfather-stepson relationships have been found to be more likely to be positive than those between stepfathers and stepdaughters (Bray & Berger, 1993; Hetherington, 1993). Hetherington and Clingempeel (1992) found that if a resident parent remarried when children were entering early adolescence, then a poor stepfather-stepchild relationship and family functioning often ensued with little improvement in adolescent socioemotional problems or social and academic competence observed 2 years later. Nevertheless, if a positive stepfather-stepchild relationship had been established, then this was associated with better school grades and fewer externalizing and internalizing problems.

In considering possible reasons for disengaged or hostile stepfather-stepchild relationships, any stepfamily needs to be viewed against the family circumstances and arrangements that preceded it—especially the adolescent's preexisting relationship with the mother—in setting the stage for a stepfather's arrival. Weaver and Coleman's (2010) qualitative study found that mothers in stepfather families saw themselves as defenders of the others, gatekeepers, mediators, or interpreters, as they stood in the middle ushering in new relationships between their children and their new partners. According to stepfathers' reports, stepfathers were found to generally have better relationships with their stepchildren in families where

the children's mothers had better relationships with their children than in stepfamilies in which mother-child relationships were poor (Marsiglio, 1992). King's (2009) analyses of longitudinal data from the Add Health study also indicate that adolescents who felt they had close relationships with their mothers prior to maternal repartnership were more likely to report that they had developed close relationships with their new stepfathers 1 year later.

A number of studies have indicated ways in which stepfathers can approach stepparenting that may lead to better outcomes for stepchildren. Ganong, Coleman, Fine, and Martin (1999) found that stepparents who did not try to push stepchildren into relating to them succeeded in building positive relationships with their stepchildren, whereas stepparents who tried to control the relationships encountered resistance. Likewise, longitudinal data from the DIS indicate that stepparents gradually developed good relationships with their stepchildren when they let the biological parents do most of the disciplining and, instead, took supporting roles (Bray & Kelly, 1998). Findings from Erera-Weatherly's (1996) study of stepparents' entry into stepfamily relationships not only showed that the "stepparent as friend" style was associated with greater acceptance by stepchildren, but also that this resulted in a positive response from the child's parent and less competition from the child's nonresident parent.

Other studies have focused on establishing how children influence the development of stepfather-stepchild relationships. Cross-lagged regression analyses of data from Hetherington's studies, in particular, have revealed that, early in remarriage, adolescent children may be more influential than mothers or stepfathers in influencing the quality of stepfamily relationships (Hetherington & Clingempeel, 1992; Hetherington et al., 1999). Observational data gathered at family mealtimes indicated that early-adolescent children, particularly girls, often behaved more negatively and less positively to stepfathers, compared with new stepfathers' positive overtures toward them (Hetherington & Clingempeel, 1992). Furthermore, the initial level of the child's externalizing behavior was a good predictor of subsequent negativity and coercive strategies displayed by stepfathers, whereas higher levels of adolescent social competence were associated with subsequent positivity by both resident mothers and stepfathers (Hetherington et al., 1999).

There has been an increasing interest in children's perceptions of stepfamily relationships. Although adults in the family might think that family transitions have been explained to children, one of the few studies to interview

children found that only 5% of the 10- to 11-year-olds interviewed felt that they had been fully informed about family changes (Dunn et al., 2001). Most of the data on children's perceptions of stepparents have been collected from university students who no longer regularly live in their parental homes. Interviews with these grown-up children have emphasized the variability in experiences of stepfamily life, both between individuals and as children mature (Cartwright, Farnsworth, & Mobley, 2009; Ganong, Coleman, & Jamison, 2011; Kinniburgh-White, Cartwright, & Seymour, 2010).

Part of the reason for the effects of growing up in stepfamilies on developmental outcomes may be due to the way in which the entry of stepparents influences the general family environment. For instance, repartnership and remarriage have been associated with improvement in adult postdivorce well-being (Wang & Amato, 2000; Williams & Umberson, 2004). However, Dunn, Davies, O'Connor, and Sturgess (2000) found evidence for selection effects, such that divorced mothers in the ALSPAC sample who had had a series of marital and cohabiting relationships and negative life events tended to be with partners who had similar histories. Dunn and colleagues (2000) suggested that children might experience a double risk of problematic parenting arising from these factors, as the partners' life-course history would also predict negativity in the children's relationships with their parents.

The addition of a stepparent to the household might mean that the stepchild can benefit from the extra resources that another adult in the household may bring: financial, practical, and emotional. Sweeney's (2007) analyses of adolescent adjustment data from the Add Health study indicate that adolescents tended to benefit from both the greater financial resources and the extra parental presence in stepfather families, as compared with single-mother families. Yet a stepparent's additional income may come with a hidden cost, as economic resources might remain the same or even diminish because a nonresident father may contribute less. For example, one study of mothers on welfare found that nonresident fathers were less likely to provide informal support to children in stepfather families, especially if there were additional children born in the repartnership (Meyer & Cancian, 2012).

Nonresident Parent-Child Relationships

In stepfather stepfamilies formed after parental separation, stepfathers need to accommodate the presence of nonresident fathers, and the children and mothers need to work out how to manage additional relationships. Several

early studies have indicated that adolescents with stepfathers tend to have less involvement with their nonresident fathers (Furstenberg, Nord, Peterson, & Zill, 1983; Seltzer & Bianchi, 1988). However, using longitudinal data from the Add Health study, King (2009) found that the entry of stepfathers made little difference to children's closeness to, or contact with, their nonresident biological fathers, and that the quality of adolescents' relationships with their stepfathers was independent of the quality of their relationships with nonresident fathers.

Previous findings from the Add Health dataset indicate that, for adolescents who lived with their remarried mothers, both adolescent self-reported closeness to their stepfathers and reported closeness to their nonresident fathers were associated with adolescent educational attainment and emotional well-being (King, 2006). Around 25% of adolescents reported close relationships with both their stepfathers and their nonresident fathers, and they were least likely to be failing at school or exhibiting higher levels of internalizing and/or externalizing problems. Boys and girls both benefited from having close relationships with their stepfathers and their nonresident fathers, and boys, in particular, showed fewer externalizing problems if they were close to both father figures. Further, King (2006) found that, if adolescents were close to one father figure, those figures were more likely to be their stepfathers than their nonresident fathers, and that close relationships with only stepfathers was nearly as advantageous in terms of adolescent well-being as was having close ties to both fathers. Nonetheless, nearly a quarter of the adolescents were without close connections to either their residential stepfathers or their nonresident fathers. These adolescents also tended to be less close to their mothers and, more often, lived in homes where mother-stepfather relationship happiness was lower. Girls, rather than boys, were more likely to report a lack of closeness to any parental figures. There were no race-ethnicity or immigrant family status differences in reported closeness to either stepfathers or nonresident fathers.

Stepmother Stepfamilies

In the United States and Europe, a rise in joint custody arrangements and residential parenting by fathers post-separation has meant that more children have been reared by their fathers and their new partners. Yet there is far less information on children's socioemotional development in father-stepmother than in mother-stepfather households. Furthermore, studies on children's adjustment

in stepmother stepfamilies have often been unable to distinguish between the effects of being brought up in simple stepmother stepfamilies and the effects of being brought up in complex stepmother stepfamilies in which the stepmothers also have their own children present in the household.

Any consideration of the role that stepparents may play in fostering children's development needs to take into account the sociocultural context of myths and fairy tales—such as "Snow White" and "Cinderella"—that colors perceptions of stepparents, particularly stepmothers. For example, when American (Fine, 1986) and Australian (Planitz & Feeney, 2009) university students were asked to complete sentences or check bipolar adjective scales to examine attitudes toward stepparents, perceptions of stepparents—especially stepmothers—were less positive than those of biological parents for students from different types of family background. However, in Fine's study, American students from both stepfamily and single-parent backgrounds expressed more positive views of stepparents than did students from nondivorced families.

Qualitative research has illustrated the diversity of relationships children can form with their stepmothers. Adult stepdaughters interviewed by Crohn (2006) reported a variety of relationships with their stepmothers, who were described variously as: "my father's wife," "an older friend," "a type of kin," or "like another mother." Stepdaughters viewed positive relationships with their stepmothers in terms of friendships or companionship in shared interests. Nevertheless, qualitative data from a subsample of adults who participated in the UK National Child Development Study and who had spent part of their childhoods in stepfamilies showed that stepchildren generally gave far less favorable accounts of stepmothers than of stepfathers (Gorell Barnes, Thompson, Daniel, & Burchardt, 1998). In their qualitative study of university students who had experienced stepfamily formation, Ganong et al. (2011) found that stepmothers who were rejected were mostly nonresident stepmothers who were perceived to be jealous either of the time children spent with their nonresidential fathers or of the financial resources given to them.

In terms of child adjustment, stepchildren in complex stepmother stepfamilies in the Avon Longitudinal Study of Parents and Children had more difficulties than children in simple stepfather families or mother–father families (O'Connor et al., 2001). Few studies have examined the long-term implications of growing up in stepmother families for young adult outcomes. However, White (1994) reported that adults raised in stepmother families

were less likely to receive either regular help from their fathers and stepmothers or to see them as sources of emergency help.

Evidence from various studies suggests that biological parent–child relationships form the cornerstone of stepmother families, just as they do in stepfather families. Fine, Voydanoff, and Donnelly (1993) using NSFH data, found children's well-being to be positively related to parental warmth in both stepmother and stepfather households. Biological parents also perceived themselves as having better relationships with their children than did stepparents with their stepchildren. Longitudinal data from a small sample of remarried fathers and their new wives indicate that stepmothers were more satisfied with stepfamily life when fathers were actively involved in parenting, when role expectations of "who does what" in the stepfamilies were less ambiguous and when postdivorce relationships with the children's mothers were better (Guisinger, Cowan, & Schulberg, 1989). Whatever the family type, biological mothers were more warm and responsive to their own children than were stepmothers, although children also expressed more hostility as well as more positive behavior toward their biological mothers than toward their stepmothers. Furthermore, stepmothers were more likely than stepfathers to have to negotiate their parenting with the children's nonresident biological parents, because nonresidential mothers were more likely to remain involved with their children than were nonresidential fathers.

Conclusions

Across the studies reviewed, a consistent picture emerges of more problematic family processes in families containing stepparents. Data from both representative surveys and detailed qualitative research have been useful in piecing together trends and processes. It would no doubt be beneficial to have further mixed-methods studies that draw subsamples from epidemiological studies to learn more of the processes behind group differences. Data from investigations such as the Developmental Issues in Stepfamilies study and the Virginia Longitudinal Study of Divorce and Remarriage have indicated that there are higher levels of couple conflict and parent–child or stepparent–child conflict in stepfamilies than in non-stepfamilies. Nevertheless, it is still unclear whether higher levels of expressed conflict are the result of selection factors (such as less effective communication or listening), increased levels of stress in the stepfamily home, less shared history, or a sociocultural narrative of stepfamily relationships that colors stepfamily

members' reports and actions. Future research could be tailored to investigate these possibilities.

When children have close relationships with at least one parental figure, they appear to benefit in terms of greater well-being. And it seems that children can benefit from adding extra parental figures to their families if they have close relationships with their nonresident parents and resident stepparents. But when do parents' partners become recognized as stepparents in the eyes of different family members? Many single parents are very cautious about introducing new partners to their children and apprehensive of the intertwining of family relationships that would incur. As yet, we know little about the stepparenting formation process and, in particular, about the early stages of stepparenting prior to coresidency.

COHABITATION

Increasingly, researchers are distinguishing between different types of family structure based on the coresidence of parents, and not just on the basis of marital status. This is important because households with two cohabiting parents may have a different set of resources, and potential problems, as compared with married parents. Across the United States and Europe, cohabitation has become a *de facto* alternative to marriage. Many cohabitantes may ultimately wish to marry, but their social and financial conditions may not support that decision (Cherlin, 2004). Around half of the children born to unmarried mothers in the United States are born to mothers who are cohabiting with their children's fathers (McLanahan & Beck, 2010), and it has been estimated that about two-fifths of U.S. children will have lived in cohabiting unions by the age of 12 (Kennedy & Bumpass, 2008). Within Europe, rates of cohabitation are also increasing, although cohabitation is not as widespread in central, eastern, and southern European nations as it is in western Europe (Wik, Keizer, & Lappégard, 2012).

Cohabiting and married couples generally have very different sociodemographic profiles, and the main studies reviewed in this chapter have controlled for these differences. As Sweeney (2010) pointed out, it is essential to take account of the influence of selection factors as to who enters marital versus cohabiting unions, in order to pinpoint the influence of family structure *per se*. In general, cohabiting parents tend to be less well-educated and have lower incomes than married couples in both the United States (Brown, 2010; Morrison & Ritualo,

2000; Waldfogel et al., 2010) and the United Kingdom (A. Goodman & Greaves, 2010). Furthermore, compared with married mothers, cohabiting mothers tend to be younger and to have lived with their children's fathers for shorter periods of time. Both racial and ethnic cultural backgrounds have also been strongly associated with mothers' marital status. In the United States, around 10% of European American children are born to cohabiting couples, compared with nearly 20% of African American and Latino American children (Bumpass & Lu, 2000), and stepfamilies that have arisen through cohabitation subsequent to nonmarital births tend to be more common among African Americans than among European Americans (Stewart, 2007). Data from the Add Health survey and the Panel Survey of Income Dynamics (PSID) suggest that, for African American children, parental marital status does not matter as much for socioemotional well-being as it does for European American children, possibly because it is more common for children to live in nonmarried couple households in African American communities and, therefore, wider social support is available to them (Brinig, 2013). In the Millennium Cohort Study (MCS), which sampled approximately 18,000 births across the United Kingdom around the turn of the century, almost all of the mothers of Southeast Asian descent, around 70% of those identifying as White, and only half of the Black Caribbean mothers were married at the time of their children's births (A. Goodman & Greaves, 2010).

Other selection factors, such as parental attitudes and values, may also influence who enters into cohabitation and who enters into marriage. And of course it is much harder to control for psychosocial selection factors than for sociodemographic differences such as family income, ethnicity, or age. Musick (2002) found that only a minority of cohabiting mothers in the U.S. National Survey of Family Growth had planned their pregnancies. Likewise, data from the MCS revealed that fewer than half of the pregnancies of the study's cohabiting mothers had been planned (A. Goodman & Greaves, 2010). Moreover, MCS children born to cohabiting parents were more likely to have been born prematurely, or to be of low birth weight, than those born to married parents, and cohabiting mothers were less likely to breastfeed, more likely to smoke, and more likely to show indications of depression during their children's first years of life.

There is also the complicated question of the direction of association between couple happiness and likelihood of marriage. No doubt relationship happiness promotes the likelihood of marriage and so selects couples into

marital status. But in order to conclude that marriage makes a difference to couple relationship quality and thus affects developmental outcomes for children, it would be necessary to demonstrate that relationship happiness is a direct product of marriage.

Child Well-Being and Parental Cohabitation

Next we consider developmental outcomes for children of different ages in two types of cohabiting families: those born into two-parent families where parents are cohabiting rather than married, and those raised in two-parent families with parents and resident partners who are not the biological parents of the children. For the sake of simplicity, the former are referred to here as cohabiting families, and the latter as cohabiting stepparent families.

Studies of children younger than 2 years old have indicated that children born into cohabiting families are disadvantaged compared with those born into married families, although selection factors appear to account for much of the difference between family types. For example, in their analyses of data from the NICHD Study of Early Child Care and Youth Development (SECCYD), Aronson and Huston (2004) accounted for between 40% and 60% of the variance in maternal sensitivity and quality of the home environment, and fully accounted for differences in infant behavior and security of attachment, by controlling for family structure differences in maternal age, maternal educational level, and ethnic group.

Similar findings were reported from the Fragile Families and Child Wellbeing Study (FFCWS), which investigated the effects of growing up in cohabiting households on children's adjustment. In reviewing findings from previous FFCWS working papers, Waldfogel et al. (2010) concluded that parental marital status at birth was more associated with children's socioemotional development at Age 3 than with children's cognitive development (Craigie, 2008; Osborne, McLanahan, & Brooks-Gunn, 2004). Waldfogel et al.'s own analyses of data from FFCWS children at Age 5 confirmed that family structure made little difference to cognitive outcomes; what seemed to matter most were changes in family structure over time. Also using FFCWS data, Guterman, Lee, Lee, Waldfogel, and Rathouz (2009) found few differences between cohabiting, single, and married mothers of 3-year-olds in rates of aggressive or punitive parenting after controlling for sociodemographic and psychosocial variables.

Similarly, kindergarten children with cohabiting parents in the Early Childhood Longitudinal Study, Kindergarten

Class of 1998–1999 (ECLS-K) were reported by their mothers to show more sadness and less self-control than children with two married parents (Artis, 2007). Nevertheless, once children's characteristics, family socioeconomic status, parental relationship stability, maternal depression, and parenting practices were controlled for, the children in cohabiting families did not differ from those with married parents.

The Millennium Cohort Study (MCS) examined the effects of parental cohabitation on children's adjustment at Ages 3 and 5 (A. Goodman & Greaves, 2010). Differences in psychological adjustment between children born to cohabiting and married parents were found to be larger than differences in cognitive development. The most negative outcomes were found among the children of cohabiting parents who subsequently separated, whereas marginally more positive outcomes were observed for children of cohabiting parents who subsequently married. Controlling for parental education and socioeconomic status halved the gap in adjustment scores between children of cohabiting and married parents.

Few studies have examined outcomes for older children and adolescents born to cohabiting couples, but data is available on children growing up in cohabiting stepfather families. For example, analyses of child protection data made by Berger, Paxson, and Waldfogel (2009) revealed that children were more likely to have been reported to child protection services due to abuse or neglect if they lived in a cohabiting stepfather family than if they lived with both biological parents. This difference remained even after controlling for selection factors.

Brown (2004) compared data on children's well-being in different types of cohabiting families using the 1999 National Survey of America's Families to find that children in cohabiting and cohabiting stepparent families fared worse than those in married families with respect to school engagement and socioemotional problems. For children aged 6 to 11, controlling for economic resources and parental psychological well-being reduced much of the difference between children in married and cohabiting couple households. However, for adolescents, a negative association between parental cohabitation and well-being persisted even after the level of family resources was controlled for. Furthermore, successive waves of the Add Health study have indicated that the adolescents in stable cohabiting stepfather families had lower levels of well-being than did those in married stepfather families (Brown, 2006). Brown's (2006) findings concur with those of previous analyses of cross-sectional data from the Add

Health study, which have shown that the adolescents in cohabiting stepfather families exhibited higher rates of delinquency and lower grade point averages than did their counterparts in married stepfather families, with a maternal history of prior residential relationships accounting for much of the variation in both adolescent delinquency and grade point average scores (Manning & Lamb, 2003).

Sweeney's (2007) analyses of the Add Health dataset indicate that having married parents benefited youth in a number of ways, even if parental marriages ended in divorce. For example, compared with adolescents born outside of marriage who then lived with their mothers and stepfathers, adolescents who lived in postdivorce stepfather families tended to have better emotional well-being. The Add Health study also revealed that the arrival of stepfathers through maternal cohabitation was associated with a decline in adolescents' reports of closeness to their mothers, whereas the entry of stepfathers due to maternal remarriage did not have detrimental effects on mother-child relationship quality (King, 2009). Buchanan, Maccoby, and Dornbusch (1996) similarly reported from their 3-year postdivorce follow-up of more than 500 children between the ages of 10 and 18 that new maternal partnerships not involving remarriage negatively affected the quality of the mother-adolescent relationships. In contrast, adolescents whose resident mothers remarried generally retained close relationships with them.

While most published studies have reached the conclusion that children in cohabiting stepfamilies have poorer psychological well-being than do children in married stepfather families, this is not true of all studies. No differences in psychological adjustment were found between 4-year-old children in cohabiting and married stepfather families in the Avon Longitudinal Study of Parents and Children (ALSPAC) (Dunn et al., 1998). Neither were differences found in behavioral problems, self-esteem, or self-efficacy between children with residential stepfathers and children who lived with their married parents in the Panel Survey of Income Dynamics (PSID) (Brinig, 2013). Both studies identified difficulties for children whether the mothers were cohabiting or married.

Why More Problems for Children in Cohabiting Unions?

Why might children in cohabiting families exhibit more problems than do children in married families? Controlling for sociodemographic selection factors clearly reduces the difference between married and cohabiting parent families.

Nevertheless, differences between children brought up by cohabiting parents and married parents remain. Various interconnected reasons for the generally poorer outcomes for children from cohabiting unions have been investigated, including parental relationship instability, low parent or stepparent involvement, poor parenting quality, and parental mental health problems.

Family instability is generally accompanied by distress for parents and children, and often leaves a vacuum in parenting as parental roles are redefined. It is also likely that parental distress contributes to dissatisfaction with the couple relationship and thus increases the likelihood of separation. A number of studies have indicated that cohabiting relationships are less stable than marital unions, both among cohabiting couples with joint children and among cohabiting stepparent families, and that this is the key factor associated with children's emotional and behavioral problems. In the Millennium Cohort Study (MCS), only 5% of married couples with children had separated by the time their children were 3 years old, in comparison with around 20% of the parents who were cohabiting when their children were born (A. Goodman & Greaves, 2010). The MCS also pointed to poorer relationship quality between cohabiting parents in the year following the birth of their children, when married parents were more likely than cohabiting parents to report that their partners were sensitive to their needs. By the time the children were 3 years old, cohabiting couples were more likely to be living apart or to have had temporary separations (A. Goodman & Greaves, 2010). Similarly, in the United States, the Study of Early Child Care and Youth Development (SECCYD) showed that children born to cohabiting parents were more likely to experience instability in parental relationships than were children born to two married parents (Cavanagh & Huston, 2006). On entry into school, SECCYD children with histories of parental relationship instability displayed more negative behaviors with both teachers and peers.

There were similar findings from the Fragile Families study. Children were more than 5 times more likely to experience parental separations by their third birthday if their parents were cohabiting rather than married (Osborne, Manning, & Smock, 2007). Differences between married and cohabiting parent families in terms of demographic factors, including the presence of children from previous unions and the quality of the couple relationship at birth, accounted for half of the variation in the rate of union stability between family types. However, the effect of parental marital status on relationship instability was

significantly greater for European American children than for African American or Mexican American children. Several factors were associated with cohabiting relationship instability for European American children, including lower parental educational qualifications, paternal substance abuse, prior marital relationships, and the presence of children from these unions. For African American and Mexican American children, none of these factors clearly explained differences in parental relationship stability. The Fragile Families study also showed that more extensive behavioral problems were displayed by children from unstable cohabiting families than from married two-parent families, whereas children from stable cohabiting and stable married families did not differ in levels of behavioral difficulties (Osborne & McLanahan, 2007). Furthermore, the level of behavioral problems children displayed increased incrementally with each family transition, with maternal stress and parenting quality mediating this increase.

The Fragile Families study indicates that couple relationship quality may play a key role in influencing the amount of time and energy each parent has to engage in effective parenting, irrespective of marital status (Fomby & Osborne, 2008). Nevertheless, it appears that parenting might be particularly vulnerable to couple relationship distress for parents who are cohabiting rather than married. Mothers in cohabiting relationships who reported relationship unhappiness were found to report higher levels of conflict and less cooperation over parenting than mothers in marital relationships (McLanahan & Beck, 2010). Poor parental relationship quality, as reported by both married and cohabiting couples, was linked to poor maternal and paternal engagement in parenting, particularly in children's infant, toddler, and preschool years (Carlson, Pilkauskas, McLanahan, & Brooks-Gunn, 2011). Carlson and colleagues (2011) found that married and cohabiting couples displayed a similar overall pattern of linkages between couple relationship quality and parenting engagement from birth to 5 years. However, couple relationship quality had a marginally larger association with cohabiting fathers' engagement in parenting, perhaps indicating that the quality of the fathers' relationships with the mothers are more likely to influence the parenting engagement of cohabiting, rather than married, fathers.

Rates of maternal depression have been shown to be higher for mothers in unstable cohabiting parent families in both the SECCYD (Cavanagh & Huston, 2006; Klausli & Owen, 2009) and the Fragile Families study (Cooper, Osborne, Beck, & McLanahan, 2010). Klausli

and Owen (2009) also found that mothers in cohabiting couples who remained together reported higher levels of depression and showed lower levels of parental sensitivity during parent-child observations than did married mothers, and that these differences persisted even after socio-demographic variables were controlled for. Nevertheless, associations between maternal depression and parental sensitivity were partly mediated by maternal reports of couple conflict and ambivalence about the relationship, suggesting that at least some of the variance in child well-being between stable cohabiting and married parent families might be explained by parental relationship difficulties. Cooper and colleagues (2010) also demonstrated that the link between parental relationship instability and children's behavioral problems is in part mediated by maternal mental health problems and associated harsh parenting. Nevertheless, it is unclear whether women with a tendency toward depression are more likely to cohabit, rather than marry, in the first instance, or whether having children in a cohabiting relationship itself influences the likelihood of maternal depression and subsequent poor parenting.

Fathers' involvement with their children appears to be associated with the longevity of cohabiting relationships. In the Fragile Families study, it was found that cohabiting fathers' reports of paternal involvement, as well as mothers' reports of the extent of coparenting at the birth of their children, were associated with a decreased probability of separation 5 years later (McClain, 2011). Paternal involvement and coparenting engagement predicted the continuation of parental cohabitation over and above the quality of the parental relationships, initial expectations of marriage, and individual characteristics of the mothers, fathers, and children. Cohabiting stepfathers have also been found to spend less time with their stepchildren than married stepfathers (Hofferth & Anderson, 2003), even after demographic variation is controlled for (Berger, Carlson, Bzostek, & Osborne, 2008).

With respect to wider societal influences, Brinig (2013) argued that, compared with formal marriage, cohabitation lacks social capital and so is not so trusted by the community surrounding the couple. Therefore, cohabiting couples may receive less legal, financial, or social support for their joint households from either their communities or extended families. The incomplete institutionalization of cohabiting families may contribute toward the greater instability of these families. The Fragile Families study showed that the way in which cohabiting families were embedded in intergenerational family relationships was associated with the stability of the couple unions,

irrespective of sociodemographic factors, couple relationship quality and attitudes, grandmother coresidence, and family of origin characteristics. On the one hand, better couple relationships and more positive relationships with each partner's parents, together with more time spent with paternal grandparents, was associated with an increased likelihood that the couple would still be cohabiting by the child's fifth birthday (Högnaas & Carlson, 2010). On the other hand, if the 1-year-old child spent more time with his or her maternal grandparents, then the parents were less likely to be cohabiting at follow-up. Without further investigation, the meaning of time spent with maternal relatives is difficult to know, because it could be a cause of parental separation, the result of a rocky couple relationship, or a simple reflection of as yet unobserved factors.

Is Marriage, Itself, Advantageous for Children?

If marriage, itself, makes a difference to children's outcomes, then we would expect to see evidence of a boost in the well-being of children whose cohabiting parents have later married. The Fragile Families study provides some support for this, in that children born to cohabiting parents who later married were similar on all outcomes to those whose parents had been married before the children's births (Waldfogel et al., 2010). Nevertheless, once sociodemographic factors and relationship stability were controlled for, group differences between cohabiting to married and stable cohabiting groups were negligible. Brown (2006) also found that the transition from cohabiting stepfather families to married stepfather families between waves of the Add Health survey made no appreciable difference to adolescent adjustment, suggesting that, as far as adolescents are concerned, parental marital status is of negligible impact.

One of the few studies to have examined the possibility that marriage might act as an "intervention" on children's well-being is a Swedish study that used national records to investigate whether a marriage boom among cohabiting couples in 1989 due to a reform of pension rights had any effect on children's grade point averages (Björklund, Ginther, & Sundström, 2007). No effects were observed for families that would have financially benefited from the reform. However, marriage did seem to have a positive effect on the grade point average of sons of cohabiting parents who married but did not stand to financially benefit. This suggests that selection factors promote marriage and child well-being, rather than marriage enhancing children's well-being per se.

Conclusions

From the evidence reviewed above, there appears to be some advantage to children in terms of socioemotional development of having married rather than cohabiting parents. However, any advantage is slight once sociodemographic factors are taken into account, and may be due to unobserved selection effects such as relationship quality. That is, cohabiting couples with good relationships may be more likely to marry and also more likely to have positive relationships with their children. Various factors may contribute to the small gap in well-being between children in cohabiting and married parent families after adjusting for possible selection effects, including a greater investment in marriage over cohabitation on the part of the couple, the higher level of institutionalized security that marriage entails, and the greater recognition and support given by extended family and others to a marital, rather than cohabiting, union. Future longitudinal research needs to investigate the various factors that distinguish stable and unstable cohabiting unions and how the quality of the cohabiting partnership influences parental or stepparental involvement.

ASSISTED REPRODUCTION FAMILIES

The first "test-tube" baby, Louise Brown, was born through in vitro fertilization (IVF) in the United Kingdom in 1978 (Steptoe & Edwards, 1978). Since that time, more than 5 million children worldwide have been born through assisted reproductive technologies (ARTs) (Adamson, 2012). There has been much concern about the potentially negative effects of ARTs on the psychological well-being of children and their families. This section examines the impact of conceiving children through "high-tech" procedures such as IVF or intracytoplasmic sperm injection (ICSI), and through third-party involvement such as egg donation, sperm donation, embryo donation, and surrogacy, on parenting and child development. Although a negative consequence of ARTs, especially of IVF and ICSI, is the high rate of multiple births (and associated problems of preterm delivery and low birth weight), this is not a focus here, because studies of the psychological outcomes of ARTs have tended to exclude such families to avoid the potentially confounding effects of multiple births on parent-child relationships and child development.

IVF involves the fertilization of an egg with sperm in the laboratory and the transfer of the resulting embryo to

the mother's uterus. In the related procedure of ICSI, a single sperm is injected directly into the egg. When the mother's egg and father's sperm are used in IVF or ICSI and the mother undergoes the pregnancy, the parents have both a genetic and a gestational connection to their child in the same way as do parents of naturally conceived children. However, a growing number of children are being born through reproductive donation (Richards, Pennings, & Appleby, 2012); that is, by the donation of gametes (sperm or eggs) or embryos, or the hosting of a pregnancy for another woman (surrogacy).

With sperm donation (usually referred to as donor insemination), the child lacks a genetic relation with the father, whereas egg donation results in the absence of a genetic link with the mother. In the case of embryo donation, the child is genetically unrelated to both parents; this situation is similar to adoption, apart from the parents' experience of pregnancy and birth. There are two types of surrogacy: gestational surrogacy, in which the child lacks a gestational relationship with the mother but the mother and father are the child's genetic parents; and genetic surrogacy, in which the surrogate and the father are the child's genetic parents and the child lacks both a genetic and a gestational link with the mother.

For the purpose of this chapter, the different family types described above are organized according to the following categories, as each raises a different set of issues and concerns: (a) "high-tech" families (IVF and ICSI); (b) donor conception families (sperm, egg, and embryo donation); and (c) surrogacy families (gestational and genetic). However, these categories are not mutually exclusive; for example, donated eggs, sperm, or embryos may be used in IVF and ICSI.

"High-Tech" Families (IVF and ICSI)

A frequently voiced concern regarding "high-tech" families is that, due to the experience of infertility and its treatment (often lasting for many years), parents may be overprotective of their longed-for children when they eventually arrive (Covington & Burns, 2006). It has also been suggested that these mothers and fathers may set themselves unattainably high standards of parenting and may have unrealistically high expectations of their children. An additional concern relating specifically to ICSI is the potential risk for children of the procedure itself, particularly the bypassing of natural sperm selection barriers and the use of suboptimal sperm (Ponjaert-Kristoffersen et al., 2005).

Parenting in IVF Families

A study of parenting in families with an IVF infant was conducted in Australia (McMahon & Gibson, 2002). IVF families and a comparison group of natural conception families were recruited during pregnancy and followed up when the infant was 4 months and 1 year old. At 4 months, the IVF mothers reported lower levels of perceived competence as parents than did the natural conception mothers, in terms of their ability to soothe their infants and understand their signals (McMahon, Ungerer, Tennant, & Saunders, 1997), and at 1 year, the IVF mothers saw their children as more vulnerable and "special" (Gibson, Ungerer, Tennant, & Saunders, 2000). Nevertheless, the IVF mothers did not differ from the natural conception mothers in sensitivity toward their infants at 4 months or 1 year, and there was no difference at Age 1 in the proportion of IVF and natural conception infants classified according to the Strange Situation test as securely attached (Gibson, Ungerer, McMahon, Leslie, & Saunders, 2000). For fathers, no differences were identified between those with IVF and naturally conceived children in perceptions of parenting competency at 4 months (McMahon et al., 1997) or 1 year (Gibson, Ungerer, Tennant, & Saunders, 2000).

Families with 2-year-old children were investigated in Belgium (Colpin, Demyttenaere, & Vandemeulebroecke, 1995), where IVF families were compared with natural conception families using observational assessments of mother-child interaction and questionnaire assessments of attitudes and emotions about the children completed by mothers and fathers. No differences were found between family types with respect to the children's behavior toward their mothers or the mothers' behavior toward the children in the interaction task, or for mothers' and fathers' thoughts and feelings toward the children. In a follow-up when the children were 8 to 9 years old, the IVF families did not differ from the natural conception families in mothers' or fathers' reports of parenting behavior or parenting stress (Colpin & Soenen, 2002).

IVF families with 4- to 8-year-old children were the focus of the first phase of the European Study of Assisted Reproduction Families conducted in the United Kingdom, the Netherlands, Spain, and Italy (Golombok et al., 1996; Golombok, Cook, Bish, & Murray, 1995). The study recruited 116 families with children conceived by IVF, and comparison groups of 115 families with children adopted in infancy and 120 families with naturally conceived children. A group of 111 families with children conceived by donor insemination was also recruited (see below).

In-depth standardized interviews designed to assess quality of parenting and the Parenting Stress Index were administered to mothers and fathers, separately. The IVF mothers were found to show greater warmth toward their children, to be more emotionally involved, to interact more, and to report less stress associated with parenting than were natural conception mothers. IVF fathers were reported by mothers to interact with their children more than were natural conception fathers, and the fathers, themselves, reported less parenting stress. The adoptive parents fell between the IVF and natural conception parents on these measures. In the first study to be conducted in a non-Western culture, Hahn and Dipietro (2001) examined IVF families with preschool and early school-age children in Taiwan. The quality of parenting was generally found to be good, although IVF mothers showed greater protectiveness of their children. The children's teachers, who were unaware of the nature of the children's conception, rated the IVF mothers as more affectionate toward their children, but not more protective or intrusive, than the natural conception parents.

In order to examine the functioning of IVF families when children approach adolescence, the parents and children in the European Study of Assisted Reproduction Families were assessed using standardized interview and questionnaire assessments of parent-child relationships when the children were aged 12. The IVF mothers and fathers were generally found to have positive relationships with their adolescent children, characterized by a combination of affection and age-appropriate control (Golombok, Brewaeys, et al., 2002; Golombok, MacCallum, & Goodman, 2001). The few differences that were identified reflected more positive functioning among the IVF than among the adopted and natural conception families, with the exception of the overinvolvement with their children of a small proportion of IVF parents. The UK families were followed up once again when the children reached Age 18 (Owen & Golombok, 2009). The IVF mothers and fathers did not differ from the other mothers and fathers on any of the variables relating to warmth or conflict, apart from greater disciplinary indulgence shown by IVF mothers. The 18-year-olds were, themselves, administered a standardized interview and questionnaires to assess the quality of their relationship with their parents (Golombok, Owen, Blake, Murray, & Jadva, 2009). The IVF young adults were found to have good relationships with their parents. Similar findings were reported in a follow-up of the Belgian study when the children were aged 15 to 16 (Colpin & Bossaert, 2008).

Children in IVF Families

The Australian study of infants found some evidence of elevated levels of behavioral difficulties in IVF infants, compared with naturally conceived infants. IVF mothers rated their infants as more temperamentally difficult at 4 months than did natural conception mothers (McMahon et al., 1997), and as showing more behavioral problems and more difficult temperaments at Age 1 (Gibson, Ungerer, Leslie, Saunders, & Tennant, 1998).

The European Study of Assisted Reproduction Families assessed the psychological adjustment of 4- to 8-year-old IVF children using the Strengths and Difficulties Questionnaire, a measure of behavioral and emotional problems completed by mothers and teachers (R. Goodman, 2001). In addition, the children were administered tests of self-esteem. The IVF children did not differ from the naturally conceived children on these measures (Golombok et al., 1995, 1996). In the Belgian study, mothers, fathers, and teachers completed the Child Behavior Checklist (CBCL) when the children were 8 to 9 years old (Colpin & Soenen, 2002). There were no differences in child adjustment between the IVF and naturally conceived children as rated by parents or teachers. Only one study, conducted in Israel, reported raised levels of emotional problems among IVF children of middle-school age (Levy-Shiff et al., 1998). In comparison with naturally conceived children, IVF children showed poorer adjustment to school as rated by teachers, and reported themselves to be more aggressive, more anxious, and more depressed. Although the reason for the discrepancy between the findings of this study and the other studies is not known, it may be associated with the older age of the IVF parents than the natural conception parents in the Israeli sample.

In the European Study of Assisted Reproduction Families, parents and teachers again completed the Strengths and Difficulties Questionnaire when the children were aged 12 (Golombok, Brewaeys, et al., 2002; Golombok, MacCallum, & Goodman, 2001). There were no differences found between family types for either mothers' or teachers' ratings. At Age 18, no differences between the IVF adolescents and the comparison groups of early-adopted and natural conception adolescents were found on the anxiety, depression, hostility, and interpersonal sensitivity subscales of the SCL-90 (Golombok et al., 2009). This study provided the first opportunity for researchers to ask young people how they felt about the unusual nature of their conception. Although a small minority reported a negative

reaction on finding out, by Age 18 not one was distressed about having been conceived by IVF.

Wagenaar and colleagues (2009) compared the behavior and socioemotional functioning of 139 IVF children with that of 143 children born spontaneously to parents who had previously experienced fertility problems. The mean age of the children was 13.5 years. Parents completed the CBCL and teachers completed the Teacher Report Form (TRF). The adolescents were found to be functioning within the normal range. Where differences were identified, these reflected higher levels of adjustment among the IVF children, particularly in relation to externalizing behavior. When the adolescents themselves reported on their behavioral and socioemotional functioning by completing the Youth Self-Report, no differences were identified according to family type. Colpin and Bossaert (2008) administered the CBCL to mothers and fathers, and the Youth Self-Report to 15- to 16-year-old adolescents, in their longitudinal study in Belgium. No differences in adjustment between adolescents conceived by IVF and those conceived naturally were found for either parents' or adolescents' ratings.

Parenting in ICSI Families

A large-scale, multisite study of 540 ICSI, 439 IVF, and 542 natural conception families with 5-year-old children was conducted in Belgium, Denmark, Greece, Sweden, and the United Kingdom. Few differences in parenting between family types were identified, although ICSI mothers reported fewer hostile or aggressive feelings toward their children and higher levels of commitment to parenting than did the mothers of naturally conceived children (Barnes et al., 2004). The children were administered the Bene-Anthony Family Relations Test to provide an assessment of parent-child relationships from the perspective of the children. No differences were found according to family type for children's positive or negative feelings toward, or involvement with, either their mothers or their fathers. Similar findings were reported from a study in the Netherlands of ICSI families, IVF families, and natural conception families with 5- to 8-year-old children (Knoester, Helmerhorst, van der Westerlaken, Walther, & Veen, 2007). In a study of 8-year-olds in Belgium (Leunens, Celestin-Westreich, Bonduelle, Liebaers, & Ponjaert-Kristoffersen, 2006), there were no differences in the parenting stress reported by mothers and fathers.

Children in ICSI Families

With respect to psychological adjustment, Barnes et al. (2004) found no differences between ICSI children and

comparison groups of IVF and natural conception children for externalizing or internalizing problems as rated by mothers and fathers on the CBCL. The CBCL was also administered to mothers by Knoester et al. (2007). Although no differences were identified between ICSI, IVF and naturally conceived boys, there was a difference found between ICSI and IVF girls, resulting from the particularly low scores of IVF girls.

Due to the specific concerns regarding ICSI noted above, attention has focused on the cognitive development of ICSI children. The Bayley Scales of Infant Development were administered to ICSI children at 2 years of age in Belgium, and no evidence was found of delayed mental development in relation to norms for this age group (Bonduelle, Joris, Hofmans, Liebaers, & van Steirteghem, 1998). A comparison between 439 ICSI children and 207 IVF children by the same research team found no differences in Bayley scale scores (Bonduelle, 2003). Similar findings were reported in the United Kingdom following the administration of the Griffiths scales to a representative sample of 208 ICSI children and a comparison group of 221 naturally conceived children aged 1 to 2 years (Sutcliffe et al., 2001). In contrast, significantly poorer Bayley Scale scores were found when 1-year-old ICSI children, particularly boys, were compared with IVF and naturally conceived children in Australia (Bowen, Gibson, Leslie, & Saunders, 1998). Seventeen percent of the ICSI children showed mildly or significantly delayed development compared with 2% of the IVF and 1% of the natural conception children.

In order to address the controversial question of whether or not the ICSI children showed developmental delay, the Australian children were followed up at Age 5 and the sample size was increased (Leslie et al., 2003). No differences were identified between the ICSI children and the comparison groups of IVF and natural conception children for IQ scores or the proportion of children who showed delayed development. In line with this finding, a study of 5-year-olds conducted in Belgium, Denmark, Greece, Sweden, and the United Kingdom (Ponjaert-Kristoffersen et al., 2005), in which 511 ICSI children were compared with 424 IVF children and 488 naturally conceived children on the Revised Wechsler Preschool and Primary Scale of Intelligence (WPPSI-R) and the Motor Scale of the McCarthy Scales of Children's Abilities, no differences were identified between the ICSI, IVF and natural conception children. In a different Belgian sample, the cognitive development of ICSI children and a comparison group of naturally conceived children was

examined at Age 8 (Leunens et al., 2006) and Age 10 (Leunens, Celestin-Westreich, Bonduelle, Liebaers, & Ponjaert-Kristoffersen, 2008), using the Wechsler Intelligence Scale for Children-Revised (WISC-R). Although the ICSI children obtained higher scores at Age 8, there were no differences between the ICSI and the natural conception children at Age 10.

Donor Conception Families (Sperm, Egg, and Embryo Donation)

It has often been suggested that the creation of families using donated sperm, eggs, or embryos may have negative consequences for parenting and children's psychological adjustment, due to either the absence of a genetic link between one or both parents and the children, or to secrecy about the children's genetic origins (Daniels, Gillett, & Grace, 2009; McGee, Brakman, & Gurman, 2001).

The view that the absence of genetic connections between parents and children may be detrimental to positive family functioning derives from research on adoptive families in which both parents are genetically unrelated to the child. Although increased rates of child psychological problems have been identified in adoptive families (Palacios & Brodzinsky, 2010), recent meta-analyses have shown the differences between adoptive and nonadoptive families to be small, with the large majority of adopted children functioning within the normal range (Juffer & van IJzendoorn, 2005, 2007). Moreover, child adjustment problems appear to be largely related to factors associated with the adoption, such as children's experience of abusive or neglectful parenting and multiple caretakers in the years before the adoptions took place, rather than to the absence of a biological link between the parents and the children (Dozier & Rutter, 2008; Palacios & Brodzinsky, 2010).

To the extent that adoption is relevant to donor conception, it is important to note that the transition to adolescence presents specific challenges for adopted children, particularly in terms of identity formation (Grotevant, Rueter, Von Korff, & Gonzalez, 2011). It has been shown that adopted adolescents need to integrate their experiences of being adopted into meaningful narratives in order to develop a secure sense of identity. As part of this process, adopted adolescents often gather information about their past, including information about their birth parents, and some search for, and make contact with, members of their birth families. The development of coherent adoptive identities is considered influential in the psychological well-being of adopted adolescents, with problems in adoptive identity development often resulting from a lack of

information about themselves and their origins. There is much variation in the extent to which being adopted is central to an adolescent's identity (Grotevant, 1999). Thus, searching for birth relatives may be important to some but viewed as irrelevant by others. Adolescents who were highly preoccupied with their adoption were found to report greater alienation from their adoptive parents (Kohler, Grotevant, & McRoy, 2002), although the direction of effects is unclear.

Children born through gamete donation differ from adopted children in that they are genetically related to one parent and are born into the families in which they are reared. However, the absence of a genetic connection to one parent is considered by some to create important similarities between donor-conceived children and adopted children (Cahn, 2009; Feast, 2003), which may have implications for identity development, adjustment, and relationships with parents.

The concern about secrecy in donor conception families has also arisen from research on adoption, which has shown that adopted children who are not given information about their birth parents are at risk for emotional, behavioral, and identity problems (Brodzinsky, 2006; Grotevant, 1997; Grotevant, Perry, & McRoy, 2005). It is now generally accepted that open communication between adoptive parents and their children, such that children are given developmentally appropriate information about their adoption and feel free to discuss adoption-related issues as they arise, is important for positive parent-child relationships and the psychological well-being of adopted children (Brodzinsky & Pinderhughes, 2002).

The family therapy literature also points to the potentially negative psychological consequences of keeping children's origins secret (Imber-Black, 1998; Papp, 1993). From a family therapy perspective, secrets are believed to be detrimental to family functioning because they create boundaries between those who know the secret and those who do not (Bok, 1982; Vangelisti, & Caughlin, 1997), and cause anxiety when topics related to the secret are discussed (Lane & Wegner, 1995). In examining the particular case of parents keeping secrets from their children, Papp (1993) suggested that children can sense when information is being withheld from them due to the taboo that surrounds the discussion of certain topics, and that children may become confused and anxious, or even develop symptoms of psychological disorder, as a result.

In relation to donor conception, it has been argued that keeping the circumstances of conception secret interferes with communication between those who know the secret (the parents) and those who do not (the children)

(Clamar, 1989). The extent to which donor-conceived children suspect that secrets about their parentage are being kept from them cannot be established, but it is thought that children may “pick up” that they are different in some way (Daniels, Grace, & Gillett, 2011). Parents of donor-conceived children have reported difficulties responding to comments or questions about family resemblances (Becker, Butler, & Nachtigall, 2005), and, in a qualitative study of adults who were aware of their donor insemination, some reported that, as children, they suspected that something was amiss (Turner & Coyle, 2000).

Rates of Disclosure in Donor-Conceived Families

The majority of parents who gave birth to donor-conceived children do not tell their children about their genetic origins. In the European Study of Assisted Reproduction Families, not one set of the 111 donor insemination parents who participated had disclosed the donor conception to their child by early school age (Golombok et al., 1996), less than 10% of parents had disclosed by early adolescence (Golombok, Brewaeys, et al., 2002), and no additional parents had done so by Age 18 (Owen & Golombok, 2009). A similar pattern was found for egg donation families in the United Kingdom (Golombok, Murray, Brinsden, & Abdalla, 1999; Murray, MacCallum, & Golombok, 2006) and in Finland (Söderström-Anttila, Sajaniemi, Tiitinen, & Hovatta, 1998). With respect to embryo donation, MacCallum and Golombok (2007) found that only 9% of parents of preschool children born through embryo donation had begun to talk to their children about the children’s biological origins, rising to only 18% by middle childhood (MacCallum & Keeley, 2008). This was in stark contrast to the comparison group of adoptive parents, all of whom had disclosed the adoption to their children (MacCallum & Keeley, 2012). Even in Sweden, where legislation giving donor offspring the right to obtain information about the donors’ identity came into force in 1985, more than a decade later, only 11% of parents had informed their children of their donor conception (Gottlieb, Lalos, & Lindblad, 2000; Lindblad, Gottlieb, & Lalos, 2000). Investigations in the United States have produced comparable findings, with rates of disclosure to the children reported to range between 14% and 30% (Leiblum & Aviv, 1997; Nachtigall, Tschann, Szkupinski Quiroga, Pitcher, & Becker, 1997). When questioned about their reasons for secrecy, parents in the European Study of Assisted Reproduction Families reported concern that their children would be upset, shocked, and confused

by the knowledge that their fathers or mothers were not genetically related to them (Cook, Golombok, Bish, & Murray, 1995; Golombok et al., 1999). They were also apprehensive about jeopardizing the positive relationships that existed between the children and their nongenetic parents. In addition, they did not know when or how to tell their children and, as the donors were anonymous, were concerned about not being able to answer the children’s inevitable questions about the donors’ identities.

There has been a rise in the number of parents who intend to tell their children about their donor conception (Daniels et al., 2009; Hahn & Craft-Rosenberg, 2002). Nevertheless, in spite of their intentions, many parents do not actually disclose this information. In a longitudinal study of children born in the United Kingdom in 2000 (the Millennium Babies Study), 46% of parents of infants conceived by donor insemination and 56% of parents of infants conceived by egg donation planned to tell their child about their donor conception. However, only 28% of donor insemination parents and 41% of egg donation parents actually did so by Age 7 (Readings, Blake, Casey, Jadva, & Golombok, 2011), the age by which most adopted children are informed of their adoption. Moreover, some parents who reported that they had told their children had done so simply by discussing the use of fertility treatment but not the use of donated eggs or sperm (Readings et al., 2011). Parents of children conceived by embryo donation have similarly been shown to give only partial information about the conception to their children (MacCallum & Keeley, 2012).

Family Functioning in Nondisclosing Families

In spite of the growing number of families formed through donor conception, few studies have investigated parent-child relationships and children’s socioemotional development in these families. The European Study of Assisted Reproduction Families included a group of families created by donor insemination and found the quality of parenting in DI families to be similar to that of IVF families, and superior to that of natural conception families (Golombok et al., 1995, 1996). This suggests that the couples who conceived children through donor insemination became highly committed parents, and that the absence of a genetic connection between the fathers and the children did not interfere with the development of positive relationships between them. The families were followed up as the children approached adolescence (Golombok, Brewaeys, et al., 2002; Golombok, MacCallum, Goodman, & Rutter, 2002). Although the donor insemination families no longer

showed higher levels of parenting quality than the natural conception families, they were characterized by high levels of warmth between parents and children, accompanied by appropriate levels of discipline and control. In a follow-up of the UK families at Age 18, higher levels of warmth and discipline were shown by donor insemination than by IVF mothers, and no differences were found for fathers (Owen & Golombok, 2009).

A sample of egg donation families was also recruited in the United Kingdom and compared with the donor insemination families (Golombok et al., 1999). The only difference to emerge was that mothers and fathers of young children conceived by egg donation reported lower levels of stress associated with parenting than did parents of donor insemination children. Again, few differences in parenting were identified when the children reached adolescence, although the egg donation mothers showed lower levels of sensitive responding and were less likely to be emotionally overinvolved with their children than were the donor insemination mothers (Murray et al., 2006). It is conceivable that these differences stemmed from the absence of a genetic relationship between the egg donation mothers and their children.

In terms of child adjustment, no differences in emotional or behavioral problems between children conceived by either sperm donation (Golombok, Brewaeys, et al., 2002; Golombok et al., 1995; Golombok et al., 1996; Golombok, MacCallum, et al., 2002) or egg donation (Golombok et al., 1999; Murray et al., 2006) and comparison groups of IVF, natural conception, and early-adopted children were found in childhood or early adolescence. This suggests that, in families where children are unaware of their donor conception, the absence of a genetic link with fathers in donor insemination families or mothers in egg donation families is not associated with raised levels of child adjustment problems.

In the only study of parenting and child development in families formed through embryo donation, families were found to be functioning well when the children were of preschool age (MacCallum, Golombok, & Brinsden, 2007) and when followed up in middle childhood (MacCallum & Keeley, 2008). The parents differed from comparison groups of adoptive and IVF parents only in terms of greater emotional overinvolvement with the children. The children were not found to be at increased risk of psychological problems either in their preschool (MacCallum et al., 2007) or their early school years (MacCallum & Keeley, 2008).

In an investigation that used parent questionnaires to compare sperm donation, egg donation, embryo donation,

and surrogacy families with families created by assisted reproductive procedures using the parents' own gametes, no differences in the psychological adjustment of 5- to 9-year-old children were found (Shelton et al., 2009). A further questionnaire-based study compared donor insemination families with naturally conceived two-parent families, single-mother families, and stepfather families in terms of parental psychological distress, parental relationship quality, general family functioning, parenting quality, and quality of parent-child relationships (Kovacs, Wise, & Finch, 2013). The children ranged in age from 5 to 13 years. Where differences were identified between the donor insemination families and the other family types, these reflected more positive functioning in the donor insemination families. Of particular interest are the more positive findings for donor insemination fathers than for stepfathers, suggesting that the intention to become non-genetic parents, and the age of the children at the time of becoming nongenetic parents, may be important factors in determining the quality of the relationship between fathers—and possibly mothers—and their genetically unrelated children. Further support for this possibility comes from Dunn et al.'s (1998) finding that many stepparents do not view their stepchildren as their "own" children.

Family Functioning in Disclosing Families

Contrary to parents' concerns, it appears that children who are told about their donor conception in their preschool years respond neutrally, or with curiosity rather than distress (Blake, Casey, Readings, Jadv, & Golombok, 2010; Mac Dougall, Becker, Scheib, & Nachtigall, 2007; Rumball & Adair, 1999). However, they appear to have little understanding of egg or sperm donation by Age 7 (Blake et al., 2010), the age by which most adopted children understand what it means to be adopted (Brodzinsky & Pinderhughes, 2002). It is not until Age 10 that most are able to give clear accounts of the nature of their conception (Blake, Casey, Jadv, & Golombok, 2013). In a study of the thoughts and feelings of adolescents who grew up with the knowledge that they were donor-conceived, the majority reported feeling comfortable about their donor conception and felt that learning about their donor conception did not have a negative impact on their relationship with their parents (Scheib et al., 2005).

The experience of those who are told, or find out about, their donor conception in adolescence or adulthood as opposed to early childhood can be strikingly different. Participants in qualitative studies have reported that secrecy about the nature of their conception has caused

them severe psychological harm, and many have felt deceived by their parents and angry toward them (Blyth, 2012; Turner & Coyle, 2000). Moreover, in a survey of 165 donor offspring who were members of the Donor Sibling Registry, those who had found out about their donor conception in adolescence or beyond were more likely to report feeling upset, angry, shocked, and confused than were those who had been told in childhood (Jadva, Freeman, et al., 2009). It is important to note, however, that the participants in these studies had either joined a support group for donor-conceived offspring or the Donor Sibling Registry, and thus the extent to which they are representative of individuals who are aware of their donor conception is not known. Also, all had been conceived by donor insemination; no data are yet available on the feelings and experiences of adolescents and young adults conceived by egg or embryo donation. This will be an important issue to research in the years to come.

In order to investigate the psychological consequences for families of openness with children about their donor conception, a longitudinal investigation of families created by donor insemination and egg donation was initiated at the millennium in the United Kingdom (the U.K. Longitudinal Study of Assisted Reproduction Families). Phase 1 was conducted when the children were 1 year old (Golombok, Lycett, et al., 2004), Phase 2 was conducted at Age 2 (Golombok, Jadva, Lycett, Murray, & MacCallum, 2005), Phase 3 was conducted at Age 3 (Golombok, Murray, et al., 2006), Phase 4 was conducted at Age 7 (Casey, Jadva, Blake, & Golombok, 2013; Golombok, Readings, Blake, Casey, Mellish, et al., 2011) and Phase 5 was conducted at Age 10 (Golombok, Blake, Casey, Roman, & Jadva, 2013). In the preschool years, the differences identified between family types pointed to more positive parent-child relationships in families created by gamete donation than in the comparison group of natural conception families, with no differences in the quality of family relationships according to whether the children lacked a genetic connection to the father (in the case of donor insemination) or the mother (in the case of egg donation) (Golombok, Lycett, et al., 2004; Golombok et al., 2005; Golombok, Murray, et al., 2006). The donor-conceived children were found to be functioning well, but, in spite of their highly involved parenting, did not show higher levels of adjustment than their counterparts from natural conception families. These findings replicated those obtained in the European Study conducted 15 years earlier.

In contrast to the more positive outcomes for the donor conception families in the preschool years, greater

difficulties emerged at Age 7 (Casey et al., 2013; Golombok, Readings, Blake, Casey, Mellish, et al., 2011), the age by which children show an understanding of biological inheritance (Gregg, Solomon, Johnson, Zaitchik, & Carey, 1996; Williams & Smith, 2010) and the meaning and implications of the absence of a biological connection to parents (Brodzinsky & Pinderhughes, 2002). The gamete (egg and sperm) -donation mothers who had kept their children's origins secret showed higher levels of emotional distress than did those who had been open with their children about their origins. With respect to the relationship between parents and children, interview and observational assessments of mother-child interaction revealed less positive interaction in the donor-conceived families in which parents had not disclosed the method of conception to the children than in the natural conception families. There were no differences for fathers apart from higher negativity shown by donor-insemination children during an observational assessment of interaction with their fathers. It is important to note that the differences identified at Age 7 are not indicative of dysfunctional family relationships, but, instead, reflect variation within the normal range.

In terms of child adjustment, the absence of genetic connection to either the mother or the father was not associated with emotional or behavioral problems at 3, 7, or 10 years old (Golombok, Blake, et al., 2013). At Age 10, the children were interviewed about their relationships with their parents; those who were aware of their origins were asked about their feelings about being donor conceived (Blake et al., 2013). The large majority in all three family types perceived their relationships with their mothers and fathers as warm and involved; the absence of genetic relationships did not appear to affect children's feelings of closeness to their parents. Most had positive feelings about their donor conception. However, they tended not to discuss this with friends and family, and some reported feeling embarrassed when talking about the subject. As the children studied so far have been preadolescent, the longer-term outcomes of the awareness of donor conception for parent-child relationships and child adjustment are not yet known. As adolescence is the developmental stage at which issues relating to identity become salient and difficulties in parent-child relationships are most likely to arise, adolescence may present particular challenges to donor-conception families. The consequences of donor conception for adolescent development and well-being is thus an important area for future research.

Searching for Donor Relations

As discussed above, the wish to obtain information about their birth family is characteristic of adopted children at adolescence (Grotevant & Von Korff, 2011; Wrobel & Dillon, 2009), and it has been argued that research on adoption provides valuable insight into how donor-conceived offspring may feel about searching for and contacting their genetic relations (Cahn, 2009; Feast, 2003). The main reason given by adopted individuals for searching for birth relatives is to gain a more complete understanding of their family history in order to enhance their own sense of identity (Brodzinsky, Smith, & Brodzinsky, 1998). In a study of the experiences of adopted individuals who had found information about their origins (Howe & Feast, 2000), the majority reported that this had helped them gain a better sense of self and had improved their psychological well-being.

There is growing evidence that similar processes are at play for children born through gamete donation, although the data available comes from those who were conceived through donated sperm rather than donated eggs or embryos. In a survey of 165 donor offspring aged between 13 and 61 years who were members of the Donor Sibling Registry, the main reasons given for searching for donor relations were to satisfy curiosity about the characteristics of their donor and to enhance their sense of identity (Jadva et al., 2010). Although many wished to meet their donor and donor siblings, not one mentioned wanting to form a relationship with their donor as their main reason for searching. Adolescents with identity-release sperm donors were studied by Scheib et al. (2005). Again, the large majority were curious to know what their donor was like as a person. Most planned to request the identity of their donor on reaching Age 18 and pursue contact with him. However, only 10% reported that he was an important person in their life and only 6.9% wanted a father-child relationship.

Surrogacy Families

Although children conceived by egg donation are genetically unrelated to their mothers, children conceived by sperm donation are genetically unrelated to their fathers, and children conceived by embryo donation are genetically unrelated to both parents, these children are all born to the parents who will raise them. In the case of surrogacy, the mother who gives birth to the child and the mother who parents the child are not the same. Children born through

gestational surrogacy lack a gestational link with their mother, and children born through genetic surrogacy lack both a gestational and a genetic link with her.

Of all the assisted reproductive procedures that have been practiced, surrogacy remains the most contentious. It has been suggested that the characteristics that distinguish surrogacy from other types of assisted reproduction may produce greater problems for surrogacy families than for families created by more traditional assisted reproduction techniques (Golombok, Murray, Jadva, MacCallum, & Lycett, 2004). Intended parents must live throughout the pregnancy uncertain whether the surrogate mother will relinquish the child, and must establish a mutually acceptable relationship with her to ensure that their relationship does not break down. From the perspective of the intended mother who is unable to give birth, herself, the relationship with the fertile and often younger surrogate, to whom she is indebted, may result in feelings of inadequacy, depression, and low self-esteem. Difficulties may also arise if the surrogate remains in contact with the family after the birth, especially if she is the genetic mother of the child. Moreover, due to the controversial nature of surrogacy, intended parents may experience disapproval from family, friends, and the wider social world. Unlike other forms of assisted reproduction, in which the mother experiences a pregnancy and can choose to keep the circumstances of the child's conception secret, parents of children born through surrogacy must explain the arrival of their newborn baby. All of these factors have the potential to negatively affect the quality of parenting in surrogacy families and, consequently, the psychological well-being of children.

In order to examine these issues, a group of surrogacy families was recruited as part of the U.K. Longitudinal Study of Assisted Reproduction Families and compared with the egg donation and natural conception families. This was the first investigation of surrogacy families in which in-depth data on family functioning and child development was obtained from infancy onward. At Age 1, the differences that were identified indicated greater parental psychological well-being and greater adaptation to parenthood by mothers and fathers of children born through surrogacy than by natural conception parents (Golombok, Murray, et al., 2004; MacCallum, Lycett, Murray, Jadva, & Golombok, 2003). The families were next assessed at the time of the children's second birthdays. In comparison to the natural conception families, the surrogacy mothers showed more positive parent-child relationships than did mothers with naturally conceived children, the surrogacy

fathers reported lower levels of parenting stress than did their natural conception counterparts, and there were no group differences in the children's cognitive development or psychological adjustment (Golombok, MacCallum, Murray, Lycett, & Jadva, 2006). Assessments of family relationships and child development were conducted again when the children reached 3 years of age (Golombok, Murray, et al., 2006). The differences found between family types reflected higher levels of warmth and interaction between mothers and children in surrogacy families than in families with naturally conceived children. Thus, the findings from the preschool phases of the study indicated more positive parent-child relationships in surrogacy than in natural conception families. At all three phases, the egg donation families were more similar to the surrogacy than to the natural conception families.

When followed up at Age 7, once the children had acquired a greater understanding of surrogacy, there were no differences in positive or negative aspects of parenting between mothers in the different family types. However, observational assessments of mother-child interaction revealed less positive interaction in mother-child dyads from the surrogacy and egg donation groups than in the natural conception families (Golombok, Readings, Blake, Casey, Marks, et al., 2011). With respect to the children, data on emotional and behavioral problems were obtained for the surrogacy, egg donation, donor insemination, and natural conception children at Ages 3, 7, and 10. Although the children were generally functioning within the normal range, the surrogacy children showed higher levels of adjustment problems than did children conceived by gamete donation at Age 7, suggesting that the absence of a gestational connection between parents and children may be more problematic for children than the absence of a genetic link (Golombok, Blake, et al., 2013). Interestingly, infant-placed internationally adopted children have been found to show a similar increase in behavioral problems at Age 7 (Stams, Juffer, Rispens, & Hoksbergen, 2000), and both the surrogacy and the internationally adopted children's behavioral problems had reduced when followed up at Age 10 and early adolescence, respectively. A possible explanation is that both groups of children struggle with identity issues earlier than other children do, as they must face up to being different at an early age. Contrary to commonly voiced concerns, the majority of families who kept in contact with their surrogate mother maintained a good relationship with her over the first 10 years of the children's lives (Jadva, Blake, Casey, & Golombok, 2012).

Conclusions

It seems that concerns about the potentially negative consequences of "high-tech" assisted reproductive technologies for children's socioemotional development are unfounded. Indeed, these extremely wanted children appear to experience particularly positive parenting. Procedures involving reproductive donation bring additional concerns, especially relating to secrecy about the children's genetic origins. Although children and young adolescents who are unaware of their donor conception do not appear to be at risk for psychological problems, little is known about older adolescents or adults in this situation. Children whose parents disclose their donor conception at an early age seem to integrate this information into their developing sense of self, whereas some donor offspring who find out about their donor conception in adolescence or adulthood report enduring psychological distress. Those who are aware of their donor conception may wish to search for their donor and donor siblings. Their main motivation is curiosity and the wish to incorporate information about their family background into their life story in order to develop a more complete sense of who they are. Further research is needed on the nature of relationships formed with donors and donor siblings, and on the consequences for parents and children of the use of known rather than anonymous donors.

SAME-SEX PARENTING

Same-sex parenting can take place through a number of different pathways. Since the 1980s onward, assisted reproduction techniques have been used by lesbians and gay men to have children within the context of same-sex couple relationships, or as single parents, in planned or *de novo* family arrangements. The majority of children in planned lesbian families appear to have been born to lesbian mothers through donor insemination at a clinic, according to parental reports in the studies reviewed below. However, an unknown number of children have been born to lesbian mothers through self-insemination at home using either sperm from anonymous donors, previously unknown men, male friends, or male relatives of the receiving women's female partners. Some gay men have planned fatherhood through donor agreements with lesbian or single heterosexual women (Segal-Engelchin, Erera, & Cwikel, 2005). Others may have initially seen themselves simply as sperm donors, but later have taken

up parenting roles through involvement in their children's lives and the agreement of the children's mothers. A few celebrity gay male couples have hit the headlines by having children through surrogacy, but few clinics offer this expensive treatment and, as yet, few legislatures support it (Berkowitz, 2013; Greenfield & Seli, 2011; Tasker 2013a).

Same-sex parenting may also come about through adopting children (Farr & Patterson, 2013; Golombok, Mellish, et al., 2013). Gates (2011) indicated that the number of lesbian and gay adoptive parents in the United States has doubled in the past decade. In countries such as the United Kingdom, in which joint adoption by same-sex couples has become possible, adoption is often the first choice, because both parents can be legally recognized as parents with an equal connection to genetically unrelated children (Jennings, Mellish, Tasker, Lamb, & Golombok, 2013). Some lesbians and gay men have also taken on *in loco parentis* roles as foster carers (Hicks, 2011).

Many men and women who parent in same-sex couples have conceived or adopted their children within a heterosexual relationship that has ended with parental separation or the death of a parent (Tasker, 2013b). The legacy of a previous relationship inevitably makes for more complex family networks than those in planned or *de novo* same-sex families. In some cases, instead of ending an established relationship, a lesbian, gay, or bisexual parent might continue to parent within a mixed-orientation marriage (Buxton, 2005). Most of the information on the developmental outcomes for children of nonheterosexual parents has been produced by studies that have recruited samples of self-identified lesbian or gay parents. Little is known about parenting by adults who identify as bisexual or queer (Ross & Dobinson, 2013).

Parenting

Data from numerous studies of lesbian mother families have indicated that parent-child relationships are just as warm and nurturing as they are in heterosexual families, and the smaller number of studies of gay father families has produced similar results. The earliest investigations, which were of children who had been conceived in heterosexual relationships but brought up by lesbian mothers after the parents had divorced or separated, found that mother-child relationships were just as close in lesbian families as they were in postseparation families headed by single heterosexual mothers (Golombok, Spencer, & Rutter, 1983; Green, Mandel, Hotvedt, Gray, & Smith, 1986; Hoeffer, 1981; Kirkpatrick, Smith, & Roy, 1981).

Surprisingly little research has focused on the parenting of gay fathers who have had children in previous heterosexual relationships, perhaps because most of these children live with their mothers rather than their fathers after their parents' separation. Studies that have asked nonresidential gay fathers about parenting have found that gay and heterosexual fathers reported similar problems keeping in touch with their children's lives (Bigner & Jacobsen, 1989a, 1989b), with gay fathers tending to be more receptive to children's needs, employing more reasoning strategies, and emphasizing limit-setting more often than do heterosexual fathers postdivorce (Bigner & Jacobsen, 1992).

It has been suggested that children raised by lesbian couples may receive a "double dose" of warm, child-centered parenting because they have two mothers (Biblarz & Stacey, 2010). For instance, Flaks, Ficher, Masterpasqua, and Joseph (1995) studied lesbian couples parenting 3- to 9-year-old children conceived by donor insemination (DI) and found them to be more likely than heterosexual couples to identify and think through critical issues in childcare situations. In an investigation of parent-child relationships in a community sample of lesbian, two-parent heterosexual, and single heterosexual parent families recruited through the Avon Longitudinal Study of Parents and Children in the United Kingdom (Golombok et al., 2003), lesbian mothers were found to engage in more imaginative and domestic play with their children and were less likely to smack their children than heterosexual mothers. Bos, van Balen, and van den Boom (2004) compared a Dutch sample of lesbian mother families with donor insemination children aged 4 to 8 with a school-recruited comparison group of heterosexual families with naturally conceived children. Lesbian and heterosexual mothers reported similarly competent parenting practices and seemed to have equivalent levels of parenting stress. However, co-mothers (lesbian mothers who had not given birth to their children) seemed to feel the need to present or justify their parenting more than the other parents in the study.

Studies of adoptive parenting by same-sex couples have produced similarly positive results. The Cambridge Study of Adoptive Family Life examined lesbian, gay, and heterosexual couples and their 3- to 9-year-old adopted children (Golombok, Mellish, et al., 2013). By the time of assessment, which took place at least 1 year after the children had been placed with the couples, generally positive parent-child relationships, characterized by parental warmth and sensitivity, had been established in all three groups. Where differences were found, these reflected more positive parental well-being and parent-child

relationships in gay, rather than heterosexual, families. In a study of adoptive two-parent families in the United States, few differences between gay, lesbian, and heterosexual families were found in parenting stress, parental discipline, or parental relationship satisfaction (Farr, Forssell, & Patterson, 2010; Tornello, Farr, & Patterson, 2010). Erich, Leung, and Kindle (2005) collected data from a convenience sample of lesbian and gay adoptive parents of children of varying ages. No significant differences between groups were found for family functioning using the Family Assessment Measure–III (FAM–III). The authors noted that the lesbian and gay parents who had adopted older children with histories of abuse generally reported higher levels of family functioning than were expected for children with difficult preadoption histories. Self-report data from lesbian and gay adoptive parents similarly indicated that adoptive parents showed good parenting skills (Ryan, 2007), again despite many of the children having experienced preadoption trauma.

Longitudinal studies of adolescent and young adult offspring of lesbian mothers have confirmed that parent–child relationships continue to be positive as children grow up. The UK follow-up of children raised by lesbian mothers after their mothers and fathers had separated found that, in their mid-20s, offspring continued to report close relationships with their mothers and had closer stepparenting relationships with their mothers' female partners than adults in the heterosexual mother comparison group had with their mothers' male partners (Tasker & Golombok, 1997). In the Fatherless Families Study, a longitudinal study of planned lesbian families that included comparison groups of families headed by single heterosexual mothers and married heterosexual parents, the children were first interviewed at Age 3 to 9 years (Golombok, Tasker, & Murray, 1997), followed up at Age 12 (MacCallum & Golombok, 2004) and again at Age 18 (Golombok & Badger, 2010). Mother–child relationships were found to be closer in both types of fatherless families in childhood, and early adolescent children in fatherless families again reported closer relationships with their mothers, although mothers in fatherless families also reported more severe disputes with their adolescent offspring. At the subsequent follow-up, young adults from different family types did not differ in the quality of their relationships with their mothers, but the mothers in fatherless families showed greater emotional involvement in the lives of their offspring than did married mothers.

Some commentators have suggested that rates of parental separation may be higher for children parented

by lesbian couples than for those parented by heterosexual couples (Biblarz & Stacey, 2010). For example, Gartrell, Bos, Peyser, Deck, and Rodas (2011) found that the rate of partnership dissolution in the National Longitudinal Lesbian Family Study was higher than the divorce rate among age-matched heterosexual parents in the U.S. National Survey of Family Growth. However, separation rates are likely to be higher than divorce rates, and it is worth bearing in mind that few of the lesbian couples had access to same-sex marriage or civil union status. Bos, Gartrell, van Balen, Peyser, and Sandfort (2008) noted a significantly higher rate of separation among lesbian couples in the U.S. sample than in a Dutch sample, further suggesting the importance of cultural context for same-sex relationship stability.

Psychological Adjustment of Young Children

The psychological adjustment of children raised in lesbian families has been a continuing focus of research since the initial publications in the field. The rationale for this body of research is that claims made in custody disputes that a child's psychological well-being will be harmed by being brought up by parents who have same-sex relationships should be put to the test. These claims are based upon psychoanalytic and classic social learning theories implying that mothers and fathers in heterosexual relationships are necessary for positive child development (Golombok, 2000; Golombok & Tasker, 1994). It is also argued that children might be at risk for anxiety or depression, either because of peer stigma or parental neglect, because their parent will be distracted from parenting by pursuit of new same-sex relationships (Logue, 2002).

None of the original studies in either the United Kingdom (Golombok et al., 1983) or the United States (Green et al., 1986; Kirkpatrick et al., 1981) of parents and children in postdivorce lesbian mother families found that these children were more challenged in their mental health than were children brought up by single heterosexual mothers after divorce. The long-term follow-up of Golombok et al.'s (1983) sample found no signs of poor mental health in adulthood (Tasker & Golombok, 1997). Other studies of children brought up by lesbian mothers after their mothers and fathers separated found no differences in intelligence test scores (Green et al., 1986) or self-concept (Puryear, 1983). Huggins (1989) compared the self-esteem of adolescents brought up by lesbian mothers and single heterosexual mothers after the mothers' and fathers' separation. No differences were

found between the two groups of young people. However, Huggins did find evidence of a bimodal distribution of self-esteem among adolescents from lesbian families: self-esteem was higher than comparison group scores for those who were positive about their mothers' lesbian identity, and correspondingly lower than comparison group scores if the adolescents held negative views. No controlled studies have examined the psychological well-being of children whose fathers have come out as gay after separating from the mothers. Nevertheless, there have been no indications from studies of gay fathers and their children that the children generally have difficulties with respect to well-being (Barrett & Tasker, 2001; Bozett, 1987a, 1987b; Miller, 1979).

Regarding children conceived through assisted reproductive technologies by lesbian and gay parents and thus reared by same-sex parents from birth, a number of studies have used the Child Behavioral Checklist (CBCL) to examine parental and sometimes teacher reports of children's internalizing and externalizing behaviors. For example, Chan, Brooks, Raboy, and Patterson (1998) studied children aged around 7 years who were conceived by donor insemination to single and two-parent lesbian and heterosexual families. It was concluded that neither family structure nor parental sexual orientation influenced children's psychological adjustment. Instead, higher levels of parenting stress, parental conflict, and relationship dissatisfaction correlated with both internalizing and externalizing behaviors, regardless of family type. Findings from the National Longitudinal Lesbian Families Study also showed that 10-year-old children did not differ from CBCL norms in terms of social competence or psychological adjustment (Gartrell, Deck, Rodas, Peyser, & Banks, 2005). Neither were there differences in the CBCL scores of elementary school aged children raised in lesbian or heterosexual two-parent families studied by Flaks et al. (1995). Similarly, studies in Belgium (Brewaeys, Ponjaert, van Hall, & Golombok, 1997) and the Netherlands (Bos, van Balen, & van den Boom, 2007) found no evidence of elevated levels of CBCL scores in DI children conceived by lesbian mothers. Again, children's CBCL scores were associated with family process variables, including parental satisfaction with their partners, power assertion, and parental concern. A similar absence of differences in child adjustment between children in lesbian and heterosexual two-parent households was found using the Strengths and Difficulties Questionnaire administered to parents and teachers in the United Kingdom (Golombok et al., 1997; Golombok et al., 2003). Predictable associations were found across

families between children's problematic behavior and higher frequencies of parenting disputes, greater parental stress, and lower levels of parental warmth (Golombok et al., 2003).

Investigators have also included positive indices of psychological well-being in studies of children in lesbian families. For example, no differences between DI children conceived by lesbian and heterosexual couples were identified in children's CBCL social competence scores measuring children's engagement in social activities at home or at school (Chan et al., 1998). Children from both family types showed higher levels of social engagement in comparison with CBCL norms. In addition, Golombok et al. (2003) found no differences in self-esteem between children in families headed by lesbian mothers, single heterosexual mothers, and married heterosexual mothers. However, in the earlier Fatherless Families Study, children in families led by lesbian mothers tended not to score as highly on self-perceived physical and cognitive competence as did children in heterosexual two-parent families (Golombok et al., 1997).

Children adopted by same-sex parents also do not appear to show higher rates of psychological problems than do children adopted by heterosexual parents. In their comparison of the psychological well-being of preschool children adopted in infancy by matched groups of lesbian, gay, and heterosexual couples, Farr et al. (2010) and Tornello et al. (2010) found that children adopted by same-sex couples were as well-adjusted as those adopted by heterosexual couples, according to both parents' and teachers' reports on the CBCL. Irrespective of family structure, the authors concluded that the factors related to child adjustment were positive parenting, the absence of parenting stress, and harmonious couple relationships. In contrast, observed competitiveness between adoptive parents and parent-reported dissatisfaction with the division of childcare were related to increased levels of behavioral problems. A smaller study that sampled children from early childhood through to adolescence also compared lesbian, gay, and heterosexual adoptive parents' reports of their children's behavior on the CBCL, again finding no significant differences in behavioral problems across family types (Erich et al., 2005). In the United Kingdom, children adopted by gay fathers showed lower levels of externalizing problems than did children adopted by heterosexual parents (Golombok et al., 2013). It was not possible to determine whether the more positive adjustment among children adopted by gay fathers resulted from gay fathers having less troubled children placed with them

or from the highly positive parenting environment they provided for their adopted children.

Psychological Adjustment of Adolescent and Young Adult Offspring

Findings from the National Longitudinal Lesbian Families Study, an in-depth qualitative study of children born to lesbian couples by donor insemination, indicate that the psychological well-being of the 17-year-olds raised in lesbian families did not differ from matched adolescents in the Washington Health Youth Survey (van Gelderen, Bos, Gartrell, Hermanns, & Perrin, 2012). Likewise, Gartrell and Bos (2010) found that these adolescents were functioning at least as well, and in some instances better, than expected from adolescent CBCL norms. Similar findings were obtained from the Fatherless Families Study in the United Kingdom when adolescents and young adult offspring parented by lesbian mothers were compared with those parented by heterosexual single mothers or heterosexual married couples (Golombok & Badger, 2010; MacCallum & Golombok, 2004), with young adults who had grown up in mother-headed families (either single heterosexual mothers or lesbian mothers) showing lower levels of anxiety, depression, hostility, and problematic alcohol use, coupled with higher levels of self-esteem, than did young adults from father-present families.

Confidence in the general psychological well-being of children and adolescents raised in same-sex parented families has been increased by findings from studies that have used large, nationally representative samples to investigate psychological adjustment in lesbian and gay families. Using the Add Health national database of U.S. high school students, adolescents from households headed by lesbian couples were not found to differ from their peers from heterosexual two-parent families on either psychological or school adjustment (Wainright, Russell, & Patterson, 2004). Adolescents in same-sex parented households also generally reported low levels of delinquent behavior and substance use (Wainright & Patterson, 2006). In addition, Rosenfeld (2010) analyzed data from the U.S. Census 2000 to find that differences in parental socioeconomic status accounted for most of the small gap in rates of retention across school grades between children living in households headed by heterosexual married couples and those living in households headed by stable same-sex couples. In the United Kingdom, Rivers, Poteat, and Noret (2008) examined the psychological adjustment of a subsample drawn from a UK school survey

of 12- to 16-year-olds who reported living with their mothers and their same-sex partners and a matched group of pupils living with their heterosexual mothers and fathers. Adolescents parented by lesbian mothers did not differ from those with heterosexual parents on a questionnaire measure of psychological problems.

Peer Relationships

A further concern about children parented by nonheterosexual parents has been that these children may be subjected to stigma through association. The likelihood of encountering stigma has been thought to relate to the extent to which their parents are "out" about their sexual identity, and also dependent on the level of acceptance and visibility of LGBTQ people in the wider society and local neighborhood. How children manage prejudice likely depends upon several factors: How apparent they think their parents' sexual orientation may be, the extent to which they, themselves, identify with their parents' sense of being different, their ages, and whether or not they reside with their lesbian or gay parents and their parents' same-sex partners.

Studies of children brought up by their lesbian mothers or gay fathers postseparation have not found these children to be more likely to be victimized than their peers. Neither Green et al. (1986) in the United States nor Golombok et al. (1983) in the United Kingdom found that children with lesbian mothers had difficulties with peer relationships or in forming friendships, in comparison with their peers from single heterosexual mother families. When the children in the UK study were followed up as young adults, those with lesbian mothers were no more likely to say that they had encountered teasing or bullying than were those in the comparison group (Tasker & Golombok, 1997). However, when asked specifically whether they had ever been teased about their own sexuality, daughters, and more particularly sons, from lesbian families tended to be more likely to say that they had been teased, perhaps because of their sensitivity to peer group comments.

Compared with the heterosexual mothers in the UK Avon Longitudinal Study of Parents and Children, lesbian mothers were slightly more likely to report that their elementary school aged children had experienced some peer relationship difficulties (Golombok et al., 2003). But no differences in peer relationship difficulties were reported by the children themselves or their class teachers. Other studies have found that overall rates of stigmatization experienced by children in planned lesbian families are

not higher than rates experienced by comparison groups. For example, in the Fatherless Families Study, no differences in rates of victimization by family type were found when children were studied at elementary school age (Golombok et al., 1997), in early adolescence (MacCallum & Golombok, 2004) or in early adulthood (Golombok & Badger, 2010). Studies in the United States (Ryan & Cash, 2004) and the United Kingdom (Mellish, Jennings, Tasker, Lamb, & Golombok, 2013) of adopted children placed with lesbian or gay parents have similarly found few reported difficulties in either peer stigmatization or friendship-forming at school. For example, none of the 59 children interviewed by Mellish and colleagues (2013) reported being teased or bullied about having lesbian or gay parents.

Aside from studies of adopted children, we still know little about the experiences of children with gay fathers, except through a few studies of gay men parenting children conceived through a previous heterosexual relationship. Adult offspring of gay fathers have not generally reported peer group problems when interviewed about their experiences (Bozett, 1987a, 1987b; Miller, 1979). Bozett's qualitative research indicated that both gay fathers and their children effectively exercised "boundary control" to limit the possibilities for prejudice. Boundary control strategies included presenting the fathers' male partners as friends or not displaying any signifiers that might indicate gay identities.

Investigators using subsamples of adolescents with same-sex parents drawn from nationally representative databases have recorded no differences in rates of victimization according to family type. Adolescents brought up by two female parents in the Add Health dataset reported no more instances of victimization than did controls (Wainright & Patterson, 2006). Similarly, Rivers et al. (2008) found no significant differences between victimization scores on a bullying questionnaire completed by adolescents in same-sex parented households and those from the matched comparison group or the wider sample. However, adolescents from same-sex parented families in the study by Rivers and colleagues (2008) were less likely to consider using school-based support systems if they encountered problems.

Nevertheless, some studies have found that some children from same-sex parented families indeed experience teasing and bullying associated with their nontraditional family background. While over 80% of National Longitudinal Lesbian Families Study mothers described their 10-year-olds as relating well to peers at school, and nearly

60% were completely out to their peers about their mothers' lesbian relationships, just over 40% of the children interviewed said that they had experienced some kind of homophobia (Gartrell et al., 2005). When offspring were 17 years old, about half reported having experienced some kind of homophobic stigmatization by the end of their school careers, with most of these incidents stemming from peer prejudice (van Gelderen, Gartrell, et al., 2012). Most of this stigmatization consisted of disapproving comments and teasing about the mothers. The majority of adolescents had been able to cope with these instances adaptively without self-blame, or had been able to confront the perpetrators either on their own or with support. Adolescents who had used other coping strategies to cope with stigmatization had often used an avoidant coping style, deciding to keep their lesbian family backgrounds a secret; boys had been more likely to do this than girls.

Cultural context seems to play an important role in whether or not children with two parents of the same sex experience peer group stigmatization. Bos, Gartrell, van Balen, et al. (2008) compared data from Dutch 8- to 12-year-old children and 10-year-old children in the National Longitudinal Lesbian Families Study. The Dutch children were found to be more open about their family backgrounds and experienced less homonegativity than did their American counterparts. Furthermore, experience of homonegativity was found to account for part of the variance in the generally poorer psychological adjustment scores in the U.S. sample.

A reason for the disparity in findings between studies may be connected to variations in the particular questions asked. For example, Wyers (1987) surveyed 32 gay fathers who had children within previous heterosexual relationships to find that around 75% of these children had experienced some peer group problems because their fathers were gay. When fathers were asked to detail what the problems had been, many involved children's concerns over what to tell peers about their fathers, or anxiety about the possibility of being bullied, rather than actual incidents. Only about 20% of children were reported by their fathers to have actually experienced one or more incidents of peer group stigma. Other authors have noted a discrepancy between asking about general rates of teasing and bullying and asking specifically about victimization related particularly to family background or sexuality, such that children with lesbian parents were no more likely to be teased or bullied than were children with heterosexual parents but when victimization occurred the negative comments were

more likely to focus on their family background or their sexuality (Tasker & Golombok, 1997).

Nevertheless, peer stigmatization can be hard to deal with when it happens. At Age 10, National Longitudinal Lesbian Family Study children who had experienced victimization were more likely to have higher problem behavior scores on the CBCL (Bos, Gartrell, Peyser, & van Balen, 2008). A similar pattern was evident at the follow-up at Age 17 (Bos & Gartrell, 2010). Likewise, the follow-up of children in the Netherlands indicated an association between homophobic stigmatization and poorer psychosocial adjustment (Bos & van Balen, 2008).

Gershon, Tschan, and Jemerin (1999) found a complex relationship between adolescent self-esteem and the perceived levels of stigma adolescents reported in their social environment. Adolescents who perceived higher levels of stigma associated with having lesbian mothers tended to have lower self-esteem. Furthermore, adolescents' assessments of their own coping skills influenced the extent to which the perception of stigma correlated with their self-esteem scores. In the face of high perceived stigma, adolescents who reported more decision-making coping skills had higher self-esteem. But adolescents who tended to rely on social support coping skills had lower levels of self-esteem if they perceived high levels of social stigma. Adolescents who reported disclosing their mothers' lesbian identities reported higher self-esteem, specifically in the ability to engage in close friendships.

Conclusions

Research on the socioemotional development of children in lesbian mother families formed after divorce or separation has consistently shown that children do not differ from children in heterosexual parent families. The same is true of children born to lesbian mothers through donor insemination and thus raised in lesbian mother families from birth. Moreover, these findings have been confirmed by studies of general population samples. Studies of adoptive gay father families have shown that gay fathers can parent as competently as can lesbian or heterosexual mothers, and that children in adoptive gay father families are functioning well. Future research on gay father families would no doubt help to investigate whether parental gender made a difference to parenting and child development under other family circumstances such as separation or divorce. The cultural context of same-sex parenting is currently changing with more states recognizing same-sex domestic unions or marriage. Further research can usefully

investigate the influence that legislation has on the social context of same-sex partnerships and parenting.

GENERAL CONCLUSIONS

So what can be concluded about the socioemotional development of children in changing family contexts? Is it the case that the traditional two-parent family is best for children? Or can children do as well, or perhaps even better, in certain types of new family forms? It is important to remember that traditional families headed by two married heterosexual parents vary enormously in the extent to which they provide supportive environments for children. The same is true of nontraditional family forms. Rather than focusing on whether individual children may be harmed or may flourish, the aim of this chapter has been to consider the consequences of different family structures for parenting and child development more generally, and to establish what is known about the processes through which children's socioemotional development may be influenced by growing up in different family contexts.

It is clear that some family types are more associated with negative outcomes for children than are others. Single-parent families formed as a result of parental separation or divorce, single-parent families headed by unmarried mothers, stepfamilies, and families with cohabiting parents are generally more likely than traditional families to result in difficulties for children. In contrast, children with lesbian or gay parents, and children conceived using assisted reproductive technologies, appear to be functioning well. So how can we explain these differences? The answer seems to lie in the circumstances surrounding the different family forms. Whereas the former set of families generally experience greater adversity than do traditional families, in terms of financial hardship, marital or relationship difficulties, and mental health problems (all of which are associated with impaired parenting and children's emotional and behavioral problems), this is not the case for families formed by same-sex parents and through assisted reproductive technologies. It may also be relevant that the latter types of family are, by necessity, planned.

Research on nontraditional family forms enables the impact of different family structures, and the relative impact of family structure and family processes, on children's socioemotional development to be explored. Families with children conceived by sperm donation, egg donation, embryo donation, and surrogacy allow the absence of genetic and/or gestational relationships between one or

both parents and the children to be investigated; studies of families with same-sex parents shed light on the influence of sexual orientation; comparisons of single-mother and single-father families, and of two-parent lesbian mother families and two-parent gay father families, provide information about the role of parental gender; and comparisons between two-parent and single-parent families with parents of the same gender increase understanding of the effects of the number of parents in the family.

Just because some family types are associated with more negative outcomes for children does not mean that family structure, in itself, has a direct impact on children's socioemotional well-being. Findings from the growing body of research on nontraditional families suggest that family processes such as warmth, communication, and conflict are better predictors of children's socioemotional development than is family structure (Biblarz & Stacey, 2010; Golombok, 2000, 2015; Lamb, 2012). This can also be concluded from the studies reviewed in this chapter showing, for example, that the differences between children with single parents, cohabiting parents or stepparents and their counterparts in traditional families are largely explained by factors such as economic disadvantage and maternal depression, which are characteristic of these nontraditional family types.

Further evidence for the greater importance of family process over family structure comes from studies that have directly examined the relative contribution of each (Chan et al., 1998; Demuth & Brown, 2004; Dunn et al., 1998; Farr et al., 2010; Golombok, Mellish, et al., 2013; Hetherington, 1989; Lansford, Ceballo, Abbey, & Stewart, 2001). These studies have shown that it is not family structure per se that influences the socioemotional well-being of children in different family forms. Instead, the quality of parent-child relationships, the quality of parents' relationships with each other, and the quality of the wider social environment appear to be more predictive of children's adjustment. Whether children have one parent or two, whether they have a genetic or gestational link to their parents, whether their parents are married or cohabiting, whether their parents are male or female, and whether their parents are of the same sex or opposite sex seem to matter less for children than does the quality of family life.

Nevertheless, the disadvantage experienced by children in some nontraditional family forms is real, and should be central to family policy and practice. Although assisted reproduction children and children raised by same-sex parents do not generally show adjustment problems, certain aspects of these family types may present difficulties for

children, too. Some who discover in adolescence or beyond that they are donor conceived are distressed by this information, and some children of same-sex parents experience stigma at school. These problems are associated, at least in part, with lack of openness and poor communication, both inside and outside the family. The provision of counseling for parents who are embarking upon assisted reproduction using donated gametes to help them consider the implications of disclosure and nondisclosure of this information to their children, and programs designed to inform schools about the needs of children with same-sex parents and to counter homophobia, are likely to enhance the well-being of children in these emerging family forms.

In terms of wider theoretical perspectives, the empirical research reviewed in this chapter has highlighted the value of a developmental systems approach that takes account of the complex interactions between children, families, and their wider social world for understanding socioemotional development in changing family contexts. As we have seen, the quality of parenting in different family forms and the psychological consequences for children are influenced by family circumstances. One example is the socioeconomic disadvantage experienced by single mothers, which has repeatedly been shown to have an adverse effect on children's adjustment. It is also essential to consider children's temperament and personality characteristics, as these may affect how children cope with different family environments. As discussed above, some children show emotional or behavioral problems in response to adverse family circumstances, whereas others appear to be more resilient. Although there are large bodies of research on temperament (see Chen & Schmidt, Chapter 5, this *Handbook*, this volume), and on risk and resilience (see Luthar, Crossman, & Small, Chapter 7, this *Handbook*, this volume), little is known about individual differences in children's responses to growing up in nontraditional families, particularly in relation to those family types that have emerged most recently. From a life-span perspective, it is also important to stress that particular challenges may arise at specific developmental transitions, similar to the identity issues faced by donor-conceived children as they enter adolescence.

The emphasis of developmental systems theory on the importance of historical time and place is especially relevant to the study of family forms that either did not exist or were invisible before the latter part of the 20th century—lesbian mother families and families created by assisted reproductive technologies—and highlights the role of societal attitudes in family functioning.

In the 1970s, prejudice and discrimination were features of nontraditional family life; lesbian mothers lived in fear of losing custody of their children, donor insemination was shrouded in secrecy, and “test-tube” babies were viewed with suspicion. Although prejudice has not been eliminated, more positive attitudes generally prevail today, creating a more favorable environment for children. Since the turn of the century, same-sex marriage has been introduced in several countries and in some U.S. states. In addition, donor-conceived half-siblings growing up in different families have begun to make contact with each other and “test-tube” babies have become commonplace. Nevertheless, children’s experiences will depend, to a large extent, on their own social environment, including their extended families, their community and the geopolitical context in which they are raised.

There are limitations to the research reviewed in this chapter that must be borne in mind. Over the past decade or so, nationally representative surveys have enabled us to establish the generality of conclusions on the effects of single-parenting, parental cohabitation, and stepparenting on children’s socioemotional development, which were previously limited by sample size and convenience sampling. The luxury of analyzing data from large datasets has also meant that researchers have been able to control for fixed effects to establish whether developmental outcome deficits shrink once variation in sociodemographic factors are controlled for. Nevertheless, even some of the excellent databases now available are limited in various ways. For example, the Add Health and Fragile Families studies relied on single-item self-report measures of couple and parent-child relationship variables that appear to play a crucial part in mediating the effects of family structure for children. Moreover, investigations of the newest family forms do not have the benefit of large nationally representative samples and, more importantly, have not yet assessed children at adolescence or beyond. Although the studies that exist today have begun to shed light on the experiences and functioning of these families, it is incumbent on the next generation of developmental psychologists to extend understanding of the socioemotional development of children in these emerging family forms, particularly in relation to different cultural, ethnic-racial, and socioeconomic contexts.

Moreover, little attention has been paid to the positive consequences for children of being raised in new family forms. This is because most research has examined negative, rather than positive, outcomes. Nevertheless, some researchers are beginning to focus on positive aspects, such

as the greater tolerance to diversity shown by children of same-sex parents. The strengths, as opposed to the weaknesses, of nontraditional families are set to be a fruitful new area of research.

Family forms that are currently emerging, or that are still on the horizon, will provide novel ways of addressing questions about family influences on children’s socioemotional development and new theoretical insights. The demographic shift toward older motherhood is a topic of current interest, as is the new phenomenon of gay fathers having children through surrogacy and egg donation; these children are being reared in families that are non-traditional on three counts: the absence of a mother from the family home, the presence of same-sex parents, and the use of assisted reproductive procedures. Even single heterosexual men are beginning to have children in this way. In addition, men and women who were previously unknown to each other are now using the Internet to create families together.

In the not too distant future, scientific advances will enable children to be born through mitochondrial DNA transfer and thus, for the first time, with genetic material from three people—a mother, a father, and a woman who donates her mitochondrial DNA. This procedure, which involves transferring the nuclear DNA of the intended parents into a donor egg containing healthy mitochondria, is being developed to enable women at risk of having children with serious mitochondrial disease to have healthy children. Moreover, artificial gametes might soon make it possible for women to produce sperm and for men to produce eggs. Although intended for use in the treatment of infertility, this will allow both partners in same-sex couples to be genetically related to their children. Research is also being conducted on “artificial wombs” (essentially machines that would simulate the uterus and enable gestation to take place outside the mother’s body), and human cloning remains a theoretical possibility. These are just some of the changing family contexts in which children will be reared in the years to come.

FEATURES OF LEGAL CONTEXTS	487

INTRODUCTION

In this chapter, we use the word *children* when referring to infants, toddlers, preschoolers, school-aged children, youth, and adolescents. Together, they are characterized by an extremely diverse and broad array of emerging cognitive, social, and emotional abilities. This fact in itself complicates researchers' understanding of children's involvement, participation, and understanding of their roles in legal contexts, as well as expectations of them. The situation is further complicated when considering developmental delays that may potentiate or be a consequence of children's involvement in the legal system and to recognize the diverse ways in which increasing numbers of young people are so involved.

In the past, legal decisions affecting children were often made without their knowledge or participation. This was due, in many cases, to a shallow understanding of children's capabilities and strengths, an overemphasis on their

perceived cognitive and social limitations, and more general disregard for psychological research, as Munsterberg (1908) lamented more than a century ago. Despite initial skepticism (Cairns, 1935; Wigmore, 1909), applied psychology is belatedly attaining some of the promise Munsterberg anticipated, perhaps especially in relation to children and the law.

Indeed, as developmental psychology emerged as a distinct discipline early in the 20th century, applied issues were at the forefront: Psychologists regularly provided parents, teachers, and pediatricians with advice, even in cases where the advice was not always well-informed by empirical research (Clarke-Stewart, 1998; Sears, 1975). By the middle of the 20th century, however, developmentalists shifted their focus to basic research questions, apparently fearing that a concern with applied issues at the expense of a solid empirical foundation made developmental psychology less credible as a science. Increases in our understanding of children's abilities have prompted another shift

in thinking with respect to children and the law. In the face of widespread beliefs that children should be as actively involved in decisions affecting their lives as their abilities allow, many developmental psychologists have sought to improve decision making and outcomes for children and families within all aspects of the legal system.

Thousands of published studies have revealed much about children's abilities in the legal realm and have provided a more accurate and realistic view of their limitations. Moreover, research has become increasingly "convincing" to non-psychologists because basic laboratory research has been complemented by methods that have clear ecological validity, yielding findings that are better understood, accepted, and applied in legal contexts. Lawyers, judges, social workers, jurors, parents, and others must make important (often life-transforming) decisions about children every day and there is increasing recognition that psychological research can and should guide many of these crucial decisions.

As Bruck, Ceci, and Principe (2006) observed, the numbers of children experiencing contact with the legal, social service, and child welfare systems around the world represent "a large and growing legal constituency, one that possesses a special set of constraints involving basic developmental competencies, including cognitive, social, and emotional, that may constrain their effective participation" (p. 777). For example, although the exact number of child-abuse victims in the United Kingdom has not been calculated, more than 66,000 children were the subjects of child protection plans and were thus considered to be at risk for physical, emotional, or sexual abuse and neglect in 2012 (National Society for Prevention of Cruelty to Children, 2013). In the United States, about 3 million investigations of suspected child maltreatment are carried out annually (Gelles & Brigham, 2011) with nearly 800,000 children classified as victims of maltreatment in 2007 (U.S. Department of Health and Human Services, Administration on Children, Youth, and Families, 2009). The situation is alarming elsewhere as well. In 2008, approximately 236,000 child maltreatment investigations were conducted in Canada, with approximately 36% of these cases substantiated by child-protection workers (Trocme et al., 2010). Between 2001–2002 and 2005–2006, the number of child-protection notifications in Australia almost doubled from 138,000 to 267,000 (Australian Institute of Health and Welfare, 2007).

Of course, children often assume other roles than victims in the legal system, with many of them considered suspects and defendants and others classed as witnesses. In England

and Wales, 241,737 juveniles were arrested in fiscal year 2009–2010, accounting for 17% of all arrests during that same period (Ministry of Justice, 2012) and law enforcement agencies in the United States arrested approximately 2.1 million juveniles in 2008 (Puzzanchera, 2009). Following arrest, 66% of those referred to court initially appeared in juvenile court and 10% were referred to adult criminal court, with other young suspects later referred to criminal court as well.

Family breakdowns and divorce also draw children into legal contexts. In the United States, the numbers of relationships that end in divorce or separation vary greatly according to ethnicity and race, but it has been estimated that about half of the children in the country spend part of their childhoods in single-parent families—a substantial number of these children drawn into legal proceedings to determine where and with whom they should live (Amato & Doriis, 2010). Unfortunately, large (though smaller) proportions of children are drawn into such proceedings in other countries such as the United Kingdom as well (Dunn & Layard, 2013).

With so many young people drawn into and affected by the legal system, it is crucial for researchers and practitioners both to recognize that diverse developmental factors—cognitive, emotional, and social—can seriously compromise the effective participation of young people in legal contexts (Bruck et al., 2006) and to explore practices that might facilitate participation and ameliorate the potentially negative effects on the children involved. Regardless of whether youth are participating in the legal system as victims, witnesses, or suspects, the primary goal is typically to obtain information from them via interviews conducted by adults. Although the legal and child protection systems have been responsive to developmental research with policies and protocols for interviewing young people who are victims or witnesses to crime, research has not similarly affected practice where juveniles are suspected of committing crimes. The age of criminal responsibility (i.e., adult responsibility) is very low in many countries. For example, in the United States, some states automatically exclude certain offenses from juvenile court discretion, even with children as young as 10 years of age (see Fagan, 2008, for a review). Furthermore, adolescent suspects are allowed to be questioned in the same manner as adult suspects. Criticizing the fact that young suspects are often treated in less developmentally appropriate ways than young victims and witnesses, Owen-Kostelnik, Reppucci, and Meyer (2006), wrote, "Our assumption is that 'kids are kids' no matter the context in which they find themselves; being

suspected of committing a crime does not make a child an adult" (p. 286).

Indeed, although legal and social service interventions are often justified by reference to children's vulnerability and dependency, the interventions themselves are seldom informed by reference to developmental theory or the results of scientific research. Instead, political, ideological, and cultural values may guide the development of policies such as those that allow the prosecution of juvenile offenders in adult courts (e.g., "get tough on crime" policies) or emphasize family preservation rather than the termination of parental rights when children have been severely and persistently abused by their parents. It is unfortunate that policy makers sometimes fail to take advantage of a burgeoning and increasingly sophisticated understanding of child development in this way because improved public policy and law would surely emerge if policies and practices were better informed by developmental research.

In this chapter, we discuss the developmental factors that affect children's legal participation in relation to child maltreatment, divorce, and juvenile justice. Children may be victims, witnesses, suspects, and affected parties and their developmental characteristics are the same regardless of their roles. Unfortunately, in legal contexts, knowledge of child development has been unevenly applied, with far more attention paid to developmental science where child victims are concerned. Accordingly, we show how applied and basic psychological research can help inform practice in legal contexts, with researchers helping guide practitioners and the latter in turn offering insights and asking questions that foster a more complete understanding of developmental processes.

We begin the chapter with a review of developmental trajectories in the principal domains of development known or likely to affect children in legal contexts. Much of the initial research was conducted in experimental contexts, but an increasing proportion of the research on the development of memory processes and the factors affecting what children remember, forget, and report is now being conducted in settings that afford a more straightforward generalization to performance in legal contexts. Children's legal participation is not only affected by memory, so we also describe, in turn, emergent understanding of such key concepts as time and numerosity, the development of metacognition, reasoning, and logical thinking, the growth of language and communicative skills, and crucial aspects of social and emotional development, with an emphasis on the development and significance of affective relationships, first with parents and later also with peers. Both

social and cognitive factors are important when seeking to understand the phenomenon of suggestibility, as we show at the end of this section on foundational constructs. In the second major section, we turn attention to the implications of normative developmental processes for children in a variety of legal contexts. We begin with discussion of the implications of developmental differences for investigative interviews, both with alleged victim/witnesses and with children who are suspected of having committed offenses, before focusing attention on the implications of the developmental literature for behavior and practices in family and dependency court. Our review is not exhaustive. The "children and the law" literature has not given equal treatment to all research areas, and our review follows suit. Furthermore, some aspects of child development (e.g., physiological development) are less relevant to children's legal involvement and performance than other aspects (e.g., cognitive development). Some relevant topics (e.g., juvenile sentencing policies) are covered in-depth by other chapters in this *Handbook* (see Cauffman, Shulman, Bechtold, & Steinberg, Chapter 16, this *Handbook*, Volume 4). Thus, our intent is to provide a broad overview of the field and discuss evidence concerning several research topics central to the study of children and the law. The chapter ends with an examination of the key questions to which researchers should turn their attention in the years to come if they are to fully realize the potential to contribute fully and informatively to knowledge and practices concerning children and the law.

THE DEVELOPMENTAL SCIENCE OF CHILDREN AND THE LAW

In this section, we review developmental trajectories in the principal domains of development (neurophysiological, cognitive, communicative, and socioemotional) known or likely to affect children in legal contexts.

Neurophysiological Development

Infants and young children show very clear limitations and emerging abilities in many domains that are directly linked to the physiological development of the brain. Human brain development is marked by a very long period of postnatal development shaped by both physiological changes and experience. At birth, the gross structures of the brain are adult-like and almost all the neural cells are present although much neural development has yet to take place

(M. H. Johnson, 2011). For the most part, this postnatal development involves increases in the numbers of synaptic connections, resulting in a doubling of the brain's size by the first birthday, following which many connections are pruned as the brain is resculpted by experience. In general terms, the primary sensory systems mature first, followed over the first year of life by changes in the neural mechanisms that allow increasing attentional control over the sensory systems. Higher-level association areas, especially in the cortex, develop later (Casey, Galvan, & Hare, 2005). The prefrontal cortex, which is especially important for many of the cognitive processes that underlie reasoning, decision making, self-control, planning, and memory, undergoes dramatic changes toward the end of the first year and then again between the ages of 4 and 6 years (Drumney & Newcombe, 2002) but continues to improve in function and capacity until early adulthood (Olson & Luciana, 2008). Not surprisingly, therefore, we see children of 4 years able to control their behavior well enough to take turns in a game or sit still when asked whereas those of 12 to 16 still have difficulty inhibiting impulsive actions when the immediate benefits are appealing and reflection is not prompted (Dansereau, Knight, & Flynn, 2013). fMRI studies consistently show that the structural and functional maturation of the prefrontal cortex is not complete until the early 20s (e.g., Blakemore & Choudhury, 2006; Casey, Tottenham, Liston, & Durston, 2005; Sowell, Thompson, Holmes, Jernigan, & Toga, 1999).

Similarly, face perception is initially under subcortical control, and although it becomes more sophisticated later in infancy (de Haan, Humphrey, & Johnson, 2002), it continues to develop at least until early adolescence (M. H. Johnson, Grossmann, & Cohen-Kadosh, 2009). The fact that changes in cortical thickness continue until at least 19 years of age, with the magnitude of these changes, rather than the thickness per se, predicting adult IQ (Shaw et al., 2006), underscores the more general point that neurological development is a slow process, shaped by both maturation and experience, that continues from birth until early adulthood. These developmental changes have obvious implications for the cognitive, memory, linguistic, and socioemotional changes described in later sections, and thus need to be accorded attention when seeking to understand developmental changes in relation to children and the law. In legal contexts, it is important to recognize that important abilities associated with attention, problem solving, and decision making, balancing short- and long-term goals, and processing different sources of information and experience are *emerging* abilities and that children and youth behave and

make decisions that are constrained or potentiated by their neurocognitive status.

Other important developmental shifts in the second decade of life are associated with puberty. Puberty is, of course, a biological transitional event but apart from the reproductive maturation of boys and girls, puberty is also associated with increases in emotionality (K. Lewin, 1939), emotional lability (Larson & Lampman-Petraitis, 1989), sensation-seeking (Steinberg et al., 2008), inadequate inhibitory self-control (Greenberger, 1982), and, more generally, many aspects of brain development (Blakemore, Burnett, & Dahl, 2010) and risky behavior (B. J. Ellis et al., 2012). These characteristics appear to be associated with the immature status of the limbic system in adolescence; a number of studies have documented that the structural and functional maturation of the limbic system is typically incomplete until mid-adolescence (e.g., Giedd, 2008; J. F. Schneider & Vergesslich, 2007). Sensation or thrill-seeking behavior coupled with a lack of inhibitory control may lead youth to engage in risky behavior, including delinquent or criminal acts (B. J. Ellis et al., 2012). Furthermore, because adolescents have difficulty regulating their emotions, disagreements or other interpersonal interactions may escalate to a point where legal intervention is needed.

As noted in an amicus brief submitted to the U.S. Supreme Court when it was considering the constitutionality of the death penalty for juveniles (*Roper v. Simmons*, 2005): "Research shows that adolescent brains are more active in regions related to aggression, anger, and fear, and less active in regions related to impulse control, risk assessment, and moral reasoning than adult brains" (p. 12). This basic neuroscience research thus confirms what research psychologists have learned about adolescent behavior (see also Hollenstein & Lougheed, 2013).

Cognitive Development

Many aspects of children's cognitive development affect legal participation. We focus here on aspects of children's memory; metacognition, reasoning, and logic; and language and communication because these areas of research have been especially influential in understanding and enhancing children's performance in legal contexts.

Children's Memory

The ability to describe experiences (e.g., what has been seen and heard) is critical in legal contexts, and psychologists' understanding of memory development has grown

dramatically in the past few decades (Bauer & Fivush, 2014). Contemporary students of children's memory have paid special attention to the use of ecologically valid methodologies to address specific questions that arise in legal and forensic contexts, thereby doing more than simply applying findings obtained in traditional theory-driven laboratory research (Hintzman, 2011). Features of our experiences and surroundings "capture" our attention and interact in ways that are not fully understood, with both conscious and unconscious mental processing then allowing some memories to be accessed again in the future (Berntsen, 2009; Erdelyi, 2010). The processes involved in remembering experiences can operate independently and in complex ways. For example, information can be "forgotten" (lost from conscious memory) and later remembered; older memories can be confused with more recent memories; and specific memories can be recalled on one occasion but not on others. In short, memory is a reconstructive process (Erdelyi, 1996). Experiences are more likely to be remembered when they make sense, which means that younger children may sometimes not store information because they do not understand what has occurred. Information about events is also more likely to be stored when associations to other experiences are readily available—experiences come to mind that share some features, or perhaps have contrasting features. Again, this places children at a disadvantage relative to adolescents and adults, because they have had fewer experiences with which to make associations or to prompt recall.

Unlike those studying memory in adults, students of children's memory have extensively addressed such factors as differences between the memories of participants and observers, dynamic changes in memory that occur as children grow older, and possible barriers to "disclosing" well-remembered events. Memory research of particular interest to legal contexts includes research concerning infantile amnesia, language, forgetting, the amount and accuracy of information provided, the stability and consistency of memory, and the effects of stress on memory. Each will be covered in turn.

Infantile Amnesia and Early Memories

For many years, it was thought that the ability to remember experiences was closely related to the development of language (see Hayne, 2004). This conclusion seemed plausible: When children learn to speak, they become able to name and describe their experiences using impressive vocabularies, and begin to locate memories "in time" by linking personal experiences to other events and concepts,

thus forming their own personal histories. Language would thus be necessary in order to fully remember experiences and to communicate them in a coherent way to others. This view is consistent with the observation that, as adults, humans have virtually no recollection of very early years of life, and that the events we do remember tend to date from the age at which we first learned to master language. This is referred to as the paradox of infantile amnesia. It is considered paradoxical because individuals cannot remember their early experiences as well as later ones even though young children and infants nevertheless can remember their experiences. For example, 3-year-olds can recount details of events that occurred 1 year earlier, but are likely to have forgotten those events by adulthood (e.g., Bruck, Ceci, Francouer, & Renick, 1995; Fivush, Gray, & Fromhoff, 1987; Quas & Schaaf, 2002). Many researchers have shown that even babies remember events for brief periods of time. Babies quickly learn that they can make a mobile above their cots move by kicking their feet: Several studies have shown that 2-month-olds remember the "kick-to-make-the-mobile-move" experience for 1 to 3 days; 3-month-olds for 6 to 8 days; and 6-month-olds for 15 to 16 days (Hayne, 2004). Thus, language appears unnecessary for memory formation.

Evidence shows infantile amnesia with respect to nonemotional and positive events such as the birth of a sibling as well as negative or stressful experiences such as distressing medical procedures or emergency room visits (e.g., Peterson & Parsons, 2005; Sheingold & Tenney, 1982; Usher & Neisser, 1993). For instance, Quas et al. (1999) tested children's memories of an invasive medical procedure that occurred when the children were between 2 and 7 years of age. The procedure (voiding cystourethrogram, or VCUG), designed to identify potential kidney disease, involves filling the bladder with fluid containing an X-ray-visible dye and then taking X-rays while the child urinates. When children were interviewed between 1 and 5 years after the VCUG, no children who had been 2 years old at the time of the procedure had any memory of the procedure. However, half of the children aged 3, and most children aged 5, remembered some details. Thus, although the procedure involved invasive genital contact and was quite distressing for most children, those who were between 2 and 3 years of age when it took place evinced no memory for it later. Focusing on nontraumatic experiences, similarly, Bauer and Larkina (2013) showed that 5- to 7-year-olds remembered only 60% whereas 8- to 9-year-olds remembered only 40% of the memories they described at 3 years of age.

Researchers and practitioners must, therefore, treat accounts dating to very early experiences, and claims that these experiences can be somehow accessed, with great suspicion. If older children or adults are asked to describe events that occurred prior to Age 3 or 4 (that is, during the phase of infantile amnesia), it is *highly unlikely* that their reports will be based on clear or detailed memories of the events in question. Instead, memories stemming from the first few years of life are likely to have been reconstructed based on what “probably” or “might” have happened rather than episodic accounts of what “did” happen. These memories can be reconstructed based on conversations with others (e.g., siblings, peers, parents), interviewer and therapist suggestions, childhood photographs, or from vague memories and beliefs that have been reinterpreted over time and possibly mixed with current knowledge and beliefs (e.g., Fivush, McDermott Sales, Goldberg, Bahrick, & Parker, 2004; Peterson, 2012). Although older children and adults cannot remember events that occurred in infancy or toddlerhood (see Bauer, 2006a, 2006b; Pillemer & White, 1989), many people hold inaccurate beliefs about early memory capabilities. In a study of adults’ perceptions of children’s eyewitness abilities, almost two-thirds (64%) agreed with the statement, “If a child has been repeatedly and painfully sexually abused as an infant, he or she can remember it” (Quas, Thompson, & Clarke-Stewart, 2005).

Unlike those of infants and toddlers, older children’s memories can be studied more easily because they can speak. A common procedure for researchers studying children’s memory for legal purposes is to “stage” or record (as with the studies of children’s medical procedures such as the VCUG) events about which the children are questioned sometime later. Because the events in question are documented in detail and objectively verifiable, it is possible to compare what is later recalled to what actually happened to determine the accuracy of memory.

How well human beings remember experiences and how quickly they forget them has direct implications for any expectations about how much children should be able to tell about their experiences, including in legal contexts. Should children be expected to remember many specific details about their experiences, especially if the events were brief, confusing, and/or happened a long time ago? Research indicates that children (like adults) remember a fraction of their experiences. For example, in one study, La Rooy, Pipe, and Murray (2005) asked 5-year-old children about a 15-minute interaction with a “friendly pirate” in a staged “pirate show” during which the children performed a series of activities such as “feeding the bird,” “painting

the map,” and “finding the treasure,” involving a total of 60 actions and associated objects. When the children were interviewed immediately after the pirate visit, at a time when recall was expected to be the best, they only recalled 15 pieces of information on average; this amounted to a mere 25% of the available details. When the children were interviewed again 6 months later, they recalled 8 pieces of information or only 13% of the details.

Studies reveal that age is the most important determinant of children’s memory capacity. As children develop, they are progressively able to remember their experiences for longer and longer periods of time—from a few days in infancy to several years by the time they are 5 years old. For example, Goodman, Hirschman, Hepps, and Rudy (1991) studied children’s memory for an inoculation at a medical clinic, finding that the 3- to 6-year-old children were able to remember some details following a 1-year delay. Other studies have confirmed that young children can remember their experiences for long delays of a year or more (Bruck et al., 1995; Fivush et al., 1987; Pipe, Sutherland, Webster, Jones, & La Rooy, 2004; Quas & Schaaf, 2002).

Forgetting

Memory declines over time. Over 100 years ago, Ebbinghaus (1964/1885) documented this phenomenon in a series of experiments in which he tested his own memory for lists of nonsense (i.e., made-up) words. Specifically, his studies, and many conducted since, revealed that forgetting is most rapid soon after a to-be-remembered event; as more time passes, the amount of forgetting decreases, until there is very little further forgetting. Jones and Pipe (2002) documented the rate of forgetting among children by asking 5- and 6-year-olds about a staged school-based event, either immediately, or 1 day, 1 week, 1 month, or 6 months later. The children were asked to provide a free-recall account of what they could recall before they were given cued recall prompts to elicit additional information. The average rate of forgetting was very similar to the rate of forgetting measured in other experimental contexts (Ebbinghaus, 1964/1885): Forgetting was rapid following brief delays but the amount of forgetting decreased after longer delays. Also, in this and other studies, forgetting was accompanied by gradual increases in the number of errors (Bruck, Ceci, & Hembroke, 2002; La Rooy, Pipe, & Murray, 2007; Melnyk & Bruck, 2004). Because children, like adults, forget information and because residual memories become increasingly fallible, the most accurate accounts are likely to be gathered soon after an event. Thus, it is crucial to interview child victims and witnesses as soon as

possible after target events. This is especially important where young children are concerned, because they tend to forget more rapidly than older children and adults: The basic finding that younger children forget more quickly than older children is underscored by the results of laboratory experiments in which children memorize and recall lists of words (Brainerd, Reyna, Howe & Kingma, 1990).

Event characteristics affect forgetting, too. Several researchers have shown that the amount of correct information recalled about experienced events does not necessarily decrease dramatically with the passage of time. Children's recall of medical treatments or procedures (Ornstein, Gordon, & Larus, 1992; Peterson, 1999) and natural disasters (Ackil, Van Abbema, & Bauer, 2003; Fivush et al., 2004) may remain relatively stable, for example. Perhaps because such events are personally significant, children's memories may be kept "alive" by more frequent opportunities to talk and think about the events. These opportunities for memory "rehearsal" ensure that memories are "consolidated" or made stronger over time, but also provide opportunities for contamination. For example, if misinformation is introduced in a conversation with a friend about a past experience it can be incorporated into future recollections (see La Rooy, Lamb & Pipe, 2009, for a review).

Amount and Accuracy of Information Reported

As mentioned above, the amount and accuracy of children's event reports depend, in part, on the salience and significance of the events themselves. In one experiment, 5- and 6-year-old children participated in a staged event directly, observed another child in the same event, or were told a story about that event (Murachver, Pipe, Gordon, Owens & Fivush, 1996). Children's memory was tested a few days later. Children who *experienced* the event produced more complete and accurate accounts of what happened than children who had only seen or heard a story about what happened (also see Baker-Ward, Hess, & Flannagan, 1990). Also, the completeness and accuracy of children's memory accounts depend at least partly on how well they comprehend their experiences and can associate or "link" them in memory with other experiences. For example, children's prior knowledge of medical experiences or what happens during a routine medical exam facilitates children's recall of specific health checks (see Ornstein, Baker-Ward, Gordon, & Merritt, 1997, for a review). Prior knowledge may help children encode events because they are better able to process and understand the events at the time. Also, this knowledge may be used subsequently to generate cues linking the events with other experiences,

thus facilitating retrieval (Hershkowitz, Lamb, Orbach, Katz, & Horowitz, 2012).

Once children begin to recall and talk about their experiences, their abilities are often impressive, although significant developmental changes continue, especially through early childhood. Young children typically recall significantly less information than older children, particularly in response to very general prompts such as "Tell me what happened," and although their recall responses are not less accurate than those of older children, they may omit information that adults consider important (see Lamb, Hershkowitz, Orbach, & Esplin, 2008; Ornstein et al., 1997, for reviews). Four- and 5-year-olds typically receive more specific prompts from interviewers (Lamb et al., 2008) to which they respond less accurately than older children do (Bjorklund, Bjorklund, Brown, & Cassel, 1998; Goodman, Quas, Batterman-Faunce, Riddlesberger, & Kuhn, 1994). Nevertheless, field research shows that children as young as 4 years of age provide proportionally as much information in response to open-ended questions as older children, although the brevity of their responses often necessitates that interviewers prompt for additional information, preferably using children's prior responses as cues to trigger further recall (Lamb et al., 2003). Field research involving investigative interviews with 3- to 6-year-olds has shown that the youngest children provide most information when prompted using a series of recall-based specific questions, with more open-ended questions, ideally incorporating references to previous responses to cue further relevant retrieval, becoming increasingly useful as children grow older (Hershkowitz et al., 2012).

Regardless of age, the accuracy of information retrieved from memory varies depending on *how* it is elicited. Studies conducted in both experimental and field contexts over nearly four decades have consistently shown that information elicited using open-ended recall prompts (e.g., "Tell me what happened") is more likely to be accurate than information elicited using more focused prompts, especially those that present the respondent with options from which to choose a response ("Was it red or black?"; "Did it hurt?") or those that imply an expected response ("It hurt, didn't it?") (e.g., Dent & Stephenson, 1979; Hutcheson, Baxter, Telfer, & Warden, 1995; Lamb & Fauchier, 2001; Oates & Shrimpton, 1991).

Stability and Consistency of Memory

How stable are memories? What changes may happen over time? As discussed, children can only recall a small

amount about their experiences initially, and what they do recall either decreases or remains stable as time goes by. Because more information is encoded into memory than they realize, correct new event details are sometimes remembered days, weeks, or even years later. What they remember about their experiences is therefore dynamic (Erdelyi, 1996, 2010; La Rooy et al., 2009). Thus, when La Rooy et al. (2005) reinterviewed 5- and 6-year-old children about a staged event the day after their first interview, all 40 children reported new accurate information in this second interview. In another study, La Rooy et al. (2007) conducted repeated interviews after a 6-month delay and found that 81% of the children recalled additional information the second time that they were questioned. Similarly, Hamond and Fivush (1991) reinterviewed preschoolers about a trip to Disneyworld and found that, although most of the information provided in the second interview was accurate, most of it (75%) was also new (i.e., not reported in the first interview). This phenomenon—called reminiscence—is also very common in adults and has been documented in studies dating back more than a century (Ballard, 1913). For example, Gilbert and Fisher (2006) asked adults who had witnessed a videotaped mock crime (bank robbery) to recall what they could remember immediately and then reinterviewed them after 48 hours: 98% of the participants reported new details that they had not reported 2 days prior.

Such well-established features of memory (i.e., instability, inconsistency) are quite troublesome when children testify in legal contexts. When new information is not mentioned initially but recalled later in time, it is often greeted suspiciously because competing explanations appear plausible; perhaps the new information is fabricated or inaccurate and this explains why it was not reported at earlier time points. In fact, jurors often rely on consistency as an indicator of veracity, and inconsistencies (including the addition of new details to subsequent retellings) are commonly viewed as troubling inaccuracies (Leippe, Manion, & Romancyzk, 1992; Quas et al., 2005). In legal contexts, witnesses, including children, are often cross-examined about earlier statements that are inconsistent with later testimony in the hopes of impeaching witness credibility (see below for a discussion of the research on cross examination).

While the accuracy of information added subsequent to an initial statement may vary for several reasons, including the way that information is elicited (La Rooy et al., 2009), the better remembered an event is, the more likely it is that new details are accurate (La Rooy et al., 2005). Interviewers and fact finders should remember that inconsistencies

in the form of new information (as opposed to blatant contradictions) are a normal function of memory and are not uncommon when children or adults recount true experiences (Fivush, Hamond, Harsch, Singer, & Wolf, 1991; Goodman, Quas, & Ogle, 2010; Hamond & Fivush, 1991; La Rooy et al., 2009; Peterson, Moores, & White, 2001).

Stress and Memory

Whether or not the stressfulness of experienced events affects memory has also elicited controversy. The relations between stress and memory are inconsistent, with some studies suggesting enhanced performance by stressed children (e.g., Buchanan & Lovallo, 2001; Goodman, Hirschman, et al., 1991) and others showing detrimental effects of stress (e.g., Quas, Bauer, & Boyce, 2004). Results may vary depending on whether one is talking about stress at encoding or stress at retrieval (see “Features of Legal Contexts” below for a discussion of the effects of stress at retrieval), but memories of stressful or even traumatic experiences are subject to the same basic encoding, storage, and retrieval principles as are memories for more mundane events, meaning that (a) humans can forget traumatic events, just as we can forget other experiences; (b) traumatic or stressful experiences are not necessarily remembered in richer detail just because the events were traumatic; and (c) *all* memories can be contaminated by suggestion (e.g., Howe, Toth, & Cicchetti, 2006). Some researchers theorize that stress may narrow children’s focus to central aspects of distressing events so that they remember these central aspects (e.g., the identity of the assailant) well but remember peripheral aspects (e.g., the color of the assailant’s shirt) in less detail (see Christianson, 1992). However, this hypothesis has not been well supported empirically.

Conceptual Understanding

To be effective legal participants, children need to understand certain concepts, which include those pertaining to time and numerosity as well as those related to the distinction between fantasy and reality.

Time

When children are witnesses in criminal cases, a critical issue is the need to establish *when* target events occurred. Although legal requirements are sometimes relaxed in cases involving young children (Poole & Lamb, 1998), the prosecution must generally specify alleged events that occurred at designated times in order to provide defendants

with sufficient opportunity to challenge the allegations (e.g., provide alibis, etc.). Furthermore, when children's testimony includes temporal information such as the time of day when an offense occurred, it may be possible for investigators to solicit further information.

Unfortunately, as Piaget (1927/1971) concluded long ago, children have difficulty conceptualizing time. The ability to make accurate temporal judgments improves gradually with age (e.g., Fivush & Mandler, 1985; see Friedman, 2008, 2014, for reviews; Tartas, 2001), especially in middle childhood (i.e., 8–10 years). However, even adolescents do not fully understand some temporal concepts, and even adults can struggle when asked to date autobiographical events (Wright, Gaskell, & O'Muircheartaigh, 1997), despite being given temporal cues (Friedman & Lyon, 2005). Such judgments require knowledge of conventional time patterns (e.g., days of the week, months, seasons), which are acquired gradually over many years (Friedman, 2014).

Although children have difficulty accurately locating events in time even in adolescence or adulthood, they are able to order or sequence events and to make judgments of relative recency at earlier ages (e.g., which one happened a longer time ago). Friedman and Lyon (2005) thus found that by about 6 years, children were able to accurately order two staged events but most children (even the oldest) were unable to judge correctly whether one of the events occurred before or after Halloween.

Researchers have rarely studied the temporal judgments of children in legal settings. In one study examining children's responses to open-ended prompts about suspected abuse, sequencing was often referenced by 4- to 8-year-old children during forensic interviews, with children as young as 4 years structuring narrative accounts of allegedly experienced events and using the appropriate relational vocabulary (e.g., next, before, after; Lamb et al., 2003). After examining 250 forensic interviews of 4- to 10-year-old alleged victims of sexual abuse, Orbach and Lamb (2007) later revealed age-related increases in children's references to temporal attributes of events using the appropriate relational terminology, both spontaneously and in response to requests for temporal information. Sequencing was the most commonly referenced temporal category. Although references to both sequences and temporal locations increased with age, there was a marked shift in the number of references to both temporal categories at Age 10.

Even when children have a firm grasp of time concepts, they must understand the questions that interviewers ask if they are to respond accurately. Temporal terms may

be problematic for children, perhaps because words like "before," "after," "first," and "last" have multiple meanings, including both spatial and temporal. Context also matters: When placed in the context of familiar daily activities, children may be able to make temporal judgments that they are incapable of making in other contexts. For example, children can specify backward sequences of familiar daily activities ("Before we went to sleep, we watched TV") earlier than they can specify backward sequences of the months of the year ("November is the month before December"). Although children as young as 3 years might know some temporal terminology and be able to recite commonly rehearsed temporal patterns (e.g., the days of the week or months in a year), they may not grasp how these concepts fit together into a temporal pattern or how to apply this knowledge in context.

Numerosity

In 2002, a kidnapping in Orange County, California made headlines. Five-year-old Samantha Runnion was abducted from her front yard. Her 5-year-old friend, witnessed the crime and provided police with a relatively detailed description of the suspect and his vehicle (T. Lewin, 2002). Based on DNA evidence, Alejandro Avila was eventually convicted for the sexual assault and murder. One year prior to Samantha's abduction, Avila had been acquitted of molesting two 9-year-old girls (*People v. Avila*, 2001) in part because the girls had difficulty judging the frequency of past alleged abuse and answering temporal questions about these events. For example, during the trial, the judge asked one of the alleged victims "how many times" Avila had performed a particular sexual act. The child responded, "I don't know. Fifty times out of the whole entire year. I don't really do numbers." The judge proceeded to follow up with several yes/no questions (e.g., "More than once?" "More than five times?"). When explaining the acquittal, one juror said, "They weren't consistent on their story. We know that they were young and we understand they are children but the story was like did he touch you three times, yes, did he touch you five times, yes, did he touch you 50 times, yes. Everything was yes, yes, yes" (Riverside Press Enterprise, 2002). (For a full description of the case, see Lyon and Saywitz, 2006.)

In Avila's case, the alleged victims' difficulties making judgments about numerosity (i.e., event frequency) appeared to damage their credibility with jurors. Many victims of child maltreatment are abused on multiple occasions (e.g., Connolly & Read, 2006), however, so many children will need to testify about repeated events. Some details may

vary across abusive episodes while some aspects of the events may remain highly similar. In many jurisdictions, children are required to “particularize” specific incidents in some detail (Guadagno, Powell, & Wright, 2006). That is, judgments about the frequency of abusive events may be needed to determine whether suspects can be charged, and estimates of the number of times particular offenses occurred may affect the type of charges. Also, establishing event frequency helps investigative interviewers proceed with effective questioning strategies, because interviews should proceed differently depending on whether interviewers are asking children to describe multiple or single incidents of abuse. When discussing multiple incidents, children may resort to “generic” language describing what *usually happens* rather than describing what *happened* during a particular incident using “episodic” language (Brubacher, Malloy, Lamb, & Roberts, 2013; Powell, Roberts, & Guadagno, 2007). It is important for interviewers to encourage children to respond episodically by isolating instances and using appropriate prompts to elicit details about each. This may be facilitated by knowledge concerning the number and timing of incidents.

Despite the fact that children are regularly asked to make numerosity judgments in forensic interviews and in courtroom testimony, there has been very little empirical research on this topic (Lyon & Saywitz, 2006). Previous research examining children’s ability to make numerosity judgments has largely focused on children’s judgments of stimuli in laboratory settings (e.g., words, sounds) rather than their judgments of event frequency, with the latter types of judgments having more relevance to legal settings (e.g., Chalmers & Grogan, 2006; McCormack & Russell, 1997).

A study conducted by Sharman, Powell, and Roberts (2011) represents an important exception. The researchers invited 4- to 8-year-olds to participate in laboratory events one time or multiple times (6 or 11 times depending on condition). When children experienced a single event, they were highly accurate in reporting that it only happened once. When they experienced repeated events, they were also highly accurate in claiming that it happened “more than once.” However, for children who experienced repeated events, performance declined considerably when they were asked to provide a more specific estimate of the number of events that they had experienced. For instance, only 9% of the children who experienced 6 events and none of the children who experienced 11 events answered the question about event frequency correctly. As expected, children’s performance improved with age.

Sharman et al. (2011) asked children about staged events, which may not be as salient or emotional to children as legally relevant experiences. Also, the events were scheduled at regular intervals, which is unlikely to be the case for legally relevant experiences. Thus, Sharman et al.’s findings may not provide an accurate picture of children’s abilities to make such judgments in the “real world.” However, Malloy, Brubacher, Lamb, and Benton (2013) examined transcripts of investigative interviews with 4- to 8-year-old suspected victims of child sexual abuse to see how they responded to the question, “Did that happen one time or more than one time?” Only eight children (12%) gave an inappropriate response (e.g., responses that used incorrect terminology or involved implausible numbers), with 4- to 6-year-olds more likely to respond inappropriately. The 7- to 8-year-olds did not provide any inappropriate responses. As they grew older, children were also more likely to use numbers and quantifiers spontaneously in their narratives about abuse, especially in reference to people, objects, and time (e.g., dates, duration). Children who alleged multiple incidents of abuse were more likely to spontaneously mention event frequency during their interviews, although these researchers had no way of knowing whether the children’s references were accurate.

Wandrey, Lyon, Quas, and Friedman (2012) also explored children’s abilities to make legally relevant judgments about event frequency, but (unlike Malloy et al., 2013) they had access to data that made it possible to objectively verify children’s responses, thus enabling them to study their accuracy. Specifically, 6- to 10-year-old maltreated children judged how many times they had attended court hearings and the number of placements that they had experienced after being removed from home. The children often gave surprisingly inaccurate answers, although they were better at reasoning about more extreme values (e.g., when the number of actual experiences differed substantially from the number of experiences that they were asked about; “Did you come to the court building more than 10 times?” versus “Did you come to the court building more than five times?” when they had visited twice). One-third (35%) of the children provided inaccurate responses to the basic event frequency question often recommended, “Did that happen one time or more than one time?”

It is crucial for interviewers and legal professionals to recognize both that children may fail to answer or give implausible or inappropriate responses to questions concerning event frequency and numerosity, even when they are able to use numbers and quantifiers correctly in some contexts and that “inaccurate responses to time and number

questions may say little about whether the event actually occurred" (Wandrey et al., 2012, p. 100). Unfortunately, children rarely mention event frequency spontaneously, meaning that interviewers may need to prompt children for this information. Further research on this topic may help future interviewers question children about event frequency in ways that better recognize and operate within children's developmental limitations.

Fantasy and Reality

Fantasy and pretend play are normative and developmentally appropriate behaviors for children. However, children's belief in fantastical characters or their judgments about fantasy versus reality may be used to discredit their testimony as victims/witnesses. Children are often portrayed as confused about and unable to distinguish between fantasy and reality, and their belief in fantastical characters is often seen to exemplify their difficulties in this area (see Woolley & Ghosaini, 2013, for a review), with "a disproportionate amount of attention" paid to children's tendency to believe in fantastical beings. Three- and 4-year-olds are also prone to erroneously label real events or entities as "pretend," presumably because they are relying on their limited knowledge and experience when making such judgments. Like adults, children over 6 years of age can discriminate easily between imagined and experienced events (Carrick, Rush, & Quas, 2013; Lindsay & Johnson, 1987; Roberts, 2000). Studies show that even 3-year-olds can make some "fantasy versus reality" judgments accurately (e.g., they are aware that imaginary objects cannot simply appear in real life and that pretend actions are not real actions; Estes, Wellman, & Woolley, 1989; Flavell, Flavell, & Green, 1987; Woolley & Wellman, 1993). For example, Carrick and Quas (2006) presented preschoolers (3- to 5-year-olds) with real versus fantastical emotional images from children's storybooks (e.g., a mother yelling at a child versus a cat yelling at kittens; mice dancing in clothes versus people celebrating) and then asked children to indicate whether the scenes depicted "could happen in real life." Regardless of how realistic the images were, children were more likely to say that the positive images "could happen in real life." Thus, it appeared that children's judgments were, at least in part, desire-based (also see Samuels & Taylor, 1994).

Motivation, context, and experience all affect children's fantasy-reality judgments. For instance, using the storybook picture paradigm described above, Carrick and Ramirez (2012) investigated the role of motivation in 3- to 5-year-olds' fantasy and reality judgments: When children

were provided with incentives to be accurate (i.e., a prize for each correct judgment), their accuracy judging fantastic emotions improved. In false memory studies, children are more likely to claim to have experienced false events that are positive in emotional valence (e.g., hot-air balloon rides) than false events that are negative (e.g., getting stitches after a fall; Ceci, Loftus, Leichtman, & Bruck, 1994). Regarding context, children are more likely to judge characters as real in religious stories than in nonreligious stories (Vaden & Woolley, 2011). Similarly, children were more likely to judge a novel entity as real when it was supposedly used by doctors (and thus introduced in a scientific context) rather than collected by dragons (and thus introduced in a fantastical context). Children's ability to use context when make fantasy-reality judgments also improves between the ages of 3 and 5 (Woolley & Van Reet, 2006).

Children's adverse life experiences play a role in their ability to correctly distinguish between fantasy and reality as well. Specifically, Carrick, Quas, and Lyon (2010) predicted that maltreated children's personal experiences with negative events and their negativity biases in processing social information would lead them to be more realistic than nonmaltreated children when distinguishing between fantasy and reality. Again, after showing preschool children storybook pictures depicting different emotions (happiness, fear, anger, and neutral/control), the researchers asked, "Can this happen in real life?" Maltreated children failed to demonstrate the response bias found in previous work: They did not claim that negative real events could not happen and instead were more likely than nonmaltreated children to correctly report that these events were possible. Maltreated children were more inaccurate, however, when it came to the frightening images, reporting that frightening fantastical images could happen in real life.

Harris (2012) noted that "testimony" from trusted others can encourage children to embrace fantastical beliefs and is often needed to convince children of things that cannot be seen but *do* exist (e.g., germs; Harris, Pasquini, Duke, Asscher, & Pons, 2006). Parents and family members often go to great lengths to foster and reinforce children's beliefs in fantasy (e.g., the character "Santa Claus" known to children in many countries), even providing "evidence" consistent with these beliefs (e.g., return letters from "Santa Claus"). Woolley, Boerger, and Markman (2004) found that such evidence helped convince older children (4- to 5-year-olds) of a novel character's existence (the Candy Witch). When providing event reports, children are more likely to provide false information about

fantastical characters (e.g., Tooth Fairy) when they believe in those characters than when they do not (Principe & Smith, 2008a, 2008b).

According to Piaget (1945), children who commonly engage in fantasy and pretend play are in the “preoperational” stage of development (Ages 2 to 7) during which they have trouble using concrete logic and conducting mental operations and so perhaps use magical thinking to explain concepts and events that they do not yet understand (e.g., how planes fly, the physical transformation of objects; Rosengren & Hickling, 1994). However, beliefs in fantastical characters, magical thinking, or the existence of imaginary companions do not, in themselves, mean that children cannot provide accurate and reliable reports of witnessed or experienced events. We later discuss interviewing techniques that should be avoided with very young children to minimize the risk that they may confuse fantasy and reality.

Metacognition, Reasoning, and Logic

Several more complex aspects of thinking, reasoning, and cognitive development affect children’s ability to participate in legal contexts.

Metacognition

Legal participation may be difficult when children have immature metacognitive skills, relatively poor comprehension monitoring, and overestimate their mnemonic abilities (Flavell, 1981; Saywitz, Jaenicke, & Camparo, 1990). Children may, for example, downplay the likelihood that they will forget information or overestimate the number of items that they can remember (e.g., Flavell, Friedrichs, & Hoyt, 1970; Kreutzer, Leonard, & Flavell, 1975). Metacognitive and metalinguistic awareness and skills develop more fully after 5 years of age, meaning that preschool children are seldom able to monitor their comprehension as effectively as older children or adults (Markman, 1977, 1979) and younger children’s deficiencies may be exacerbated by the associated situational stresses, complexity, and unfamiliarity of forensic interviews and courtroom testimony (see “Features of Legal Contexts”). Such failures to recognize miscomprehension may help explain why children rarely ask for clarification of interview questions (Malloy, Katz, Lamb, & Mugno, in press; Saywitz, 1995; Saywitz, Snyder, & Nathanson, 1999). Also, when interviewers misrepresent what children say, they tend not to be corrected, and thus the mistakes, rather than the correct information, may be reported by the children later (Roberts & Lamb, 1999).

Reasoning and Logic

Developmental researchers have long been aware that there are dramatic increases in the ability to engage in logical thinking and problem solving during childhood. For example, during middle childhood, children’s thought becomes more organized and flexible, but generally when focused on more concrete, rather than abstract, problems. According to Piaget (1957), children in the concrete operational stage (i.e., approximately 7 to 11 years of age), develop several cognitive skills including seriation (ordering objects on quantitative dimensions) and more sophisticated classification skills (grouping objects into hierarchies). Once children can simultaneously consider more than one aspect of a problem, they are able to engage in much more sophisticated reasoning.

However, many developmental changes in reasoning and logic that are critical to legal decision making only take place between approximately 11 and 15 years of age (e.g., Neimark & Lewis, 1967; Saarni, 1973). Regardless of their legal roles (e.g., defendants, adolescents involved in custody battles), youth may be asked to reason about and make important and potentially life-altering decisions (e.g., whether to accept plea deals or help develop appropriate postdivorce parenting plans). Many of these legal decisions involve the calculation of risk and/or the evaluation of alternative scenarios, and the ability to engage in such complex decision making does not develop until adolescence.

By the time of Piaget’s “formal operational” stage, adolescents have an understanding of risk and probability that is roughly comparable to that of adults (Acredolo, O’Connor, Banks, & Horobin, 1989; Schlottmann, 2001; Schlottmann & Wilkening, 2011) but their ability to understand risk and probability is not accompanied by an equivalently sophisticated ability to use that information (M. Gardner & Steinberg, 2005; van Leijenhorst, Westenberg, & Crone, 2008). Older teenagers appear less capable than adults at using information about risk (e.g., estimating the probability of being caught following a transgression) because they tend to overvalue the possible benefits (for instance, of shoplifting) while simultaneously underestimating the potential costs (for example, of being caught; W. Gardner & Herman, 1990; Halpern-Felsher & Cauffman, 2001).

Research using several laboratory paradigms (e.g., gambling tasks, computerized driving games; Cauffman et al., 2010; M. Gardner & Steinberg, 2005; Steinberg et al., 2008) has shown that adolescents are more impulsive and less future-orientated than adults, even young adults

(e.g., Steinberg et al., 2009). When they consider the future consequences of their actions, they tend to focus on potential short- rather than long-term consequences, perhaps because their greater sensitivity to rewards than risks makes their judgments immature (Cauffman & Steinberg, 2000; B. J. Ellis et al., 2012; Steinberg & Cauffman, 1996; Steinberg et al., 2008; Steinberg et al., 2009). Shulman and Cauffman (2013) examined over 2,000 10- to 30-year-olds and found that, relative to preadolescence and adulthood, a self-reported bias toward rewards was elevated during adolescence. Further, even after controlling for key variables (e.g., intelligence, SES), adolescents' reward bias was more strongly correlated with their criminal behavior than was the bias of adults. Shulman and Cauffman (2013) suggested that the findings were consistent with the "dual systems" model of adolescent development in which increased risk-taking in middle adolescence is explained by the development of reward sensitivity *before* the ability to manage impulses effectively and exercise self-control (Steinberg, 2010).

Older adolescents are better able than children and younger adolescents to appraise the future consequences of their behavior (e.g., Crone & van der Molen, 2004; Spear, 2000) and to perform other complex executive functions (e.g., Leon-Carrion, García-Orza, & Pérez-Santamaría, 2004; Luciana, Conklin, Hooper, & Yarger, 2005) although these skills do not fully develop until late adolescence and early adulthood, probably because they depend on the structural and functional maturation of the pre-frontal cortex. Legal decision making and legal reasoning abilities improve with age (e.g., Grisso et al., 2003; Peterson-Badali & Abramovitch, 1993; Redlich, Silverman, & Steiner, 2003), although inadequate safeguards are in place for youth with emergent decision-making skills. Immature reasoning may be even more common among youth involved in the justice system, who are disproportionately affected by mental health issues and impairments in intellectual ability (e.g., Cauffman, 2004; Closson & Rogers, 2007; Quinn, Rutherford, Leone, Osher, & Poirier, 2005; Redlich, 2007).

When apprehended, suspects must decide (a) whether to submit to police questioning (which in the United States means deciding to waive Miranda rights) (b) whether to confess (truthfully or falsely) when interrogated, and (c) whether to plead guilty or proceed to trial, all of which are "high stakes" decisions. Several of the basic psychological principles that influence young people's ability to make mature decisions about their behavior and make them ineligible for the death penalty (see Cauffman,

Shulman, Bechtold, & Steinberg, Chapter 16, this *Handbook*, Volume 4) also increase their vulnerability in the interrogation room, as discussed below.

In the United States, the *Miranda v. Arizona* (1966) Supreme Court decision reaffirmed that suspects in custodial interrogations must be apprised of their rights to remain silent and to have legal counsel before anything they say can be admissible in court proceedings. The *In Re Gault* (1967) decision extended these rights to adolescents. Suspects can waive their Miranda rights but must do so in a "knowing, intelligent, and voluntary" manner. However, even adults of average intelligence who understand their Miranda rights may fail to comprehend the basic implications or relevance of their Miranda rights to their own case (see Kassin et al., 2010) with stress impairing Miranda comprehension by adults (Scherr & Madon, 2012).

Whereas adults frequently waive their Miranda rights (or equivalent rights in other jurisdictions) and submit to police questioning, adolescents are especially likely to misunderstand or to waive those rights and rarely ask for attorneys to be present (Goldstein, Condie, Kalbeitzter, Osman, & Geier, 2003; Grisso, 1980, 1981, 1997; Grisso et al., 2003; Malloy, Shulman & Cauffman, 2014; Viljoen, Klaver & Roesch, 2005). This is of particular concern with respect to youth with intellectual impairments and those younger than Age 14 (see Kassin et al., 2010). Adolescents who understood their legal rights poorly are more likely to report having waived them than those who understood them better (Viljoen et al., 2005). Although older youth (15 years of age and over) appear to have a factual understanding of their rights, they may still fail to recognize their relevance or to reason appropriately about their significance. For example, although adolescents may understand the right to have an attorney present when they are interrogated, they may withhold information from their attorneys or fail to express disagreements with them because they misunderstand their attorneys' roles (Viljoen et al., 2005).

Basic knowledge of the right to remain silent and receive legal advice does not necessarily mean that youth have the capacity or skills to reason about waiving these rights. For example, youth often fail to consider the evidence against them or the nature of the allegations when making hypothetical waiver decisions (Abramovitch, Peterson-Badali, & Rohan, 1995). Viljoen et al. (2005) found that, while 15- to 17-year-old juvenile defendants used the strength of the evidence against them to decide whether to make statements to the police, 11- to 14-year-olds did not. Thus, it is important to bear in mind developmental factors when considering

whether suspects have sufficient reasoning skills to waive rights in a “knowing” and “intelligent” manner as required by law.

An overwhelming majority of juveniles waive their Miranda rights (Feld, 2006; Grisso & Pomicter, 1977) and must then decide whether to confess. Grisso et al. (2003) presented community and justice-system-involved juveniles and young adults with vignettes describing police interrogation situations and asked participants to indicate what would be the “best choice” for the suspects: confess, remain silent, or deny involvement in hypothetical crimes. Over half of the 11- to 13-year-olds but only one-fifth of the adults reasoned that the “confess” option was the most sensible choice, highlighting juveniles’ general propensity to confess. Viljoen et al. (2005) found that 55% of the juvenile defendants they studied had confessed when questioned as suspects by the police, with confessors significantly younger than those who had remained silent. Furthermore, juveniles (and adults) sometimes reason that their best option is to confess *false*. Consider the case of DNA exoneree Jeffrey Deskovic. Jeffrey was 16 years old when the police in his hometown of Peekskill, New York, thought that his behavior following a crime was suspicious (e.g., he was displaying too much emotion about a classmate’s death). Over the succeeding months, he was interrogated several times, with only segments of the interrogations recorded, and confessed when told by police that DNA at the scene showed that the victim had been raped. Eager to terminate the interrogations and reasoning that the DNA evidence would exclude him, he confessed to this serious crime. The DNA evidence did exclude him, but he was convicted nonetheless and spent 16 years in prison before his exoneration in 2006. Indeed, when presented with hypothetical interrogation situations, 25% of male juvenile offenders report that they would choose to confess falsely in at least some circumstances (Goldstein et al., 2003), underscoring why false confessions are so problematic.

Numerous false confessions have been documented around the world. Over the last 30 years, advances in DNA testing have exonerated over 300 individuals in the United States, and in 25% of these cases, false admissions contributed to the wrongful convictions (Innocence Project, <http://www.innocenceproject.org/>). Although false confessions occur at all ages, young people are disproportionately likely to confess falsely. For example, in a study of individuals whose innocence had been verified using DNA evidence, Gross, Jacoby, Matheson, Montgomery, and Patel (2005) found that, whereas only 13% of the

adults had confessed falsely, 42% of the juveniles had done so, with the youngest exonerees (12- to 15-year-olds) confessing to murder or rape 69% of the time. In another study of “proven false confession cases,” Drizin and Leo (2004) found that 33% involved false confessions by juveniles, with 55% by juveniles who were 15 or younger. The U.S. National Registry of Exonerations reported that, over a 25-year period, 38% of juvenile exonerations, but only 11% of adult exonerations, involved false confessions (Gross & Shaffer, 2012).

Self-report data also speak to the frequency with which juveniles confess falsely (e.g., Gudjonsson, Sigurdsson, Sigfusdottir, & Asgeirsdottir, 2008; Viljoen et al., 2005). In a large study conducted in several European countries, youth were asked about their interrogation and false confession experiences. Of the 11.5% (2,726) interrogated by the police, 14% claimed to have falsely confessed (Gudjonsson, Sigurdsson, Asgeirsdottir, & Sigfusdottir, 2006). Among 193 male adolescents (14- to 17-year-olds) incarcerated for serious crimes in the United States, Malloy et al. (2014) found that 17% claimed to have falsely confessed to the police at least once.

Laboratory studies confirm that juveniles are more likely than adults to take responsibility for acts they have not committed. Redlich and Goodman (2003) accused adolescent and adult research participants of causing a computer to crash by hitting the “Alt” key, after warning them that they would have to enter data for 10 hours if they pressed this key. Young adults were the least likely to take responsibility for crashing the computer (59%); 12- and 13-year-olds were the most likely (78%); 15- and 16-year-olds fell in between (72%). Young participants may have reasoned that signing the confession represented the best way out of the situation or they may have done so in order to comply with adult authority figures.

Suspects must also decide whether to plead guilty or go to trial. In the United States, an estimated 95% of convictions are resolved by pleas (Cohen & Reaves, 2006), yet considerably more research and public attention has focused on trial dynamics than on the plea-bargaining process and there is a well-documented “trial penalty” (i.e., harsher penalties for those who do not plead but are convicted at trial; Ulmer & Bradley, 2006). When deciding whether to plead guilty, there are several factors that defendants might logically consider (e.g., the strength of evidence against them, the likelihood of conviction at trial, the proposed plea sentence compared to the sentence if convicted at trial, etc.) and there is some evidence that children as young as 10 years of age consider the strength

of the evidence against them when making plea decisions (Peterson-Badali & Abramovitch, 1993), although Viljoen et al. (2005) found in a field study that evidence strength was considered by older adolescents (15- to 17-year-olds) only. However, seemingly irrelevant characteristics such as race, gender, and age are correlated with plea decisions as well (Ball, 2006; Viljoen et al., 2005). Grisso et al. (2003) found that age was negatively associated with the willingness to plead guilty in hypothetical situations: Only half of adults but almost three-quarters of 11- to 13-year-olds accepted plea bargains. Moreover, adolescents reasoned in a less sophisticated way about plea agreements, focusing on the absolute length of the plea sentence rather than the alternative sentences or the probability of conviction.

Most research on guilty pleas has not differentiated true from false guilty pleas. In fact, research on the propensity of youth to plead guilty falsely has lagged substantially behind research on their tendency to confess falsely (Redlich, 2010). However, the decision to plead guilty falsely has enormous implications as well: The right to jury trials and the associated legal protections (e.g., the right to confront and cross-examine witnesses) are relinquished when defendants plead guilty. Plea "bargains" typically involve decisions to accept lesser sentences than might result from conviction at trial, so the abilities to reason about risk, probability, and long-term consequences are paramount. Redlich (2010) has argued that innocent individuals deciding whether to make deals are faced with "Hobson's choices" (i.e., the illusion of a free choice): They can take deals in exchange for reduced sentences or remain in jail and face more punitive sentences at trial.

On the one hand, youth may be particularly likely to plead guilty falsely. As explained below, the situations in which plea decisions are rendered may bear some similarities to the contexts in which youth decide to confess falsely (e.g., pressure from adult authority figures). On the other hand, research on immature decision making and risk proneness suggests that youth may be *unlikely* to plead guilty falsely because they are willing to take their chances at trial, even when positive outcomes are improbable. Unfortunately, very little research on the prevalence of false guilty pleas exists. Malloy et al. (2014) found that 25% of 193 incarcerated male adolescents (aged 14 to 17) reported having entered false guilty pleas whereas 17% reported making false confessions to the police. Similarly, Redlich, Summers, and Hoover (2010) found that false guilty pleas were more common than false confessions in a sample of mentally ill adult offenders, another population at disproportionate risk for false confession.

Although cases involving false guilty pleas have been documented (Redlich, 2010) and many individuals report having pled falsely, much remains to be learned in this area. More research is needed on the implications of the developing reasoning and logic skills of youth for their decisions to plead guilty both truthfully and falsely. Pleas are difficult to withdraw, and thus wrongful convictions based on pleas are difficult to discover and overturn (Redlich, 2010). Also, many youth may choose to plead guilty falsely after having confessed falsely. In fact, Malloy et al. (2014) found that, of the 17% of youth who reported making false confessions, 42% had also pled guilty falsely. As discussed below, "high stakes" plea decisions are further complicated by the sophisticated terminology and complexity of plea colloquies and tender-of-plea forms.

Development of Language and Communication

To be full and active participants in the legal process, individuals must understand and appreciate the language used in different legal contexts and communicate effectively with individuals playing various legal roles (e.g., judges, lawyers, social workers, evaluators, forensic interviewers). Although miscommunication can and does occur with all age groups, effective communication may present a significant challenge for many children and adolescents involved in the legal system.

At a basic level, interlocutors may misunderstand very young children's statements, in part because young children do not always articulate individual sounds consistently or appropriately (Reich, 1986). Also, compared to adults, young children's vocabularies are more limited and idiosyncratic and less descriptive (Dale, 1976; de Villiers & de Villiers, 1999). For example, children may say that they have never visited an alleged perpetrator's house, but answer differently if they are asked whether they have been to the alleged perpetrator's "apartment" (A. G. Walker & Kenniston, 2013). Preschoolers, in particular, may use words before they know their conventional adult meaning, use words that they do not understand at all or only understand in certain contexts, and understand poorly some apparently simple concepts such as "any" and "some." Indeed, children under 6 often understand narrowly some words like "touch" that may be important for forensic interviews. Bruck (2009) found that children failed to report touches in laboratory analogue situations because they classified the "touching" as rubbing or scratching instead.

Children may also struggle with legal jargon or terminology. For example, Cooper, Wallin, Quas, and Lyon

(2010) examined 4- to 14-year-olds' knowledge of legal terms. Half of the children were child maltreatment victims who had experience with the dependency court system, yet the youngest children (4- to 7-year-olds) understood very few legal terms (e.g., attorney, judge, foster parent) with one-fifth of them providing no correct information about any of the terms. There was substantial room for improvement among the 11- to 14-year-olds, too, indicating that even adolescents may need or benefit from assistance in understanding legal terms and the various roles of legal professionals.

Saywitz et al. (1990) also explored children's knowledge of legal vocabulary by asking 5-, 8-, and 11-year-old children to define 35 legal terms likely to be heard by children during legal proceedings. As expected, there were age-related improvements in children's performance, with the 11-year-olds accurately defining 25 terms on average, while the 8- and 5-year-olds accurately defined only 15 and 6 terms, respectively. Compared to the 11-year-olds, younger children were more likely to commit auditory discrimination errors ("Jury is like the stuff ladies wear on their fingers and ears and around their neck," mistaking "jury" for "jewelry") and homonym errors ("Charges are something you do with a credit card"), although they were asked about the legal context in particular. Both types of errors have the potential to damage children's testimonial credibility.

Unfortunately, adults often overestimate children's linguistic capacities and use words, sentence structures, or concepts that are developmentally inappropriate and exceed the children's competencies (Evans, Lee, & Lyon, 2009; A. G. Walker & Kenniston, 2013; Zajac & Hayne, 2003). Several decades of research findings make clear that the accuracy of children's eyewitness accounts is influenced by the linguistic style and the complexity of the language addressed to them by questioners (Carter, Bottoms, & Levine, 1996; Imhoff & Baker-Ward, 1999; Perry et al., 1995; Zajac, Gross, & Hayne, 2003). When testifying, children may be asked to negate adult statements (e.g., "Is it not true that . . . ?") or to confirm multifaceted "summaries" of their accounts. They may become confused when responding to syntactically complex or ambiguous compound sentences (Evans et al., 2009; N. E. Walker & Hunt, 1998). For example, consider the questions, "Did you say that when they were playing this game called Bingo that you knew that somebody was going to hurt people and when that happened you hid? Do you remember that?" and "Do you recall telling us that your mother had cleaned up after you throwing up back

in April when you testified?" Both of these complex questions were asked of children participating in actual criminal trials (Evans et al., 2009; A. G. Walker, 1993).

Children must also develop the social or pragmatic aspects of communication to provide rich and useful accounts in legal contexts. In part, providing coherent and structured narratives is learned through social interaction (Nelson & Fivush, 2004). Learning how to participate effectively in conversations may still be in process at the time that children are interviewed for forensic purposes. Young children are still developing their metalinguistic abilities—coming to know what listeners want to know, and how to report information coherently, monitor the success of their communication, and modify strategies as necessary to ensure that the listeners have understood (Lamb & Brown, 2006; Saywitz & Snyder, 1996). Children must learn how to stay on topic and how to adapt their speech appropriately to different audiences (e.g., unfamiliar interviewers who do not know their family members and were not present during the events in question). They must learn to "read between the lines" and avoid interpreting some questions literally (e.g., "Do you remember his name?" "Can you tell me where he touched you?"; A. G. Walker & Warren, 1995; Warren, Woodall, Hunt, & Perry, 1996). The challenge for interviewers is to obtain organized accounts that are sufficiently rich in descriptive detail to permit the children's testimony to be understood. Interviewers' word choices and the complexity of their utterances may profoundly influence the course and outcome of legal interactions with children, too.

As children grow older, the length, informativeness, and complexity of their narratives increase (see Fivush, 1997; Saywitz & Campano, 1998; W. Schneider & Pressley, 1997), but even very young children provide temporally organized and coherent narratives (e.g., Flin, Boon, Knox, & Bull, 1992; Hershkowitz et al., 2012; Lamb et al., 2003).

Young children are used to being questioned by adults who are already knowledgeable about the topics of conversation (Lamb, Orbach, Warren, Esplin, & Hershkowitz, 2007), but alleged victims of abuse are often the sole sources of information about the suspected events. As a result, interviewers need to communicate their needs and expectations clearly, motivating children to provide as much information as they can. One of the goals of the "presubstantive" portions of forensic interviews is to ensure that children understand the unique demands of forensic interview contexts (e.g., Sternberg, Lamb, Esplin, Orbach, & Hershkowitz, 2002). If children fail to appreciate that the interviewers have little, if any, knowledge

of the alleged events, or attribute superior knowledge to them (e.g., Ceci, Ross, & Toglia, 1987), they may fail to report all they know or defer to the interviewers' interpretation of events, as potentially revealed through leading or suggestive questions. Children are cognizant of differences between knowledgeable and naïve adults and vary their responses and trust in these individuals accordingly (Koenig & Harris, 2005; Welch-Ross, 1999).

Even when interviewers have attempted to communicate that they do not know what the children experienced, they may, by using the wrong sorts of questions, inadvertently encourage young children to respond as though they were being tested. For example, forensic interviewers frequently ask very specific questions (e.g., "Did he touch you?"). Young children (those under 6) have special difficulty answering specific questions, and may exhibit a response bias (e.g., Ahern, Lyon, & Quas, 2011; Fivush, Peterson & Schwarzmueller, 2002; Peterson, Dowden, & Tobin, 1999), or a reluctance to give "don't know" responses when they would be appropriate (Bruck & Ceci, 1999; G. Davies, Tarrant, & Flin, 1989; Poole & White, 1991; Saywitz & Snyder, 1993). Children do not provide more "don't know" responses to complex as opposed to simple questions (Carter et al., 1996). In fact, Waterman, Blades, and Spencer (2000, 2001, 2004) showed that 5- to 9-year-olds often attempted to answer impossible (nonsensical) or unanswerable (where the information has not been provided) questions, especially if they were phrased as yes/no rather than wh- questions and even when they accurately judged that the questions were nonsensical. The type of questions asked and their context thus determine whether questions enhance or degrade the reliability of children's reports. Detailed preinterview instructions focused on reminding children that the interviewers were not present at the target events can increase children's (at least 6-year-olds') tendency to give "don't know" responses to unanswerable questions (Waterman & Blades, 2013).

Older children's and adolescents' linguistic and communicative abilities may also be challenged in legal situations. For example, only 5% (3/66) of the 11- to 14-year-olds in Cooper et al.'s (2010) study of children involved in dependency court proceedings provided correct answers about five of the seven legal terms that they were asked to define, and one-fifth provided no correct definitions. Brennan and Brennan (1988) showed that fewer than two-thirds of the questions addressed to 6- to 15-year-olds in court were comprehensible to their peers. Regardless of age (kindergarten to university), Perry and colleagues (1995) found that students were more accurate answering

simple rather than complex questions about witnessed events. Furthermore, the kindergarteners often failed to recognize that they misunderstood the complex questions. Examining felony child sexual abuse cases, Evans et al. (2009) demonstrated that neither defense *nor* prosecution attorneys varied the length or complexity of their sentences directed to children despite the fact that the age range of the alleged child victims varied widely (i.e., 5 to 15 years). Even mental health professionals and trained investigative interviewers ask children developmentally inappropriate or complex questions in investigative interviews (Korkman, Santtila, Drzewiecki, & Sandnabba, 2008; Plotnikoff & Woolfson, 2009).

In order to assist in and make legal decisions, adolescents must be able to understand the relevant language, interactions, and proceedings; appreciate their significance; and communicate effectively with lawyers and other professionals. Although some studies show that adolescents feel comfortable disclosing information to their attorneys (e.g., Grisso et al., 2003), others report substantial amounts of distrust in attorneys by adolescents (e.g., Catton, 1978). Viljoen et al. (2005) found that 31% of juvenile defendants would not tell or were unsure about telling their attorneys what really happened.

Youth may also have difficulty making reasoned decisions about whether to waive their rights or enter a plea agreement, in part because both involve complex language. In one study, the warnings or cautions concerning Miranda rights offered to 122 juvenile Americans ranged in length from 64 to 1,020 words ($M = 214$) and the reading level required ranged from 7-year-old to post-college (Rogers, Hazelwood, Harrison, Sewell, & Shuman, 2008), leading the researchers to conclude, "The most obvious and far-reaching conclusion from the current data is that typical juvenile Miranda warnings are far beyond the abilities of the more than 115,000 preteen offenders charged annually with criminal offenses" (p. 75).

When alleged offenders plead guilty, they must answer questions designed to ascertain whether any additional promises were made (i.e., beyond the plea agreement), whether they understand their legal rights and the consequences of pleading guilty, and whether they are incapacitated in any way. However, there is no standard manner in which these questions are asked and there are no requirements regarding their comprehensibility (Redlich, 2010). Kaban and Quinlan (2004) found that youth involved in the juvenile justice system were able to define very few (an average of 2) of 36 terms contained in the Massachusetts tender-of-plea form or plea colloquies

in that state. Even youth who were instructed about court proceedings were able to define only five items correctly, on average.

In sum, linguistic competence is a substantial concern in legal contexts, regardless of whether those contexts involve victims or suspects, or 4-year-olds or teenagers. In every case, a failure to recognize the capacities of the individuals involved may seriously compromise communication and deny those children the justice they deserve.

Socioemotional Development

In addition to developmental changes in children's memory, thinking, and communicating, aspects of social and emotional development affect children's participation in legal contexts as well.

Rapport and Trust

Children are often reticent with strangers and most adults thus recognize the need to establish rapport when initiating conversations with unfamiliar children, especially when the topics are stressful or embarrassing as when they are being questioned about alleged instances of abuse (Collins, Lincoln, & Frank, 2002; Goodman, Bottoms, Schwartz-Kenney, & Rudy, 1991; Lamb et al., 2007; Sternberg et al., 1997). When questioned by unfamiliar adults or authority figures, some children may be reluctant to describe personally meaningful experiences that are intimate or embarrassing (e.g., Saywitz, Goodman, Nicholas, & Moan, 1991), and a substantial proportion of children are reluctant to disclose their abuse (see London, Bruck, Ceci, & Shuman, 2005, 2007, for reviews). Establishing rapport may help facilitate communication with children and encourage them to affirm and describe traumatic experiences in clinical (Boggs & Eyberg, 1990; Morgan & Friedemann, 1988), evaluative (Kanfer, Eyberg, & Krahn, 1992; Powell & Lancaster, 2003), or investigative (Aldridge & Wood, 1998; Goodman & Bottoms, 1993; Powell & Thomson, 1994) interviews. However, many forensic interviewers fail to make more than perfunctory efforts to establish rapport before broaching the substantive issue under investigation (Sternberg, Lamb, Esplin, & Baradaran, 1999; Warren et al., 1996).

Social Relationships With Parents, Other Adults, and Peers

As detailed by Thompson (2006; see also Thompson, Chapter 6, this *Handbook*, this volume), scholars have

long recognized that the attachments (i.e., close, enduring bonds) formed to parents are among the most critical achievements of the first year of life, and that attachment formation depends on reciprocal interactive processes that foster infants' abilities to discriminate their parents from other adults and to develop emotional ties to them (Lamb, Thompson, Gardner, & Charnov, 1985). By the middle of the first year of life, children's attachments are consolidated and characterized by the onset of separation anxiety and separation protest. Infants who receive sensitive, responsive care from specific adults tend to become securely attached to them (Dozier, Zeanah, & Bernard, 2013). Even relatively low levels of responsive parenting lead to the development of infant-parent attachments, although some of these attachments may be classified as "insecure" or "disorganized." Disorganized attachments, which are more common among children who have experienced maltreatment, put children at risk for a host of negative outcomes (see Cicchetti & Toth, Chapter 13, this *Handbook*, this volume). However, it is more advantageous for children to form insecure attachments than to fail to form attachment relationships at all because these enduring ties play essential formative roles in later social and emotional functioning (Thompson, 2006).

Infants and toddlers need regular interaction with their "attachment figures" in order to foster and maintain their attachments (Lamb & Kelly, 2009) and help them develop the abilities to appropriately regulate their behavior, emotions, and physiology (Hofer, 2006). Extended separations from either parent are undesirable because they unduly stress developing attachment relationships. Even though fathers typically spend less time with their infants than mothers do (e.g., Pleck, 2010), most infants form meaningful attachments to both of their parents at roughly the same age (6 to 7 months; Lamb & Lewis, 2010). Most infants come to "prefer" the parents who take primary responsibility for their care (typically their mothers), but relationships with secondary caregivers are still important.

Children's attachment relationships with parents play a crucial role in shaping children's socioemotional development (Lamb & Lewis, 2011). For example, these attachments influence perceptions of self, perceptions and expectations of others, social competence with peers, and emotional expressiveness (S. C. Johnson, Dweck, & Chen, 2007; Lucas-Thompson & Clarke-Stewart, 2007). Disrupted parent-child attachments have adverse effects on children's development and adjustment, and children who are deprived of meaningful relationships with one of their parents are at greater risk psychosocially, even

when they are able to maintain relationships with their other parent (e.g., Lamb & Kelly, 2009). Such data are, of course, extremely relevant when legal professionals are making decisions about children's living arrangements following their parents' separation.

In addition to the critical influence that attachment relationships have on child development, children's attachments to parents have implications for their behavior and decision making in legal contexts. For example, much attention and debate have focused on how and when children disclose adult wrongdoing (e.g., child maltreatment that is often perpetrated by adults who are close to them). London et al. (2005, 2007) and London, Bruck, Wright, and Ceci (2008) concluded that a majority of children delay disclosure of child sexual abuse for long periods of time, often until adulthood, with some children failing to disclose at all. Children may disclose reluctantly, fail to provide detailed accounts of their experiences, or recant prior allegations of abuse (Goodman-Brown, Edelstein, Goodman, Jones, & Gordon, 2003; Hershkowitz, Horowitz, & Lamb, 2007; Malloy, Lyon, & Quas, 2007; Pipe, Lamb, Orbach, & Cederborg, 2007). In laboratory analogue studies, children often deny or fail to disclose even the minor wrongdoings of adults (e.g., spilling something, breaking a toy, playing with a forbidden toy; Bottoms, Goodman, Schwartz-Kenney, & Thomas, 2002; Lyon, Malloy, Quas, & Talwar, 2008; Pipe & Wilson, 1994).

Whether children disclose adult wrongdoing also depends on the adults' identity. Due to their attachments to and dependency on known and trusted adults, especially parents, children appear less likely to disclose their wrongdoings. For example, several studies have demonstrated that children are less likely to disclose and more likely to delay disclosing abuse by family members than less familiar adults (see London et al., 2008; Lyon, 2009; Paine & Hansen, 2002, for reviews), and more likely to recant abuse allegations made against parent figures (e.g., Malloy et al., 2007). If nonoffending caregivers (typically mothers) react unsupportively to abuse disclosure, recantation is more likely (Elliott & Briere, 1994; Malloy et al., 2007), highlighting the important influence parents exert, even indirectly, on what children are willing to reveal (and maintain) in legal contexts.

Similar findings are evident in laboratory contexts. In one study, 6- to 10-year-old children witnessed either research assistants or parents steal books. In both conditions, the "thieves" told the children that the thefts were secret and encouraged them to lie and blame another research assistant. When the thief was the research

assistant, most children (81%) levied an accusation against him or her. However, when the parents stole, 56% of the children accused the research assistant rather than the parents, thus appearing more willing to lie to protect parents (Tye, Amato, Honts, Devitt, & Peters, 1999). Also, responding to hypothetical vignettes, children were less likely to endorse disclosure of wrongdoing by parents rather than strangers (Lyon, Carrick, & Quas, 2010). This may be, in part, related to developmental changes in children's understanding of family loyalty and obligation (Leibig & Green, 1999). In sum, both naturalistic field studies and experimental research indicate that, when parents are implicated in wrongdoing, children are less forthcoming with interviewers than when other individuals are implicated.

Children may be more reluctant to report parents' transgressions because they expect negative consequences to befall their parents, others close to them, or even themselves. Adults who claim that they were abused as children often report that they considered the potential effects of disclosure on themselves and others when deciding whether and when to disclose (Anderson et al., 1993; Fleming, 1997). Child victims have also reported fears and expectations of harmful outcomes as reasons for delayed disclosure (Goodman-Brown et al., 2003; Hershkowitz, Lanes, & Lamb, 2007; Sas & Cunningham, 1995). Malloy, Brubacher, and Lamb (2011) found that nearly half of the alleged victims whose interviews they studied mentioned at least one expected consequence of disclosure, with children who alleged abuse by parent figures no more likely to mention expected consequences. However, children who alleged abuse by parent figures were more likely to mention expected consequences for *others* (e.g., siblings, mothers) and to mention serious consequences for themselves (e.g., physical harm, death). Clearly, these motivations and expectations may affect children's statements when they are questioned in Family or Dependency Court about their preferences and beliefs (see below).

Peer Relationships

Although parents remain important influences on child development through adolescence, children are increasingly eager to spend time with other children, and these relationships become more important with age. This can have important implications. For example, in many of the infamous daycare cases, "co-witness" information had a powerful influence on children's reports, leading many children to acquiesce to suggestions about adult misbehavior (Garven, Wood, Malpass, & Shaw, 1998). Indeed,

information from peers spread through the “rumor mill” may be reported in detail when children are asked to recount staged events (e.g., Principe, Kanaya, Ceci, & Singh, 2006), creating false beliefs that nonexperienced events occurred (Principe, Haines, Adkins, & Giuliano, 2010).

Beginning in middle childhood, children shift from using parents to using peers as primary reference sources and this trend accelerates during the period between 10 and 14 years of age. The latter period is thus marked by a sharp shift from focus on behavior that may elicit approval from parents to that which might elicit approval from peers (Nickerson & Nagle, 2005; Steinberg & Silverberg, 1986). This transition is often accompanied by anxiety and concern on the part of adolescents about their own identities and social standing (Erikson, 1968). As at other points in the life cycle, such uncertainty increases the extent to which individuals look to others for guidance and approval. The increased desire to gain social approval parallels the focal shift from parents to peers, a shift that leads children and adolescents to be particularly focused on obtaining approval from peers who, like the adolescents themselves, have much less mature and effective means of judging the appropriateness and suitability of behavior.

Adolescents are more affected than younger children or adults by peer pressure, taking more chances and making more risky decisions when in groups rather than alone (e.g., M. Gardner & Steinberg, 2005). Some choices may have minimal long-term consequences, but other choices (e.g., deciding to commit illegal acts or engage in other risky behaviors) reveal the potentially problematic nature of the susceptibility of youth to peer influence. In multiple studies examining adolescents’ self-reported false confessions to the police, the desire to protect someone else has been the most common reason reported by youth for falsely confessing (Malloy et al., 2014; Viljoen et al., 2005). Thus, not only are youth at risk for engaging in illegal behavior with peers, but they may also put themselves at risk of prosecution by covering up for others’ bad behavior and attempting to spare them the consequences.

Compliance, Obedience, and Approval Seeking

Young children are typically motivated to earn social approval from others, especially adults whom they respect or like, such as parents and teachers, and other authority figures, like police officers. As indicated above, peers become increasingly important to children and adolescents, but this tends to broaden the range of people from whom they seek to gain approval, and these motivations can powerfully affect children’s behavior when they are questioned.

For example, if children infer that interviewers would prefer particular responses, they may tailor their accounts in order to appear cooperative (Ceci, Kulkofsky, Klemfuss, Sweeney, & Bruck, 2007; Melnyk, Crossman, & Scullin, 2007). Ceci and his colleagues (2007) found, for example, that preschoolers are less likely to accept false suggestions made by 7-year-old children rather than by adults. In the forensic context, therefore, interviewers must be sensitive to children’s perceptions of their knowledge and status.

Although adolescents are often portrayed as rebellious, they are more obedient to authority than adults and this may be of particular consequence during interrogations or when considering the legal advice of parents and lawyers. Not only are there clear linear age differences in adolescents’ willingness to take responsibility for acts they have not committed, but there are similar developmental differences in the willingness to question authority (Redlich & Goodman, 2003). Thus, the majority (65%) of 12- and 13-year-olds took responsibility by signing confessions without questioning the researchers, but this tendency decreased with age (46% of the 15- and 16-year-olds and 33% of the young adults asked at least one question before signing confessions).

Suggestibility and Contamination: The Confluence of Social and Cognitive Factors

Suggestibility is “the degree to which children’s encoding, storage, retrieval, and reporting of events can be influenced by a range of social and psychological factors” (Ceci & Bruck, 1993, p. 404). Social factors, such as the interviewers’ superior status, and cognitive factors, including those relating to pretense or imagination, profoundly influence children’s suggestibility and susceptibility to misinformation (Ceci & Bruck, 2006). Initial laboratory-based research appeared to produce inconsistent findings regarding the suggestibility of young children. Goodman and her colleagues showed that children as young as 3 to 4 years of age could successfully resist misleading questions suggesting actions that were very different from those that had occurred or been witnessed (Goodman & Aman, 1990; Goodman, Aman, & Hirschman, 1987; Goodman et al., 1991; Goodman, Rudy, Bottoms, & Aman, 1990). When the suggestive pressure was more persistent, however, preschoolers appeared especially susceptible to suggestion (e.g., Ceci et al., 1987; King & Yuille, 1987). Leichtman and Ceci (1995) showed that preschoolers who were repeatedly led to believe that a person was very clumsy acquiesced more easily over a 10-week period to

allegations consistent with the clumsy stereotype than children who were given neutral information about the person. Specifically, the combination of suggestive interviewing and negative stereotyping led 30% of the 5- to 6-year-olds and 46% of the 3- to 4-year olds to agree that they had seen the person misbehave, although half of the youngest children did not acquiesce to suggestions.

Children may, under certain conditions, come to provide elaborate accounts of entire events that they never experienced (e.g., Bruck et al., 2002; Ceci, Huffman, Smith, & Loftus, 1994; Ceci, Loftus, et al., 1994; Quas et al., 2007; Strange, Garry, & Sutherland, 2003). For example, Ceci, Huffman, et al. (1994) asked 3- to 6-year-olds to repeatedly imagine experiencing fictitious events (e.g., getting their fingers caught in a mousetrap and having this injury treated). Many children later claimed to have experienced these events, and even after debriefing, some of the children refused to accept that the events were only imagined. Bruck, Hembrooke, and Ceci (1997) found that, when subjected to such techniques as repeated suggestion, instructions to imagine or pretend, and selective reinforcement in a series of interviews, preschool children assented to 95% of the false events mentioned (e.g., claiming that they witnessed the theft of food at daycare) by the third interview session.

Findings concerning suggestibility and false reporting are not limited to children, however, with several studies demonstrating that adults, too, may come to produce detailed "memories" of entirely fictitious events (see Loftus, 1997, 2003, for reviews). Nevertheless, it is clear that suggestive questioning played a major role in leading preschoolers in several multi-accuser cases to believe falsely that they had been abused. For example, Garven et al. (1998) showed that the techniques used in the McMartin Preschool case (offering positive or negative consequences for making or not making allegations of abuse, posing the same questions repeatedly, and suggesting that other children had already disclosed) led 3- to 6-year-old children to respond inaccurately when questioned about staged events. The children who were interviewed using a combination of highly suggestive techniques (e.g., repeated suggestive questions plus rewards for making allegations) produced significantly more false accusations than children who were interviewed using only one suggestive technique. In fact, after being interviewed with multiple suggestive questioning techniques for only 4.5 minutes, children acquiesced to the false accusations nearly 60% of the time, whereas those interviewed using only one suggestive technique acquiesced 17% of the

time. Garven, Wood, and Malpass (2000) later showed that children interviewed suggestively using reinforcement made false allegations about mundane events (e.g., that a man said a bad word) 35% of the time, whereas those interviewed without such reinforcement made false allegations 12% of the time. Children who were reinforced also alleged fantastic events (e.g., that a man took a child on a helicopter ride) more often than children in the control group. In Leichtman and Ceci's (1995) study, very few children who were interviewed nonsuggestively made claims about the "bad deeds" of a classroom visitor even when negative stereotypes (i.e., clumsiness) about him had been introduced beforehand.

Researchers have largely been unsuccessful in their efforts to identify reliable individual differences in suggestibility (see Bruck & Melnyk, 2004, for a review). Although this line of study may help researchers understand the mechanisms underlying suggestibility, it also signals that, rather than attempting to identify "suggestible" children, it is important to recognize that children enter the forensic interview or courtroom with different abilities and characteristics and having had different experiences. Children inevitably vary with respect to how much information they provide, how long it takes them to build rapport, how acquiescent they are to adult authority and suggestion, and how shy they appear when talking with new adults. Findings concerning individual differences underscore the need for interviewers to adhere to best practice guidelines.

Cross-examination, one of the most feared parts of legal involvement, has also been examined experimentally because it underscores children's vulnerabilities when questioned suggestively, coercively, and confusingly. In both analogue (Zajac & Hayne, 2003, 2006; Zajac, Jury, & O'Neill, 2009) as well as courtroom (Zajac & Cannan, 2009) settings, cross-examination has negative effects on the accuracy of children's testimony. Zajac and Hayne (2003) interviewed 5- and 6-year-olds about a visit to a police station using both direct and cross-examination. During the cross-examination, interviewers used several techniques often observed in actual court cases (e.g., complex, leading, irrelevant questions; challenges to children's certainty; expressions of disbelief), and most (over 85%) of the children changed at least some answers that they had provided during direct testimony. The changes occurred regardless of whether children's original responses were accurate or inaccurate. Some changes were considered small alterations in specific details, whereas others represented total retractions of children's original reports. In fact, nearly a third of the children changed all of their

original responses! In a later study, Zajac and Hayne (2006) reported that 9- to 10-year-old children changed fewer accurate than inaccurate answers, although they still changed 40% of correct answers under cross-examination, suggesting that the accuracy of older children's testimony is also compromised during cross-examination.

Cross-examination style questioning also affects the accuracy of 5- to 10-year-old children's accounts of both neutral and transgressive events (Fogliati & Bussey, 2013) and following both short (1 week) and longer (6 month) delays (O'Neill & Zajac, 2013). In comparable studies of adult witnesses, participants also made many changes to their previous statements and altered both correct and incorrect answers when cross-examined (Valentine & Maras, 2011); adults' accuracy decreased in real courtroom cross-examinations as well (Zajac & Cannan, 2009). Interestingly, however, aggressive cross-examination of young witnesses does not always achieve the desired results. Evans et al. (2009) found that convictions rather than acquittals were more likely when American defense lawyers asked more complex questions, whereas the complexity of the questions asked by prosecutors was not associated with the likelihood of conviction. Whether the same results would be obtained in other jurisdictions is unknown.

Children's changing responses can involve either changed memories or simply acquiescence—the tendency to agree when asked leading questions (e.g., Greenstock & Pipe, 1997; Pipe & Wilson, 1994). Acquiescence increases when a power imbalance exists between the person asking the questions and the person answering them (Ceci et al., 1987), and this is certainly the case when adults, especially adults in positions of authority (e.g., police officers, judges), question children. At least in the experimental laboratory, however, information suggested by interviewers is often incorporated by eyewitnesses into their memories of experienced events (Ackil & Zaragoza, 1995; Ceci & Bruck, 1993, 1995) especially when preschool children are involved (Brady, Poole, Warren & Jones, 1999; Cassel & Bjorklund, 1995; Ceci & Bruck, 1993; Ceci & Crotteau-Huffman, 1997; Leichtman & Ceci, 1995; Quas et al., 1999) and the suggestions are repeated (Mitchell & Zaragoza, 1996). In addition, Endres, Poggenpohl, and Erben (1999) and Orbach and Lamb (2001) showed that suggestive prompts led preschoolers to contradict information that they had provided earlier.

The contaminating effects of option-posing (e.g., Yes/No) and suggestive utterances are aggravated when they are repeated. That is, children contradict themselves at a

higher rate when option-posing questions are asked again (Andrews & Lamb, 2014; Bruck, Ceci, & Hembrooke, 1998) and repeated exposure to yes/no and suggestive questions reduces children's overall accuracy (Memon & Vartoukian, 1996; Poole & White, 1991, 1993, 1995; but see Lyon et al., 2008). Whereas repeated open-ended questions are often perceived as requests for additional information, suggested Poole and White (1991), repeated yes/no questions might be perceived, especially by younger children (4-year-olds), as indications that the initial responses were unacceptable and thus should be changed.

As mentioned earlier, children's sensitivity to the interviewers' status and knowledge may also foster compliance with suggestive or misleading prompts because children misunderstand the purpose of the interviewers' statements, assume that interviewers have superior knowledge, or simply want to be cooperative. As shown below, when interviewers (a) adequately prepare children for their role as experts, empower them to correct interviewers, and admit that they "don't know" some answers, (b) avoid asking children to pretend or imagine, (c) avoid being coercive, (d) do not repeat misleading questions, and (e) keep children focused on central details of personally experienced events, children are better able to resist misleading questions and provide meaningful and accurate accounts of their experiences (Pipe et al., 2004).

In addition, research indicates that awareness of suggestion, also labeled meta-suggestibility, continues during the school years. For example, in a study conducted by London, Bruck, Poole, and Melnyk (2011), 6- and 7-year-olds who had watched a filmed suggestive interview, failed to recognize its effects on a boy who made a false allegation. Awareness of suggestibility increased between 8 and 11 years of age, so that 12-year-olds understood the suggestibility process well.

Children's Deception

In forensic interviews, interrogations, and the courtroom, it is imperative that individuals provide honest reports of experienced events only, so researchers, parents, legal professionals, and fact finders have long been concerned that children might intentionally make false reports of nonexperienced events. Researchers are also interested in children's deceptive abilities because lying is a "lens through which one can examine a multitude of behaviors, including children's developing cognitive, social, and moral abilities" (Talwar & Crossman, 2012, p. 337). Like suggestibility, both cognitive and social factors influence

children's lying behavior. In fact, although parents and other adults tend to be displeased when children lie, the ability to intentionally deceive others signifies cognitive and social competence, such as advanced theory of mind, executive functioning skills, and sophisticated navigation of social situations (e.g., Evans & Lee, 2011; Talwar & Lee, 2008; Talwar, Murphy, & Lee, 2007).

The Development of Lie-Telling

Lie-telling is normative, begins early in development, and takes several different forms (see Talwar & Crossman, 2012; Talwar, Crossman, Muir, & Williams, 2011, for reviews). For example, children may tell prosocial lies, sometimes encouraged by adults, in order to avoid hurting someone's feelings. However, antisocial lies (i.e., lies told to protect oneself or for personal gain) are most relevant to the legal system. Observational and experimental studies have revealed that lie-telling emerges as early as Age 2 and increases dramatically after Age 3 alongside the development of theory of mind (Evans & Lee, 2013; Newton, Reddy, & Bull, 2000; Talwar & Lee, 2002; Wilson, Smith, & Ross, 2003; see also Hughes & Devine, Chapter 14, this *Handbook*, this volume; Carpendale & Lewis, Chapter 10, this *Handbook*, Volume 2). Typically, children's early lies are told to avoid punishment (e.g., conceal a wrongdoing), and tend to be relatively easy for others to detect (Talwar & Crossman, 2011, 2012; Talwar & Lee, 2008). Prior to the age of 6 or 7, children are not very skilled lie tellers, often revealing the deceptive nature of their statements via their nonverbal behavior or by failing to conceal their knowledge or evidence inconsistent with their lies (Talwar, Gordon, & Lee, 2007; Talwar & Lee, 2002, 2008). Older children have enough sense to clean up the incriminating "evidence" or to feign ignorance (Talwar et al., 2012) because they have developed "semantic leakage control." As children grow older, they become more sophisticated liars and are better able to demonstrate semantic leakage control; key developmental changes in lie maintenance emerge around 7 years of age (Talwar & Crossman, 2011).

The temptation resistance paradigm is commonly used to study children's lie-telling behavior. This experimental paradigm was designed to measure children's use of antisocial lies to conceal minor transgressions. A typical version of the paradigm involves guessing games during which children are asked to guess the identity of toys based solely on musical jingles; the children cannot see the toys. After multiple trials, experimenters leave the room after setting out the final toys, playing musical clips, and instructing

the children not to peek. Upon returning, the experimenters ask the children whether they peeked and then, to measure semantic leakage control, to guess the toys' identity. The children's behavior is recorded covertly.

Many studies have used the temptation resistance paradigm, with fairly consistent results. Most young children are tempted to peek, and most lie about it later. Overall, peeking rates have ranged from 50% to almost 90%, depending on the ages of the children studied. For example, Talwar, Lee, Bala, and Lindsay (2002) found that over 80% of the 3- to 7-year-olds peeked while the experimenter was gone, while around 80% lied about having peeked. Using a version of the temptation resistance paradigm modified for older children (i.e., a trivia game instead of a toy), Talwar, Gordon, et al. (2007) found that approximately half of the 6- to 11-year-olds peeked, and that the majority (93.1%) who did lied about having peeked.

Detecting Lies

If children's lies were easily identifiable by adults, then the honesty of their reports would not be of serious concern in legal contexts. However, adults detect children's deception poorly. For example, in Talwar, Lee, Bala, and Lindsay's (2006) study, adult participants watched recorded mock testimony of children who had been coached by adults to provide true or fabricated reports. Most adults rated the children as honest and truthful and did not identify truths and lies at better than chance levels. Other studies have also found that adults exhibit a "truth bias" when judging children's reports (e.g., Strömwall, Granhag, & Landström, 2007). However, evidence demonstrates that the accuracy of adults' judgments may depend on the type of lies being told. Block et al. (2012) asked adults to judge video-recorded interviews conducted with 3- and 5-year-olds making accurate reports, false reports, accurate denials, or false denials. Adult judges had the most difficulty judging children's false denials, often expressing confidence that the events had not occurred when, in fact, they had. These results suggested that adults (including investigators and fact-finders) may be particularly prone to believe children's claims that they have not been abused when they have been victimized, leaving those children inadequately protected.

Investigators and fact-finders seldom know with confidence whether children have indeed been abused as they allege (or deny) so field research on credibility assessment has been rare. However, Lamb et al. (1997) used the Criterion Based Content Analysis (CBCA) procedure developed by Raskin and Esplin (1991) to assess the testimonies

of 98 children, some of whom were determined to have been describing incidents that were improbable, while others described events for which there was strong corroborating evidence. CBCA scores differentiated between the plausible and implausible accounts, but there was considerable overlap between the scores and the technique was clearly not precise enough to be used in forensic contexts.

Lamb et al. (1997) noted that most of the testimonies included few narratives, making it difficult for raters to identify the crucial criteria. In a later study, Hershkowitz, Fisher, Lamb, and Horowitz (2007) showed that investigators assessed credibility more accurately when the children provided more narratives and the interviews had been conducted in accordance with best-practice guidelines (see below) although, as in previous studies, the raters correctly identified plausible statements much more accurately than they identified implausible ones.

Promoting Truth-Telling

Concerns about children's false allegations (i.e., accusations against innocent individuals) and false denials (i.e., nondisclosure and delayed disclosure of child maltreatment) have led researchers to attempt to develop empirically based methods to promote children's honesty in legal contexts. One particularly promising method is eliciting a promise to tell the truth, or a child-friendly version of "the oath." Lyon et al. (2008) found that administering a developmentally appropriate version of the oath ("Do you promise to tell the truth? Will you tell me any lies?") improved the honesty of 4- to 7-year-old maltreated children's reports of their play with forbidden toys. Lyon and Evans (2014) later showed that even very young children (4-year-olds) understood that "promising" to do something is stronger than saying one "might" do something. Promising to tell the truth is effective with older children as well: Evans and Lee (2010) found that 8- to 16-year-olds were 8 times more likely to change their responses about peeking at a test answer from dishonest to honest after promising to tell the truth. Eliciting a promise to tell the truth is more effective than reassuring children that they will not be in trouble for telling the truth (Lyon et al., 2008); statements of reassurance that mention specific transgressions may increase false reporting (Lyon & Dorado, 2008).

Summary

Child development is a complex and multifaceted process, as the contents of these four volumes indicate! In the

preceding pages, we have tried to show that many aspects of development affect children's interactions with the legal system. Importantly, whether the discussion is about the neural mechanisms that underlie cognitive processing, behavioral inhibition, and motivation, the ways in which children understand and remember their experiences, the changing nature of children's social relationships and understanding, their emergent communicative skills, their susceptibility to social influence, their decision making and evaluations, or their motivation to be honest or seek approval, it is clear that development is an extended process that is, in many respects, incomplete even by the time children are conventionally relabeled as young adults. The material reviewed above gives some limited insight into the developmental sequences while making clear how much has yet to be learned about each of the relevant developmental trajectories and, especially, about the interrelations among development in different domains. That ignorance notwithstanding, our collective understanding has grown dramatically over the three decades prior to the time of this writing, and we can now claim sufficient knowledge to guide developmentally sensitive practice in many legal domains.

FEATURES OF LEGAL CONTEXTS

Children, like adults, often find encounters with the legal system stressful. For child witnesses, testifying in open court (or while facing defendants) and being cross-examined are among the most distressing aspects (for a detailed review, see Spencer, 2011), and both are associated with poorer memory performance (e.g., Nathanson & Saywitz, 2003; Quas & Lench, 2007).

In one well-known field study, Goodman et al. (1992) found that children who were more fearful about testifying in front of the accused adults were less able to answer prosecutors' questions than children who were less fearful. In experimental studies, where it is possible to verify the accuracy of children's memory, children's free recall is less complete and their responses to direct questions are less accurate when they are questioned in courtrooms rather than in more familiar (e.g., classrooms) or less intimidating locations (e.g., P. E. Hill & Hill, 1987). Similarly, Saywitz and Nathanson (1993) found that children who rated the "legal process" as stressful provided less information about staged events than children who rated it as less stressful. The stress associated with testifying may interfere with retrieval by consuming some cognitive resources. For example,

children may need to devote some of their cognitive or attentional resources to coping with their emotions instead of to memory retrieval (e.g., Quas et al., 2004). The stress of legal involvement may also lead to long-term negative consequences for children and adolescents (see below).

Although testifying in court may be particularly distressing for children, forensic interviews have several potentially stressful characteristics as well. Forensic interviews represent unfamiliar contexts for children. Children, especially young children, are not accustomed to being in the role of “experts” when being questioned by adults. However, in forensic interviews, they are supposed to be the “experts” and to do most of the talking. The demand characteristics of the situation are worth noting: Children may feel that they *must* answer the questions posed to them. As noted above, however, they may be asked complexly worded questions sometimes including legal terms that they do not understand. Depending on the nature of the interview, it may be necessary for them to discuss in detail experiences about which they feel embarrassed or ashamed. They may need to make accusations against family members or other loved ones, and this may lead to feelings of guilt or distress. And, while coping with these various stressors, children must conduct challenging memory searches and recount information in a detailed and accurate manner. It is thus not surprising that children may need time to build rapport with investigative interviewers before delving into the issues at hand.

To better understand the features of the legal contexts in which young suspects perform, it is similarly imperative to look closely at the interrogation context. The “Reid Technique” (Inbau, Reid, Buckley, & Jayne, 2013), now in its 5th edition, is taught and used by interrogators around the world and is the most widely used method in the United States (e.g., Kassin et al., 2007; Leo, 1996; Meyer & Repucci, 2007). This technique involves creating a confrontational environment in which the ultimate goal is to obtain confessions. Generally, these interrogations are guilt presumptive and accusatorial, permitting such tactics as lying to suspects, presenting fictitious evidence, minimizing and justifying crimes and their consequences (e.g., providing face-saving excuses for the crimes), interrupting and disallowing denials, and asking suspects to report hypothetical details about the crimes. Some of the face-saving minimization strategies are recommended for juveniles specifically: For example, interrogators might suggest that the lack of parental supervision or the temptation to use drugs partially justified criminal behavior (Inbau et al., 2013). Such techniques are designed to make suspects feel that it is in their

best interest to confess (Ofshe & Leo, 1997) and are known to increase false reporting by children and adults in other contexts (see Loftus, 1997, 2003, for reviews).

The various components of the Reid Technique are legal in the United States, for the most part regardless of the suspects’ age, and research indicates that these techniques are commonly used. Many U.S. police officers reported presenting fictitious evidence (23%), using deception (32%), and repeating questions (58%) when interrogating juveniles (Reppucci, Meyer, & Kostelnik, 2010). Observational studies similarly showed that police officers often confronted juvenile suspects with evidence against them (54%), accused them of lying (33%), and emphasized the seriousness of the alleged crimes (14%) (Feld, 2013; see also Feld, 2006). An alarming proportion of the incarcerated male adolescents (Aged 14 to 17) questioned by Malloy et al. (2014) claimed that they had experienced threats (81%), deception (81%), and verbal insults (59%). Many youth also claimed to have experienced the use of force (21.2%) and refusals (e.g., of breaks to rest or opportunities to speak to lawyers or parents; 38.7%), almost 40% claimed to have been interrogated while under the influence of drugs or alcohol, and nearly a third (30%) reported having felt “pressured or forced” by police to confess. Unlike the observational studies of recorded interrogations, there was no way to confirm the veracity of the reports of youth in this study. However, taken together, the observational and self-report studies suggest widespread use of techniques that may exert considerable pressure on youth to confess.

These tactics can be extremely effective in obtaining confessions from juvenile suspects (see Kassin et al., 2010). For example, Michael Crowe, a 14-year-old boy who falsely confessed to murdering his sister, was told several lies by police, including that his hair was found in her hands, his blood found in her room, and that he had failed a lie detector test. Martin Tankleff, a 17-year-old student who discovered the bodies of his stabbed parents, confessed after several hours of denial. He too was presented with false evidence. Most persuasive of all was the claim that his father had awoken from his coma and identified his son as the assailant. It took almost two decades before Tankleff was released from prison.

These real-world examples are consistent with a growing body of research demonstrating how some interrogation techniques elicit confessions in the laboratory and in the field. For example, lengthy interrogations and the use of deception (e.g., the false evidence ploy) increase the incidence of false confession (see Kassin et al., 2010).

Research suggests that presenting false evidence may not be necessary; merely *bluffing* that the evidence exists appears sufficient to induce false confessions of wrongdoing (i.e., pressing a forbidden computer key, cheating) at the same rate as presenting false evidence (Perillo & Kassin, 2010). Implying or promising lenient treatment are also associated with increases in the rate of false confessions (Kassin & McNall, 1991; Russano, Meissner, Narchet, & Kassin, 2005). Some techniques (e.g., minimization, bluffing) that appear relatively benign (in comparison with threats or the use of force) may nonetheless convince people that their best option is to confess, even if those confessions are false.

As discussed above, little is known about the contexts in which youth make plea decisions, but these contexts may actually share some similarities with police interrogations. For example, youth may be pressured to make immediate decisions (e.g., accept “one-time offer” plea deals) or they may be pressured by adult authority figures such as their lawyers (e.g., Drizin & Luloff, 2007; Malloy et al., 2013; Redlich, 2010). Indeed, the contexts in which plea deals are brokered may involve more pressure or coercion than police interrogations: Police are allowed to *imply* leniency using minimization tactics, but are prohibited from *promising* leniency explicitly. In contrast, explicit promises of leniency are the basis of plea agreements; plea deals generally involve “bargaining” for a lesser sentence than what would be at stake if the defendants were convicted at trial.

IMPLICATIONS FOR INTERVIEWS WITH ALLEGED VICTIMS, WITNESSES, AND SUSPECTS

Regardless of the types of experiences being remembered or reported, the methods used to elicit children’s and adolescents’ accounts of their experiences affect both the quantity and quality of information obtained. Different types of interviewer prompts access different types of memory. For example, free-recall memory and recognition memory are often considered opposite ends of a memory continuum. Recall is accessed when prompts provide no specific memory cues: Requesting that someone “tell everything that happened” does not specify or cue particular aspects of memory. What is recalled depends on the memory search conducted by the person being questioned. In contrast, recognition memory involves more specific questions about particular event details or aspects. These questions may involve asking interviewees

to select between alternatives offered by interviewers (e.g., “Was the touch over or under your clothes?”). These multiple-choice questions restrict the possible responses and tend to increase inaccuracies because options may be chosen even if the correct responses were not offered. Wh-questions (i.e., *what*, *when*, *why*, *where*, and *how*) fall somewhere between free recall and recognition memory. They do not force respondents to choose between options provided by interviewers, and instead ask for more details about something the interviewees have already mentioned, but they nonetheless require only short answers about aspect of the events or objects that may or may not be well encoded or remembered.

When adults and children are asked to describe events with free-recall prompts (“Tell me everything that happened”), their accounts may be brief and sketchy, but, as mentioned earlier, are more likely to be accurate than if more focused or closed-ended questions prompts are used. When provided with open-ended follow-up prompts such as “Tell me more about that” or “And then what happened?,” children and adults often report additional details by accessing recall memory. When interviewers prompt with leading questions such as “Did he have a beard?,” “Did he touch you with his private?,” or “Did this happen in the day or in the night?,” they shift from recall to recognition testing, and the probability of error rises dramatically (see Lamb et al., 2008, for a review). When open-ended prompts are used, respondents attempt to provide as much relevant information as they “remember,” whereas children may have to confirm or reject information provided by interviewers when focused questions tapping recognition memory are asked. Recognition questions or prompts refocus children on domains of interest to investigators and exert greater pressure to respond, regardless of whether the respondents are sure of their responses. Recognition probes are more likely to elicit erroneous responses in eyewitness contexts because of response biases (i.e., tendencies to say “yes” or “no” without reflection) and false recognition of details that were only mentioned in previous interviews or are inferred from the gist of the experienced events (Brainerd & Reyna, 1996). Focused or recognition questions vary greatly in their complexity, however. As mentioned earlier, answers to questions about the timing of past events may be difficult (especially for children) to answer accurately. Because questions like these seem very reasonable, children often make educated guesses in response rather than recalling information from memory. By contrast, other focused questions (e.g., “What is your brother’s name?”) are easier to answer because the

requested information involves semantic general knowledge rather than memory of a specific event. Questions such as "How come he got away with it for so long?" may seem similarly reasonable but unfortunately invite speculation, and do not direct respondents to search for memories of experienced events. Some questions (e.g., "Why did he do that?") are simply impossible for children to answer even with the best of event memories and thus should be avoided.

Effective interviewers should thus maximize the reliance on recall memory by offering open-ended prompts so as to minimize the risk of eliciting erroneous information. Free-recall reports are not always accurate, of course, especially when the events occurred long before or there have been opportunities for either pre- or postevent contamination (Bruck & Ceci, 2004; Leichtman & Ceci, 1995; London, Bruck, & Melnyk, 2009; Poole & Lindsay, 1995; Quas et al., 2007; Warren & Lane, 1995) but they are likely to be considerably more accurate than reports elicited using recognition cues or prompts. Furthermore, the completeness of brief initial responses can be increased when interviewers use the information provided by respondents as prompts for further elaboration (e.g., "You said the man touched you; tell me more about that touching"; Lamb et al., 2003).

Best Practice When Interviewing Alleged Victims of Child Abuse

Child maltreatment is, at times, very difficult to investigate and substantiate. Regarding sexual abuse in particular, corroborative evidence rarely exists either because the nature of the abuse does not lend itself to physical evidence (e.g., fondling), or physical evidence has disappeared due to delayed reporting, which is quite common (Goodman-Brown et al., 2003; London et al., 2005; Pipe et al., 2007). Physical evidence may also not identify particular perpetrators. As a result, children's eyewitness testimony is often critical. Without it, it is more difficult for the goals of justice, child protection, and treatment to be met. Thus, it is imperative that children's reports are clear, detailed, and accurate. When children's accounts are vague, inconsistent, and/or incomplete, their reports tend to be met with skepticism (e.g., Leippe et al., 1992; see Myers, 1992).

Informed by the research summarized earlier in this chapter, expert professional groups have long agreed that children should be interviewed as soon as possible after the alleged offenses by interviewers who themselves introduce as little information as possible while encouraging

children to provide as much information as possible in the form of narratives elicited using open-ended prompts ("Tell me what happened"). Before substantive issues are discussed, interviewers are typically urged to explain their roles, the purpose of the interview, and the "ground rules" (for example, ask children to limit themselves to descriptions of events "that really happened" and to correct the interviewer, request explanations or clarification, and acknowledge ignorance, as necessary). Investigators are consistently instructed to give priority to open-ended recall prompts and use recognition prompts as late in the interview as possible and only when needed to elicit undisclosed forensically relevant information. The presence of props (such as toys or dolls) usually associated with fantasy (Thierry, Goh, Pipe, & Murray, 2005) and interviewers prompting children to "imagine" or "pretend" are associated with the presence of fantastic elements in children's accounts of abuse so forensic investigators are routinely advised to avoid both (Pipe & Salmon, 2009; Poole, Bruck, & Pipe, 2011).

Unfortunately, researchers have repeatedly shown that these research-based and expert-endorsed recommendations are widely proclaimed but seldom followed. Descriptive studies of forensic interviews conducted in various parts of the United States, United Kingdom, Canada, Sweden, Finland, and Israel have consistently demonstrated that forensic interviewers used open-ended prompts quite rarely, even with the knowledge that such prompts reliably elicit more information than more focused prompts (see Lamb et al., 2007, 2008, for reviews). To the distress of trainers and administrators, furthermore, such deviations from "best practice" were evident even when the interviewers had been trained extensively, were well-aware of the recommended practices, and often believed that they were adhering to those recommendations. For these reasons, a group of researchers at the U.S. National Institute of Child Health and Human Development (NICHD) developed a structured interview protocol designed to translate professional recommendations into operational guidelines (Lamb et al., 2008; Orbach et al., 2000).

Characteristics of the NICHD Investigative Interview Protocol

The NICHD Protocol covers all phases of the investigative interview (see Lamb et al., 2008; Lamb, La Rooy, Malloy, & Katz, 2011, for the entire Protocol). In the introductory phase, the interviewer introduces him- or herself, clarifies the child's task (the need to describe events in detail and to tell the truth), and explains the

ground rules and expectations (i.e., that the child can and should say "I don't remember," "I don't know," "I don't understand," or correct the interviewer when appropriate). In many jurisdictions, law enforcement agencies have also requested the inclusion of several questions designed to establish that children understand the difference between true and false statements. These questions typically ask the child to confirm or negate true or false statements (e.g., "If I said that my shoes were red, would that be true or not true?") rather than asking children to complete the developmentally inappropriate task of providing definitions for abstract concepts such as "truth" and "lie" (Lyon, 2011).

The rapport-building phase that follows the introductory phase comprises two sections. The first is designed to create a relaxed, supportive environment for children and to establish rapport between children and interviewers. In the second section, children are prompted to describe recently experienced neutral events in detail. This "episodic memory training" is designed to familiarize children with the open-ended investigative strategies and techniques used in the substantive phase while demonstrating the specific level of detail expected of them.

In a transitional part between the presubstantive and the substantive phases of the interview, a series of prompts are used to identify the target event(s) under investigation nonsuggestively and with prompts that are as open as possible. The interviewer only moves on to some carefully worded and increasingly focused prompts if the child fails to identify the target event(s). If the child makes an allegation, the free-recall phase begins with an invitation ("Tell me everything...") and other free-recall prompts or invitations are recommended as follow-up questions. As soon as the first narrative is completed, the interviewer prompts the child to indicate whether the incident occurred "one time or more than one time" and then proceeds to secure incident-specific information using follow-up ("Then what happened?") and cued (e.g., "Earlier you mentioned a [person/object/action] invitations. Tell me everything about that") making reference to details mentioned previously by the child to elicit uncontaminated free-recall accounts of the alleged incident(s).

Only after exhaustive free-recall prompting do interviewers proceed to directive questions (focused-recall questions that address details previously mentioned by the children) and request information within specific categories (e.g., time, appearance) such as "When did it happen?" or "What color was that [mentioned] car?" If important, forensically relevant details are still missing, interviewers then ask limited option-posing questions (mostly yes/no

or forced-choice questions referencing issues or details that the children failed to address previously). Suggestive utterances, which communicate the expected responses, are strongly discouraged.

Evaluation of the NICHD Investigative Interview Protocol

The findings obtained in independent field studies in four different countries (Cyr & Lamb, 2009; Lamb et al., 2009; Orbach et al., 2000; Sternberg, Lamb, Orbach, Esplin, & Mitchell, 2001) demonstrate convincingly that, when forensic investigators employ recommended interview procedures by following the structured NICHD Protocol, they enhance the quality of information elicited from alleged victims. Interviewers relying on the Protocol use at least 3 times more open-ended and approximately half as many option-posing and suggestive prompts as they do when exploring comparable incidents, involving children of the same age, without the Protocol. In each study, about half of the informative and forensically relevant details and more than 80% of the initial disclosures of sexual abuse were provided by preschoolers in response to free-recall prompts. Such findings suggest that the likely accuracy of information provided by alleged victims is enhanced when interviewers use free-recall prompts exhaustively before turning to more focused prompts. These findings also indicate that cued-invitations should be exhausted before "wh-" prompts are introduced because cued-invitations are input-free and thus foster retrieval of free-recall information without limiting responses to investigator-specified categories. Nonsuggestive yes/no and forced-choice questions (i.e., option-posing prompts), in which interviewers introduce information, should be used only if essential information is still missing after free-recall and directive prompts have been exhausted, because these riskier alternatives are more likely to elicit inaccurate information and their introduction may contaminate subsequent information.

Interviewers using the Protocol also introduce option-posing and suggestive questions later in the interview process than do peers not using the Protocol. Because option-posing and suggestive questions by definition involve the introduction of information by investigators, they have the potential to contaminate later phases of the children's reports, especially when younger children are involved (Bjorklund et al., 1998; Ceci & Bruck, 1995; Memon, Wark, Holley, Bull, & Koehnken, 1996), and thus their delayed utilization is forensically important. Clearly, forensic interviewers should provide children

with opportunities to recall information in response to open-ended prompts before assuming that special (i.e., more risky) interview techniques are needed.

When priority was given to open-ended strategies and techniques in Protocol interviews, there were also significant increases in the number of facilitators and other supportive comments addressed to child witnesses (Hershkowitz, Orbach, Lamb, Sternberg, & Horowitz, 2006); this further enhanced the recall and reporting of information by encouraging children to be more cooperative.

Children Who Are Reluctant to Make Allegations

Despite the use of evidence-based interviewing strategies, many suspected victims of child maltreatment are reluctant to allege abuse when formally interviewed in forensic contexts, even when there is clear evidence that they were, in fact, abused. Investigative interview protocols, including the NICHD Protocol, emphasize techniques that help motivated children to report information about experienced events but pay less attention to the motivational factors (such as loyalty to parents) that make some children reluctant to disclose abuse or other negative experiences. Research has yielded new insight into the dynamics of interviews with reluctant children (Hershkowitz et al., 2006; Hershkowitz, Horowitz, et al., 2007; Hershkowitz, Lamb, Katz, & Malloy, 2013; Katz et al., 2012; Orbach, Shiloach, & Lamb, 2007), however. In these studies, reluctant children avoided establishing rapport with the interviewers and signaled their reluctance verbally and nonverbally in the presubstantive phase of the interview, with manifest reluctance increasing as the interviews proceeded. In a study of interviews with children whose victimization had been independently corroborated, Hershkowitz et al. (2006) found that interviewers tended to respond to reluctance counterproductively by (a) putting pressure on reluctant children rather than giving them support, (b) shifting the discussion to sensitive issues before the children seemed comfortable, and (c) using intrusive rather than open-ended prompts when exploring the possibility that abuse might have occurred.

Recognizing the need to enhance rapport with allegedly abused children, especially those who are reluctant to talk, Hershkowitz et al. (2013, 2014) formulated a revision of the NICHD Protocol. In order to enhance trust and cooperation, rapport-building preceded (rather than followed) explanation of the ground rules and expectations, and additional guidance was provided to interviewers with respect to building and maintaining rapport. In addition to inviting narratives about recent experiences during the

rapport-building phase, interviewers were encouraged to express interest in the children's experiences, both verbally and nonverbally, and to show empathy with the children's expressed feelings. Close comparisons between interviews conducted with alleged victims using either the "standard" or "revised" Protocols showed that the enhanced focus on rapport indeed encouraged children to be more cooperative and less resistant. When 1,424 4- to 13-year-old suspected victims of intrafamilial abuse in Israel were interviewed using either the standard NICHD Investigative Interview Protocol ($n = 613$) or the revised version ($n = 811$), Hershkowitz, Lamb, and Katz (2014) reported that use of the revised protocol reduced reluctance during the interview and increased the willingness to disclose abuse, underscoring the importance of rapport when children are asked to talk about abuse, especially when family members are suspected of involvement (Hershkowitz, Horowitz, et al., 2007). As a result, significantly more children who were known to have been abused by family members made allegations when interviewed using the Revised rather than the Standard Protocol (Hershkowitz et al., 2014).

Interrogating Young Suspects

The Protocols discussed above for interviewing young victims and witnesses were designed with children's developmental strengths and limitations in mind. Clearly, children *can* be competent witnesses if they are well-interviewed by experts who understand the relevant developmental factors. Interviewed less appropriately, children may be rendered incompetent and/or incredible. Much is at stake when youth are questioned as suspects as well. Research has led to various recommendations concerning the interrogation of young suspects. However, these recommendations have yet to produce major change in the laws and procedures concerning how youth are interrogated (Owen-Kostelnik et al., 2006).

Unfortunately, the rather obvious fact that children have the same characteristics whether they are called victims or suspects has not been widely respected. In 1993, the year after the *Memorandum of Good Practice on Video Recorded Interviews with Child Witnesses for Criminal Proceedings* was published by the British Home Office, Jon Venables and Robert Thompson were arrested by the police for their role in the murder of a toddler named James Bulger. These 10-year-old youngsters would have benefited from the involvement of skilled and specially trained interviewers had they been suspected victims of abuse; instead, they were subjected to some 20 hours of

questioning by police officers who were guided more by their experiences as interviewers of adult criminals rather than by developmentally sensitive evidence documenting the special needs and circumstances of young children in forensic contexts. The Police and Criminal Evidence Act of 1984 (PACE), which served as the interviewers' guide, recognizes that British suspects under 17 should have access to a responsible "appropriate adult," whose role is to give advice, facilitate communication, and ensure that the interview is conducted properly and fairly (Home Office, 2008). Unfortunately, further guidance was not given. Compared to professional guidelines for interviewing child victims, the rubric pertaining to young suspects is thus considerably less detailed, less informed by the developmental research, and outdated in light of the considerable amount of research conducted since 1984 and summarized above.

"Appropriate adults" such as parents, relatives, and social workers infrequently intervene in ways that prevent children and adolescents from incriminating themselves (Drizin & Colgan, 2004; Medford, Gudjonsson, & Pearse, 2003; Sim & Lamb, 2013). Only the presence of lawyers is systematically associated with reductions in the likelihood that British adolescents will provide incriminating information or make admissions during questioning (Clarke, Milne, & Bull, 2011; Medford et al., 2003; Sim & Lamb, 2013). Presumably, lawyers are more aware than other appropriate persons that arrest and prosecution are typically impossible in the absence of corroborated evidence concerning the suspects' misbehavior.

Despite the developmental differences discussed earlier in this chapter, proponents of Reid-like interrogation techniques pay little or no attention to the age of suspects being interviewed. In fact, when interrogating adolescents, the Reid training manual recommends, "Apart from statutory requirements prescribed in a few states, and except for particular rules established by a few state courts...the interrogation of juvenile suspects may be conducted in essentially the same way as for adults" (Inbau et al., 2013, p. 419). As discussed above, research confirms that Reid-like techniques are used commonly with juvenile suspects in the United States (Feld, 2006; Malloy et al., 2014; Meyer & Reppucci, 2007).

In their white paper, Kassin et al. (2010) warned:

There is a strong consensus among psychologists, legal scholars, and practitioners that juveniles and individuals with cognitive impairments or psychological disorders are particularly susceptible to false confession under pressure. Yet little action

has been taken to modulate the methods by which these vulnerable groups are questioned when placed into custody as crime suspects. (p. 30)

As Kassin et al. (2010) recommended, individuals who conduct interviews and interrogations with juveniles should receive special training concerning the risks associated with youthful age (as well as the risks associated with other vulnerabilities such as mental retardation and mental illness). Ideally, this training would cover the relevant aspects of developmental psychology and interview strategies and structure discussed earlier in this chapter.

Even the authors of the Reid training manual have started recognizing that juveniles (and others with intellectual vulnerabilities) are at increased risk for false confession. Accordingly, more recent versions of the manual (Inbau, Reid, Buckley, & Jayne, 2001, 2013) recommend taking some precautions when interrogating juvenile suspects. In discussing the presentation of fictitious evidence, for example, they note,

This technique should be avoided when interrogating a youthful suspect with low social maturity or a suspect with diminished mental capacity.... These suspects may not have the fortitude or confidence to challenge such evidence and, depending on the nature of the crime, may become confused as to their own possible involvement. (Inbau et al., 2013, p. 255)

They recommended that adolescents' "level of social responsibility" and "general maturity" be given consideration before police use the fictitious evidence technique. However, researchers have not established whether police interrogators can accurately judge adolescents' social maturity or social responsibility, especially as these terms have not been clearly defined.

Researchers interested in reforming interrogation procedures for youth have also tested alternative interrogation techniques. In one study, 9- to 14-year-olds suspected of committing sexual offenses were interviewed using a modified version of the NICHD Protocol (Hershkowitz, Horowitz, Lamb, Orbach, & Sternberg, 2004). Young suspects who partially or fully admitted their offenses reported absolutely and proportionally more details in response to invitations as opposed to suggestive prompts, confirming that, like alleged victims, youthful suspects can provide considerable amounts of forensically relevant information in response to open-ended prompts, even when they minimize their own involvement and culpability. However, interviewers behaved differently when addressing alleged

suspects as opposed to victims, providing suspects with proportionally fewer invitations and proportionally more intrusive (e.g., suggestive) prompts. The study underscored the fact that the suspects were children, and that they should be interviewed sensitively, with consideration for their developing cognitive and interpersonal skills and limitations.

Such findings are important because of their relevance to false confessions, and their far more serious and surprisingly common counterpart, coerced confessions (Drizin & Colgan, 2004). As mentioned earlier, juveniles are more likely than older suspects both to confess (Redlich, Silverman, Chen, & Steiner, 2004) and to confess falsely (Drizin & Leo, 2004). These differences are especially significant considering the crucial role that confessions play in the criminal justice system. Confessions may establish a confirmatory bias that leads investigators to discount possibly exculpatory evidence while evaluating the available evidence (e.g., C. Hill, Memon, & McGeorge, 2008; Kassin, Bogart, & Kerner, 2012; Kassin, Goldstein, & Savitsky, 2003; Narchet, Meissner, & Russano, 2011; Snook, Luther, Quinlan, & Milne, 2012). Indeed, suspects who have provided confessions are treated differently at every subsequent stage of the criminal process (Leo, 1996).

Not only are the interviewing techniques drastically different for young victims/witnesses and suspects, but the evaluations and assumptions that fact finders and investigators make about youth may also vary considerably depending on their legal role. As Malloy and Lamb (2010) have observed, different assumptions seem to be made about the capabilities and credibility of young victims, witnesses, and suspects, especially when one considers the contrasting ways in which fact finders and investigators view inconsistencies in the testimonies of alleged offenders and victims. When victims change their testimony, either by adding additional embellishments to their accounts or by recanting allegations they have made, considerable skepticism ensues, and there is substantial evidence that courts often fail to convict when principal victim-witnesses significantly alter their accounts (Myers, 1992; Quas et al., 2005). By contrast, when suspects change their accounts, especially when they claim to have confessed falsely, this tends to have very little effect on fact finders, who instead tend to regard such recantations as tactical changes that do not undermine the probative value of the initial confessions. Malloy and Lamb (2010) proposed that fact finders and investigators must be similarly cautious when considering changes in any forensic statements, particularly when the individuals involved are children or adolescents

whose developmental characteristics may affect the quality, reliability, and trustworthiness of the statements they are believed to have provided.

Post-Adjudication Issues With Respect to Young Offenders

Looking beyond the interrogation context, developmental differences also need to be considered when focusing on the possibility for rehabilitation. Importantly, the majority of youth who engage in delinquent behavior in adolescence (as many do, for reasons explained earlier in this chapter) are most likely not to engage in further misbehavior as they grow older (Moffitt & Caspi, 2001; Moffitt, Caspi, Harrington, & Milne, 2002; Odgers et al., 2008). Because of this, it is extremely important not to punish young offenders in ways that increase the likelihood that they may embrace lives of crime. For example, it makes little sense to punish offenders by placing them in custodial circumstances where they may encounter and learn from others who are criminally inclined. Similarly, it is important not to stigmatize or label youth in ways that limit their ability to resume more conventional law-abiding behavioral trajectories as they grow older. One of the best predictors of further criminality on the part of young offenders is educational attainment (Blomberg, Bales, & Piquero, 2011; Katsiyannis, Ryan, Zhang, & Spann, 2008), and thus any forms of punishment that restrict the ability of youngsters to complete their education and training can significantly and destructively impede their chances to become productive members of society in the future. This is a matter of particular concern in those jurisdictions, especially but not only in the United States, where young offenders are increasingly treated as adults and may find themselves spending part or all of their incarceration in adult prisons where there are fewer opportunities for education and training in preparation for their return to the civilian world.

Although, as Steinberg (2009) noted, sensitivity to developmental issues is not a panacea, decision making can and should be informed by the lessons learned by developmental psychologists. The U.S. Supreme Court's decision to abolish the death penalty for adolescents is illustrative. In *Roper v. Simmons* (2005), the Supreme Court ruled that the execution of offenders for crimes committed at the age of 16 or 17 constituted cruel and unusual punishment in violation of the Eighth Amendment to the Constitution. In prior decisions, the death penalty had already been deemed unsuitable for those under 15 in *Thompson v. Oklahoma*

(1988), but left standing for 16- and 17-year-olds in *Stanford v. Kentucky* (1989). The court's decision in *Roper v. Simmons* was based on evidence mitigating adolescent culpability as a result of developmental status summarized in an amicus curiae brief (American Medical Association et al., 2004) submitted by a coalition of academic professional bodies. Reviewing some of the information presented in this chapter and in that by Cauffman et al. (see Cauffman, Shulman, Bechtold, & Steinberg, Chapter 16, this *Handbook*, Volume 4), the brief argued that "Older adolescents behave differently than adults because their minds operate differently, their emotions are more volatile, and their brains are anatomically immature" (p. 4), and thus that "Executing adolescents does not serve the recognized purposes of the death penalty" (p. 21). One such purpose is to deter future crime. However, research has shown that punitive policies (e.g., transfer to adult criminal court) are not only costly to taxpayers (Greenwood, 2006) but also fail to deter future criminal activity (Bishop & Frazier, 2000; Singer & McDowall, 1988; see Fagan, 2008 for review) and jeopardizes the safety, mental health, and future prospects of many juveniles (e.g., Bishop & Frazier, 2000; Cauffman, Lexcen, Goldweber, Shulman, & Grisso, 2007; Cesaroni & Peterson-Badali, 2005; see Fagan, 2008).

Although the past 20 years have seen a rapid development of effective and developmentally oriented interventions, most services provided in the juvenile justice system have not been evaluated or shown to be effective. In their critical review, Henggeler and Schoenwald (2011) concluded that common practices (including residential placement) designed to reduce recidivism are often ineffective (Drake, Aos, & Miller, 2009; Howell, 2003; Lipsey, 2009). Similarly, a meta-analysis of controlled studies (Petrosino, Turpin-Petrosino, & Guckenborg, 2010) showed that processing through the juvenile system seemed to increase rather than decrease criminal behavior. Transferring youth to adult criminal court, which is supposed to have an additional deterrent effect, further increased criminal behavior (Redding, 2010; but see Bechtold & Cauffman, 2014). These conclusions are especially alarming because of the high economic costs of such ineffective services. Resources could have been used for therapeutic and educational services instead.

Juvenile Sex Offenders

Juvenile sex offenders represent one of the few remaining populations for whom long-term institutional care is accepted on a routine basis and for whom public

registration or notification and community management practices apply (Chaffin, 2009). Such approaches were founded on misperceptions and unproven assumptions drawn from theories about adult pedophilia and apparently do not promote either youth rehabilitation or child protection (Chaffin, 2009). Many children and youth are likely to be harmed needlessly by the failure to adopt evidence-based policies and practices.

Placing youth on public registries not only causes permanent stigmatization but can also lead to social exclusion and marginalization as registered individuals are expelled from educational institutions and have difficulty finding employment. These youth are often referred to separate treatment programs operated by professionals trained to treat sex offenders, even when they have unrelated problems such as learning difficulties. Treatment components are routinely borrowed from programs for adult pedophiles, even though they may be irrelevant and counterproductive. For example, a meta-analysis of intervention effectiveness conducted by St. Amand, Bard, and Silovsky (2008) showed that focus on the treatment of misconduct (e.g., by strengthening the behavior management skills of parents or caregivers) was beneficial for juvenile sex offenders whereas elements specific to sex-offending were counterproductive (see also Borduin & Dopp, 2012).

A growing body of data shows that children who display sexually intrusive behaviors, similar to adolescent sex offenders, are unlikely to commit sex crimes later (Alexander, 1999; Caldwell, 2002; Carpentier, Silovsky, & Chaffin, 2006), often improving without treatment (Silovsky, Niec, Bard, & Hecht, 2007), and that effective treatment reduces the display of inappropriate sexual behavior (Carpentier et al., 2006), sometimes to the same level as in groups of nonoffending children with other developmental disorders. Contrary to mistaken beliefs attributable to the confusion between prospective and retrospective data (for many adult pedophiles, sexually aggressive behavior began in childhood or adolescence but very few sexually offending children and adolescents continue misbehaving in adulthood), sexually aggressive behavior is neither compulsive nor addictive and tends not to persist, especially in the face of effective treatment.

IMPLICATIONS OF DEVELOPMENTAL SCIENCE FOR FAMILY AND DEPENDENCY COURT

Developmental considerations are relevant not only when considering children involved in the criminal justice

system; they affect children caught up in family and dependency courts processes as well.

Developmental Considerations in Dependency Court

Although many factors affect children's adjustment, both family break-up and maltreatment can profoundly affect children's cognitive, socioemotional, and even physical development. These effects may be long-lasting: Child maltreatment is a major risk factor for short- and long-term adjustment problems, including adult psychopathology (see Cicchetti and Toth, Chapter 13, this *Handbook*, this volume). Early identification of maltreatment is critical for ending victimization, protecting children, and providing children, families, and perpetrators with appropriate services and treatment while also allowing offenders to be punished when appropriate. Early identification is clearly facilitated by attention to the recommendations made in this chapter.

Many children are removed from home due to substantiated child abuse or neglect during their first few years of life. These interventions are designed to protect children from further maltreatment and allow time for intervention and assessment of the suitability of family reunification or permanent alternative placement. Research shows that intensive interventions can successfully address problems in some families (improving parenting skills and parent-child relationships), obviating the need for prolonged foster care placements or adoption (Bernard et al., 2012; Cicchetti, Rogosch, & Toth, 2006; Kirk & Griffith, 2004). Of course, even short-term separations can adversely affect child-parent attachments and it is important to recognize that most abused children are attached to their parents, even if those attachments are insecure or disorganized (e.g., Lamb et al., 1985; Lyons-Ruth, Bronfman, & Parsons, 1999). Furthermore, children placed in foster or adoptive homes need to establish new relationships and often face repeated disruption as they are moved between foster homes despite stated commitments to stability and permanence (Bernard et al., 2012).

As discussed above, the formation and maintenance of attachment relationships during these early years is critical for optimal development. Consequently, developmentally sensitive intervention strategies have been devised to help very young, vulnerable children in both foster/adoptive and birth families. As Dozier et al. (2013) state, "Foster care for children younger than about 5

should be considered as an intervention that is fundamentally different from that for older children" (p. 4). Two intervention strategies that have received empirical support are worth noting in this regard: Attachment and Biobehavioral Catch-Up (ABC) and the New Orleans Intervention.

The ABC approach was designed to improve caregivers' responses to their children, specifically increasing both birth and foster parents' synchronous and nurturing responses and decreasing their threatening or intrusive responses. In the course of 10 home visits, parents learn how to modify their behaviors via coaching, feedback on video-recorded interactions, and live commentary on their "real-time" interactions with their children. Several studies have examined the ABC intervention in families involved in the child welfare system. Randomized clinical trials have shown that this intervention improves parents' behaviors toward their children, making them more "synchronous" (i.e., appearing to follow children's leads in the interactions). Furthermore, there are lower rates of disorganized attachment following intervention (see Dozier et al., 2013, for a review). This relatively brief intervention (10 sessions) holds promise for producing positive outcomes following adverse experiences in early life.

The New Orleans Intervention is another "attachment-based" intervention strategy aimed at children who experience maltreatment in the first few years of life (Zeanah et al., 2001). It is a large-scale "systems" intervention that involves coordination among multiple service providers. Mental health components are integrated into foster care and child protective services as multidisciplinary teams strive to enhance children's relationships with caregivers by focusing on synchrony, nurturance, stability, and commitment. Depending on the individual circumstances, the New Orleans Intervention may target biological parents, foster parents, and childcare providers. Families who participated in the New Orleans Intervention were at reduced risk for having children placed in foster care later (Zeanah et al., 2001).

Unfortunately, interventions such as these are exceptional rather than normative, with the majority of abused children and their families receiving inadequate interventions, and most alternative placements both unstable and unsatisfactory. Unsurprisingly, outcomes for children who have been in care tend to be extremely poor and long-lasting (e.g., Oosterman, Schuengel, Slot, Bullens, & Doreleijers, 2007; Racusin, Maerlender, Sengupta, Isquith, & Straus, 2005).

Developmental Considerations in Family Court

Although divorce and parental separation clearly affect more children than child maltreatment, the effects tend to be less dramatic. On average, children benefit from being raised in two-parent families rather than separated, divorced, or never-married single-parent households (see Amato & Doriis, 2010, for a review), although there is considerable variability within groups, and the mean differences (in psychosocial adjustment, behavior and achievement at school, educational attainment, employment trajectories, income generation, involvement in antisocial and even criminal behavior, and the ability to establish and maintain intimate relationships) between groups are relatively small (Lamb, 2012). Approximately 25% of the children in postseparation and divorced families give evidence of adjustment problems, compared to 12%–15% in two-parent families. Thus, the majority of children from separated families evince no psychopathology or behavioral symptoms, although they are likely to experience psychic pain for at least some period of time (Hetherington & Kelly, 2002). The crucial individual differences in children's adjustment are accounted for by economic stresses, declines in the quality of parent–child relationships, and conflict between parents or between parents and their intimates (see reviews by Carlson & McLanahan, 2010; Fabricius, Braver, Diaz, & Velez, 2010; Lamb, 2012; Marsiglio & Hinojosa, 2010).

When parents separate, there is considerable evidence that postdivorce arrangements should specifically seek to maximize positive and meaningful paternal involvement rather than simply allow minimal levels of visitation. As in nondivorced families, in other words, the quality of continued relationships with both parents is crucial (Lamb & Kelly, 2009; Warshak, 2014). Stated differently and succinctly, the better (richer, deeper, and more secure) the parent–child relationships, the better the children's adjustment, whether or not the parents live together. More involved parents are also more likely to provide financially for their children whether or not they live together most of the time.

Unfortunately, legal decision-makers do not always appear to understand what sort of interaction is needed to consolidate and maintain parent–child relationships and attachment bonds. As a result, their decisions seldom ensure either sufficient amounts of time or adequate distributions of that time for children and parents. Traditional "visiting guidelines" in many jurisdictions assign every other weekend to the nonresident parent (with perhaps a

brief midweek visit), and mental health professionals often rely on unsubstantiated beliefs that every other weekend is best for children because it ensures that children continue to have only one "real home."

These plans have left much to be desired for many families, and have caused great dissatisfaction and sense of loss to the majority of children in postdivorce arrangements (Fabricius et al., 2010). Research on children's and young adults' retrospective views of their postdivorce living arrangements indicates that the majority express strong wishes and longing for more time with their fathers, a desire for more closeness, and favorable views of shared physical custody arrangements (see Fabricius et al., 2010). Even young children should regularly spend overnight periods with both parents when both have been involved in their care prior to separation (Lamb & Kelly, 2009; Pruitt, Insabella, & Gustafson, 2005; Warshak, 2014).

To facilitate children's adjustment to their parents' separation, many jurisdictions have introduced education programs that explain to separating parents the effects of divorce on children, the impact of parent conflict, the particular risk when parents use their children to express their anger and disagreement, the need to separate children's needs from adult needs, parenting skills, and often provide skill-based training to minimize conflict and promote more effective communication. At least in the short term, these courses appear to be effective (e.g., Arbuthnot & Gordon, 1996; Bacon & McKenzie, 2004; D. Ellis & Anderson, 2003; Pedro-Carroll, Nakhnikian, & Montes, 2001), particularly when the content is empirically based and includes skill-based training and role-play exercises. More extensive research-based parent education programs appear to bring about meaningful behavioral changes in both mothers and fathers (for reviews, see Braver, Griffin, Cookston, Sandler, & Williams, 2005; Haine, Sandler, Wolchik, Tein, & Dawson-McClure, 2003). Parents should also talk to their children about those aspects of the separation and divorce that directly affect them, though this seldom happens (Dunn, Davies, O'Connor, & Sturgess, 2001; Smart, 2002; Smart & Neale, 2000), leaving children to cope with major and hard-to-understand changes in their lives without emotional support.

Especially in the United States, many divorcing couples make use of custody evaluations, conducted by mental health professionals who advise the court on postdivorce parenting arrangements most likely to advance the best interests of the children involved, whether or not they are "fair" to the parents. Custody evaluators should be familiar with and guided by the empirical literature regarding

attachment, child development, parent-child relationships, parental separation, and children's adjustment and attend to individual circumstances as well as the parents' and children's strengths, schedules, and needs (Kelly, 2005, 2007; Kuehnle & Drozd, 2012; Smyth & Chisholm, 2006). There is some controversy about the extent to which they do so (Tippins & Wittman, 2005), however, with Emery and his colleagues (Emery, Otto, & O'Donohue, 2005) severely criticizing widespread practices. To date, there has been little research on the value of custody evaluations.

Cashmore and Parkinson (2009) have articulated the view that children have the right to participate in legal processes destined to affect them, although they recognize, as Fidler, Bala, and Saini (2013) make clear, that children's expressed views should not be determinative and that there are some circumstances in which it may be preferable not to involve children in decision making. Exactly how children's voices should be heard varies depending on their ages, characteristics, and circumstances, with various options (including legal representation, and informal or formal interviewing by judges or mental health professionals) discussed by Fidler et al. (2013). In many cases, a mental health professional or custody evaluator interviews affected children and considers their preferences and best interests, which are conveyed in reports prepared for the court.

As noted earlier, conflict between parents is reliably associated with the increased likelihood of maladjustment on the part of the children involved, whether or not the parents live together and whether or not they are separating (Amato & Doriis, 2010; P. T. Davies, Martin, & Cicchetti, 2012; Kelly, 2004). Not surprisingly, therefore, considerable attention has been paid by researchers to interventions that might minimize children's exposure to harmful levels of conflict. Research shows that custody and divorce mediation can have substantial short-term (e.g., earlier settlement of parenting disputes, reduced parental conflict, improved parental support) and longer-term (e.g., more sustained contact between nonresident fathers and children 12 years later) benefits for the families involved (Emery, Laumann-Billings, Waldron, Sbarra, & Dillon, 2001; Kelly, 2004). On a more mundane level, it is important to ensure that exchanges between the homes take place in neutral settings and at times that limit contact between the parents (Flory, Dunn, Berg-Weger, & Milstead, 2001).

Postdivorce, parenting coordinators are also increasingly used in the United States to address the needs of children when there is very high conflict between the parents by helping parents settle disputes regarding their

children in a timely manner, while facilitating compliance with parenting plans and related court orders (*Family Court Review*, 2001; Kelly, 2010). Surveys show that parent coordinators can be very effective, especially in reducing the frequency and intensity of disputes (Coates, Deutsch, Starnes, Sullivan, & Sydlik, 2004), although to date there has been no systematic research on their impact. Of course, there are some situations in which at least one of the parents is incapable of providing parental support of adequate quality or in which the levels of conflict or violence are so high and so intractable as to preclude regular contact between children and their parents, but these families appear to be rare (Kelly, 2012). More research is needed on the adjustment of children in these families, and on techniques that might promote their well-being.

Summary

Children involved with the Family and Dependency/Juvenile Courts have developmental and situational needs that need to be recognized and accommodated by the professionals with whom they interact. In addition to the possible sequelae of stressful experiences, such as maltreatment or their parents' separation, many children and youth must also grapple with concerns about competing loyalties to their parents in the context of continuing levels of dependency and emotional vulnerability. Mental health professionals have developed some techniques to minimize the adverse effects and increase the chances that parent-child relationships can be enhanced, but their use is exceptional, rather than normative. In Dependency Court settings, the focus is often on obviating the risk of future abuse, regardless of the possible effects on children's relationships with their parents and other family members, whereas in Family Court, the tendency to focus on the needs of the litigating parents often obscures focus on the children's best interests. In both contexts, insufficient attention is paid to developmental differences in the children's preferences or understanding of the proceedings and their possible outcomes.

CONCLUSION AND SUGGESTIONS FOR FUTURE RESEARCH

In this chapter, we have shown how children's development in a variety of domains profoundly affects their participation in the legal system, regardless of the specific

roles—as victims, as offenders, as witnesses, and as affected parties—they are called upon to play. Despite the best efforts of researchers, especially psychologists, to focus their attention narrowly on specific aspects of psychological function (attention, memory, language, emotion, social understanding, logic and reasoning), children (like adults) are coherent holistic entities whose behavior and performance are constrained, made possible, and guided by capacities and limitations in a varied array of interrelated dimensions or facets. Accordingly, we used the first portion of this chapter to describe the relevant developments in each of the domains known to affect children's performance in legal contexts and then showed both how these intersecting developmental trajectories affect behavior in legal contexts and how recognition of these factors can be used to maximize children's participation while ensuring that legal processes yield outcomes that are most likely to address children's interests and needs. This collective intellectual exercise is very much a work in progress, with considerably more research needed to flesh out the implications of developments delineated in experimental contexts and to document their implications for children in diverse legal contexts, not simply in specific domains. Equally clear is the fact that different questions have provoked different amounts of attention from scholars and researchers. Our review is not exhaustive, though we have attempted to provide a broad overview and to discuss the available evidence concerning several central topics.

The vast majority of research and theorizing in relation to children and the law has focused on the testimonial capacities and weaknesses of victimized children—especially young children—as witnesses, with considerable research also focused on the less obvious weaknesses and characteristics of youth who have allegedly committed offenses. There has been substantially less research on children whose living arrangements are determined by legal proceedings, either because their parents have separated or because their parenting skills and motivation have been unacceptably poor, even though many more children fall into the latter categories than into the former. Many of the children affected by parental separation are adversely affected, but there have been relatively few studies in which children in such circumstances have been followed over time to allow examination of the factors accounting for individual differences in adjustment. Accordingly, we have made the case both that there is a serious need for sophisticated research on children in these civil law (family and dependency court) circumstances, and that many of the same developmental considerations that affect the

performance of young witnesses describing their victimization also warrant consideration when considering the testimony and culpability of juvenile offenders, or the preferences and well-being of children whose long-term considerations are being decided by professionals in the legal system, many of whom have had little training in or understanding of child development.

There are, of course, some differences between the different legal contexts and the different roles played by children, and it would behoove future researchers to explore some of these differences in depth. In the criminal law context, for example, young victims or offenders may be asked to describe in detail specific experienced events, but they may be motivated to emphasize or minimize certain types of details, and explanations or justifications may be more important in one context than in another. In other legal contexts, however, the focus is not on specific incidents but on patterns of behavior over time (quality of parenting, neglectful behavior) and expectations of future behavior. It is very likely (though the issue has yet to receive any substantial attention) that different techniques and questions would be needed both to elicit these different types of information and to evaluate it. For example, by definition, neglectful behavior involves acts of omission, so children's accounts of neglectful parental behavior should be elicited using different techniques than their accounts of acts of commission (e.g., physical or sexual abuse).

Certainly, children's behavior in legal contexts is affected by motivational factors associated with the nature of their relationships, especially with the adults involved. Thus, for example, researchers know that young victims often fail to, delay, recant, or minimize reports and accusations of abuse by those they love or on whom they are dependent, and these findings underscore the need for considerably more research on the extent to which affective and motivational factors influence the extent to which children encode, recall, or recount details about their experiences. Although some research illustrates the role of motivation in affecting the performance of young victim-witnesses, for example, very little is known about the psychological mechanisms, especially as they pertain not simply to recounting, but to the other psychological processes (e.g., encoding, forgetting) involved. In the civil law domain, furthermore, studies have documented the value of well-designed interventions promoting beneficial relationships between birth, foster, or adoptive parents and their children, but there is still very little methodologically sound research on the relative psychological costs of maltreatment, estrangement (e.g., from one parent), legally

enforced separations (e.g., during temporary placement in foster care), or repeated transitions (e.g., from one foster family to another) on the well-being of children at different developmental stages and of differing dispositions. Indeed, research on individual differences is extremely rare in the literature on children and the law, with the few relevant findings either weak or inconsistent. Thus there is a clear need to conduct more intensive and systematic research on individual differences in the future.

INTRODUCTION

In this chapter, we provide an overview of historical issues accompanying the study of child maltreatment and address advances, as well as challenges that have emerged over decades of research in this area. We infuse a developmental psychopathology perspective into our understanding of the sequelae of maltreatment. Specifically, we highlight the importance of utilizing a multilevel perspective when examining aspects of socioemotional, cognitive,

psychophysiological, neurobiological, and genetic functioning. Employing a developmental lens, we discuss: affect differentiation and emotion regulation, emotion recognition, attachment, the development of an autonomous self, peer relationships, adaptation to school, memory, and personality organization and psychopathology. We also present findings on gene \times environment interaction (G \times E), allostatic load, neuroendocrine functioning, physical health outcomes, and neurobiological development. Studies elucidating resilience despite caregiving adversity also are presented. The importance of better understanding maltreatment in the context of racial and ethnic differences, as well as possible differential outcomes associated with maltreatment subtype and gender, are highlighted. We then address methodological issues in maltreatment research

and the translation of research into prevention, intervention, and social policy arenas. We conclude by turning our attention to the next generation of work in this area, highlighting new approaches to research that are likely to advance the field's understanding of child maltreatment and its effects across the life course, as well as recommending strategies for fostering advances and addressing challenges that have and will continue to accompany the investigation of this enormous societal problem.

Child maltreatment represents a pathogenic relational environment that confers significant risk for maladaptation across both psychological and biological domains of development. Importantly, the deleterious sequelae accompanying child maltreatment not only result in adverse consequences during childhood, but also often initiate a negative developmental cascade that continues throughout the life course (Masten & Cicchetti, 2010). The proximal environment involving the nuclear family, as well as more distal factors associated with the community and culture more broadly, transact to undermine normal biological and psychological developmental processes in children who have experienced maltreatment (Cicchetti & Toth, 2006a). Childhood maltreatment has been associated with increased internalizing and externalizing problems, suggesting that etiological pathways exist between these symptoms and a number of psychiatric disorders (Keyes et al., 2012). In a meta-analytic examination of 16 epidemiological studies with over 23,000 participants, childhood maltreatment was associated with an elevated risk of experiencing recurrent and persistent depressive episodes (Nanni, Uher, & Danese, 2012). A further meta-analysis of 10 clinical trials with over 3,000 participants found that childhood maltreatment was also related to lack of response to treatment or lack of remission of depression during treatment (Nanni et al., 2012).

The public health implications of the adverse effects accompanying child maltreatment are enormous. According to the Center for Disease Control (Fang, Brown, Florence, & Mercy, 2012), 1 year of confirmed cases of child maltreatment (including cases of physical, sexual, and verbal abuse and neglect) costs \$124 billion over the life span of the abused children. Information garnered from the Adverse Childhood Experiences (ACE) Study (Anda, Dube, & Giles, 2006), one of the largest and arguably most important public health studies in the United States, indicates that childhood trauma, including maltreatment, is associated with an extraordinary number of adult health risk behaviors, including psychosocial and substance abuse problems. Importantly, individuals with elevated ACEs

are also at increased risk for diseases, including diabetes, immunological and cardiovascular problems, and early morbidity. Perhaps most strikingly, the ACE findings demonstrate that childhood trauma is not a rare occurrence, with over two thirds of the adults surveyed in this middle-income population having experienced one or more types of adverse childhood experiences and with 87% having experienced two or more types of trauma. Thus, the magnitude of the effects of childhood maltreatment and the toll it exerts on society cannot be understated.

Over the years, the sophistication of research conducted on this significant societal problem has increased substantially. Although early studies were fraught with methodological limitations, current approaches are empirically rigorous and both intervention and social policy initiatives are increasingly informed by the results of empirical studies (Toth & Cicchetti, 2006). We begin our discussion of the consequences of child maltreatment by addressing aspects related to the definition of child abuse and neglect, a fundamental issue that must be grappled with if this area of research and practice is to continue to move forward.

DEFINITIONAL CONSIDERATIONS

Perhaps one of the most important advances in understanding child maltreatment was related to refining the approach to defining child maltreatment. In order to be able to compare findings across laboratories and effectively communicate research results more broadly to both clinicians and policy makers, systematized definitions of maltreatment are essential. Historically, problems in agreeing upon an operational definition of maltreatment arose due to a lack of consensus about what constitutes acceptable versus inappropriate parenting, uncertainty about whether to define maltreatment based on caregiver actions, child outcome, or a combination of the two, controversy over whether criteria of harm or endangerment should be utilized, and disagreements about whether similar definitions were applicable to scientific, legal, and clinical purposes.

One of the most comprehensive and sustained efforts to understand the magnitude of the problem of child abuse and neglect in the United States emanated from the National Incidence Study (NIS), a congressionally mandated effort initiated in 1974 in response to the requirements of the Child Abuse Prevention and Treatment Act. Initially, data were collected beginning in 1979. The NIS includes not only children reported to Child Protective Services (CPS), but also those who were screened out by CPS without an

investigation. Thus, NIS estimates are based on a nationally representative sample that includes both maltreated children designated as such by CPS and those identified by the community who were not officially designated as maltreated.

NIS-4, the most recent survey, was conducted in 2005 and 2006 (Sedlak et al., 2010). According to NIS classifications, maltreatment includes both abuse (physical, sexual, and emotional) and neglect (physical, emotional, educational). Standardized NIS definitions describe both acts of commission and omission for each subtype. In addition, a number of additional features such as the child's relationship to the perpetrator, the severity of the harm, and the amount of evidence existing about the perpetrator are recorded. NIS definitional standards include the Harm Standard, which is the more stringent definition requiring demonstrable harm to the child, and the Endangerment Standard, which includes children who are endangered but not yet harmed. NIS-4 reports an overall decrease in the incidence of maltreatment since NIS-3, with a 19% decrease according to the Harm Standard. When accounting for the growth in the child population during this time period, this equated to a 26% decline in maltreatment. Statistically reliable changes were not apparent in the incidence of children who experienced maltreatment according to the Endangerment Standard. Importantly, NIS-4 documents that maltreatment is also associated with a number of co-occurring risk factors, including parental unemployment, low socioeconomic status, and race. With respect to race, a higher incidence of maltreatment was observed for African American children. Because socioeconomic status and race are often highly correlated, it is difficult to disentangle the relative contributions that each of these factors may make to the increased rate of maltreatment. NIS-4 was the first U.S. survey to detect racial differences in rates of maltreatment (we will discuss this later in the chapter).

It is important to note that maltreatment is a global problem. In 2000, the National Society for the Prevention of Cruelty to Children (NSPCC) published groundbreaking information on the prevalence and impact of child maltreatment in the United Kingdom. A subsequent report by the NSPCC that included a random probability sample of parents, children, and young adults found similar rates of neglect but found that rates of severe child maltreatment were lower in 2009 than in 1998, suggesting a similar decline in the prevalence of maltreatment as was found in the United States (Radford et al., 2011). Despite this decline, a substantial number of children continued to experience severe maltreatment, with 5.9% of children

under 11 years and 18.6% of those aged 11–17 years experiencing severe maltreatment. All forms of abuse during childhood were associated with worse mental health outcomes and elevated delinquent behavior. According to the NSPCC, maltreatment is defined as

All forms of physical and/or emotional ill-treatment, sexual abuse, neglect or negligent treatment, or commercial or other exploitation, resulting in actual or potential harm to the child's health, survival, development or dignity in the context of a relationship of responsibility, trust, or power. (Butchart, Putney, Furniss, & Kahane, 2006, p. 9)

Determination of the incidence of maltreatment is intertwined with reporting procedures and definitions utilized and, thus, the extent of documented maltreatment varies considerably across Europe and is also related to societal norms and values (Daro, 2006). Compared to incidence rates reported in the NSPCC survey, a World Health Organization prevalence study of maltreatment in Romanian families found that 24% of adolescents aged 13–14 years had experienced physical abuse, 9% had experienced sexual abuse, and 46% had experienced physical neglect (Browne, 2002). In general, between 7% and 36% of women and 3% and 29% of men internationally have experienced sexual abuse, with rates remaining constant for almost two decades (Finkelhor, 1994; Pereda, Guilera, Forns, & Gómez-Benito, 2009).

Despite an emerging consensus regarding classification of maltreatment subtypes (Manly, 2005), some divergence remains in the field regarding how best to ascertain the presence of maltreatment. Although some advocate for reliance on information obtained from officially documented reports of maltreatment (Manly, 2005), other investigators argue that caregiver and child reports are preferable because reliance on officially documented cases may result in only the most severe forms of maltreatment being captured. Ideally, a multipronged approach to defining maltreatment is preferable, including systematic coding of documented reports, access to information obtained in medical records, and interview information from caregivers and children. One system for coding official records examined in the aforementioned study, the MCS (Barnett, Manly, & Cicchetti, 1993) captures not only subtypes of maltreatment, but also dimensions such as severity, frequency/chronicity, perpetrator(s), and developmental period(s) during which maltreatment occurred. The MCS has been used in more than 50 research laboratories in both the United States and Europe and has demonstrated excellent reliability and validity. In order to obtain

supplementary information, the Maternal Maltreatment Classification Interview (MMCI; Cicchetti, Toth, & Manly, 2003) also can be administered to caregivers. Other widely utilized measures for assessing childhood maltreatment include the Childhood Experience of Care & Abuse instrument (Bifulco, Brown, & Harris, 1994) and the Childhood Trauma Questionnaire (Bernstein & Fink, 1998).

Despite advances related to improved definitions of child maltreatment, far too many investigations fail to utilize validated classification systems or to provide comprehensive information on the maltreatment experience. Issues related to the perpetrator of maltreatment, chronicity and severity of maltreatment, and when in the developmental period maltreatment occurred frequently are not considered. The ascertainment of a comprehensive portrayal of maltreatment becomes even more difficult in retrospective investigations that rely on the recall of maltreated individuals. Moreover, societal mores and attitudes toward corporal punishment vary considerably across cultures and further complicate estimates on the incidence and prevalence of child maltreatment. These issues can contribute to widely discrepant conclusions across investigations and warrant increased attention in future studies (Baker, 2009; Barnett et al., 1993).

In addition to arriving at a consensus on how child maltreatment is defined, considerations regarding conceptualization of the etiology of child maltreatment are of paramount importance in investigations of maltreatment.

ETIOLOGICAL MODELS OF CHILD MALTREATMENT

In discussing the etiology of child maltreatment, it is important to recognize that most forms of maltreatment are part of a pattern of maladaptive behavior that emerges over time. Early views on the development of maltreatment emerged from a “main effects” perspective, in which it was thought that single risk factors such as parental psychopathology, poverty, or a parental history of maltreatment could provide an etiological account of the occurrence of child maltreatment (Cicchetti & Rizley, 1981). These unidimensional views on the etiology of child maltreatment soon gave way to more complex causal models, as it became clear that no single risk factor or set of risk factors would explain the development of maltreatment (Belsky, 1980; Cicchetti & Rizley, 1981).

Applying Bronfenbrenner’s (1979) theory of human development, the etiological model proposed by Belsky (1980) initiated dramatic changes in the conceptualization

of child maltreatment, as it necessitated the consideration of the broader environment in which maltreatment occurs. According to Belsky (1980), child maltreatment is a social-psychological phenomenon that cannot be understood in isolation from the community and the culture within which the family and the individual are embedded. As such, his model contains four levels of analysis: the *macrosystem*, including the cultural beliefs and values that contribute to and influence child maltreatment; the *exosystem*, including aspects of the community that contribute to the incidence of maltreatment; the *microsystem*, including factors within the family that contribute to the occurrence of maltreatment; and *ontogenetic* development, including factors within the individual that are associated with being a perpetrator of maltreatment. Given that proximity to the individual increases with each subsequent level of the ecology (from the macrosystem to the ontogenetic context), Belsky (1980) further highlighted that risk factors at ecological levels that are closer to the individual exert a more direct influence on an individual’s development. Moreover, interactions exist between and among all levels of the ecology, contributing to and influencing the occurrence of child maltreatment.

Cicchetti and Rizley (1981), drawing on the work of Sameroff and Chandler (1975), introduced additional elements to the etiological model of maltreatment by proposing a transactional model. This model focused on the reciprocal interactions of the environment, the caregiver, and the child, which together contribute to the outcomes of child development. An important distinction was made between two classes of risk factors: those that are *potentiating*, thereby increasing the risk for maltreatment, and those that are *compensatory*, which decrease the risk for maltreatment. Additionally, a temporal dimension was added to distinguish between risk factors that are *transient* versus those that are *enduring*. By combining these categorical and temporal dimensions of risk factors, Cicchetti and Rizley (1981) proposed four classes of determinants for the occurrence of child maltreatment:

1. *Enduring vulnerability factors* include all relatively long-lasting factors, conditions, or attributes that serve to potentiate maltreatment. These may involve parental, child, or environmental characteristics. Vulnerability factors may be biological in nature, historical (e.g., a parent with a history of being maltreated), psychological, and sociological.
2. *Transient challengers* include short-term conditions and stresses such as loss (of status, a job, or a loved one),

physical injury or illness, legal difficulties, marital or family problems, discipline problems with children, and the emergence of a child into a new and more difficult developmental period.

3. *Enduring protective factors* include relatively permanent conditions that decrease the risk of maltreatment. Examples of likely protective factors include a parent's history of good parenting and a secure quality of intimate relationship between the parent figures.
4. *Transient buffers* include factors that may protect a family from stress, such as sudden improvement in financial conditions, periods of marital harmony, and a child's transition out of a difficult developmental period.

It is the transactions among ecological levels that result in potentiating and compensatory factors and in mechanisms for the precursors and sequelae of child maltreatment. The Cicchetti and Rizley (1981) model conceptualized the risk for child maltreatment as probabilistic, proposing that the likelihood of maltreatment occurring is determined by the balance among risk and protective factors and processes. Overall, the balance of potentiating and compensatory factors that are present in the various ecological levels is thought to determine in a probabilistic fashion the absence or presence of child maltreatment.

Integrating the etiological models of Belsky (1980) and of Cicchetti and Rizley (1981), Cicchetti and Lynch (1993) proposed the ecological-transactional model of child maltreatment. By incorporating the ideas of the average expectable environment (Cicchetti & Lynch, 1995) and probabilistic epigenesis (Gottlieb, 1992) into a broad integrative framework, this model explains how processes at each level of the ecology exert reciprocal influences on each other and shape the course of child development (Cicchetti & Lynch, 1993). As such, potentiating and compensatory risk factors associated with maltreatment are present at each level of the ecology and can influence processes in the surrounding environmental levels. These dynamic transactions, which operate both horizontally and vertically throughout the levels of ecology, determine the amount of risk for maltreatment that an individual faces at any given time. The levels of ecology most proximal to the child have the most direct impact on child development relative to the more distally located macrosystem. Although characterized by an overall pattern in which risk factors outweigh protective factors, there are infinite permutations of these risk variables across and within each level of the ecology, providing multiple pathways (known as equifinality) to the occurrence of maltreatment.

It is important to consider that factors that increase or decrease the likelihood of risk during one period of children's development may not do so during other developmental periods. Moreover, the temporal dimension of potentiating and compensatory risk factors is not static. Risk factors that are enduring can become transient and vice versa. For example, potentiators that originally are associated with relatively transient factors, such as initial unemployment, can become enduring when they persist over time, as in the case of chronic unemployment. Risk factors that had acted as potentiators can also be associated later on with compensatory risk factors. Perhaps the successful handling of a challenge can result in the development of new compensatory factors. For example, children who are able to survive the direct and indirect challenges presented by such potentiating factors as child maltreatment, poverty, and community violence develop inner characteristics that later are able to function as compensatory factors. The reverse is also possible. A compensatory risk factor could become a potentiating risk factor for maladaptation. Behaviors that are positive at one developmental period, such as a young child's dependence on a caregiver for support, might become counterproductive if continued into late adolescence, when more autonomy is expected.

Ultimately, it is the child's own ontogenetic processes, as manifested by the particular developmental pathway that individuals engage in, that culminate in eventual adaptation or maladaptation. The challenges or supports presented to children by the family, community, and society contribute to these ontogenetic processes; however, children also play an active role in their organismic development as they respond to these influences and engage in the resolution of stage-salient developmental issues. In the case of child maltreatment, one could imagine how the increased presence of enduring vulnerability factors and transient challenges associated with maltreatment at each level of ecology contributes to unsuccessful resolution of stage-salient developmental issues, setting the child on a pathway to maladaptive developmental outcomes and psychopathology (Cicchetti & Toth, 2006a). The ecological-transactional model of Cicchetti and Lynch (1993) may also aid in providing an account for resilient outcomes. The presence of enduring protective factors may approximate features of the average expectable environment, thus allowing some children to display successful adaptation in the face of maltreatment (Cicchetti, 2013).

We next turn our attention toward the effects of child maltreatment, with a particular focus on the developmental processes involved.

SEQUELAE OF CHILD MALTREATMENT

Empirical research on the developmental sequelae of child maltreatment has been conducted for the past half century. Studies of the consequences of maltreatment are very important for enhancing the quality of clinical, legal, and policy-making decisions for maltreated children. Decisions concerning such issues as whether to report a child as maltreated, whether to remove a child from the home, how to develop interventions to meet the specific psychological needs of maltreated children, and how to evaluate the efficacy and the effectiveness of these interventions all necessitate a solid and sophisticated database on the developmental sequelae of child maltreatment. As Aber and Cicchetti (1984) cautioned, “without rigor in design and method . . . myth will be put forward in place of knowledge as a guide to social action” (pp. 196–197).

Child abuse and neglect represent a severe dysfunction in parenting, as well as a substantial disturbance in parent-child relationships that may result in serious child maladaptation and aberrant development across the life span (Belsky & Jaffee, 2006). In fact, child maltreatment may constitute the greatest failure of the caregiving environment to provide opportunities for normal development (Cicchetti & Lynch, 1995). Moreover, maltreatment experiences may provide serious challenges to the species-typical organism–environment “coactions” that play important roles in the emergence and timing of normal developmental change.

The most important early study of the developmental consequences of child abuse and neglect is also the most controversial. Previously, none of the studies investigating the effects of child abuse and neglect had employed a matched comparison group; however, Elmer (1977) studied abused children matched on age, race, gender, and socioeconomic status (SES) to a group of children who had experienced accidents but were not abused. The abused children and the accident children initially were studied when they were approximately 12 months of age. These children were followed up again eight years later. Additionally, Elmer (1977) added a nontrauma comparison group of children at the follow-up assessment.

The major findings of the study were the absence of group differences in health history, intellectual status in school, language development, and self-concept. Despite the maltreatment classification, measurement, conceptual, and sampling flaws in the study (see Aber & Cicchetti, 1984), Elmer concluded that membership in the low-SES may have as profound an impact as abuse on child

development. Elmer’s conclusion placed the issue of what constitutes “developmental risk” in a stark sociopolitical light. It was essential that future investigations transcend the scientific flaws of Elmer’s study (see Aber & Cicchetti, 1984).

Developmental scientists took up the challenge during the 1980s and began conducting investigations of the sequelae of child maltreatment (see, e.g., Cicchetti & Carlson, 1989; Egeland & Sroufe, 1981; Lamb, Gaensbauer, Malkin, & Schultz, 1985). Consistent with the tenets of the field of developmental psychopathology, these investigators believed that it was possible to learn more about an individual’s normal functioning by studying its pathology and, likewise, more about its pathology by studying its normal conditions (Cicchetti, 1984; Cicchetti & Toth, 2009; Sroufe & Rutter, 1984). It was thought that theorizing about development without considering deviations that might be expected from the prominent and wide-ranging intra- and extraorganismic disturbances, as well as the transactions that occur among them, would eventuate in incomplete and ambiguous accounts of developmental processes. Methodologically rigorous examinations of the consequences of child maltreatment, in comparison to comparable groups of nonmaltreated children drawn from low-SES environments and informed by developmental theory and research, provided researchers with an excellent opportunity to test the veridicality of Elmer’s (1977) conclusions and to uncover potential developmental deviations, as well as the ecological disturbances associated with them. These initial developmentally informed and well-designed investigations, as well as decades of subsequent sound research, unquestionably demonstrate that the deleterious effects of child maltreatment transcend those of poverty (Cicchetti & Toth, 2005).

The study of maltreated children can make numerous contributions to the processes underlying normal development—primarily through contributing precision to developmental theory, affirming it, challenging it, and impelling theoreticians and researchers to examine extant developmental theories more critically in relation to knowledge about maladaptation, psychopathology, and resilience. Conversely, before one is capable of grasping deviances that exist in a developing system, one must also possess an accurate description of the system itself. In order to comprehend how abnormalities are transmitted from one developmental level to another, one must know how the normal transitions from one level of functioning to another are accomplished. Only when one understands the total ongoing development of normal systems can

one comprehend developmental deviations as adaptational irregularities of those systems (Cicchetti, 1984, 1993; Sameroff, 1983; von Bertalanffy, 1968).

Through investigations of the effects of severe environmental disturbances such as child abuse and neglect, researchers may be able to gain insight into processes that normally are so subtle and gradual that they are not observed. For example, by examining the development of children who have not experienced a benign rearing environment, such as is the case with children who have been maltreated, researchers may be able to elucidate the impact that the quality of caregiving can exert on neurobiological structure and function (Belsky & de Haan, 2011; Cicchetti, 2002a, 2002b).

Research on child maltreatment also informs, and can be informed by, the significant functions of normal parenting (Belsky & Vondra, 1989; Rogosch, Cicchetti, Shields, & Toth, 1995). The specific acts of omission and commission that define child maltreatment are salient features of maltreated children's microsystems. It is in this immediate context of deviant parenting that maltreated children's atypical development takes shape. Close analysis of the maltreating caregiving environment and its links with poor developmental outcomes can shed light on the protective processes associated with appropriate parenting.

Investigations of the determinants of resilient functioning in maltreated children also can provide information about the multiple possible pathways of development. Despite having different specific experiences, many maltreated children exhibit similar failures in the stage-salient tasks of development (i.e., "equifinality"). On the other hand, not all maltreated children are equally affected by their experiences (i.e., "multifinality") with some achieving resilient outcomes and the rest exhibiting maladaptive development (Cicchetti, 2013). Investigations of maltreated children's development and struggles with adaptation can teach researchers about the range and variability of individual response to challenge and adversity. Instances of maltreated children succeeding at particular developmental tasks or who otherwise achieve resilient adaptation can teach researchers about the self-righting properties inherent to development despite poor-quality care (Sameroff & Chandler, 1975; Waddington, 1957). On the other hand, findings that reveal the relative rarity with which maltreated children display resilient outcomes highlight some of the real constraints on children's self-righting abilities.

Although a comprehensive review of the sequelae of child maltreatment is not addressed in the present chapter, we cover developmental issues that forebode later

maladaptation in the absence of efficacious evidence-based intervention. Moreover, although some investigations reveal negative sequelae associated with specific subtypes of maltreatment, it is extremely difficult to disentangle specific effects of maltreatment by subtype given their frequent overlapping occurrence. As investigations continue to refine definitions of dimensions of maltreatment, it will be increasingly possible to ascertain if there are any sequelae that are more likely to be associated with a specific subtype of maltreatment.

THE ORGANIZATIONAL PERSPECTIVE ON DEVELOPMENT

Much research conducted on the effects of child abuse and neglect is guided by the ecological-transactional model and an organizational perspective on development, a powerful theoretical framework for conceptualizing the intricacies of a life-span approach to risk and resilience, as well as to normal development (Cicchetti, 1989; Cicchetti & Toth, 1995, 1998; Sroufe, 1997; Sroufe & Rutter, 1984). The organizational perspective focuses on the quality of integration both within and between the biological and psychological systems of the individual. Moreover, the organizational perspective addresses how development occurs, specifically identifying a progression of qualitative reorganizations within and among the biological and psychological systems that proceed through differentiation and subsequent hierarchical integration (Werner & Kaplan, 1963). In accord with the organizational perspective, development is not viewed as consisting of a series of tasks that need to be accomplished and that subsequently decrease in importance. Rather, development is conceived as comprising a number of age- and stage-relevant tasks. Although the salience of these tasks may wane in relation to newly emerging issues, the tasks remain important to adaptation over time (Cicchetti, 1993). A hierarchical picture of adaptation emerges in which the successful resolution of an early stage-salient issue increases the probability of subsequent successful adjustment (Sroufe & Rutter, 1984). As each new stage-salient issue comes to the fore, opportunities for growth and consolidation, as well as challenges associated with new vulnerabilities, arise. These tasks include the development of emotion regulation, the formation of attachment relationships, the development of an autonomous self, the formation of effective peer relationships, and successful adaptation to school. To our knowledge, little research has been conducted

on the stage-salient issues of adolescence and emerging adulthood in child maltreatment, such as psychological autonomy, forming close relationships within and across gender, and deriving a cohesive sense of self-identity (Cicchetti & Rogosch, 2002; Masten & Coatsworth, 1998). These issues deserve future research attention.

Despite the fact that more distal historical factors and current influences are important to the process of development, individual choice and self-organization have increasingly been viewed as exerting critical influences on development (Cicchetti & Rogosch, 1997; Cicchetti & Tucker, 1994). Across the developmental course, the evolving capacities of individuals and their active choices allow for new aspects of experience, both internal (e.g., genetic/biological) and external, to be coordinated in increasingly complex ways. Moreover, not only because biological factors can influence psychological processes, but also because social and psychological experiences exert actions on the brain by feeding back on it to modify gene expression and brain structure, function, and organization (Cicchetti & Tucker, 1994; Eisenberg, 1995; Kandel, 1998; Szyf & Bick, 2013), developmental plasticity can be brought about by both biological and psychological self-organization (Cicchetti, 2002a; Cicchetti & Tucker, 1994). Thus, for example, the fact that most maltreated children evidence at least some self-righting tendencies in the face of extreme adversity attests to the strong biological and psychological strivings toward resilience that virtually all humans and living organisms possess (Cicchetti & Curtis, 2006; Cicchetti & Rogosch, 1997; Waddington, 1957). In contrast, the absence of such resilient self-strivings in some maltreated children attests to the deleterious and pernicious impact that traumatic experiences can exert on core biological and psychological developmental processes. We next address the effects of maltreatment on stage-salient issues.

Affect Differentiation and Emotion Regulation

An early stage-salient issue in infancy involves the ability to differentiate and regulate emotions. Conceptualized as the monitoring, evaluating, and modifying of emotional reactions for the purpose of achieving individual goals, emotion regulation optimizes one's adaptive engagement with the environment (Thompson, Lewis, & Calkins, 2008). Cicchetti, Ackerman, and Izard (1995) argued that emotion regulation is critical both in initiating, motivating, and organizing adaptive behavior, and in preventing stressful levels of negative emotions and maladaptive behavior.

Emotion regulation is a developmentally acquired process that emerges from increasing differentiation and hierarchical integration of biological and psychological systems. Emotion regulation evolves as a function of both intrinsic features and extrinsic socioemotional experiences within the context of early parent-child interactions (Cicchetti, Ganiban, & Barnett, 1991). At the biological level, important intraorganismic factors for the development of emotion regulation include individual differences in genotypic variation, organizational changes in central nervous system structure and function, cerebral hemispheric lateralization, and the development of neurotransmitter systems. Extraorganismically, children's emotional experiences, expressiveness, and arousal are influenced by caregivers' response to and tolerance of affect (Sroufe, 1996). Parents' socialization of affect displays during early interpersonal exchanges serves as the model through which aspects of emotional regulation may be learned (Hesse & Cicchetti, 1982; Thompson et al., 2008).

Child maltreatment represents a significant threat to the optimal development of affective processing abilities. Given the severe disturbances in the average expectable environment provided by maltreating families, considerable evidence has mounted to demonstrate the detrimental effects of aspects of maltreatment on children's emotional development and regulation. Specifically, maltreated children have shown deviations in emotion expression, recognition, communications, and understanding (Cicchetti & Ng, 2014). Moreover, in accord with the organizational perspective, adequate emotion regulation serves as a foundation for the development of secure attachment relationships, an autonomous and coherent self-system, and effective relationships with peers, whereas early affect-regulatory failures increase the probability that a child will develop future insecure disorganized attachment relationships, self-system impairments, and peer difficulties (Cicchetti & Valentino, 2006).

Divergence in maltreated children's emotional expression has been noted as early as 3 months of age, where severely physically abused infants have evinced increased rates of fearfulness, anger, and sadness during mother-infant interactions (Gaensbauer, Mrazek, & Harmon, 1981). The expression of fear and anger among physically abused infants at 3 months of age is a particularly salient finding considering that the normative ontogenetic development of these affects does not typically occur until approximately 7 to 9 months of age (Sroufe, 1996). In contrast, neglected infants have been shown to display an attenuated range of emotional expression and an increased

duration of negative affect as compared to nonmaltreated infants (Gaensbauer et al., 1981). Thus, excessive amounts of negative affect or blunted patterns of affect have been observed in maltreated infants long before they occur in normal development.

It is likely that early malevolent care accelerates the development of negative affect circuitry in the brains of maltreated infants. This may be accomplished by excessive synaptic pruning of the positive affect neurobiological circuits as a result of inadequate or insufficient early positive experiences by abused babies. The accelerated development of negative affect circuitry may lay the groundwork for the "negativity bias" (Ayoub et al., 2006) manifested by abused children in behavioral and psychophysiological studies of attention to facial expressions and in studies of social information processing (Pollak, 2005; Teisl & Cicchetti, 2008). Thus, maltreated children may already be at risk for developing differential emotion regulation developmental pathways by 3 months of life.

The early maladaptive processing of stimuli that contributes to affective regulatory problems may lay the foundation for future difficulties in modulating affect. Corroboration for the prediction, emanating from the organizational perspective, that maltreated children are at increased risk for evidencing a developmental progression from affect-regulatory problems to behavioral dysregulation has been obtained in a number of cross-sectional investigations. Maltreated toddlers have been shown to react to peer distress with poorly regulated and situationally inappropriate affect and behavior, including anger, fear, and aggression, as opposed to the more normatively expected response of empathy and concern (Main & George, 1985). Likewise, maltreated preschool and school-age children have been found to exhibit a range of dysregulated behaviors that are frequently characterized by disruptive and aggressive situations. In addition, physically abused preschool boys who witnessed an angry simulated interaction directed at their mothers evinced greater aggressiveness and more coping directed toward the alleviation of maternal distress than did nonabused boys (Cummings, Hennessy, Rabideau, & Cicchetti, 1994).

Shields, Cicchetti, and Ryan (1994) have shown in an observational study that maltreated children are deficient in affective and behavioral regulation, and that this attenuated self-regulation mediates the negative effects of maltreatment on children's social competence with peers. In accord with an organizational perspective, although affective and behavioral self-regulatory processes were interrelated, each appeared to represent a distinct

developmental system that differentially and individually affects children's competence. Finally, in an investigation of 4- to 6-year-old children, approximately 80% of maltreated preschoolers exhibited patterns of emotion dysregulation (i.e., undercontrolled/ambivalent and overcontrolled/unresponsive types) in response to witnessing interadult anger, compared to only 37% of the nonmaltreated comparison children. Undercontrolled/ambivalent emotion regulation patterns were associated with maternal reports of child behavior problems and were found to mediate the link between maltreatment and children's symptoms of anxiety or depression (Maughan & Cicchetti, 2002). Findings such as these support a sensitization model whereby repeated exposure to anger and familial violence results in greater emotional reactivity.

During the school-age years, children continue to develop emotion regulation skills as they encounter increasing socialization demands from peers as well as from family. In an investigation conducted in the context of a research summer day camp, Shields and Cicchetti (1998) examined the interplay among emotion, attention, and aggression in a sample of school-age maltreated and nonmaltreated children. A central focus of this investigation was to examine processes underlying maltreatment's deleterious effects on behavioral and emotional dysregulation.

Shields and Cicchetti (1998) found that maltreated children were more verbally and physically assaultive than were the nonmaltreated comparison children, with physical abuse placing children at heightened risk for aggression. Maltreated children also were more likely than comparison children to exhibit the distractibility, overactivity, and poor concentration characteristic of children who experience deficits in attention modulation. Physically and sexually abused children also displayed attention disturbances suggestive of subclinical or nonpathological dissociation, including daydreaming, blank stares, and confusion. Deficits in emotion regulation also were evident, in that maltreated children were less likely than comparison children to show adaptive regulation and more likely to display emotional lability/negativity and contextually inappropriate emotion expressions. Such pervasive deficits in maltreated children's regulatory capacities are cause for special concern, as the ability to modulate behavior, attention, and emotion underlie children's adaptive functioning in a number of key domains, including self-development, academic achievement, and interpersonal relationships (Cicchetti, 1989, 1991; Shonk & Cicchetti, 2001).

Shields and Cicchetti (1998) also demonstrated that impaired capacities for attention modulation contribute to

emotion dysregulation in maltreated children. Specifically, attention deficits mediated maltreatment's effects on emotional lability/negativity, inappropriate affect, and attenuated emotion regulation. Attention processes that suggest subclinical or nonpathological dissociation also contributed to maltreated children's deficits in emotion regulation. Thus, abuse seems to potentiate disruptions in attention that result in both a relative detachment from and unawareness of one's surroundings, as well as in hyperattention and hyperreactivity to the social surround (Pollak & Tolley-Schell, 2003; Rieder & Cicchetti, 1989). Together, these deficits appear to compromise maltreated children's ability to regulate behavior and affect in social settings.

In another investigation, Shields and Cicchetti (2001) examined children who were maltreated by their caregivers in order to ascertain whether these children would be more likely to bully others and to be at increased risk for victimization by peers than would nonmaltreated comparison children. An additional focus was to investigate emotion's role in bullying and victimization among maltreated children. Maltreated children were found to be more likely than nonmaltreated children to bully other children. Bullying was especially prevalent among abused children who experienced maltreating acts of commission (physical or sexual abuse). Maltreatment also placed children at risk for victimization by peers. As expected, both bullies and victims evidenced problems with emotion regulation. Furthermore, logistic regression analyses suggested that emotion dysregulation made a unique contribution to differentiating bullies and victims from children who did not evince bully or victim problems. Additionally, maltreatment's effects on children's risks for bullying and victimization were mediated by emotion dysregulation.

In a short-term longitudinal study, Kim and Cicchetti (2010) found that children who are more adept at regulating negative emotions show higher social competence in peer interactions and higher peer competence, resulting in lower levels of internalizing symptomatology. In contrast, poor emotion regulation is a significant predictor of both maladaptive social functioning, such as peer rejection and internalizing symptomatology. Furthermore, Kim-Spoon, Cicchetti, and Rogosch (2013) investigated the longitudinal contributions of emotion regulation and emotion lability-negativity to internalizing symptomatology. A sample of more than 300 maltreated ($N = 171$) and nonmaltreated ($N = 151$) children were followed from Age 7 to 10 years. For both maltreated and nonmaltreated children, emotion regulation was a mediator between emotion lability-negativity and internalizing symptomatology,

whereas emotion lability-negativity did not mediate the relation between emotion regulation and externalizing symptomatology. Early maltreatment was associated with high emotional lability-negativity (Age 7) that contributed to poor emotion regulation (Age 8), which in turn was predictive of increases in internalizing symptomatology (from Age 8 to 9).

These findings suggest that emotion regulation and emotion lability-negativity may be important factors in identifying distinct pathways to child psychopathology. Specifically, low emotion lability-negativity and adaptive emotion regulation appear to play protective roles in the development of internalizing symptomatology. The findings also suggest that emotion regulation is an important mediational process between emotion lability-negativity and internalizing symptomatology. Therefore, to alter emotional processes that are related to the subsequent development of internalizing symptomatology, a focus on improving emotion regulation skills in children is likely to be an effective strategy that can impede the progression of internalizing problems. The results also imply that emotion regulation can be targeted to reduce the deleterious effects of emotion lability-negativity heightened by early maltreatment experiences, thus preventing internalizing symptomatology.

In a particularly important mega-analytic study designed to examine the effects of family violence on children's behavioral problems, Sternberg and colleagues (Sternberg, Baradaran, Abbott, Lamb, & Guterman, 2006) found that children who experienced multiple forms of family violence were at heightened risk for behavior problems compared with those who experienced only a single type of violence. Regardless of type of abuse, age, or gender, more children had behavior problems in the nonclinical than in the clinical range. This was the case even for children who were abused and also witnessed family violence, where only 28%–50% of the children in any group had clinically significant behavior problems. These results highlight the remarkable resilience that can be present, even in the context of extreme family adversity.

Emotion Recognition

To examine the affective input that maltreated children receive, Camras and colleagues (1988, 1990) conducted a series of investigations of maternal facial expressions. When asked to deliberately produce facial expressions, maltreating mothers' demonstrations of emotion faces were less easily identified by observers than were the expression

of nonmaltreating mothers (Camras et al., 1988). During mother-child interactions, maltreating mothers differed from nonmaltreating mothers with regard to the expression of sadness (Camras et al., 1990). Taken together, the emotion displays of abused and neglected infants highlights the centrality of interactions with caregivers in shaping the development of affect expression or differentiation. Moreover, maternal emotional expression ability contributes to their children's ability to recognize facial expression of emotions (Camras et al., 1988).

Difficulties in mentally representing and processing social information have also been noted in children with histories of maltreatment. Children who have been neglected have difficulty discriminating emotional expressions, whereas physically abused children demonstrate a response bias to angry emotional expressions (Pollak, Cicchetti, Hornung, & Reed, 2000). Pollak et al. (2000) hypothesized that physically abused preschool children would demonstrate an increased sensitivity to anger-related cues, perhaps also resulting in decreased attention to other emotional cues. The results of their study revealed that, when physically abused children were exposed to a perceptual scaling task, they perceived angry faces as highly salient and more distinctive than other emotion categories (Pollak et al., 2000). Additionally, when asked to match facial expressions to an emotional situation, physically abused children showed a response bias for anger such that, when they were uncertain which facial expression to choose, they showed a lower threshold for selecting anger. Pollak and Sinha (2002) further demonstrated that physically abused children required less sensory input than did comparison children in order to accurately identify facial displays of anger. Pollak and Sinha (2002) utilized a gradual evolution of images depicting facial expressions of various emotions. Physically abused children detected angry emotions at lower steps of the sequence but did not exhibit increased sensitivity for the other facial displays. The authors concluded that physically abused children have facilitated access to representations of anger. Similarly, in a task in which pairs of photographs of emotional expressions were morphed into each other (Pollak & Kistler 2002), physically abused children detected anger with lower signal strength than did controls. In combination, these studies suggest that physically abused children can detect facial expressions of anger more accurately and at lower levels of perceptual intensity than other emotions.

In an investigation of the attentional mechanism underlying the finding that physically abused children overattend

to angry experiences, Pollak and Tolley-Schell (2003) found that children who had experienced physical abuse demonstrated delayed disengagement when angry faces served as invalid cues and exhibited increased attention to valid angry trials. These results suggest that early adverse experiences influence maltreated children's selective attention to threat-related signals.

In addition, Pollak, Vardi, Putzer-Bechner, and Curtin (2005) examined the effects of early child physical abuse on 4-year-old children's regulation of attention in the presence of interpersonal hostility. Pollak et al. (2005) measured abused children's reactions to the unfolding of a realistic interpersonal emotional situation through multiple methods, including autonomic nervous system changes (i.e., heart rate, skin conductance level) and overt behavioral performance on an attention task. Although the physically abused and nonabused comparison children did not differ in terms of their baseline levels of arousal, marked differences emerged in physically abused children's regulatory responses to background anger. The findings suggest that children with physical abuse histories exhibit anticipatory monitoring of the environment in response to the emergence of anger. Relatedly, Pollak, Messner, Kistler, and Cohn (2009) presented abused children with arrays of stimuli that depicted the unfolding of facial expressions, from neutrality to peak emotions. These investigators found that abused children were able to recognize anger early in the formation of the facial expression, when few physiological cues were available. The speed of children's recognition was associated with the degree of self-reported anger/hostility by the child's parent. Thus, these findings highlight the ways in which perceptual learning can shape the timing of emotion perception.

Perlman, Kalish, and Pollak (2008) conducted an investigation of emotion understanding in maltreated and nonmaltreated children. To assess how well children understood the antecedents of emotional reactions in others, children were presented with a variety of emotional situations that varied in outcome and equivocality. Children were told the emotional outcomes and asked to rate whether a situation was a likely cause of such an outcome. The investigators tested the effects of maltreatment experience on children's ability to map emotion to their eliciting events and their understanding of emotion-situation pairings. Nonmaltreated children were able to distinguish between common elicitors of positive and negative events, whereas children who developed within maltreating contexts interpreted positive, negative, and equivocal events as being equally plausible causes of sadness and anger.

Maltreated children are exposed to an atypical emotional environment, characterized by less positive emotion (Bugental, Blue, & Lewis, 1990) and more negative emotion (Herrenkohl, Herrenkohl, Egolf, & Wu, 1991) in comparison to that expressed in nonmaltreating homes. Among maltreating families, physically abusive parents are more negative than neglecting parents and engage in higher rates of aggression directed toward their children. Neglected children experience an impoverished emotional environment, marked by infrequent affective exchanges with their caregivers (Crittenden, 1981). Ultimately, it is believed that these aberrant emotional experiences eventuate in neuropathological connections that undermine effective emotion-regulation capabilities.

Shackman et al. (2010) evaluated the quality of facial and vocal emotional expressions in abusive and nonabusive mothers and assessed whether mothers' emotional expression quality was related to their children's cognitive processing of emotion and behavioral problems. Relative to nonabusive mothers, abusive mothers produced less prototypical angry facial expressions, and less prototypical angry, happy, and sad vocal expressions. In addition, children's cognitive processing of their mothers' angry faces was related to the quality of mothers' facial expressions. The finding that abusive mothers' expressions of anger were characterized by less intensity and arousal may lead to their children interpreting these expressions of anger as hard to predict and more difficult to interpret (Shackman et al., 2010). Accordingly, abused children's exposure to poorer quality emotional signals may deprive them of an important source of information about the meaning of emotional expressions.

Psychophysiological studies also provide evidence that maltreated children allocate more attentional resources to the detection of anger (Pollak, Klorman, Thatcher, & Cicchetti, 2001). In particular, measurement of cognitive event-related brain potentials (ERP) indicates that school-age maltreated children display larger P3b amplitude when their attention is directed toward angry, as opposed to happy, targets (Pollak et al., 2001; Pollak & Tolley-Schell, 2003; Shackman, Shackman, & Pollak, 2007). Moreover, this pattern of response appears to be specific to anger, rather than to negative emotions in general (Pollak et al., 2001). Similar findings indicate that maltreated infants exhibit brain-based abnormalities in the processing of facial affect as early as 15 months of age (Curtis & Cicchetti, 2013). Together, these results suggest more efficient cognitive organization and processing of anger among abused children.

Behavioral and psychophysiological evidence of maltreated children's differential processing of affective information suggests that early experience influences subsequent emotional development and shapes implicated brain circuitry (Cicchetti, 2002a). The effects observed among maltreated children may reflect experience-dependent processes that involve the fine-tuning of attention, learning, perceptual, and memory systems that facilitate the rapid identification of anger (Pollak, 2009).

For the physically abused child, displays of anger may be the strongest predictor of threat; however, increased sensitivity to anger could result in decreased attention to other emotional cues. Conversely, the neglected child may suffer from an extremely limited emotional learning environment. A solution to the problem created for maltreated children by aberrant emotional signals from parents may be general constraints imposed on children in the form of immature or limited resources, which require young children to filter or select some environmental cues over others (Bjorklund, 1997). This developmentally normal aspect of selective attention suggests that, irrespective of the initial state of the organism, emotional development is contingent on the nature of the input or experiences made available to the child.

In a meta-analysis examining emotion recognition and understanding in children with histories of maltreatment (including abuse and/or neglect), maltreated children evidenced poorer performance on a range of indicators (Luke & Banerjee, 2013). Moderator analyses revealed more pronounced deficits in emotion understanding than in emotion recognition. Developmental effects were also found, with poorer performance emerging in early and middle childhood, but not in adolescents and adults. Taken in conjunction with the extant body of research, this meta-analysis confirms that maltreated children evidence deficits in a wide range of skills associated with social understanding. The meta-analysis also highlights the importance of future investigations utilizing a developmental framework and striving to disentangle the effects of specific dimensions of maltreatment on functioning.

Formation of Attachment Relationships

The establishment of a secure attachment relationship between an infant and his or her caregiver represents a primary task during the first year of life. As development proceeds, attachment theorists have posited that a secure attachment relationship provides a base from which to explore and, ultimately, contribute to the integration of cognitive, affective, and behavioral capacities that influence

ongoing and future relationships, as well as the understanding of the self (Bowlby, 1969; Sroufe, 1990). Children construct “internal working models” of their attachment figures out of their interactions with their caregivers, their own actions, and the feedback they receive from these interactions. Once organized, these internal working models tend to operate outside of conscious awareness and are thought to be relatively resistant to change. Children formulate their conceptions of how acceptable or unacceptable they are in the eyes of their attachment figures (i.e., their self-image) based on their interactional history with their primary caregivers. Exposed to insensitive and pathological care, maltreated children develop negative expectations regarding the availability and trustworthiness of others, as well as mental representations of the self as incompetent and unworthy.

Maltreated children are especially at risk for developing insecure disorganized attachments (see Cyr, Euser, Bakermans-Kranenburg, & van IJzendoorn, 2010, for a meta-analysis). Estimates of the manifestation of disorganized attachment among maltreated children range from 80% to over 90% (Cyr et al., 2010). In the Strange Situation paradigm, Type D infants demonstrate inconsistent and disorganized strategies for coping with separations from and reunions with their caregivers (Hesse & Main, 2006). In addition, these infants display bizarre behaviors such as freezing, stilling, and stereotypies, as well as contradictory behavior directed toward their attachment figures (e.g., approaching their parent with heads averted; Hesse & Main, 2006).

A number of explanations have been proffered to account for the preponderance of disorganized attachment relationships between maltreated children and their primary caregivers. Because inconsistent care is a hallmark of maltreating families (Rogosch et al., 1995), some have hypothesized that the combination of insensitive overstimulation and insensitive understimulation may lead to the contradictory behaviors observed among maltreated infants classified as Type D. According to Hesse and Main (2006), attachment disorganization is caused by frightened and frightening (FR) parental behavior, which is believed to have its origins in unresolved parental trauma. Maltreating behaviors are arguably among the most frightening parenting behaviors, placing children in an irresolvable paradox in which their attachment figures are simultaneously their source of safety and their source of fear (Hesse & Main, 2006).

Genetic variation also has been explored as a contributor to the development of disorganized attachment; however,

little consistent evidence has emerged for a candidate gene main effect on attachment disorganization (see Luijk et al., 2011). Among maltreated children, Cicchetti, Rogosch, and Toth (2011) found that neither the serotonin transporter gene (5-HTT) nor the dopamine receptor D4 gene (DRD4) were associated with disorganized attachment. They concluded that the anomalous aspects of maltreating parenting may be so robust that they overpower the potential effect of genetic variation in the etiological pathway to attachment disorganization (Cicchetti, Rogosch, & Toth, 2011).

Although attachment is conceptualized as an important stage-salient developmental task during the first year of life, attachment security continues to exert its influence on development across the life span. First, substantial stability in insecure and disorganized patterns of attachment have been observed among maltreated children (Barnett, Ganiban, & Cicchetti, 1999). Second, disorganized attachment initiates a maladaptive trajectory that heightens the risk for future relational dysfunction, as well as various forms of psychopathology (Hesse & Main, 2006).

Development of an Autonomous Self

The development of an integrated sense of self typically occurs in the toddler and preschool years, arising from the successful resolution of previous stage-salient tasks, such as the formation of a secure attachment relationship. Early caregiving experiences serve as the basis for the development of representational models of the attachment figure, as well as corresponding and coherent representational models of the self and of the self in relation to others (Sroufe & Fleeson, 1986). As discussed above, many maltreated infants fail to develop an organized pattern of attachment, increasing the probability of subsequent perturbations in representational development. Indeed, maltreated children show disruptions in many aspects of the self system.

Aberrations in self development have been observed as early as 18 months of age, as demonstrated by investigations of visual self-recognition. On the mirror-rouge paradigm, an assessment of the presence of a cognitive self, maltreated and nonmaltreated children are comparable in their capacity to recognize themselves; however, differences emerge with respect to their affective responses (Schneider-Rosen & Cicchetti, 1991). Specifically, maltreated toddlers are more likely than nonmaltreated comparison children to display neutral or negative emotions upon seeing their images in a mirror, which may be interpreted as reflecting negative feelings about the self.

In a longitudinal study of mother–child play and emerging social behavior among infants from maltreating and nonmaltreating families, no group differences were found in infants' play maturity at 13 or 28 months. However, infants from abusing families demonstrated more imitative play than infants from nonmaltreating families, and engaged in less independent play than infants from neglecting and nonmaltreating families, suggesting a delay in emerging social behaviors. At 28 months, once again there were no differences among the groups of children from abusing, neglecting, or nonmaltreating families in child play maturity. However, children from abusing families again engaged in less child-initiated play than the children from neglecting or nonmaltreating families. Evidence that toddlers from abusing families continued to demonstrate less autonomous and self-initiated behaviors suggests that it would be important for early intervention efforts to concentrate on supporting child autonomy and facilitating maternal autonomy support among abusing families (Valentino, Cicchetti, Rogosch, & Toth, 2011).

At 30 months of age, maltreated children demonstrate disruptions in their development of an internal-state lexicon. Even after controlling for receptive vocabulary, maltreated toddlers produce proportionately fewer internal state words, show less differentiation in their attributional focus, and are more context-bound in their use of internal-state language than nonmaltreated comparisons (Beeghly & Cicchetti, 1994). In particular, maltreated children appear to be most reluctant to talk about their negative internal states (Beeghly & Cicchetti, 1994). This result is corroborated by findings that maltreated children may actually inhibit negative affect, especially in the context of their relationships with their caregivers (Lynch & Cicchetti, 1991). Maltreated children may adopt a strategy designed to suppress the expression of their own negative feelings to avoid eliciting adverse responses from their caregivers. Although this approach may be adaptive in the context of a maltreating relationship, it can become maladaptive and lead to social incompetence in other interpersonal contexts. Additionally, the inability of maltreated children to identify and discuss their own distress may play a major role in these children's difficulties in displaying empathy toward their peers.

Negative self-system processes continue to be evident in the preschool period. Maltreated children's narrative representations of parents and of self are more negative than those of nonmaltreated children (Toth, Cicchetti, Macfie, Maughan, & VanMeenen, 2000). With respect to maltreatment subtype, neglected children have been found to tell

narratives containing more negative self-representations than nonmaltreated children, whereas physically abused children possess more grandiose self-representations. These variations by subtype may reflect differences in maltreating experiences. For example, grandiose self-representations may reflect a coping process to maintain personal control in an adverse and threatening home environment, while negative self-representations may develop from the chronic absence of attention and validation in a neglecting home (Toth et al., 2000).

Maltreated children also show delays in the development of false belief understanding, an important aspect of theory of mind (TOM) (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003). The onset of maltreatment during the toddler period and physical abuse were the features of maltreatment associated with delay in the development of false belief understanding. The centrality of the relation between maltreatment during the toddler period and TOM deficits flows from the importance of self-development for false belief understanding. Internal state language, increased individuation and self-other differentiation, advances in language, conceptual development and symbolic maturity, and the development of self-conscious emotions all occur during early childhood. Maltreated youngsters manifest difficulties in these aspects of self-development, each of which is a precursor of TOM development. Thus, harsh caregiving, especially early in a child's life, impairs the development of TOM abilities.

Research among school-age maltreated children provides further evidence of self-system deviation. Relative to teacher ratings, younger maltreated children overestimate their own sense of social competence and peer acceptance (Vondra, Barnett, & Cicchetti, 1989). These children may be engaging in defensive processing in order to increase their sense of competence. In fact, research indicates that the development of a grandiose self, as reflected by inflated social self-efficacy, may serve as a protective factor in the link between maltreatment and internalizing symptomatology (Kim & Cicchetti, 2003). However, as maltreated children mature, they tend to underestimate their competence and are rated by teachers as having lower self-esteem (Vondra et al., 1989).

Finally, maltreated children are at risk for developing dissociative features and disorders, perhaps the most severe deficit in the integration of the self (Macfie, Cicchetti, & Toth, 2001a, 2001b; Toth, Pickreign Stronach, Rogosch, Caplan, & Cicchetti, 2011; Valentino, Cicchetti, Rogosch, & Toth, 2008a). The link between maltreatment and dissociation has been observed across a wide age range, from

preschoolers to adults. Among preschoolers, physical and sexual abuse appear to be most robustly related to dissociative features, with physical abuse emerging as particularly salient for the development of dissociation at clinical levels. Furthermore, longitudinal research indicates that fragmentations in self-organization have been found in sexually abused adolescent girls, who demonstrated deviant splitting between both positive and negative self-references (Calverley, Fischer, & Ayoub, 1994).

Peer Relationships

Consistent with an organizational perspective on development, it has been theorized that the negative relational patterns acquired in a maltreating environment become incorporated into the structures that are pertinent for successful peer relations. Within the context of their early caregiving experiences, maltreated children may develop negative expectations regarding the self and others, as well as a concept of relationships as involving victimization and coercion. These internalizations lead to the selection and structuring of later social interactions, such that familiar relationship patterns are recreated and validated (Sroufe & Fleeson, 1986). Research supports this conceptualization of continuity in relational functioning, as maltreated children have been shown to exhibit a broad range of difficulties in the peer domain.

With regard to peer relations, maltreated children appear to traverse one of two general developmental pathways: (1) withdrawal from peer interactions, or (2) heightened aggression toward peers. In addition to these two generally diverging pathways, a subgroup of maltreated and nonmaltreated children has been identified who demonstrate both aggressive and withdrawn behaviors (Rogosch & Cicchetti, 1994). Among maltreated children, those who evidence high aggression and high withdrawal demonstrate lower social effectiveness than is the case for nonmaltreated youngsters. This unusual pattern of interaction with peers is consistent with the attachment history of maltreated children, which may be related to disorganized representational models and may result in disturbances in social encounters. By revealing indications of a response predisposition to both "fight" and "flight," maltreated children's interactions with peers lends support to the notion that these children have internalized both sides of their relationships with their caregivers (Troy & Sroufe, 1987). Thus, maltreated children's representational models may have elements of both the victim and the victimizer, and these models may be enacted in their peer relationships. The link between

maltreatment and aggressive behavior is particularly robust (e.g., Cullerton-Sen et al., 2008; Shields & Cicchetti, 2001). Moreover, aggression appears to largely account for the association between maltreatment and peer rejection (Bolger & Patterson, 2001).

Maltreatment also places children at risk for being victimized by their peers. Schwartz, Dodge, Pettit, and Bates (1997) demonstrated that abusive family treatment predicted boys' status as aggressive victims. In an investigation of bullying and peer victimization that included both boys and girls, Shields and Cicchetti (2001) found that maltreated children were more likely than nonmaltreated children to bully other children and more likely to be victimized by their peers. Gender did not act as a moderator, suggesting that maltreated boys and girls are at comparable risk for bullying and victimization (Shields & Cicchetti, 2001).

The effects of maltreatment on disrupted peer group functioning may be explained by perturbations in cognitive and emotional processes. With regard to social information processing, physically abused children make errors in encoding social cues, exhibit biases toward attributing hostile intent, generate more aggressive responses, and positively evaluate aggression as an appropriate response (Teisl & Cicchetti, 2008). These deficits, in turn, mediate the association between physical abuse and aggression in the peer context. Whereas maladaptive social cognition emerges as a salient explanatory factor for physically abused children, emotion dysregulation appears to play an integral role in the link between maltreatment and aggression for all maltreated groups. Poor emotion regulation also mediates the association between maltreatment and victimization by peers (Shields & Cicchetti, 2001; Teisl & Cicchetti, 2008).

In addition to their difficulties in the larger peer group, maltreated children demonstrate weaknesses in developing and maintaining friendships (Parker & Herrera, 1996). Maltreated children report less caring and validation and more conflict and betrayal in their friendships than nonmaltreated children. In an observational setting, Parker and Herrera (1996) found that friendship dyads containing a physically abused adolescent displayed more conflict and less intimacy than dyads without an abused adolescent. Alternatively, having friends may serve as an important buffer for maltreated children against feelings of loneliness, low self-esteem, and victimization by the larger peer group.

Adaptation to School

Adaptation to school represents the major extrafamilial environment in which children are exposed to a novel

group of unfamiliar peers and adults. As such, it presents both a challenge to functioning and an opportunity to break free of patterns that have been established within a maltreating home. However, because an organizational perspective suggests that children's experiences in the home provide a foundation on which future transitions are built, probabilistically children who have been maltreated are at risk for failure in the school environment.

Abused and neglected children are at considerable risk for academic failure (Eckenrode, Laird, & Doris, 1993). Maltreated children perform worse on standardized tests, achieve lower grades, and are more likely to repeat a grade. Furthermore, they score lower on tests that assess cognitive maturity. However, it is unclear whether these difficulties can be attributed to cognitive or motivational issues. With regard to motivation, Aber and Allen (1987) proposed that effectance motivation, which is the intrinsic desire to deal competently with one's environment, and successful relations with novel adults are important factors related to children's ability to adapt to their first major out-of-home environment. As such, they defined the concept of "secure readiness to learn," as characterized by high effectance motivation and low dependency, as a representation for the ability to establish secure relationships with adults while feeling free to explore and engage in the environment in ways that promote cognitive development. Maltreated children score lower on secure readiness to learn than do nonmaltreated children, which is consistent with what one might expect given the insecurity or atypicality that pervades maltreated children's attachment histories. In efforts to identify those factors that might further mitigate against the impact of abuse on school performance, Trickett, McBride-Chang, and Putnam (1994) conducted an investigation with adolescent girls who had been sexually abused. Previous abuse was found to predict poorer social competence, impaired competence in learning, and lower overall academic performance. Higher levels of anxious depression, bizarre destructiveness, and dissociation were also present in victims of sexual abuse. Importantly, cognitive ability and perceived competence emerged as mediators of overall academic performance and achievement, whereas dissociative and destructive behaviors exacerbated the children's level of school success. Okun, Parker, and Levendosky (1994) also sought to examine the independent and interactive effects of physical abuse, recent exposure to additional life events such as death or illness, and social disadvantage on children's social, cognitive, and affective adjustment during middle childhood. Abused children were found to evidence difficulties in three areas:

peer adjustment, self-perception, and depression. Further analyses identified unique effects of negative events and socioeconomic disadvantage on children's adjustment. Additive contributions of abuse status and socioeconomic disadvantage also predicted behavior problems at school and in the home.

In yet another investigation of links between relationship patterns and school adaptation, Toth and Cicchetti (1996) found that the security that a child experienced in relation to his or her mother, in interaction with maltreatment status, significantly affected school functioning. Nonmaltreated children who reported secure patterns of relatedness to their mothers exhibited less externalizing behavior problems, more ego resilience, and fewer school risk factors (e.g., poor attendance, poor achievement test performance, suspensions, failure in 50% of courses, and grade retention) than did maltreated children who reported insecure patterns of relatedness. Moreover, nonmaltreated children with secure patterns of relatedness to their mothers exhibited more positive school adaptation than did nonmaltreated children who reported insecure patterns of relatedness.

In an investigation of more than 200 low-income children, impairments in academic engagement, social skills, and ego resiliency were found to be present in children with histories of maltreatment (Shonk & Cicchetti, 2001). Maltreated children manifested multiple forms of academic risk and exhibited more externalizing and internalizing behavior problems. The effects of maltreatment on academic adjustment were partially mediated by academic engagement, whereas maltreatment's effects on behavior problems were fully mediated by social competencies and ego resiliency.

Finally, Lansford and colleagues (2002) conducted a 12-year prospective study of the long-term consequences of early childhood physical maltreatment on academic, behavioral, and psychological problems in adolescence. These investigators found that adolescents who were maltreated early in life were absent from school more often and were less likely to anticipate attending college compared with nonmaltreated adolescents. Maltreated adolescents also exhibited higher levels of aggression, anxiety/depression, social withdrawal, dissociation, PTSD symptoms, and thought problems than those evidenced by nonmaltreated adolescents. The participants in the Lansford et al. (2002) study were recruited from a randomly selected sample of children from the community. The results of the Lansford et al. (2002) investigation demonstrate that undetected maltreatment in adolescents who are

not receiving protective services warrants identification and intervention.

Now that we have addressed stage-salient aspects of the sequelae of maltreatment, we next direct our attention toward memory, personality organization, and molecular genetic and neurobiological domains.

Effects of Maltreatment on Memory

There are a number of reasons maltreatment might be expected to alter basic memory processes (Howe, Cicchetti, & Toth, 2006). For example, the experience of stress associated with living in a maltreating home may potentiate neurological changes in the structures implicated in encoding and storing information. Observed delays in intellectual functioning, executive functioning, and language may also play roles in potential memory deficits. Furthermore, maltreated children are at risk for the development of post-traumatic stress disorder (PTSD) and dissociation, both of which have been linked to memory distortion among adults.

For the most part, hypothesized adverse effects of maltreatment on memory have not been empirically supported. Although the field is still in its infancy, many studies show no differences between maltreated and nonmaltreated children in terms of basic memory processes. Maltreated children are comparable to their nonmaltreated peers with respect to basic recall and recognition, as well as in their degree of suggestibility to misinformation (Eisen, Goodman, Qin, Davis, & Crayton, 2007; Howe, Cicchetti, Toth, & Cerrito, 2004; Porter, Lawson, & Bigler, 2005). Moreover, Beers and De Bellis (2002) did not find any differences in basic memory processes between maltreated children with PTSD and normative comparison youth. Similarity in memory functioning is evident in studies involving both neutral and emotionally laden stimuli (Howe et al., 2004; Howe, Toth, & Cicchetti, 2011). In addition, differences in memory processes fail to emerge with respect to ecologically valid and stressful information (Eisen et al., 2007). For example, Eisen and colleagues (2007) tested memory for an anogenital exam that occurred in the context of an inpatient abuse assessment. Memory accuracy and suggestibility did not vary by abuse status.

Although no between-group differences have been discovered, within-group investigations suggest variation in basic memory processes as a function of maltreatment subtype. For example, in a depth-of-processing incidental recall task of self-referent information, neglected children demonstrated a greater proportion of negative false recall

and less positive false recall than did the abused children, suggesting greater memory inaccuracy among neglected children (Valentino, Cicchetti, Rogosch, & Toth, 2008b). In another study by Valentino et al. (2008a), subtype differences emerged for memory of maternal-referent information, such that abused children exhibited lower recall compared to neglected children. These findings are suggestive of defensive processing of information that activates the attachment system as a protective mechanism among abused children. Relatedly, Lynch and Cicchetti (1998b) examined the links among trauma, representational models of caregivers, and children's memory for mother-referent information. Results were consistent with the hypothesis that experiences of trauma and representational models of caregivers are associated with differences in the way children process and retrieve information about positive and negative mother-attribute words. Specifically, victimized children with insecure representational models of their caregivers recalled the highest proportion of negative mother stimuli. Finally, Cicchetti, Rogosch, Howe, and Toth (2010) showed that children with a history of neglect and/or emotional maltreatment and low cortisol evinced increased levels of memory inaccuracy.

In addition to subtype differences in basic memory processes, Valentino, Toth, and Cicchetti (2009) revealed subtype-specific variation in autobiographical memory for nontraumatic events. Abused children's memories were more overgeneral than the memories of neglected and nonmaltreated children. Retrieving memory in generic form may reflect a strategy for avoiding negative affect associated with painful memories. Consistent with a dynamic skills framework, defensive, traumatogenic responses become more habitual and generalized over time, resulting in less integration of memories.

Personality Organization and Psychopathology

Child maltreatment ushers in motion a probabilistic path of epigenesis for abused and neglected children that often results in a profile of relatively enduring vulnerability factors that increase the probability of the emergence of maladaptation and psychopathology. Indeed, consistent with the concept of multifinality, maltreated children develop a broad range of psychopathological outcomes.

In general, the literature indicates that exposure to child maltreatment increases the risk for greater lifetime prevalence of high levels of many psychopathological symptoms and disorders. These include, but are not restricted to, mood and anxiety disorders (Kim & Cicchetti,

2006; Widom, DuMont, & Czaja, 2007), dissociation and suicidal behavior (Yates, Carlson, & Egeland, 2008), substance use disorders (Rogosch, Oshri, & Cicchetti, 2010; Widom, Marmorstein, & White, 2006), disruptive and antisocial behaviors (Egeland, Yates, Appleyard, & van Dulmen, 2002; Widom & Maxfield, 2001) and psychosis (Arseneault et al., 2011; Toth et al., 2011). Longitudinal research by Kaplow and Widom (2007) suggests that the age of onset of maltreatment may be an important factor in differentiating the effects of maltreatment on later mental health outcomes. In particular, individuals who were maltreated earlier in life (i.e., before the age of 6 and/or during the infancy or preschool years) evinced higher levels of internalizing problems as adults, whereas those who were older at the time of maltreatment went on to develop more externalizing outcomes in adulthood. The preschool years emerged as a potential sensitive period during which maltreatment may have an especially robust effect, potentiating the development of both internalizing and externalizing disorders (i.e., anxiety, depression, antisocial personality disorder).

Manly, Kim, Rogosch, and Cicchetti (2001) found that the severity of emotional maltreatment in the infancy-toddlerhood period and physical abuse during the preschool period predicted externalizing behavior and aggression. Severity of physical neglect, particularly when it occurred during the preschool period, was associated with internalizing symptomatology and withdrawn behavior. Additionally, maltreatment during the school-age period contributed significant variance after earlier maltreatment was controlled. Chronic maltreatment, especially with onset during infancy-toddlerhood or preschool periods, was linked with more maladaptive outcomes (Manly et al., 2001). The significance of chronic maltreatment attests to one of the tenets of the organizational perspective on development, in terms of links between adversity across multiple developmental periods and detrimental impact on later functioning. An examination of the interplay among developmental timing, severity, and subtype in relating to adaptation of maltreated children in the Manly et al. (2001) study provided a more clearly delineated picture of multifinality of outcomes within the phenomenon of maltreatment than a global categorization could provide.

Keiley, Howe, Dodge, Bates, and Pettit (2001) conducted a longitudinal study from kindergarten (roughly Ages 4 to 5) through the eighth grade (Age 12). Growth modeling was used to determine the developmental trajectories of mother-reported and teacher-reported internalizing and externalizing behaviors for two groups of

physically abused children—early-harmed (pre-Age 5), later-harmed (after Age 5) and a group of nonharmed children. Children who experienced early physical harm from significant adults in their lives were more likely to experience adjustment problems in early adolescence. Over multiple domains, early physical maltreatment was related to more negative sequelae than the same type of maltreatment occurring at later periods. In addition, the fitted growth models revealed that the early-harmed group exhibited somewhat higher initial levels of teacher-reported externalizing problems in kindergarten and significantly different rates of change in these problem behaviors than other children, as reported by mothers over the 9 years of this study. The early-harmed children also were seen by their kindergarten teachers as exhibiting higher levels of internalizing behavior. The later-harmed children were seen by their teachers as increasing their externalizing problem behaviors more rapidly over the 9 years than did the early- or nonharmed children. Like those of Manly et al. (2001), these findings indicate that the timing of maltreatment is a salient factor in examining the developmental effects of physical harm.

Maltreatment has also been implicated in the etiology of personality disorders. Given that personality disorders do not emerge spontaneously at the age of 18, the age cut-off established in the psychiatric nomenclature, some researchers have adopted a developmental psychopathology approach by seeking to identify early precursors and processes that confer vulnerability to later personality pathology (Cicchetti & Crick, 2009). Consistent with this approach, Rogosch and Cicchetti (2005) found that maltreated children exhibit higher mean levels of potential precursors to borderline personality disorder (e.g., emotional lability, conflictual relationships with adults and peers, relational aggression, self-harm) than do nonmaltreated comparisons. An examination of early risk factors for paranoid personality identified a history of child maltreatment as a predictor, alongside significant behavioral disturbances and negative peer relationships (Natsuaki, Cicchetti, & Rogosch, 2009). In a prospective investigation of personality organization, Rogosch and Cicchetti (2004) found that 6-year-old maltreated children exhibited lower agreeableness, conscientiousness, and openness to experience, as well as higher neuroticism than did nonmaltreated children. Analysis of personality clusters revealed that the majority of nonmaltreated children were represented in the adaptive *Gregarious* and *Reserved* personality clusters, whereas maltreated children largely accounted for the makeup of less adaptive personality profiles (i.e.,

Undercontroller, Overcontroller, and Dysphoric). Furthermore, longitudinal stabilities were observed across Ages 7, 8, and 9, suggesting continuity in maltreated children's personality liabilities.

Gene \times Environment Interaction (G \times E)

Research in molecular genetics suggests that maltreated children's risk for psychopathology is not inevitable. G \times E interaction (G \times E) occurs when the effect of exposure to an environmental factor on a behavioral, health, or biological phenotype is conditional upon a person's genotype or, conversely, when the genotype's effect is moderated by the environment (Moffitt, Caspi, & Rutter, 2005). Since 2005, the role of the environment and its interaction with genes has been further clarified, with reciprocal coactions between the environment and the individual resulting in differential expression of genetic material. Environmental conditions may interact with an individual's genetic makeup to alter processes such as the timing of the initiation of transcription and translation for a specific gene, the direction for which it does so, or whether the gene will ultimately be expressed.

In a landmark epidemiological study, Caspi and colleagues (2002) followed a large sample of male children from birth to adulthood to ascertain why some maltreated children grow up to develop Antisocial Personality Disorder, whereas others do not. Results revealed that a functional polymorphism in the promoter of the monoamine oxidase A (MAOA) gene moderated the effect of child maltreatment. The MAOA gene is located on the X chromosome and encodes the MAOA enzyme, which metabolizes neurotransmitters such as norepinephrine, serotonin, and dopamine, rendering them inactive. Maltreated children with the genotype conferring high MAOA activity were significantly less likely to develop antisocial behavior problems than maltreated children with the low MAOA-activity genotype. In addition, maltreatment and nonmaltreatment groups did not differ on MAOA activity, suggesting a lack of an evocative gene–environment correlation as an explanation for the G \times E findings. Many, but not all, subsequent studies have been successful in replicating Caspi et al.'s (2002) original findings and in extending them downward to samples of children and adolescents (Kim-Cohen et al., 2006).

In another seminal study, Caspi et al. (2003) examined the prospective link between maltreatment and depression. Caspi et al. (2003) found that genetic variation in a functional polymorphism (5-HTTLPR) in the promoter region

of the serotonin transporter gene (5-HTT) plays a moderating role. The particular serotonin gene variants (*s/s*, *s/l*, and *l/l*) affect the amount of serotonin transporter protein that is produced. The serotonin transporter is a protein that is critical to the regulation of serotonin function in the brain, through terminating the action of serotonin in the synapse via reuptake. The serotonin transporter gene plays a pivotal role in brain development and in individual differences in mood and behavioral regulation. Thus, 5-HTTLPR was an excellent candidate gene for Caspi et al.'s (2003) research. Adults carrying the *s* allele (*s/s* or *s/l*) were found to exhibit more depressive symptoms, diagnosable depression, and suicidality in response to stressful life events than individuals homozygous for the *l* (*l/l*) allele. In addition, an examination of early life stress showed that a history of child maltreatment predicted depression in adulthood, but only among *s* carriers.

Whereas work in behavior genetic and molecular genetic research using genome-wide association studies did not examine gene–environment interaction (G \times E), the Caspi et al. (2002, 2003) investigations generated much excitement because they suggested that the combination of molecular genetic elements and well-measured environments and phenotypes could not only increase understanding of the development of psychopathology, but also uncover additional genes that play roles in the etiology of psychopathology that would not have been discovered in “main effects” molecular genetic studies. G \times E research, however, has not been without its critics (Duncan & Keller, 2011). Some of the most notable emanated from the findings of the meta-analysis conducted by Risch et al. (2009) in which they conclude that 5-HTTLPR does not moderate the relation between stress and depression in contrast to the findings of Caspi et al. (2003).

In response, Caspi, Hariri, Holmes, Uher, and Moffitt (2010) evaluate multiple lines of evidence for the 5-HTT stress-sensitivity hypothesis. The evidence was drawn from experimental neuroscience, nonhuman primate research, and studies of genetically engineered 5-HTT mutations in rodents and dispels some misconceptions about G \times E research. Relatedly, Karg, Burmeister, Sheden, and Sen (2011) critically reviewed two meta-analyses that examined the interaction between 5-HTTLPR and stress in the development of depression (Munafo, Durrant, Lewis, & Flint, 2009; Risch et al., 2009). Contrary to Risch et al.'s (2009) meta-analysis, Karg and colleagues (2011) found strong evidence in support of the hypothesis that 5-HTTLPR moderates the relation between stress and depression.

We next selectively review G×E research on maltreated children, adolescents, and adults who report having experienced maltreatment in their childhoods. We focus on studies that examined the most commonly studied candidate genes in G×E research on child maltreatment, namely 5-HTTLPR, corticotropin releasing hormone receptor gene (CRHR1), and MAOA.

Kaufman et al. (2004) found that maltreated children with the *s/s* genotype of 5-HTTLPR evinced depression scores that were almost twice as high as the depression scores of maltreated children with the *s/l* and *l/l* genotypes. Kaufman et al. (2006) replicated these findings in a subsequent study, the results of which revealed a significant three-way interaction between brain-derived neurotrophic factor (BDNF) genotype, 5-HTTLPR, and maltreatment in predicting heightened levels of depression. In another instance of G×G×E, Cicchetti, Rogosch, and Sturge-Apple (2007) found that adolescents with a history of sexual abuse who carried both the *s/s* genotype and the low MAOA-activity genotype evinced higher levels of depression symptomatology than sexually abused adolescents with alternative combinations of the variants of the 5-HTT and MAOA genes.

Banny, Cicchetti, Rogosch, Oshri, and Crick (2013) examined child maltreatment, peer victimization, and 5-HTTLPR as predictors of depressive symptomatology. Path analyses revealed that both relational and overt victimization mediated the association between child maltreatment and depressive symptoms. Bootstrapping procedures used to test moderated mediation demonstrated that genotype moderated the indirect effects of relational and physical victimization on child depressive symptoms, such that victimized children with the *l/l* genotypic variant of 5-HTTLPR were at increased risk for depressive symptoms compared to victimized children carrying a short allele.

A number of investigations have demonstrated that individuals who had been maltreated possessed a significantly greater risk of experiencing suicidal behaviors (i.e., suicidal ideation, suicide attempts, completed suicide) than comparable samples of nonmaltreated persons from the same socioeconomic status. These studies have demonstrated that the experience of sexual and physical abuse are risk factors for suicidal behaviors in adolescents and adults (Brodsky & Stanley, 2008). Cicchetti, Rogosch, Sturge-Apple, and Toth (2010) investigated whether genotypic variation of 5-HTTLPR moderated the effect of maltreatment on suicidal ideation in a sample of low-income maltreated and nonmaltreated school-age children.

Higher suicidal ideation was found among maltreated than nonmaltreated children. Children with one to two maltreatment subtypes and *s/s* or *s/l* genotypes had higher suicidal ideation than those with the *l/l* genotype; suicidal ideation did not differ in nonmaltreated children or in children with three to four maltreatment subtypes based on 5-HTTLPR variation. Results were applicable to emotionally maltreated/neglected and to physically abused/sexually abused children. Interestingly, for the more extensively maltreated (i.e., those with three to four subtypes), children expressed higher levels of suicidal ideation, irrespective of genetic variation. Thus, the pathogenic relational environment of children who experienced extensive maltreatment appears to have predominated over genotypic variation in the risk for, or protection against, suicidal ideation.

In a final illustration of 5-HTTLPR as a moderator of depression in maltreated children, Uher et al. (2011) conducted a prospective longitudinal examination of G×E interaction in two large samples, one in New Zealand, and one in England. The former sample was followed until Age 32, the latter until Age 40. The prospective nature of this analysis is unique in that most studies of 5-HTTLPR × maltreatment on depression have been cross-sectional.

Uher and colleagues (2011) found that, in both longitudinal cohorts, statistical analyses of G×E interactions revealed positive results for depression that runs a persistent course in adulthood, but not for single-episode depression. Individuals with two short 5-HTTLPR alleles and child maltreatment had elevated risk of persistent but not single-episode depression. Thus, research that does not distinguish persistent course and single-episode depression may underestimate G×E effects and could explain some of the nonreplications found in G×E research (Duncan & Keller, 2011).

CRHR1 is another gene that has been shown to be a viable candidate gene that influences vulnerability to depression. Corticotropin-releasing hormone is the key activator of the hypothalamic-pituitary-adrenal (HPA) axis, binding to receptors that initiate the stress response, culminating with release of cortisol from the adrenal cortex. Overactivity of the HPA-axis has been shown to be partially caused by hyperactivity of CRH neurons. Additionally, CRH activity at the CRH type 1 receptor (CRHR1) in extra-hypothalamic regions also are thought to bring about internalizing disorders, such as depression and anxiety (Bradley et al., 2008). Published investigations to date suggest that hyperactivity of the HPA axis may be a function of early life stress (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Heim, Newport, Mletzko, Miller, & Nemeroff, 2008).

Bradley and colleagues (2008) conducted a study to test the hypothesis that genetic polymorphisms that alter the functionality of CRHR1 may moderate the effects of child maltreatment on adult depression. These investigators found that a G×E interaction was important for the expression of depressive symptoms, or lack thereof, in adults who possess CRHR1 risk or protective alleles in conjunction with a history of child maltreatment. In keeping with Moffitt et al. (2005), the findings of Bradley et al. (2008) underscore the importance of taking the environment into account in genetic association and linkage studies that otherwise might miss many important genetic variants that are involved in the etiology of complex diseases. An extension and partial replication of the Bradley et al. (2008) study was conducted by Polanczyk et al. (2009). As in the investigation of Bradley et al. (2008), a CRHR1 haplotype was shown to exert a protective effect against depression in adults who were maltreated in their childhood; however, the replication only occurred when a retrospective, but not a prospective, measure of child maltreatment was used. The authors speculated that the protective effect of the CRHR1 haplotype was likely related to its function in consolidating memories of emotionally arousing experiences.

DeYoung, Cicchetti, and Rogosch (2011) examined the influence of CRHR1 variation on neuroticism, in interaction with child maltreatment, in a large sample of maltreated children and a well-matched nonmaltreated comparison group. Neuroticism, one of the Big Five personality characteristics, is a risk factor for mood and anxiety disorders. The biological systems involved in neuroticism are thus of great import in the etiology of internalizing disorders. Genes that are involved in the systems that are stress responsive, such as CRHR1, are thus important candidates for studies of the genetic moderation of the effects of major stressors like maltreatment.

DeYoung et al. (2011) found that the CRHR1 TAT haplotype significantly moderated the association of child maltreatment with neuroticism. Having two copies of the TAT haplotype of CRHR1 was associated with higher levels of neuroticism among maltreated children relative to nonmaltreated children, with the exception of sexually abused children and children who had experienced three or four types of maltreatment. The findings of this study are also important because they contribute to a growing body of evidence that variation in the CRHR1 gene moderates the effects of child maltreatment.

Research reviewed shows that G×E interactions mediating depressive symptomatology have been identified in both the stress-sensitive serotonergic (5-HTTLPR) and

corticotropin-releasing hormone (CRHR1) systems. In an investigation of African Americans of low-SES, Ressler et al. (2010) sought to determine whether the effects of child maltreatment are moderated by G×G×E interactions between CRHR1 and 5-HTTLPR polymorphisms. Ressler and colleagues (2010) first replicated the interaction of child maltreatment and 5-HTTLPR on lifetime major depressive disorder. They next replicated earlier work in their laboratory by Bradley et al. (2008), once again finding that an interaction between a CRHR1 haplotype and child maltreatment predicted current depressive symptoms. Furthermore, Ressler et al. (2010) discovered that a G (5-HTTLPR *s* allele) × G (CRHR1 haplotype) interaction with child maltreatment predicted current depressive symptoms.

MAOA is a mitochondrial enzyme that is expressed predominantly in catecholaminergic neurons and is responsible for the degradation of a variety of biogenic amines (Caspi et al., 2002). A well-characterized *u*-VNTR polymorphism exists in the promoter region of the MAOA gene that is known to affect gene expression. The number of tandem repeats of this polymorphism (i.e., 2, 3, 5 versus 3, 5, 4) determines the efficiency (i.e., high activity, low activity) with which MAOA is transcribed and ultimately produced within individuals (Caspi et al., 2002).

Weder et al. (2009) examined a G×E interaction of MAOA genotype and maltreated children. The maltreated children represented the extreme on a continuum of adversity. They were assessed at a highly stressful time—shortly after they had been removed from their parents' care because they had been physically abused. A total trauma index score was derived based on inclusion of physical abuse, sexual abuse, domestic violence exposure, multiple out-of-home placements, and community violence exposure. Scores were rated from mild to moderate to extreme. Weder et al. (2009) detected a significant interaction between exposure to moderate levels of trauma and the low activity MAOA genotype in conferring increased risk for aggression. Children who were exposed to extreme levels of trauma had high aggression scores regardless of MAOA genotype. Extreme levels of trauma appear to overshadow the effects of MAOA genotype, especially during a period when traumatized children are experiencing acute stress. The findings of Weder and colleagues are consistent with those of Caspi et al. (2002).

To provide a final example, as in Caspi et al.'s (2002) original study, Cicchetti, Rogosch, and Thibodeau (2012) conducted an investigation to examine a G×E interaction of MAOA genotype and child maltreatment on early signs

of antisocial behavior in school-age children. Because the MAOA gene is sex-linked and located on the X chromosome, males have one allele on the X chromosome. In contrast, females have an MAOA allele on each X chromosome; however, only one of the alleles is active. Consequently, ambiguity results in determining which allele is active among females who are heterozygous for MAOA activity level alleles (i.e., high-low or low-high activity). Thus, analyses involving MAOA were conducted only among boys.

For lifetime antisocial behaviors, Cicchetti et al. (2012) did not find MAOA to contribute to models of antisocial behavior as reported by peers or adults beyond the influence of maltreatment effects. The G×E interaction effect was significant. Among nonmaltreated children, those with low activity MAOA genotypes had higher observer-reported symptoms of antisocial behavior than those with high-activity MAOA genotypes. Moreover, maltreated children in the low-activity MAOA group had higher self-reported antisocial behavior than nonmaltreated children. A similar pattern of findings was observed for child self-report of antisocial behavior in the past 6 months, as the G×E interaction was significant. Specifically, maltreated children with low MAOA-activity genotypes had higher recent antisocial behavior than those with high activity genotypes. No significant differences were found among nonmaltreated children based on the MAOA genotype group. Furthermore, maltreated children with low MAOA activity genotypes had higher-level self-reported antisocial symptoms than nonmaltreated children. The risk for antisocial behavior associated with child maltreatment was reduced among children with high MAOA-activity genotypes. The findings of Cicchetti et al. (2012) are consistent with those reported by Caspi et al. (2002) and Weder et al. (2009) (for a meta-analysis, see Kim-Cohen et al., 2006).

Maltreatment and Allostatic Load

In addition to G×E effects, child abuse and neglect are also implicated in the disruption of biological systems, including neuroendocrine functioning, health outcomes, and neurobiology. The concepts of allostasis and allostatic load (AL) provide an integrative framework for understanding how exposure to chronic stress, such as child maltreatment, potentiates long-term liabilities for physical and mental health (Danese & McEwen, 2012). Allostasis is a process that involves the activation of multiple interactive physiological systems (e.g., HPA, sympathetic-adrenal-medullary axes, cardiovascular, immune, and metabolic

systems). In the short term, mobilization of these systems exerts a protective effect on the body and promotes an adaptive response to stress; however, with chronic activation, physiological reactions to stress become less efficient in protecting the individual. Ensuing damage to the body results in allostatic overload, which, in turn, contributes to changes in brain structure and function and the development of various disease states.

Shonkoff, Boyce, and McEwen (2009) differentiated among three types of stress that children may experience. Normative and routine life challenges that are embedded within a context of protective factors are examples of positive stress. Time-limited stresses within supportive relationships are considered tolerable stress. Toxic stress involves conditions in which the child is exposed to chronic, severe, and prolonged stress, often occurring in the absence of protective factors. Abuse and neglect constitute an example of toxic stressors.

Neuroendocrine Regulation and Reactivity

Cicchetti and Rogosch (2001a) examined the extent to which maltreated children vary with respect to cortisol regulation, a biomarker of AL. Although no differences in cortisol regulation were found between the maltreated and nonmaltreated groups, findings revealed significant within-group variation as a function of maltreatment subtype. In particular, children who had experienced both physical and sexual abuse, in combination with neglect and/or emotional maltreatment, exhibited substantial elevations in morning cortisol levels (i.e., hypercortisolism). In addition, a subgroup of physically abused children showed a trend toward lower morning cortisol relative to nonmaltreated children (i.e., hypocortisolism). Furthermore, the neglected and emotionally maltreated groups did not differ from nonmaltreated children in terms of cortisol regulation.

Longitudinal analysis of the developmental course of cortisol dysregulation accommodates findings of both hyper- and hypocortisolism among maltreated children. Trickett, Noll, Susman, Shenk, and Putnam (2010) measured cortisol activity at six time points spanning childhood, adolescence, and young adulthood to determine the effects of maltreatment on cortisol regulation. Although the cortisol levels of sexually abused females were initially higher compared to nonabused females, their levels were lower by early adulthood. Results support an attenuation hypothesis, whereby the HPA axis adapts to hypersecretion by downregulating its response to stress, eventually resulting in hyposecretion.

Research investigations also have examined whether cortisol differentially relates to social and psychological functioning based on maltreatment status (see Tarullo & Gunnar, 2006, for a review). This hypothesis was supported by the findings of Cicchetti and Rogosch (2001b), which indicated that depressed maltreated children exhibited a pattern of cortisol dysregulation that was not evident among depressed nonmaltreated children. Similarly, in a later study by Cicchetti, Rogosch, Gunnar, and Toth (2010), children who had experienced early sexual and/or physical abuse (i.e., in the first 5 years of life) and who also had high internalizing symptoms uniquely exhibited an attenuated diurnal decrease in cortisol, whereas nonmaltreated children with high internalizing symptomatology did not evince neuroendocrine dysregulation. The findings were specific to early sexual and physical abuse rather than later-onset physical and/or sexual abuse or early occurring neglect or emotional maltreatment.

Tyrka et al. (2009) conducted a study to determine whether CRHR1 polymorphisms interact with child maltreatment to predict HPA-axis reactivity, which has been linked both to early life stress and to depression. Several single nucleotide polymorphisms (SNPs) of CRHR1 showed interaction with maltreatment in the prediction of cortisol response to the dexamethasone (DEX) suppression test. For the adults who experienced maltreatment in their childhood, the GG genotype of each of the CRHR1 SNPs was associated with elevated cortisol responses to DEX. Tyrka et al. (2009) conjectured that excessive HPA axis activation could represent a mechanism of interaction of risk genes with stress in the development of mood disorders.

Relatedly, Cicchetti, Rogosch, and Oshri (2011), within an allostatic load framework, investigated the effect of G×E interactions on diurnal cortisol regulation and internalizing symptomatology. Variation in the CRHR1 TAT haplotype and 5-HTTLPR was identified in a sample of maltreated and nonmaltreated children. G×E effects for CRHR1 and maltreatment and early abuse (before Age 5) on diurnal cortisol regulation were observed; CRHR1 variation was related to cortisol dysregulation only among maltreated children. Early abuse and high internalizing symptoms also interacted to predict atypical diurnal cortisol regulation. The interaction of CRHR1, 5-HTTLPR, and child maltreatment (G×G×E) identified a subgroup of maltreated children with high internalizing symptoms who shared the same combination of the two genes. The findings provide support for an allostatic-load perspective on the effects of the toxic stress associated with child maltreatment on

cortisol regulation and internalizing symptomatology as moderated by genetic variation.

There are different models of how the effects of excesses, deficits, and dysregulation in the primary mediators of AL, particularly cortisol, may affect brain structure and function. Further, developmental considerations are important. In this regard, the timing of periods of severe stress may be critical. For example, variation in the age of maturation of brain structures, notably the hippocampus, prefrontal cortex, and the amygdala, may result in differential effects on functioning and health (Lupien, McEwen, Gunnar, & Heim, 2009; Shonkoff et al., 2009). Sensitive periods in the development of these brain structures may generate heightened vulnerability to the neurotoxic effects of excess glucocorticoids, thereby creating a long-term liability as development proceeds. Alternatively, the cumulative exposure to stressful experiences and concomitant dysregulation of the HPA axis may contribute to ongoing wear and tear on these brain structures. These effects of chronic stress are heightened, given that these areas of the brain have dense concentrations of glucocorticoid receptors, thereby promulgating progressive inefficiency in brain structure and function. For children in low-income environments and those subjected to abuse and neglect, the consequences may be particularly salient for health outcomes across the life span.

Adverse Physical Health Outcomes

In addition to cortisol dysregulation, maltreatment appears to be associated with other adverse health outcomes that may be implicated in the development of allostatic overload. For example, maltreatment predicts increased risk for hospital-based treatment of asthma, cardiorespiratory, and infectious disease in childhood (Lanier, Jonson-Reid, Stahlschmidt, Drake, & Constantino, 2010). Early child abuse has been linked to more health-related symptoms (e.g., sleep, eating, general health status), higher body mass index (BMI), and compromised immune system functioning in childhood and adolescence (Danese et al., 2011; G. E. Miller, Chen, & Parker, 2011; Shirtcliff, Coe, & Pollak, 2009). Furthermore, health liabilities extend into adulthood, as child maltreatment has been found to predict adult cardiovascular disease, elevated inflammation levels, type II diabetes, HIV risk, self-reported physical symptoms across a range of organ systems, and decreased longevity (Danese, Pariante, Caspi, Taylor, & Poulton, 2007; Felitti et al., 1998; Wilson & Widom, 2011). Moreover, child maltreatment has been linked to shortened leucocyte telomere

length and it is thought that maltreatment may influence cellular aging (Tyrka et al., 2010).

As discussed earlier, a valuable series of studies has examined diverse, long-term health outcomes in an extensive sample of HMO members who were exposed to varying adverse childhood experiences (ACE; Felitti et al., 1998). The ACE factors that were examined included exposure to childhood emotional, physical, and sexual abuse, substance abuse in the family, parental mental illness, domestic violence, and adult criminal behavior. The accumulation of adverse experiences across these risk domains was determined and linked to a range of adult health outcomes. For example, a gradient of exposure to increasing numbers of ACE factors was associated with a cumulative index of health risk behaviors linked with adult disease and mortality, (i.e., smoking, alcoholism, drug abuse, suicide attempts, high number of sex partners, sexually transmitted diseases, inactivity, obesity). Moreover, a dose-response relationship between ACE exposures and leading causes of death, including heart disease, cancer, chronic bronchitis or emphysema, hepatitis, skeletal fractures, and poor self-rated health, was also observed. Furthermore, ACE factors have been associated with hospitalization for diagnosed autoimmune diseases decades into adulthood and graded relationships between ACE factors and prescription rates for psychotropic medications have been found. This latter finding further illustrates the high rate of serious adult psychiatric morbidity that ensues among children exposed to high levels of adversity.

Consistent with the concept of AL, Rogosch, Dackis, and Cicchetti (2011) conducted a multidomain assessment of stress-sensitive systems among low-income maltreated and nonmaltreated comparison children. An AL composite was created from measurements of salivary cortisol and dehydroepiandrosterone (DHEA), BMI, waist-hip ratio, and blood pressure. Results indicated that maltreatment and AL independently predicted psychopathology and health difficulties (i.e., parent report of child's physical health status and utilization of health care system). As AL increased, the level of child health and psychological problems increased for all low-income children. Child maltreatment had an additive effect, contributing to the degree of physical and mental health problems beyond that accounted for by the AL composite. Therefore, children with both high AL and a history of maltreatment had the most health problems.

The findings of this investigation have important implications for programs designed to promote physical and mental health in the lives of low-income and maltreated children. Heckman (2006) has emphasized the economic

and humanitarian value to society of reducing the impact of adverse early family environments on developing children in order to ameliorate the diminished cognitive capacities ensuing from deprivation and high stress. AL is likely a major influence on these unrealized potentials, through the negative sequelae of stress occurring in early sensitive periods of brain development and progressive accumulation of liabilities that extend to other stress-sensitive systems. Although broad-based efforts to reduce the impact of poverty are crucial, targeted interventions to advance cognitive functioning and self-regulatory capacities (Blair & Diamond, 2008) are vital for enhancing self-righting processes and promoting resilience. For the most vulnerable children in low-SES environments, concerted efforts to prevent the occurrence of child abuse and neglect are of fundamental importance. Early intensive interventions in child maltreatment to establish more sensitive and nurturant parenting, secure attachment, and neurobiological reorganization in maltreated youngsters (Cicchetti, Rogosch, & Toth, 2006; Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011) hold great promise for instilling adaptive developmental trajectories. Consolidated, multisystemic approaches beginning early in development are necessary to reduce environmental stress exposure, child maltreatment, and allostatic overload in order to improve physical and mental health across the life span.

MALTREATMENT EXPERIENCES AND NEUROBIOLOGICAL DEVELOPMENT

Abnormal brain development is a dynamic, self-organizing process. The perturbations that occur during abnormal brain development can potentiate a cascade of maturational and structural changes that eventuate in the neural system proceeding along a trajectory that deviates from that generally taken in normal neurobiological development (Cicchetti, 2002b; Cicchetti & Tucker, 1994; Courchesne, Chisum, & Townsend, 1994). For example, early maltreatment, either physical or emotional, may condition young neural networks to produce cascading effects through later development, possibly constraining the child's flexibility to adapt to new challenging situations with new strategies rather than with old conceptual and behavioral prototypes. Thus, early psychological trauma may eventuate not only in emotional sensitization, but also in pathological sensitization of neurophysiological reactivity.

Children who are endowed with normal brains may encounter a number of experiences (e.g., poverty,

community violence, child maltreatment) that exert a negative impact on developing brain structure, function, and organization and contribute to distorting these children's experiences of the world (Hackman, Farah, & Meaney, 2010). These findings proffer a unique opportunity for comprehending how environmental factors can bring about individual differences in neurobiological development.

Children may be especially vulnerable to the effects of pathological experiences during periods of rapid creation or modification of neuronal connections. Pathological experience may become part of a vicious cycle, as the pathology induced in brain structure may distort the child's experience, with subsequent alterations in cognition or social interactions, thereby causing additional pathological experience and added brain pathology (Cicchetti & Tucker, 1994). Because experience-expectant and experience-dependent processes may continue to operate during psychopathological states, children who incorporate pathological experience may add neuropathological connections into their developing brains instead of functional neuronal connections (Black, Jones, Nelson, & Greenough, 1998).

As has been stated, child maltreatment affects both neurobiological and psychological processes. Physiological and behavioral responses to maltreatment are interrelated and contribute to children's making choices and responding to experiences in ways that typically produce pathological development. Because maltreated children experience the extremes of "caretaking casualty" (Sameroff & Chandler, 1975), they provide one of the clearest opportunities for scientists to discover the multiple ways in which social and psychological stressors can affect biological systems. Numerous interconnected neurobiological systems are affected by the various stressors associated with child abuse and neglect (De Bellis, 2001, 2005). Moreover, each of these neurobiological systems influences and is influenced by multiple domains of biological and psychological development. Furthermore, in keeping with the principle of multifinality, the neurobiological development of maltreated children is not affected in the same way in all individuals. Of note, not all maltreated children exhibit anomalies in their brain structure or functioning and identifying protective mechanisms in these children emerges as an important area of future research.

Neuroimaging and Child Maltreatment

There has been a burgeoning of interest in comprehending how early adverse experiences, such as child maltreatment, exert their effects on the developing brain (Lupien et al.,

2009). Multiple brain regions and neural circuits are disrupted by the experience of child abuse and neglect. The aberrant neuronal circuitry most likely contributes to the multifinal phenotype observed in maltreated individuals. Magnetic resonance imaging (MRI) technology provides a noninvasive and safe methodology for examining brain morphology, physiology, and function in individuals who have been maltreated. Over the past several decades, neuroimaging investigations increasingly have been conducted with maltreated children and adolescents. Herein, we provide a selective review of these studies.

De Bellis and colleagues (1999) reported the results of an in-depth whole-brain volumetric analysis of a group of hospitalized maltreated children and adolescents with PTSD and a group of medically and psychiatrically well nonmaltreated comparison subjects. In contrast to findings reported in studies of adults who retrospectively reported their histories of child maltreatment, De Bellis et al. (1999) did not find a reduction in hippocampal volume in the group of maltreated children and adolescents with maltreatment and PTSD. The discrepant findings between the child and adult studies on the effects that maltreatment exerts on hippocampal volume may be a function of the increase in volume that normatively occurs in neurobiological development during adolescence (Spear, 2000). During adolescence, subcortical gray matter structures that include the hippocampus continue to develop, and these normative processes of adolescent brain development may mask any effects that maltreatment and PTSD may exert on the developing limbic system. Alternatively, because the maltreated children with PTSD who comprised the De Bellis, Hall, Boring, Frustaci, and Moritz (2001) sample were involved in ongoing individual or group treatment, these psychotherapeutic interventions may have contributed to an increase in hippocampal neurogenesis, thereby eliminating any actual difference between hippocampal volume in maltreated and nonmaltreated individuals.

After controlling for intracranial volume and SES, De Bellis and colleagues (1999) discovered a number of additional MRI-based brain structural anomalies in their sample of maltreated children and adolescents with PTSD. These included smaller intracranial volumes, cerebral volumes, and mid-sagittal corpus callosum areas and larger lateral ventricles than in the group of nonmaltreated comparison children and adolescents. De Bellis et al. (1999) also found a positive correlation between intracranial volumes and age of onset of PTSD trauma as well as a negative correlation with the duration of maltreatment that led to a PTSD diagnosis, suggesting that there may

be sensitive periods and dose effects for stress-related alterations in brain development. Furthermore, according to De Bellis et al. (1999), their finding that enlarged lateral ventricles in maltreated children and adolescents were correlated positively with the duration of the maltreatment experienced suggested that there may have been neuronal loss associated with severe stress.

In another investigation, De Bellis, Keshavan, Spencer, and Hall (2000) used magnetic resonance spectroscopy (MRS), a safe neuroimaging methodology, to investigate the *in-vivo* neurochemistry of neurobiological alterations in children's brains. De Bellis and colleagues (2000) measured the relative concentration of N-acetyl aspartate (NAA) and creatine in the anterior cingulate cortex of a small group ($n = 11$) of maltreated children and adolescents who also had PTSD and a healthy nonmaltreated comparison group ($n = 11$) matched on SES. NAA is considered to be a marker of neural integrity; moreover, decreased concentrations of NAA are associated with increased metabolism and loss of neurons. De Bellis et al. (2000) found that maltreated children and adolescents with PTSD had lower NAA-to-creatinine ratios, which are suggestive of neuronal loss in the anterior cingulate region of the medial prefrontal cortex, than did the nonmaltreated, SES-matched comparisons. The reduction in the ratio of NAA to creatine buttresses the hypothesis that maltreatment in childhood may alter the development of cortical neurons.

Approximately a dozen studies have replicated the results of De Bellis et al. (1999) that maltreated children and adolescents with PTSD do not have lower hippocampal volume than nonmaltreated comparisons (McCrory, DeBrito, & Viding, 2010). Thus, it appears that the hippocampal reduction effect may be specific to adults with a history of maltreatment. Perhaps the stress-induced prolonged exposure to glucocorticoids had a neurotoxic effect and contributed to a reduction in the complexity of hippocampal cells and even to cell death (Lupien et al., 2009). Preclinical research suggests that repeated exposure to stress hormones during development negatively affects neuronal migration, myelination, and neurogenesis, resulting in reduced dendritic spines, gray matter, and white matter connectivity in affected brain regions (Dackis, Rogosch, Oshri, & Cicchetti, 2012). Therefore, child maltreatment may lead to neurotoxic effects within limbic regions during sensitive periods of development.

Teicher and colleagues (2004) investigated the corpus callosum in children who had been abused or neglected to ascertain whether there were structural abnormalities in the regional anatomy. The corpus callosum connects the left

and right hemispheres and is the major myelinated tract in the brain. Regional corpus callosum area was measured by MRI in three groups of children: abused and neglected children, children admitted for psychiatric evaluation, and healthy comparisons. Teicher et al. (2004) found that the total area of the corpus callosum of the children who had experienced abuse and neglect was smaller than that of the children evaluated for psychiatric problems and the healthy comparisons. The latter two groups of children did not differ from each other. Child neglect was associated with a 15% to 18% reduction in corpus callosum regions; in contrast, reduced corpus callosum size in girls was most strongly associated with sexual abuse. These findings are congruent with the earlier assertion that negative early experiences can adversely affect neurobiological development.

With respect to corpus callosum and cerebellar volume, there is sound evidence for reduced volume in individuals who have experienced adversity (McCrory et al., 2010). On the other hand, structural MRI results are less consistent for the prefrontal cortex (PFC). It is unclear why there are inconsistent results for volumetric studies of the PFC. Among the possibilities are age differences across studies, variation in maltreatment subtype experienced (e.g., sexual abuse versus witnessing domestic violence), and methodological differences in scoring MRI scans (e.g., manual tracing, which characterized early studies, versus automated techniques such as voxel-based morphometry).

Structural neuroimaging studies also provide evidence for deficits in gray and white matter in several regions of the brain. The most prominently affected appear to be the anterior cingulate cortex, and the dorsolateral, orbitofrontal, and ventromedial prefrontal cortex (Hart & Rubia, 2012). Diffusion tensor imaging (DTI) studies have revealed deficits in structural connectivity between these areas, thereby suggesting abnormalities in neural networks.

In comparison to the number of studies that have examined structural neurobiological differences in maltreated children, adolescents, and adults, far fewer studies have investigated brain functional differences between maltreated and nonmaltreated individuals. Moreover, a very small percentage of these functional studies have been conducted with children. In terms of functional MRI (fMRI), investigations suggest that maltreatment experiences are associated with hypoactivity in the PFC of the dorsofrontal and ventromedial prefrontal cortex. The atypical activation in these brain regions occurs during response inhibition, working memory, and emotion-processing tasks (Hart

& Rubia, 2012). Investigations of maltreated children and adolescents should include both multimodal structural and functional measures and focus on neural networks in addition to isolated regions of interest.

Although our discussion of the sequelae of child maltreatment elucidates numerous negative outcomes, it is important to recognize that not all maltreated children are affected similarly and not all succumb to the adverse outcomes accompanying maltreatment. Within developmental psychopathology, the identification of resilience in the context of extreme adversity also has received considerable attention.

Child Maltreatment and Resilience

Deviations from the average expectable environment potentiate some individuals toward the development of maladaptive functioning, whereas others demonstrate positive adaptation in the face of the same challenges (Cicchetti, 2010; Masten, 2001). Resilience is conceived as a dynamic developmental process encompassing the attainment of positive adaptation despite exposure to significant threat, severe adversity, or trauma that typically constitute major assaults on the processes underlying biological and psychological development (Cicchetti, 2010; Luthar, Cicchetti, & Becker, 2000). Resilience is not a “magical” phenomenon (Masten, 2001). The same developmental cascades that can amplify maladaptive outcomes over time can perpetuate or amplify positive outcomes when the individual benefits from some combination of experiences and/or biological propensities that tip the initial balance toward adaptive outcomes (Cicchetti, 2013).

The occurrence of resilient outcomes in approximately 10%–25% of maltreated children point out that self-righting tendencies in human development may be strong, even in the face of deviance and failure in the environment (Cicchetti, 2013; Sameroff, 1983). At one level, different parts of the brain may attempt to compensate, and at another, maltreated individuals may seek out new experiences in areas where they possess strengths. Because plasticity is a central feature of the mammalian brain, early neurobiological anomalies or aberrant experience should not be considered as determining the ultimate fate of the maltreated child (Cicchetti & Curtis, 2006). Discovering how maltreated children develop and function resiliently despite their multitude of adverse experiences offers promise for informing the design, implementation, and multilevel evaluation of prevention and intervention programs (Luthar & Cicchetti, 2000).

Research on the correlates, pathways, and developmental course of resilient functioning in maltreated children has predominantly been gleaned from investigations that have focused on psychosocial variables (see Cicchetti, 2013, for a review). For example, in a 3-year longitudinal study conducted in a summer camp context, Cicchetti and Rogosch (1997) found that ego-resiliency and moderate ego-control, as well as self-system variables, predicted resilient functioning in maltreated children; in contrast, ego-resiliency, perceived emotional availability of the mother, and relationship quality with camp counselors were significantly more likely to be predictive of resilient functioning in nonmaltreated children from comparable low-SES backgrounds. Relationships were more critical to developing resilient outcomes in nonmaltreated children, whereas self-system processes and personality characteristics were more central to resilient outcomes in maltreated children. Thus, self-reliance, personal conviction, and self-confidence, in concert with interpersonal reserve, may bode well for the development of resilient adaptation in maltreated children.

In 2003, Curtis and Cicchetti urged researchers to incorporate neurobiological and molecular genetic assessments into their measurement batteries aimed at discovering pathways to resilient functioning. Technological advances in neuroscience and molecular genetics have helped to pave the way for an unprecedented opportunity to examine resilience from a multiple levels of analysis perspective. To date, few multilevel studies of resilient functioning in maltreated children have been completed. As investigations of biological contributions to resilience only have been conducted recently, each of these studies has been cross-sectional in nature.

Curtis and Cicchetti (2007) sought to discover whether the positive emotionality and increased emotion regulatory ability associated with resilient functioning would be related to greater left frontal EEG activity. A large body of literature concerning the meaning and correlates of hemispheric asymmetries in EEG activity has suggested that this ubiquitous phenomenon indexes a neural system that has emotion-specific influences whereby the two hemispheres of the cerebral cortex have been found to be differentially involved in emotion (Davidson, 2000). Specifically, the left hemisphere is associated with positive emotions/approach behavior and the right hemisphere is linked with negative emotions/withdrawal behavior. Emotions, and in particular, positive emotion and good emotion regulatory abilities, have consistently been associated with resilient adaptation. For example, Bonanno et al. (2007) coded genuine

(Duchenne) smiling and laughter and non-Duchenne smiling from videotapes of older adolescent and young adult females. Approximately half of the women had experienced sexual abuse during their childhoods. Bonanno and colleagues found that women who displayed genuine positive affect were significantly more likely to have better social adjustment 2 years later. In contrast, sexually abused women who expressed positive emotion in the context of describing a prior childhood sexual abuse experience had poorer long-term social adjustment, whereas those who exhibited positive affect when describing nonabuse experience had improved social adjustment. Thus, the potential connection of hemispheric EEG asymmetry with resilience lies in their common linkages with emotion and emotion regulation.

EEG asymmetry across central cortical regions distinguished between children with high and low resilient functioning such that left hemisphere activity characterized those maltreated children, who were adapting resiliently based on a competence composite index (e.g., good peer relations, adapting successfully to school, low levels of depressive symptomatology, low externalizing and internalizing psychopathology). Moreover, a behavioral measure of emotion regulation based on 35 hours of observation of the children, also independently contributed to the prediction of resilience in maltreated and nonmaltreated children.

The investigation of a neural-level phenomenon such as hemispheric EEG asymmetry, in the context of resilient adaptation underscores that there is certainly no one single characteristic that will be ascendant in the process of resilience over the course of development. Resilience is a dynamic, interactive, and bidirectional process between multiple levels across time, none of which holds primary importance at any given moment. However, the relative importance of various biological and psychological processes, although inevitably interrelated, may also vary across development.

In another multilevel investigation, resilient functioning in maltreated and nonmaltreated low-income children in relation to the regulation of two stress-responsive adrenal steroid hormones, cortisol and dehydroepiandrosterone (DHEA), as well as the personality constructs of ego resiliency and ego control, was examined. The steroid hormones chosen as potential predictors of resilience were the two primary adrenocortical products of secretory activity of the hypothalamic-pituitary-adrenal (HPA) axis. The capacity of individuals to elevate cortisol levels in response to exposure to acute trauma is important for survival.

DHEA exerts an impact upon a diverse array of biological actions, including effects on the immune, cardiovascular, endocrine, metabolic, and central nervous systems.

A composite measure of resilience was utilized that included multimethod, multi-informant assessments of competent peer relations, school success, and low levels of internalizing and externalizing symptomatology. Cicchetti and Rogosch (2007) found that personality characteristics, ego resiliency and moderate ego overcontrol and the adrenal steroid hormones associated with stress (i.e., cortisol and DHEA) made independent and noninteractive contributions to resilience. Although operating at different levels of analysis, behavioral/psychological and biological factors each made unique contributions to resilience.

Cicchetti and Rogosch (2007) found that higher morning levels of cortisol were related to lower levels of resilient functioning for the nonmaltreated children. High basal cortisol may indicate that nonmaltreated children are experiencing greater stress exposure and, consequently, are constrained in their ability to adapt competently. Within the group of maltreated children, differences in cortisol regulation were found as a function of the subtype(s) of maltreatment experienced. Physically abused children with high morning cortisol had significantly higher resilient functioning than physically abused children with lower levels of morning cortisol. The positive role of increased cortisol for physically abused children is divergent from the more general pattern of higher cortisol being related to lower resilient functioning that was discovered in the nonmaltreated and sexually abused children in this study.

Prior research on neuroendocrine regulation has indicated that physically abused children generally exhibit lower levels of morning cortisol secretion (Cicchetti & Rogosch, 2001a), especially those children who experienced physical abuse early in life (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Cicchetti, Rogosch, & Oshri, 2011). It may be that the subgroup of physically abused children who were able to elevate cortisol to cope with stressful vicissitudes in their lives were demonstrating a greater striving for resilient adaptation. In contrast, the larger subgroup of physically abused children with lower levels of morning cortisol may have developed hypocortisolism over time in response to chronic stress exposure. As a result, for these children there may be a diminished capacity to mobilize the HPA axis to promote positive adaptation under conditions of ongoing stress. In addition, Cicchetti and Rogosch (2007) found that the very low level of resilience among sexually abused children with high basal cortisol may be a product of their different traumatic experiences

and consequences of chronic excessive vigilance and preoccupation, with commensurate HPA axis hyperarousal.

Finally, maltreated children with high resilient functioning exhibited a unique atypical pattern of a relative DHEA diurnal increase. Maltreated children who have the capacity to elevate DHEA over the course of the day may be better equipped to cope with the demands of high chronic exposure to stress and to adapt competently. In contrast, the nonmaltreated children who functioned resiliently did not exhibit the pattern of diurnal DHEA increase; instead they displayed the lowest levels of DHEA across the day. DHEA has been shown to generate effects that are associated with resilience. For example, DHEA counteracts the harmful effects of hypercortisolism, thereby potentially conferring neuroprotection on the brain (Charney, 2004).

The G×E studies on psychopathology reviewed earlier in this chapter are instructive and relevant for research on resilient functioning because they provide an illustration of how genetic variation may confer protection against mental disorder on individuals who have experienced child maltreatment. However, in our view, the absence of mental disorder is conceptually distinct from resilience, a dynamic multidimensional developmental process indicated by positive adjustment across domains of competent functioning despite the experience of significant adversity. Moreover, the presence of mental disorder does not preclude the achievement of resilient functioning. Many persons with mental disorder not only experience periods of remission, but also an appreciable number manage to function in an adaptive fashion for prolonged periods of their lives (Hinshaw & Cicchetti, 2000).

To our knowledge, there has been only one molecular genetic investigation that has specifically set out to test the hypothesis that particular genetic variants might be related to resilient functioning in the presence of child maltreatment. To examine the processes underlying the development of resilience at the molecular genetic level of analysis, Cicchetti and Rogosch (2012) embarked on research aimed at discovering whether there were genetic elements, in interaction with the experience of child maltreatment, that were associated with higher levels of resilient functioning in maltreated and nonmaltreated school-aged children. A multicomponent index of resilient functioning was identified. Four theoretically and empirically informed genes that have been found to be related to behaviors known to be associated with resilient functioning, 5-HTTLPR, CRHR1, DRD4 -521C/T, and OXTR, were chosen and genetic variants in each of these genes were investigated.

Maltreatment consistently exerted a strong, adverse main effect on resilient functioning; however, none of the gene variants of the four respective genes were shown to have a main effect on resilience. In contrast, G×E interaction (G×E) effects were obtained and a similar pattern emerged for all four genes—a particular genotype was found to differentiate between the level of resilient functioning in maltreated and nonmaltreated children more strongly. Contrary to the typical gene–environment interaction (G×E) studies on psychopathology, the results of the Cicchetti and Rogosch (2012) investigation revealed that genetic variation had a negligible effect for the maltreated group in predicting resilient functioning. In contrast, genotype was shown to contribute to higher resilient functioning in nonmaltreated children when they possessed a particular genotype, at least relative to the maltreated children with the same genotype.

In the case of 5-HTTLPR, nonmaltreated children with the *s/s* genotypic variant were more likely to have higher resilient functioning, whereas maltreated children who possessed the same genetic variant had lower resilient functioning. These findings are consistent with a differential susceptibility to environmental influences interpretation (Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011). According to this perspective, the characteristics individuals possess that render them disproportionately vulnerable to adverse experiences also make these same individuals disproportionately likely to profit from supportive contexts. For children who possess the same *s/s* genotypic variant of 5-HTTLPR, nonmaltreated children, in the context of a more normal childrearing environment, achieved higher resilient functioning, whereas maltreated children, in the context of an adverse childrearing environment, demonstrated lower resilient functioning (see van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012).

For CRHR1, nonmaltreated children with zero copies of the TAT haplotype had higher levels of resilient functioning relative to maltreated children with the same number of copies of the TAT haplotype. Once again, these findings are consistent with a differential susceptibility to the environment perspective (Belsky & Pluess, 2009; Ellis et al., 2011). Maltreated and nonmaltreated children had the same genetic variant (i.e., zero copies of the TAT haplotype); however, the nonmaltreated children showed higher levels of resilient functioning, whereas the maltreated children (living in a more stressful context) evinced lower levels of resilient functioning.

Analyses of the DRD4 (dopamine receptor)-521C/T single nucleotide polymorphism (SNP), revealed that

nonmaltreated children and, in particular, those with the TT genotype, were more likely to exhibit higher resilient functioning scores than were maltreated children with this same genotype. The maltreated children manifested lower levels of resilient functioning. As with the previous results for 5-HTTLPR and CRHR1, findings with DRD4-521C/T provide support for the differential susceptibility to environmental influences perspective.

In further analyses, Cicchetti and Rogosch (2012) examined the relation between number of maltreatment subtypes and DRD4 -521C/T genotype to resilient strivings. Maltreated children who had experienced three or four subtypes fared dramatically worse with the TT genotype, whereas nonmaltreated children with this genotype fared the best. Maltreated children with three or four subtypes of maltreatment with the CC or CT genotypes were indistinguishable in level of resilient functioning from nonmaltreated children with these genotypes. Despite the very large detrimental effect that extensive maltreatment exerts on resilient functioning independent of genotype, these results exemplify how the three to four maltreatment subtype groups exhibit the same level of resilient functioning as do nonmaltreated comparisons with the same CC or CT genotypes.

Finally, with OXTR (oxytocin receptor), not being maltreated was related to higher resilient functioning scores; in contrast, maltreatment was strongly related to lower levels of resilient functioning. In particular, nonmaltreated children who had either the AA or AG genotypes of OXTR displayed greater levels of resilient functioning than maltreated children with these same genotypes. Consistent with the findings obtained with the three previous candidate genes, the results provide strong support for the differential susceptibility to environmental influences framework.

It is noteworthy that Cicchetti and Rogosch (2012) identified different gene variants as differentially important through contrasting maltreated and nonmaltreated children and their level of resilient functioning (i.e., low, medium, high). The variation among the genotypes and their relation to functioning differences would not be apparent without the consideration of experience. The genes did not have a singular role, outside of experiential context. The contrast between groups of maltreated and nonmaltreated children was therefore important for understanding development in normal and atypical rearing environments.

Cicchetti and Rogosch's (2012) findings suggest that the genes included in this investigation appear to be minimally related to resilient functioning in maltreated children. Maltreatment consistently had a main effect on resilient

functioning for each of the genes examined. Genetic variation had more of an impact on resilient functioning among the nonmaltreated children who also resided in stressful poverty-laden environments. Accordingly, it appears that the powerful maltreatment main effects may have overshadowed any potential contribution of genetics to resilient functioning in abused and neglected children. Despite the multidomain assessment of adaptive functioning and the large well-defined sample of maltreated and nonmaltreated children, a limitation of the study is its cross-sectional nature. Because resilience is a dynamic developmental construct that is not immutable, future investigations of gene-environment interaction and resilient functioning should be prospective and longitudinal.

Although many investigations of child maltreatment include racially and ethnically diverse populations, possible differences associated with these demographic characteristics are not consistently discussed. Thus, we next turn our attention to this important demographic variable.

Race and Ethnicity

In part as a function of concerns about the overrepresentation of children of color in the child welfare system and heightened awareness about disparities in access to quality health and mental health services for ethnic minorities, examinations of child maltreatment have increasingly sought to incorporate an understanding of issues related to race and ethnicity. The importance of this movement is underscored by findings from the most recent National Incidence Study. As stated earlier, NIS-4, the first NIS to detect racial and ethnic differences in rates of child maltreatment in the United States (Sedlak et al., 2010), found that African American children experience maltreatment at higher rates than do European American children in several subtypes of maltreatment, including higher rates of physical abuse, overall abuse, and overall maltreatment according to both the Harm and the Endangerment Standards. Under the Endangerment Standard, African American children also had higher rates of emotional neglect and overall neglect. The authors of the report qualified these findings by noting that NIS-4 estimates were more precise than those contained in prior NIS reports. Importantly, they also highlighted the role of socioeconomic status in these findings, noting widening income gaps between African American and European American families, with children in African American families being more likely to reside in low-income families.

A growing body of literature has examined factors such as ethnic differences in the disclosure of abuse (Meston,

Heiman, & Trapnell, 1999), utilization of varied definitions of abuse (Collier, McClure, Collier, Otto, & Polloi, 1999), and differences between what constitutes culturally sanctioned parenting and abusive parenting (A. Miller & Cross, 2006). However, despite recognition of the importance of better understanding maltreatment in the context of racial and cultural milieus, research in child maltreatment to date has done little to clarify these issues (Elliott & Urquiza, 2006). Unfortunately, progress on research in this area has been hindered by confounds between race and ethnicity, considerations related to low socioeconomic status among minorities, reliance on retrospective reports of maltreatment, and the utilization of small and geographically diverse samples. Thus, with the exception of robust differences in parenting styles identified among diverse ethnic and racial groups, research on race, ethnicity, and child maltreatment has yielded conflicting results (Elliott & Urquiza, 2006; Sedlak et al., 2010).

However, although there is inconsistency with respect to racial/ethnic differences in child maltreatment, clear differences emerge with respect to case status in the child welfare system (Hill, 2007). African American and Latino American children are more likely to be removed from their homes, to remain in foster care longer, to have more placement changes once removed from their homes, and to be less likely to be reunified with their parents once removed (Hill, 2007). Thus, the criticality of continuing to understand the role of ethnic and racial factors in relation to child maltreatment and the importance of incorporating these variables into future research cannot be minimized. Similarly, considerations associated with gender also warrant attention.

Gender

As with race and ethnicity, the literature on gender differences and child maltreatment has yielded mixed and often inconclusive findings. According to NIS-4, maltreatment gender differences with respect to subtype experienced are present, with girls being at a disproportionately higher risk for sexual abuse than boys (Sedlak et al., 2010). This finding is consistent with prior NIS reports and contributes to an overall increased incidence of abuse in general among girls. When examining the sequelae of child maltreatment, however, the results of investigations to date are much less clear. Over two decades ago, the National Research Council's Panel on Child Abuse and Neglect recommended that research be conducted to ascertain whether differential consequences of abuse occurred by gender

(National Committee on Science Education Standards and Assessment and National Research Council, 1993). Subsequent studies on the long-term consequences of child maltreatment have produced mixed findings. However, in general it appears that although both men and women with histories of abuse were at increased risk for anxiety disorders and alcohol abuse/dependence, only women were found to be at increased risk for depression or drug abuse/dependence (MacMillan et al., 2001). Findings that abused and neglected females were at higher risk for substance abuse/dependence than males also were found in a large longitudinal study (Widom & White, 1997). Data from the National Violence Against Women Survey, which included 16,000 men and women, found that men and women were equally likely to experience physical abuse during childhood and that both genders experienced negative consequences. However, abuse was generally more detrimental for girls, with increased mental health and physical health problems being present in adulthood (Thompson, Kingree, & Desai, 2004). Interestingly, this survey did not reveal gender differences with respect to alcohol or drug use. In an examination of over 5,000 adults, both men and women with histories of maltreatment were more likely to meet criteria for a major depressive disorder, but gender did not moderate the risk of depression (Arnow et al., 2011), contradicting the results of MacMillan and colleagues (2001).

A number of factors need to be considered in trying to understand these discrepant findings. First, the results are typically based on adult retrospective recall of maltreatment, introducing the very real possibility of biases associated with current life difficulties affecting memories. Second, many years elapsed from the occurrence of childhood abuse to adult reports and many intervening life events could influence adult functioning over and above childhood maltreatment. Additionally, few studies have examined gender by victimization interactions, raising the possibility that increased risk, for example, of depression among women could be confounded by higher rates of victimization in women. Investigations also do not consistently examine multiple subtypes of maltreatment or co-occurring subtypes, raising the possibility that the assessment of maltreatment may be incomplete and that the resulting sequelae could differ as a function of subtypes experienced. Finally, definitional differences related to maltreatment commonly exist across studies.

Given the potential difficulties involved with adult retrospective recall, targeting investigations toward childhood emerges as an important avenue for better understanding

possible gender effects and child maltreatment. Although some studies have not detected gender differences in the effects of family violence on children's behavior problems (Sternberg, 2006), others have found effects associated with gender. Sexually abused girls have been shown to experience difficulties controlling intrusive thoughts and to report increased hyperarousal compared to boys (Feiring, Taska, & Lewis, 1999). Perhaps as a consequence of a more ruminative style, maltreated girls have been found to be at increased risk for internalizing symptoms, whereas boys have been shown to be at increased risk for externalizing symptoms (Keyes et al., 2012). However, when externalizing symptoms are present in girls, they may be particularly significant. In a one-year longitudinal investigation, maltreated girls who evidenced early externalizing behavior were found to be at heightened risk for the emergence of subsequent depressive symptoms (Brensilver, Negriff, Mennen, & Trickett, 2011). Moreover, in an investigation of the association among maltreatment, aggression, and gender in school-age children, maltreatment was found to be associated with increased aggression, a relatively robust finding across the maltreatment literature (Cullerton-Sen et al., 2008). However, different patterns of aggression emerged. Maltreatment was associated with physical aggression in boys and with relational aggression in girls. Moreover, physical abuse was associated with physical aggression in general, but sexual abuse was related to relational aggression for girls only. These findings suggest that boys and girls may internalize the experience of maltreatment in different ways, initiating gender-specific pathways to the expression of externalizing behaviors. For example, maltreated girls may learn from their early parent-child interactions that love and affection can be withdrawn as punishment. When confronted with conflict in the peer group, maltreated girls may draw upon what they have learned in the home, such that they use the relationship as a vehicle of harm against their peers (i.e., relational aggression; Cullerton-Sen et al., 2008). In an investigation of the effects of family violence in a cohort of Israeli children, girls were found to be at increased risk for both internalizing and externalizing behavior problems compared to boys (Sternberg, Lamb, Guterman, & Abbott, 2006). Finally, in an investigation of the role of family environment in contributing to the emergence of oppositional defiant disorder (ODD), Burnette (2013) found that girls and boys evidenced equal levels of ODD symptoms. However, gender differences emerged with respect to the impact of physical abuse and emotional responsiveness, with the former being a significant predictor of ODD for

girls and the latter being significant for boys. The emerging literature does suggest gender differences with respect to behavioral symptoms and possible psychopathology and, it in fact mirrors retrospective report surveys that suggest that women victimized during childhood may be at increased risk for some negative mental health outcomes. Taken as a whole, however, issues related to sample size, the examination of developmental timing in relation to maltreatment, and possible delayed consequences need to be considered before definitive conclusions on maltreatment sequelae and gender can be made.

To our knowledge, only one study to date has examined gender differences in stress-hormone neurobiology functioning in maltreated children (Doom, Cicchetti, Rogosch, & Dackis, 2013). In an examination of the neuroendocrine profiles of school-age maltreated and demographically comparable nonmaltreated children, elevated daily cortisol levels were found for boys compared with girls in children having more pervasive maltreatment. Boys with less pervasive maltreatment had lower DHEA and higher cortisol/DHEA ratio levels than girls with similar experiences, nonmaltreated boys, and boys with more pervasive maltreatment. Down-regulation of cortisol was evident in girls with more pervasive maltreatment and in girls who experienced early onset maltreatment.

Although the extant literature is relatively sparse with respect to a consensus regarding gender differences associated with childhood maltreatment, results to date underscore the importance of striving to incorporate gender into investigations. An increased understanding of possible gender differences could ultimately have implications for the assessment of psychopathology and inform the provision of preventive interventions directed toward the amelioration of future psychopathology in children who have been maltreated.

Now that we have concluded our discussion of the consequences of child maltreatment, it is important to consider methodological issues that may affect the strength of conclusions to be drawn from this body of work.

METHODOLOGICAL ISSUES IN MALTREATMENT RESEARCH

Despite important advances that have occurred with respect to the quality of empirical research in the area of child maltreatment, a number of thorny methodological issues require ongoing attention. As evident from our discussion of the sequelae of child maltreatment, research in

maltreatment is complex for a number of reasons, which we elaborate on next.

Definitional Considerations

Perhaps first and foremost, increased agreement needs to occur with respect to defining child maltreatment. Despite the fact that progress has been made in terms of increased rigor in this domain, investigators continue to vary in their approaches to definition. Results are likely to diverge considerably if single subtypes of maltreatment are examined rather than dealing with the reality of a high prevalence of multiply occurring subtypes. Issues pertaining to perpetrator, severity, chronicity, and developmental period during which maltreatment occurs also should be routinely considered. However, limitations related to sample size, difficulty accessing comprehensive information due to legal restrictions on access to maltreatment registries, and report biases in parents and children often impede such efforts. Although the conduct of statistical analyses for all such variables may not be possible, ideally investigators should present descriptive information on these issues. In addition, clear information needs to be provided on how the maltreatment experience, including decisions on the assignment of subtype, was determined. Moreover, sequelae associated with particular subtypes that may not be immediately evident but may emerge over time highlight the importance of conducting longitudinal investigations.

Multiple Subtypes

It is rare that a child who has been maltreated experiences a single subtype of maltreatment. When multiple subtypes occur, it is challenging to determine how best to categorize the maltreatment experience. One strategy that has been used involves basing the “main” subtype designation for analytic purposes on the most societally egregious form of maltreatment, with categorization of sexual abuse, physical abuse, neglect, and emotional maltreatment ranging from most to least severe. In this methodological approach, if a child had been both physically abused and neglected, then they would be categorized as physically abused. Another approach suggests that assignment of the main subtype of maltreatment be based on the most severe form of maltreatment experienced. Thus, if a low level of physical abuse occurred, but a very severe neglect experience were present then the child would be classified as neglected. Regardless of the method adopted, it is critical that investigators clearly describe how the assignment to maltreatment group was made.

Comorbidity

Although concerns around the presence of comorbid disorders are a challenge for psychopathology research in general, this is a particularly problematic issue when investigating the sequelae of child maltreatment. Research consistently demonstrates that maltreatment is highly associated with other negative outcomes, including depression, PTSD, antisocial behavior, and substance use/abuse. When present, therefore, it becomes difficult to ascertain if a given negative outcome is directly attributable to maltreatment or to the co-occurring psychopathology. This is particularly challenging because it is usually impossible to ascertain which condition preceded the other. Again, although it may not be possible to categorize and analyze participants by the presence/absence of co-occurring psychopathology, descriptive information on the presence of psychopathology should be provided when possible.

Economic Adversity

Much of the extant research on child maltreatment has been conducted with economically disadvantaged samples. Although maltreatment is not limited to the low-income sector, children who come to the attention of authorities are much more likely to reside in families from the lower socioeconomic strata. Because a myriad of risks accompany residing in poverty, including exposure to community and/or domestic violence, stressors associated with difficulty meeting basic needs, and being a member of a racial or ethnic minority group, it can be particularly challenging to recruit and to retain participants. In fact, no-show rates with this population, even when home visits are scheduled, frequently average 50% of scheduled appointments. Moreover, research staff are routinely faced with very difficult situations when they enter high-crime communities. Thus, safety concerns need to be addressed. In addition to challenges accessing and retaining research samples, it is difficult to disentangle the effects of maltreatment from the co-occurring risk factors that are present. In efforts to minimize these issues, increased research needs to be conducted with maltreated children from a range of socioeconomic backgrounds.

Prevention and Intervention

Methodological challenges also accompany the conduct of research on prevention and intervention outcome studies. As discussed earlier, recruitment and retention, even for basic research studies, is quite difficult. This becomes

even more complex when enrolling maltreating families in intervention trials. Maltreating families are often not seeking treatment and typically may not even acknowledge that there is a problem and that they or their children require assistance. Retention in randomized control trials (RCTs) is problematic even in treatment-seeking populations, so it is not surprising that it emerges as a significant issue with non-treatment-seeking maltreating families. Once enrolled, further complications arise. When ongoing maltreatment is detected, a report must be filed with Child Protective Services, often resulting in a family becoming angry and withdrawing from treatment. Attrition is further exacerbated if a child is placed in foster care or, when studying children already in foster care, if placement changes occur. Issues related to high housing mobility and too often disconnected or changing cell phone numbers also make the consistent tracking of families difficult. Given the high co-occurrence of domestic violence and child maltreatment, the offending partner may be threatened by the involvement of the child or partner in services and interfere with their participation. All of these variables coalesce to make the attainment of large samples in maltreatment intervention studies particularly challenging. Unfortunately, smaller sample size results in reduced statistical power to detect treatment effects. As the conduct of multilevel investigations of treatment outcome becomes increasingly important, the incorporation of psychophysiological and genetic assessments into research batteries will require even larger samples. Although investigators have developed creative methods of facilitating recruitment and retention of participants, attaining large samples remains difficult. One possible solution is to utilize multiple sites for enrollment. However, the feasibility of this is hampered by the high costs of RCTs in combination with federal funding caps.

In summary, although much progress has occurred since child maltreatment was first identified as a factor that undermines the normative developmental process, significant challenges remain that need to be addressed if this area of research is to continue to advance. Moreover, the importance of ensuring the translation of this body of knowledge into clinical and social policy domains has been increasingly recognized.

Translational Research

Translational research refers to the examination of how basic behavioral and biological processes can inform the diagnosis, prevention, treatment, and delivery of services

for individuals at risk for, or who have developed, a mental illness (National Advisory Mental Health Council, 2000). Consistent with a developmental psychopathology perspective (Cicchetti & Toth, 2006b, 2009; Rutter & Sroufe, 2000), translational research can best be viewed as reciprocal in nature, with both basic researchers and individuals involved in the provision of clinical care benefiting from input derived from the other domain. The impetus to conduct translational research in the behavioral sciences emanated largely from the National Institute of Mental Health (Insel, 2005; Insel & Scolnick, 2006) and was spurred by the recognition of the tremendous individual, social, and economic burdens associated with mental illness (National Advisory Mental Health Council, 2000). As discussed earlier, a considerable body of research has examined the effect of child maltreatment on psychological and, increasingly, biological functioning (Cicchetti & Valentino, 2006; McCrory et al., 2010) and this scientific knowledge lends itself to the development, evaluation, and exportation of models of intervention designed to disrupt the cascade of negative developmental processes (Masten & Cicchetti, 2010).

Because the formation of a secure attachment relationship with the primary caregiver is one of the most important and universal tasks during the first year of life, and because child maltreatment has been shown to disrupt the development of secure attachments, the provision of interventions to promote attachment security in maltreated children has emerged as an important area of translational research.

Dozier, Peloso, Lewis, Laurenceau, and Levine (2008), working with a maltreated foster care population, developed Attachment and Biobehavioral Catch-up (ABC) as an intervention for foster parents. The three main components of this brief attachment theory informed intervention are to (1) provide an environment in which the foster child can feel nurtured and loved even when the parent feels pushed away by the child; (2) help the caregiver work through personal issues that may be interfering with their caregiving abilities; and (3) offer a highly controllable interpersonal environment to allow children to better regulate at the biobehavioral level (Dozier, 2003; Dozier et al. 2009). The ABC intervention is delivered in 10 joint parent-child sessions, and research supports its efficacy at promoting adaptive child attachment behaviors and regulating cortisol. Children from dyads participating in the ABC intervention displayed fewer avoidant behaviors in attachment system-eliciting situations compared to children from dyads who received an educational intervention (Dozier et al., 2009). Additionally, cortisol production in

foster infants and toddlers who received the ABC intervention resembled patterns similar to those found in children who had never been in foster care and was different from patterns found in foster infants and toddlers whose caregivers participated in an educational intervention (Dozier et al., 2008).

Moss and colleagues (2011) demonstrated the efficacy of a very brief (eight 90-minute sessions) parent-child intervention compared to a control condition to reorganize attachment for maltreated children Ages 1 to 5. Intervener structured parent-child play sessions were video-recorded and then watched immediately with the parent during the session to discuss parental observations and reinforce sensitive parental behavior (Moss et al., 2011). Children in the intervention condition were more likely to change from insecure or disorganized attachments to secure attachments after the 8-week intervention than the children in the control condition.

A widely utilized and evaluated intervention for young children with histories of maltreatment, Child Parent Psychotherapy (CPP; Lieberman & Van Horn, 2005) has its origins in attachment theory, developmental psychopathology, and stress and trauma work, and is also informed by cognitive-behavioral and social learning theories (Lieberman & Van Horn, 2009). CPP has gained increased attention as an evidence-based, culturally sensitive treatment for maltreated children and their caregivers.

Rather than focus individually on the child or parent, the therapist's client in CPP is the relationship between the caregiver and child. Through dyadic sessions, the therapist utilizes the child's spontaneous play and naturally occurring interactions between the parent and child as a vehicle for understanding maladaptive relational patterns and as an entryway for therapeutic change. The therapist encourages mutually enjoyable interactions between the parent and child, provides a voice for the child in order to interpret needs that the parent may be struggling to understand, and encourages developmentally appropriate parental expectations.

An additional focus of CPP involves helping the parent develop insight into how the "ghosts" from maladaptive relationships in his or her past can be influencing the present day interactions with the child in an effort to break the intergenerational transmission of maladaptive relational representations from parent to child (Fraiberg, Adelson, & Shapiro, 1975). The CPP model also recognizes the influence of broader contextual factors on the occurrence of child maltreatment and on the developing relationship between the parent and the child.

CPP has been found to be efficacious in a number of RCTs. Cicchetti and colleagues (2006) conducted an RCT of CPP compared to a psychoeducationally based parenting intervention (PPI) for maltreated infants and their primary caregivers. Preintervention, 87.5% of infants in the CPP condition and 83.3% in the PPI intervention evidenced disorganized attachments. Postintervention, these rates had decreased to 32% and 45%, respectively, for CPP and PPI, with the majority of toddlers in each intervention developing secure attachments by the end of the intervention. The two intervention groups had higher rates of securely attached children postintervention than the community standard group, although they did not differ from each other. Results provide strong support for the efficacy of CPP in promoting secure attachments in infants from maltreating families.

Another randomized clinical trial, conducted by Toth and colleagues, sought to explore the impact of CPP on preschool children's representations of self and mother (Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002). Children and their caregivers were randomly assigned to CPP, PPI, or community standard, and representational models were assessed with the MacArthur Story-Stem Battery (Bretherton, Oppenheim, Buchsbaum, Emde, & The MacArthur Narrative Group, 1990). Children in the attachment-based intervention, CPP, experienced declines in negative self-representations and maladaptive maternal representations and increases in positive self-representations and mother-child relationship expectations from pre- to postintervention. While changes in representations were also found in the PPI condition, negative self-representations decreased significantly more in CPP than with PPI, and positive self-representations and mother-child relationship expectations improved nonsignificantly in the CPP relative to the PPI condition. These findings highlight the efficacy of CPP for reworking representations of self and other in maltreated children.

In addition to promoting attachment security in maltreated infants and improving representations of the self in maltreated preschoolers, CPP also promotes positive child adaptation in other domains. CPP was more effective than community-standard-plus-case-management at decreasing child behavioral problems and trauma symptoms for children aged 3 to 5 who had been exposed to marital violence (Lieberman, Van Horn & Ghosh Ippen, 2005). A 6-month follow-up study of CPP found that reductions in child behavior problems were maintained, suggesting the durability of CPP for treating child symptoms (Lieberman, Ghosh Ippen & Van Horn, 2006). The sustained

efficacy of CPP in promoting secure attachment 1 year posttreatment has been demonstrated (Pickreign Stronach, Toth, Rogosch, & Cicchetti, 2013). Not only did children receiving CPP have higher rates of security than children in the psychoeducational parenting model, but rates of disorganized attachment did not differ between children who received CPP and the nonmaltreated comparison children. Thus, although CPP and a psychoeducational parenting intervention both facilitated the completion of treatment, only CPP resulted in sustained security of attachment, suggesting that, although parenting interventions alone may be effective in the short term, they may not result in sustained attachment security over time.

The above findings support the efficacy of CPP in controlled research trials; however, it is critical that preventive interventions be exported to the clinical world more broadly once efficacy has been established. CPP was examined in a community setting emphasizing wraparound care for diverse youth in foster care (Weiner, Schneider, & Lyons, 2009). Child traumatic stress symptoms and behavioral and emotional needs decreased significantly for African American, biracial, and Latino American children receiving the CPP intervention, but not for European American children (Weiner et al., 2009). Additionally, risk behaviors decreased and strengths increased for African American and biracial children participating in this study (Weiner et al., 2009).

The feasibility and effectiveness of CPP was also examined in a community setting with families in which the parents had maltreated their children and were court-ordered to participate or were identified as at high risk for abuse or neglect (Osofsky et al., 2007). Attrition was high, with more than 50% of families dropping out before engagement or during treatment; however, increased behavioral and emotional responsiveness and positive discipline were observed in the caregivers who completed treatment, as was decreased intrusiveness. Additionally, development improved in at least one domain (communication, gross motor, fine motor, problem solving, or personal-social) for 50% of the children receiving CPP who had previously been screened as at risk for developmental delay. Importantly, during the first 3 years of the pilot study, there were no new reports of child abuse or neglect involving children completing CPP with their caregivers. These studies provide preliminary evidence for the feasibility of utilizing CPP with families willing to engage in a community setting, and results suggest that child symptom reduction and improved parenting are attainable when CPP is exported from the laboratory into the nonacademic clinical arena.

Research has coalesced to suggest that early preventive interventions with maltreated children are capable of promoting normative neurobiological development (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; Fisher, Stoolmiller, Gunnar, & Burraston, 2007), highlighting the continued importance of studying change processes in the lab while applying efficacious interventions in the community.

A relatively new frontier with respect to evaluating and translating knowledge on efficacious interventions emanates from genetics research. As knowledge on the interplay of genes and the environment has increased, the benefits for prevention efforts have been suggested by both animal and human research. Importantly, as knowledge of genetic moderation with respect to prevention and treatment outcome increases, ethical questions also arise. Some may suggest that more cost-effective and efficient interventions could be delivered if youth with particular genetic constellations that place them at risk for maladaptive outcomes are screened and that only those most likely to benefit from a given intervention subsequently receive it. However, a number of considerations argue against this approach (Howe, Beach, & Brody, 2010). First, single genes or single $G \times E$ combinations fail to account for sufficient variance in outcomes to support screening for intervention provision. Most likely, multiple developmental pathways will eventuate in positive outcomes, a concept consistent with multifinality. It is more likely that genes will constrain or enhance various pathways than that they will deterministically contribute to outcomes, in part because the same genetic pattern may constrain a pathway in one context and enhance the same pathway in another context (Howe et al., 2010). The multiply influenced course of development cautions that genetic screening for selective intervention is unlikely to provide significant benefits in advancing intervention efforts, particularly given the current nascent state of research on $G \times E$ and intervention outcomes.

Although basic research is increasingly being translated to the prevention and treatment of child maltreatment, the growth of basic research knowledge has surpassed its application to mental disorders more generally. The prevention and treatment of the sequelae of child maltreatment is not an exception to this unfortunate reality. In order to bridge the gap between basic and applied research and its application to problems of clinical importance, investigators and clinicians must stretch beyond traditional boundaries. Collaborations across disciplines are necessary if areas as diverse as neuroscience, genetics, emotion, cognition, social cognition, and interpersonal processes are to be

incorporated into addressing the needs of children in maltreating families. As efforts have expanded to incorporate basic research knowledge into clinical arenas, it has become increasingly clear that this is necessarily a gradual process. To begin, it is critical that those conducting basic research are committed to conceiving their questions with the goal of having findings ultimately inform applications of the knowledge gained (Cicchetti & Toth, 2006b). Clearly, before theoretically informed models of prevention or intervention can be developed, applied to maltreating populations, and evaluated, there must be an understanding of the mechanisms and processes that contribute to a maladaptive course of development. As an exemplar of this process, the extensive basic research conducted on attachment theory and the consequences associated with children developing insecure or disorganized attachments to their primary caregivers contributed to the development of CPP. This theoretically derived intervention was then rigorously tested in multiple efficacy trials to determine its utility for maltreating families and for families with domestic violence in highly controlled research settings. Now that efficacy has been established, effectiveness studies have been and are currently being undertaken to determine the feasibility of exporting this empirically based treatment into the broader clinical arena. As a last step in this process, it is important for the scientific community to be open to feedback from those implementing interventions in the field and to use this information when revising interventions and seeking mediators and moderators of treatment efficacy. As will be discussed below, it also is critical that evidence-based models of intervention continue to be evaluated once exported to new community settings. Such initiatives will increase the probability that research will ultimately result in informing social policy for maltreated children.

Social Policy Perspectives

The value of translational research leads directly into considerations related to the social policy arena. The personal and economic burden of child maltreatment highlights the importance of utilizing information derived from research to inform policy initiatives. However, despite what should be an almost seamless integration of research, practice, and social policy, reciprocally beneficial interactions among these arenas have been difficult to achieve (Toth & Cicchetti, 2006). In reflecting upon impediments to this integration, Shonkoff (2000) suggested that, whereas scientists are trained to raise questions and to be guided by facts, policy makers are more prone to be governed by

political and economic forces. Similarly, service providers are more like policy makers because they are often faced with situations that require immediate action before empirical data are available to inform specific intervention strategies. In reflecting on this tension, Shonkoff (2000) stated, "Science is focused on *what we do not know*. Social policy and the delivery of health and human services are focused on *what we should do*" (p. 182, italics in the original). Even when data are available to inform intervention strategies, the realities of heavy clinical caseloads and lack of access to easily assimilable empirical information by clinicians and policy advocates may limit the likelihood of clinicians and policy advocates adopting evidence-based interventions. Unfortunately, over a decade since these observations were made, individuals committed to addressing the problem of child maltreatment continue to struggle to achieve an integration of research, practice, and social policy.

Increased calls have been made for the utilization of science to guide policy making and funding decisions (Baron & Haskins, 2011; Haskins & Baron, 2011). In fact, the Obama Administration has done much to advance the incorporation of scientific data into policy-making decisions. During his initial inaugural address, Obama stated that an important goal of his presidency would be to expand social programs that work and to eliminate those that are ineffective (Haskins & Baron, 2011). Early in his administration, six initiatives to expand evidence-based social programs were launched, including the utilization of home visitation to improve maternal and child health, early childhood development, and family functioning and programs to prevent teen pregnancy (see Orszag, 2008). Unfortunately, even when evidence exists that a program is ineffective, political forces may make it difficult to eliminate funding for these programs and redirect the funding toward those that are evidence-based (Baron & Sawhill, 2010).

Haskins and Baron (2011) argued that better population-level outcomes in education, crime reduction, and child well-being would occur if policy and funding decisions were made based on evidence of what works. The call for the utilization of evidence-based approaches, referred to as technocracy, is the norm in physical health care (Dodge & Mandel, 2012). However, in addressing the contrast between health care and issues affecting children, Baron (2007) stated:

In medicine...rigorous evaluations are common, and often drive policy and practice. By contrast, in education and most other areas of social policy, such studies are relatively rare.

In these areas, policy and practice tend to be driven more by advocacy studies and anecdote than by rigorous evidence, costing billions of dollars yet often failing to produce meaningful improvements. (p. 32)

In view of the magnitude of the adverse consequences of child maltreatment on both psychological and physical health outcomes, it is imperative that policy makers address and remedy difficulties in accessing high quality trauma-informed services. Because evidence-based services for children who have been maltreated are increasingly available (Toth, Gravener, Guild, & Cicchetti, 2013), the failure to ensure their widespread availability is particularly egregious. In order to reduce impediments to access, partnerships among professionals working with children, elected officials, and public interest advocates are critical (Harris, Lieberman, & Marans, 2007; Toth & Cicchetti, 2006).

It is unlikely that anyone invested in promoting the welfare of children would disagree with the importance of attaining the above-stated objectives. Why then has the reduction of the divide among research, practice, and social policy been so difficult to realize? A number of issues need to be considered, including points of entry to care, allocation of resources, and community-wide uptake.

Entry to Care

Chu and Lieberman (2010) discuss entry points to care for young children exposed to trauma. Although pediatric care providers are the professionals most likely to come in contact with young traumatized children, their effectiveness in identifying possible trauma may be hindered by a number of issues, including the brief visit duration, lack of training in recognizing trauma flags, and minimal knowledge regarding referral sources if trauma is revealed. Mental health providers may similarly lack knowledge regarding the identification of trauma in young children and when trauma is identified they may not have adequate training on the provision of evidence-based models of intervention. Childcare providers also are unlikely to have adequate training on the identification of trauma. Despite the high co-occurrence of domestic violence and child maltreatment, domestic violence shelter staff most typically focus on the needs of adult victims and fail to assess or address the presence of child trauma. Although the court system can mandate treatment for victims of child abuse, court personnel are also unlikely to be adequately versed in understanding the effects of trauma and the need for treatment. Unfortunately, the child welfare

system also often focuses on addressing parenting and may fail to consider the needs of maltreated children. When the need for treatment is recognized, far too few professionals are available to provide evidence-based trauma-informed treatments. Fortunately, systemic barriers to access to care can be minimized through large-scale educationally based initiatives that encourage collaborations among professionals from diverse disciplines. One such national initiative, the National Child Traumatic Stress Network (<http://www.nctsn.org>), has been very successful in increasing the availability of evidence-based services for traumatized children and improving the quality of care for children and families throughout the United States.

Allocation of Resources

Although there has been increased recognition of the importance of supporting evidence-based social programs, political forces that operate do not always act in accord with this goal. The decisions of policy makers are governed by myriad issues, including program cost, input from constituents, the position of party leaders, public opinion, pressure from lobbyists, and their own political philosophies. Far too often, politically “favored” programs are held intact or allocated increased resources. At times, even scientific evidence that identifies iatrogenic effects of programs is ignored (Barlow, 2010). As researchers accrue more and more evidence regarding effective prevention and treatment programs for children who have been maltreated, it will be increasingly important that they strive to ensure that findings are disseminated to and incorporated into the funding decision process. However, that is not to say that funding should be eliminated to support efforts to develop new innovative programs. Unfortunately, it is all too clear that even programs with strong scientific support are not equally effective for all individuals. Moreover, despite decades of research dedicated to evaluating programs designed to foster positive outcomes for children faced with economic and familial disadvantage, many with favorable outcomes, the overall effect sizes for these programs remain within the small to moderate range (Shonkoff & Fisher, 2013). Moreover, some evidence-based models, although shown to be effective for a designated population, address only a small percentage of individuals in need. For example, although the outcomes for the Nurse-Family Partnership home visitation program have been shown to be effective in a number of important arenas, such as improving parental caregiving and child health and preventing child abuse and neglect (Kitzman et al., 1997; Olds, Henderson,

& Kitzman, 1994), it limits enrollment to first-time mothers who are identified during their first trimester of pregnancy. Because many young mothers living in poverty do not seek prenatal care, these inclusion criteria result in the ineligibility of significant numbers of very high-risk mothers. Therefore, although efforts to increase the availability of evidence-based programs should be applauded, it would be premature to conclude that resources should be directed only toward those programs that have been supported by rigorous evaluation. Rather, *funding should be eliminated for programs that have been shown to be ineffective* and resources should be *channeled toward a combination of evidence-based models and innovative approaches* designed to address unmet needs or to improve the magnitude of positive outcomes for vulnerable children and families.

Community-Wide Uptake

Most typically, the “evidence base” for programs is derived from university-based randomized control trials (RCTs). Although these approaches reflect the “gold standard” in the field, they are not without challenges with respect to dissemination into community settings (Sternberg, 2006; Toth & Manly, 2011). RCTs are conducted under very controlled and often ideal settings, including utilization of strict inclusion and exclusion criteria for participants that make them unrepresentative of those seeking mental health care in community settings. Unfortunately, and not surprisingly, when such social programs are disseminated into community settings, they yield not only low rates of utilization with respect to individuals eligible for such services, but also tend to be less effective due to issues such as lower credentialed and less experienced providers, lack of supervision, and failure to ensure fidelity of implementation (Dodge & Mandel, 2012). This has been referred to as the “scale-up penalty” and estimated at 50% (Welsh, Sullivan, & Olds, 2010). Moreover, some changes during dissemination are planned and do not always lead to the intended positive outcome, resulting in considerable variation in the effectiveness of programs provided as part of RCTs and those exported to community settings (Weisz & Jensen, 1999). The way in which an intervention is conceptualized is also very likely to contribute to whether a community is invested in providing it and adhering to its fidelity (Dodge, 2008). Therefore, in order to promote community uptake, it is critical to consider the ultimate goal of exportation from the initial conceptualization of an RCT. Loosening parameters around the inclusion/exclusion of participants,

for example, ultimately might result in the likelihood that the intervention can be disseminated more effectively (Toth, Pianta, & Erickson, 2010). Regardless, despite best efforts to ensure effective implementation of an evidence-based model in community settings, it is critical that evidence on fidelity of implementation and outcomes within a given community be assessed. For this reason, some advocate that legislation should provide a mandate for ongoing evaluation of federally funded programs once evidence-based models have been disseminated to communities and provide the funding to make such evaluation possible (Haskins & Baron, 2011).

Now that we have concluded our discussion of definitional considerations and etiological models of child maltreatment and addressed the psychological and biological sequelae accompanying maltreatment, as well as implications for intervention, translational research, and social policy, we turn our attention toward exciting future opportunities for those committed to continuing the journey to prevent child maltreatment and its deleterious consequences.

THE NEXT GENERATION: NEW FRONTIERS IN CHILD MALTREATMENT RESEARCH

It is clear that the experience of child abuse and neglect, and the concomitant poor quality care received, exert a harmful impact on the development and functioning of multiple biological and psychological systems across the life course. However, despite considerable progress in understanding the consequences of maltreatment, important frontiers remain to be discovered.

It is of paramount importance that rigorous and precise definitions of the maltreatment experience be incorporated into all investigations of child maltreatment. Unless this very basic goal is routinely achieved, it will be impossible to move forward in increasing convergent findings related to the sequelae associated with various subtypes and dimensions of maltreatment. Such coherence is particularly important when seeking to translate research from basic investigations into the design and evaluation of prevention and intervention trials.

Studies of psychopathology and mental health have largely neglected the period between adolescence and adulthood (Schulenberg, Sameroff, & Cicchetti 2004). This unfortunate omission is no less true in research that has been conducted on child maltreatment. Although early experience is critical, its influence on subsequent

psychopathology and mental health is highly likely to be moderated by later experience (Cicchetti & Tucker, 1994; Sroufe, 1997). The failure to adequately account for the effect that experiences during this critical transitional period may exert on future functioning becomes particularly problematic when the retrospective recall of adults is relied upon to gauge the effects of early maltreatment. The conduct of investigations on the transition to adulthood in individuals with histories of child maltreatment emerges as a largely untapped arena. In this regard, the examination of relevant stage-salient mechanisms that may be operative during this period is particularly important. Longitudinal research will be needed to provide vital information about how maltreated adolescents and adults resolve later stage-salient developmental issues such as identity formation, autonomy, the development of personal relationships, intimacy, and work.

Most investigations of the consequences of child maltreatment have examined neurobiological and psychological systems separately. The time has come to emphasize the conduct of longitudinal research that examines biological and psychological systems concurrently over developmental time. In addition to multilevel investigations in basic maltreatment research, the incorporation of multi-level measurement strategies into RCTs of interventions for individuals with histories of maltreatment will be particularly important (Cicchetti & Gunnar, 2008). Such strategies may highlight very divergent mediators and moderators of treatment outcome in individuals with the same disorder who have or who have not experienced maltreatment. Moreover, determining the multiple levels at which change is engendered through RCTs that incorporate biological and psychological assessments of intervention efficacy will provide more insights into the processes of change and the extent to which neural plasticity may be promoted.

It is important to conduct longitudinal neuroimaging studies of maltreated children and adolescents. Moreover, there is a paucity of neuroimaging investigations that focus on brain function (i.e., fMRI and magnetoencephalography [MEG]) in maltreated individuals. Likewise, it is essential that neuroimaging research includes community samples of maltreated persons. Most of these studies have been conducted on maltreated individuals residing in psychiatric hospitals. These samples present many challenges to disentangling the effects of maltreatment on brain structure and function from other competing conditions (e.g., comorbid psychopathology; substance abuse; medication; psychotherapy).

Although groups of abused and neglected children have been found to differ from groups of nonmaltreated children from similar social class backgrounds on the vast majority of the biological and psychological systems investigated to date, not all maltreated children are affected by their experiences in the same fashion. Despite experiencing significant adversity, there are maltreated children who develop in a psychologically resilient fashion.

Furthermore, the neurobiology of some maltreated children does not appear to be structurally or functionally aberrant and may be reflective of an enhanced neural plasticity in resilient individuals (Cicchetti & Curtis, 2006). It remains to be discovered whether the neurobiological structural and/or functional difficulties displayed by abused and neglected children are irreversible, or, if reversible, whether there are sensitive periods when it is more likely that neural plasticity can occur. In addition, investigations must be conducted that examine whether some neural systems may be more plastic than other neural systems or whether particular neural systems may be more refractory to change, or have a more time-limited window when neural plasticity can occur. Because the brain is a dynamic, self-organizing system that is mutable, future neuroimaging research should strive to ascertain whether the brain structure and functioning of resilient maltreated children differ from those of resilient nonmaltreated children.

Relatedly, because resilience is a dynamic developmental process, it is critical that short- and long-term longitudinal studies on the determinants of resilient functioning are conducted in the future. Resilient functioning is not immutable. Transitional “turning points” (Rutter, 2012) provide opportunities and challenges for individuals either to remain on a positive trajectory despite ongoing adversity, to “bounce back” from a decline in functioning, to persist on a maladaptive trajectory, or to exhibit a decline in functioning from positive functioning (Cicchetti & Rogosch, 1997). In these longitudinal investigations, resilience should be conceptualized as a multidomain, multidimensional construct. Changes in one domain of competent functioning can cascade to affect other developmental domains over time (Cicchetti & Tucker, 1994; Masten & Cicchetti, 2010). Hence, a longitudinal multiple levels of analysis approach to investigating resilient functioning in maltreated children will help to ensure that resilience processes are examined in a thorough and developmentally appropriate fashion.

Findings from examinations of resilience in maltreated children hold great potential for informing preventions and intervention initiatives. When indicators of resilience

are identified, they can be incorporated into the development of RCTs. The conduct of longitudinal investigations of resilience will be particularly important in ensuring that interventions are timed, guided, and implemented as closely as possible to the identification of deviations from adaptive functioning (Luthar & Cicchetti, 2000; Toth & Cicchetti, 1999).

Although the number of evidence-based interventions that are available to treat children and adults with histories of maltreatment has increased, the dissemination and wide availability of evidence-based models must be expedited. Toward this end, exportation to community settings and the subsequent conduct of effectiveness trials must be a priority for individuals involved with the development and conduct of RCTs demonstrating efficacy. Unless a commitment to dissemination is made upon the completion of successful efficacy trials, valuable treatments may languish in academic settings. In addition, far more evidence-based models are available for treating the aftermath of maltreatment than for preventing its occurrence. Therefore, more attention needs to be directed toward the development of interventions directed toward the prevention of maltreatment. The field also would benefit greatly from research targeted toward identifying factors related to stopping the transmission of maltreatment across generations so that protective factors could be built into interventions for families that are at risk for multigenerational maltreatment.

Future investigations of molecular genetic contributions to resilience also should pay more attention to the process of development (D). For example, G×E×D studies could provide valuable information about how a particular genotypic variant may operate differently depending on the developmental period or environmental context.

We possess virtually no information about the effects of child maltreatment in middle- or upper-socioeconomic environments. Maltreatment clearly transcends social class. Consequently, research on the developmental consequences of child maltreatment and on pathways to resilient adaptation in children raised in non-low-SES environments is important to conduct to discover similarities and differences in the development of resilient functioning across various social class strata. It would be interesting to ascertain whether family and community protective factors are more likely in middle-SES maltreating families than in maltreating families from the low-SES. Would any of the resources that are more common in non-low-SES maltreating families result in different pathways to maladaptive or resilient functioning, or to a significantly higher percentage

of resilient children? Nonmaltreated children in affluent backgrounds are not immune to developing substance abuse or psychopathology (e.g., depression). Indeed, youth from affluent families can even exhibit more problematic functioning than youth from the low-SES (Luthar & Barkin, 2012). Thus, comparison of maltreated children from different SES backgrounds may shed light on differential pathways to resilient functioning.

In view of the paucity of cohesive findings on race and ethnicity, it will be increasingly important for investigators to conduct research with diverse samples. Moreover, rather than simply utilizing demographics on race and ethnicity in a descriptive manner, examining possible differences among individuals with diverse backgrounds will be particularly important. In this regard, it is equally important to conduct multilevel research on the pathways to resilient adaptation in maltreated children from different cultures.

As discussed earlier, although findings on gender and maltreatment are beginning to emerge, this line of inquiry requires much more development. Given the attentional biases with respect to anger that have been identified in maltreated children, it is possible that boys and girls may vary in their reactions to different emotional expressions and that these differences could relate to the type of psychopathology that occurs. In a related vein, it is possible that gender differences may occur with respect to how maltreated children process and understand their abusive experiences and that these processes could vary by gender/subtype interactions. Both of these lines of research could ultimately possess implications for the development of intervention strategies.

Epigenetics, the study of heritable changes in gene function that do not alter the DNA sequence, but instead provide an extra layer of transcriptional control that regulates gene activity and plays an important role in the acute regulation of genes in response to environmental changes, is a promising avenue for both basic and intervention research on child maltreatment. Epigenetic research has the potential to serve as a mechanism to explain how maltreatment experiences confer risk for physical and mental health problems.

DNA methylation has been the most studied epigenetic mechanism in research on child abuse and neglect. Alterations in methylation, which manifest as changes in CpG (a site at which cytosine [C] resides next to guanine [G] in the DNA sequence) motifs, may persist in a stable form over a long time. Alterations in the structure of chromatin influence gene expression. Specifically, genes

are switched off when chromatin is silent, and they are switched on (i.e., expressed) when chromatin is active. These dynamic states of chromatin are controlled by a number of processes, including epigenetic patterns of DNA methylation. Individual differences in DNA methylation thus are a potential biomarker of the contributions that environmental factors make to the divergence in phenotypes of maltreated individuals who possess similar genetic endowments.

Several investigations have used a candidate gene approach to examine the effects of child abuse and neglect on methylation. Epigenetic regulation is a viable candidate mechanism through which caregiving behaviors, including child maltreatment, may exert long-term effects on HPA activity and neuronal function (Szyf & Bick, 2013). Candidate genes utilized in this regard to date include the serotonin transporter gene, the glucocorticoid receptor gene, and FKBP5 (the binding protein 5 gene). These studies have found that child abuse was associated with increased methylation in both the serotonin transporter and the glucocorticoid receptor genes (see Yang et al., 2013, for a review).

For example, Klengel et al. (2013) found that FKBP5, an important functional regulator of the stress hormone system, increased the risk of developing stress-related psychiatric disorders in adulthood through allele-specific (i.e., a particular functional polymorphism), childhood trauma-dependent DNA demethylation in functional glucocorticoid response elements of FKBP5.

Most investigations with humans have employed a candidate gene approach to identify specific sites of DNA methylation changes. Investigations that have utilized a genome-wide approach have found that these methylation changes occur at many gene loci. Research with animals who experience abuse demonstrates that experience-induced changes in DNA methylation occur in brain circuits that have functional relevance to trajectories of normal and abnormal behavior. Accordingly, experience-driven DNA-methylation changes in maltreated individuals also have implications for disruptions in neural circuitry and behavior (Szyf & Bick, 2013). Likewise, using salivary DNA specimens, whole-genome methylation differences have been found between maltreated and nonmaltreated children at 2,868 CpG sites. A substantial number of genes implicated in prostate, colorectal, breast, colon, and ovarian cancer were contained in the set of genes that showed differential methylation between maltreated and nonmaltreated children (Yang et al., 2013). These studies each focused on a site-specific gene and collected DNA from lymphoblasts

(Beach, Brody, Todorov, Gunter, & Philibert, 2011) or from whole postmortem brain tissue in maltreated adults who committed suicide (McGowan et al., 2009). The results of these investigations suggest that epigenetic mechanisms also may be associated with risk for developing major health problems in later life (Yang et al., 2013).

There is nothing that can be done to prevent the DNA sequence variations that eventuate in the emergence of risky phenotypes. On the other hand, DNA methylation changes in response to experiences such as child abuse and neglect could help to bring about the design, implementation, and multilevel prevention and intervention strategies that change the expression of risky genes through reversal or demethylation and thereby promote healthy physical and mental health development. Szyf and Bick (2013) concluded that DNA methylation adaptations early in life are system-wide and that they involve multiple gene circuits. Thus, because responses to social adversity such as child maltreatment are not limited to the brain and also likely affect peripheral tissues, it is also possible to assess the efficacy of an intervention in peripheral cells.

Prevention and intervention strive to alter the environment in order to bring about positive outcomes. Research on epigenetics suggests that prevention and intervention also may change the epigenome and that this also could result in improved outcomes. If researchers are to understand the processes through which early adverse experiences such as child maltreatment impart maladaptation, psychopathology, or resilience, then it is critical that genetic variation (functional polymorphisms) and epigenetic modifications are examined (cf. Klengel et al., 2013).

The knowledge base on the effects of child abuse and neglect has increased exponentially since the early stages of this research were initiated approximately 50 years ago. Technological advances open up more avenues for elucidating the mechanisms and processes that contribute to the deleterious consequences associated with maltreatment, and to the development of resilient functioning in the face of adversity, as well as for shedding light on the development and implementation of exciting and effective prevention and intervention strategies.

Despite vast increases in the knowledge base, far too many children continue to be victimized by child maltreatment and the toll of child maltreatment can last a lifetime. It is therefore critical that knowledge not only continues to increase, but also that the resulting information is disseminated to society more broadly. Only then will scholars have truly succeeded in addressing the lifelong tragedy that all too often accompanies child maltreatment.

Longitudinal Studies of Parent–Child Conversation	576
Theory of Mind and Children’s Relationships With Siblings	579
Friends, Peers, and Theory of Mind	580

The capacity to attribute mental states to others has been studied in various disciplines, under a variety of different names: “folk psychology”; “common-sense psychology”; “mentalizing”; “social understanding”; “mindreading”; and, of course, “theory of mind” (Apperly, 2011; Carpendale & Lewis, 2004; Frith & Frith, 2003; Premack & Woodruff, 1978; Ratcliffe, 2007). Our use of the term *theory of mind* in this chapter does not signal an alliance with a particular theoretical perspective but is, instead, pragmatic. Although the terms “social understanding” and

Individual Differences in Theory of Mind Reflect a Complex Interplay of Social and Cognitive Influences	600
Individual Differences in Theory of Mind May Underpin Variation in Social and Academic Outcomes	601
REFERENCES	602

“folk psychology” encompass a wide range of psychological constructs, such as the ability to attribute emotions and feelings to an agent (e.g., Hughes, 2011) or to appreciate the influence of traits and biographical details on behavior (e.g., Morton, 1980), the term theory of mind usually refers more specifically to children’s understanding of epistemic and volitional mental states (i.e., beliefs and desires). Research in this field has thus centered on children’s (and, to a lesser extent, adults’) understanding of these two types of mental state; as a result, the understanding of these two types of mental state are key foci for this review chapter. The term theory of mind has, since its introduction to the literature on children’s cognitive development become very widely used in fields as diverse as

We would like to thank Eva Filippová for her comments about earlier drafts of this chapter.

philosophy of mind (e.g., Ratcliffe, 2007), comparative psychology (e.g., Emery & Clayton, 2009), neuroscience (e.g., Frith & Frith, 2003), psychopathology (e.g., Sprong, Schothorst, Vos, Hox, & Van Engeland, 2007), economics (e.g., Gummerum, Hanoch, & Keller, 2008), and literary theory (e.g., Zunshine, 2007). Many different explanations for this breadth of research interest in theory of mind can be offered. For developmental psychologists, young children's acquisition of a concept of mind is intrinsically impressive, in that it implies that children, like psychologists, speculate about the unobservable causes of behavior. Preschool children's awareness of mental states is all the more remarkable when one considers that at this age children can be deceived by the simple physical transformations (e.g., pouring liquid between differently shaped containers or rearranging an array of chocolate treats). Moreover, many preschool children also appear adept at applying their understanding of mind to engage in sophisticated social interactions such as joking, teasing, and cooperative pretend play. For researchers in other disciplines, the concept of theory of mind has been valuable in a variety of other ways. For example, success or failure in anticipating people's reactions to situations is pivotal to accounts of how fortunes are made and lost by players in either financial or the political sectors; likewise, literary success depends upon a writer's ability to enable readers to inhabit fictional characters' mental worlds. Interest in why people differ from one another in their ability to "read minds" and the extent to which these differences matter is therefore not limited to developmental psychology.

Our introductory section begins by outlining how the focus of research on theory of mind has shifted—from developmental changes and impairments associated with autistic spectrum disorder (ASD) to the origins of individual differences, to the integration of findings from different age groups, different cultural groups and a broader array of atypical groups. Next, this section considers corresponding shifts in theoretical accounts of development in theory of mind: the "big three" theories (that is, theory theory, simulation theory, and modularity); the individual differences perspective; and new alternative accounts that attempt to integrate findings from infancy and adulthood.

The second section is quite lengthy and divided into seven parts, devoted to distinct lines of research that provide converging evidence for social influences on children's understanding of mind. These strands of evidence include: investigations into the relative similarity of fraternal and identical twins on tests of theory of mind, studies of deaf children with hearing versus deaf parents, training

studies, longitudinal studies of relations between family discourse and theory of mind, studies of sibling influences on theory of mind, studies of how friends and peers may contribute to children's theory-of-mind skills, and cross-cultural comparisons of children's understanding of mind. The third section then turns to cognitive correlates of theory of mind or, more specifically, to the links between theory of mind and executive function (the set of higher order skills that underpin flexible, goal-directed thought and action) on the one hand and language ability (both semantic knowledge and mastery of different forms of syntax) on the other. Research on these parallel topics has been prolific and there are now meta-analytic reviews that enable researchers to examine the developmental claims more closely. The fourth section summarizes the relatively sparse literature on social and academic outcomes associated with individual differences in children's acquisition of a theory of mind. This is followed by a conclusion in which we identify overarching themes and key questions for future research in this field.

At this point it is worth noting three key ways in which our chapter differs from Carpendale and Lewis's chapter on social understanding, which appears in another volume of this *Handbook* (see Carpendale & Lewis, Chapter 10, Volume 2). First, as described above, we will focus on research into children and adolescents' understanding of beliefs and desires; in contrast, Carpendale and Lewis spread their net more widely to include a more diverse set of skills, including skills (such as gaze-monitoring and pointing) that emerge during infancy. Second, whereas our focus is upon the causes and consequences of individual differences in understanding mind, Carpendale and Lewis focus on normative patterns of development. Third, while Carpendale and Lewis devote considerable space to theoretical debates in this field, our goal is to provide a comprehensive review of the evidence to support a social perspective on individual differences in theory of mind.

Also worth noting is that (unless explicitly stated otherwise) much of the research on theory of mind has been based on middle-class, Western samples. Although there have been efforts to extend the scope of theory-of-mind research beyond these narrow confines (e.g., Hughes et al., 2005; Liu, Wellman, Tardif, & Sabbagh, 2008), this remains a clear challenge for future research in the field.

For consistency, we will use the terms "weak," "moderate," and "strong" to describe effect sizes throughout this chapter. Using the metric of Pearson's *r*, weak effects range

between .10 and .29, moderate effects range between .30 and .49, and strong effects are those greater than .50 (Ellis, 2010). Where available, we will report the actual magnitude of effect sizes from relevant meta-analyses.

HISTORICAL AND THEORETICAL PERSPECTIVES

Before examining historical and theoretical shifts within theory-of-mind research, it is worth considering the origins of developmental psychologists' interest in children's understanding of others' minds. Indeed, research on children's ability to appreciate others' perspectives can be traced back to Piaget's work on children's social egocentrism (Piaget, 1959) and understanding of three-dimensional space (Piaget & Inhelder, 1956). Using children's naturally occurring conversations and experimental tasks (such as the "Three Mountains Task"), Piaget argued that young children struggle to appreciate the perspectives of their conversational partners (Piaget, 1959) and fail to identify what other people can see when looking at the same scene from different vantage points (Piaget & Inhelder, 1956). Later work, undertaken by Flavell and colleagues (e.g., Flavell, Everett, Croft, & Flavell, 1981) brought experimental rigor to the study of children's perspective taking and led to a distinction between recognizing what others can and cannot see (Level 1 perspective taking) and the ability to appreciate that the same object can appear differently to those with different points of view (Level 2 perspective taking). Note that these early investigations focused mainly on children's understanding of others' perceptual mental states, which, arguably, does not require an appreciation of others' mental states. That is, visual perspective taking involves taking someone else's point of view in the literal sense and can simply be achieved using visuospatial skills (e.g., Baron-Cohen, Leslie, & Frith, 1985; Donaldson, 1978) without being able to know or understand that another person is representing something (Gopnik & Wellman, 1992). Although developmental research on theory of mind can be viewed as a continuation of the Piagetian tradition of research on childhood egocentrism (Flavell, 2004), it is not simply "old wine in new bottles" (Carpendale & Lewis, 2006, p. 24). The theory-of-mind research enterprise can be distinguished from what came before by its emphasis on directly testing children's ability to attribute epistemic mental states (as opposed to perceptual mental states), in particular knowledge and beliefs, to others (Baron-Cohen et al., 1985).

Landmark Studies That Launched Theory-of-Mind Research

Premack and Woodruff (1978) first coined the term "theory of mind" in a study of chimpanzees' understanding of mental states. Academic peer commentaries on this study also had a seminal influence on the field. In particular, Dennett (1978) outlined the minimal requirements for an empirical test to demonstrate that a person or animal possessed a theory of mind. In doing so, Dennett drew upon casual observations of young children's reactions to watching "Punch and Judy" shows and in particular their excitement when they knew something that Punch did not know (e.g., when Punch thinks Judy is still in the box but they know she has escaped). In order to rule out alternative explanations (such as habit or association) and so credit a child (or animal) with having beliefs about another's beliefs, Dennett argued that the child must be able to predict or explain the behavior of an agent who has a mistaken (i.e., false) belief about the circumstances and sketched out a scenario in which this ability could be tested. This object-transfer false-belief scenario would become the litmus test for crediting humans (or animals) with having a theory of mind.

Within developmental psychology, the term "theory of mind" first emerged in studies of children's natural language (e.g., Bretherton & Beeghly, 1982) that were directly influenced by the Piagetian tradition (e.g., Piaget, 1959). Two landmark studies provided a crucial departure from this tradition. In the first of these, Wimmer and Perner (1983) developed a child-friendly version of Dennett's (1978) object-transfer scenario in order to establish the age at which children could be credited with attributing beliefs to others. Their story involved a protagonist (Maxi) who placed some chocolate in one location and then departed. During his absence, a second character (Maxi's mother) moved it to another location. Children were asked a test question (Where will Maxi look for the object when he returns?) and two control questions, included to ensure participants were able to remember the original location of the object and had correctly followed the story and so knew the object's actual location. Wimmer and Perner (1983) found that, despite performing similarly on the control questions, 4- to 5-year-olds performed significantly worse than 6- to 9-year-olds on the prediction question, with only 33% of the former group passing compared with 92% of the latter group. Given the strong association between age and task performance, the authors concluded that, between the ages of 4 and 6, children develop the ability to understand another's false beliefs.

The second landmark study provided support for the validity of the false-belief task. Baron-Cohen et al. (1985) gave three groups of children (typically developing children, children with autism spectrum disorder [ASD], and children with Down syndrome), all with a verbal mental age above 4 years, a modified version of Wimmer and Perner's (1983) object-transfer task that involved two child characters: Sally and Ann. These three groups all performed well on the reality and memory control questions, but just 20% of the children with autism (as compared with over 80% of the children with Down syndrome and typically developing children) passed the false-belief test question. These findings provided vital support for the ecological validity of the false-belief task and offered a new cognitive account of the marked social impairments associated with ASD. That is, without the ability to attribute mental states, engaging with others becomes very difficult; as a result, it appeared that a specific impairment in the cognitive architecture needed to attribute mental states might underpin a diverse array of social difficulties.

The “First Wave”: Developmental Changes and Impairments in ASD

In this summary of the key trends in developmental research on theory of mind, we borrow Dunn's (1999) “waves” metaphor. Rather than demarcating discrete historical periods, these waves mark temporally overlapping research trends. The “first wave” of theory-of-mind research within psychology adopted a dual focus on: (a) the age at which a typically developing child could be credited with having a theory of mind and (b) the study of what was later called the “Mindblindness” theory of ASD (e.g., Baron-Cohen, 1995). Addressing the first of these points, Wellman, Cross, and Watson (2001) conducted a meta-analysis of 178 studies (representing > 4,000 participants) of children's performance on a range of different false-belief tasks (measuring children's understanding of others' mistaken beliefs about the contents of a prototypical box, the location of an object, or the apparent identity of a familiar object) that confirmed a dramatic improvement between the ages of 2 and 5 years (regardless of whether children had to attribute false beliefs about an object's location, appearance, or contents). Specifically, the meta-analysis showed that about 50% of children pass the false-belief task at 44 months, as compared with 75% at 56 months, such that the odds of passing the false-belief task increase almost threefold with every year's increase in age. Alongside tests of false-belief comprehension, other studies included

measures of putative “precursors” to theory of mind. These included behavioral measures, such as protodeclarative pointing (i.e., pointing to draw someone's attention to an object of interest as opposed to “protoimperative” or instrumental pointing in which the goal is to obtain a desired object) and experimental tasks designed to tap children's understanding of other mental states such as desires and knowledge (e.g., Carpenter, Nagell, & Tomasello, 1998; Wellman & Liu, 2004). A comprehensive overview of the origins of social understanding in infancy is provided in another volume of this *Handbook* by Carpendale and Lewis (see Carpendale & Lewis, Chapter 10, Volume 2).

The “Mindblindness” account of ASD, although not unchallenged (e.g., Russell, 1997), continues to have a prominent influence on research (e.g., Senju, Southgate, White, & Frith, 2009), galvanizing neuropsychological studies and prompting a reconsideration of other complex disorders such as conduct disorder (e.g., Hughes, Dunn, & White, 1998) and schizophrenia (e.g., Corcoran, Mercer, & Frith, 1995). Research interest in theory of mind in ASD also gave rise to the first attempts to study the neural basis of theory of mind (e.g., Happé et al., 1996). Neuroimaging studies have converged upon a circumscribed set of structures, most notably the medial prefrontal cortex, superior temporal sulcus, and temporoparietal junction, that activate during a range of theory-of-mind tasks (Frith & Frith, 2003). The neuroscientific research on social understanding is also covered in more detail by Carpendale and Lewis (see Carpendale & Lewis, Chapter 10, this *Handbook*, Volume 2).

The “Second Wave”: Individual Differences in Theory of Mind

In a pioneering paper, Dunn, Brown, Slomkowski, Tesla, and Youngblade (1991) argued that the focus on age-related changes in children's theory of mind had led investigators to overlook the potential importance of individual differences as predictors of children's social development. A key feature of this second wave was a shift away from small-scale studies of homogeneous (middle-class) samples of children categorized as theory-of-mind “passers” or “failers” on the basis of performance on a single task. Instead, adopting a psychometric approach, studies began to include both larger and more diverse samples and batteries of tasks. This task-battery approach is more sensitive to variation in performance and enables one to construct aggregate measures that are more reliable than individual task scores (Rushton, Brainerd, & Pressley,

1983). For example, task batteries that include multiple measures of false-belief understanding (e.g., the classic change of location task, the unexpected contents task, belief-emotion tasks, and second-order false-belief tasks) have good internal consistency and test-retest reliability in young children (Hughes et al., 2000; Wellman et al., 2001). Moreover, studies using confirmatory factor analysis have revealed that together these measures load onto a single latent false-belief understanding factor (Hughes et al., 2014; Hughes, Ensor, & Marks, 2011). This approach led to evidence that challenged early “watershed” models (that emphasized dramatic changes in children’s understanding between children’s third and fourth birthdays), documenting instead striking variation in preschoolers’ performance on theory-of-mind tasks that was robustly related to a variety of both cognitive and social factors (described in detail in later sections of this chapter). However, the scarcity of developmentally appropriate theory-of-mind tasks for older children and adolescents has constrained research on the origins and consequences of individual differences in theory of mind beyond the preschool years. Related to this developmental gap is a conceptual gap, regarding the *nature* of individual differences in theory of mind beyond the preschool years (Apperly, 2012).

The “Third Wave”: Expanding the Developmental Scope

Research on theory of mind continues apace and a new trend in this field, which might be called a “third wave,” is an expansion of the developmental scope both downward into infancy (e.g., Onishi & Baillargeon, 2005) and upward into adulthood (e.g., Apperly, Samson, & Humphreys, 2009). Although there is a long history of interest both in testing the lower boundaries of theory-of-mind understanding in young children (e.g., Clements & Perner, 1994) and in exploring whether adults with ASD (e.g., Happé, 1994) or schizophrenia (e.g., Corcoran et al., 1995) display deficits in theory of mind that are similar to those shown by children with ASD, since 2005 research has sought to revise the established timetable for the emergence of theory of mind (e.g., Baillargeon, Scott, & He, 2010). Using paradigms based on classic false-belief tests, researchers have studied children’s spontaneous responses (e.g., using the violation-of-expectations paradigm) and reported that children as young as 15 months look reliably longer when an agent behaves in a way that contrasts with his or her beliefs about the true state of affairs (e.g., an agent reaches to a box to obtain an object despite being unaware that the

object was transferred to that box) (Onishi & Baillargeon, 2005). In a similar departure from the traditional focus on theory-of-mind development in preschoolers, researchers have begun to examine theory of mind in middle childhood (e.g., Banerjee, Watling, and Caputi, 2011), adolescence (e.g., Dumontheil, Apperly, & Blakemore, 2010) and adulthood (e.g., Apperly, 2011). Studies of adults provide both useful information on the end-point of theory-of-mind development and an opportunity to reevaluate theories about the relations between theory of mind and other aspects of cognition (Apperly et al., 2009). The third wave thus opens up exciting new possibilities for extending the developmental scope of theory-of-mind research and reassessing existing theoretical accounts of theory of mind.

Theoretical Accounts of the Development of Theory of Mind

Over the past four decades, researchers have adopted a variety of different theoretical frameworks to explain the development of theory of mind.

The “Big Three”: Prominent Early Theories of Theory of Mind

Early findings within research on theory of mind were discussed in light of three competing accounts: “theory theory,” simulation theory, and modularity theory. According to the first of these camps, human understanding of other minds is “theory-like” in nature in that mental-state concepts are unobservable theoretical entities that can be used to predict behavior (Carruthers & Smith, 1996; Morton, 1980). Moreover, the acquisition of a theory of mind is held to involve a sequence of theoretical or conceptual changes from being able to explain action with recourse to simple nonrepresentational internal states such as desires, to being able to predict behavior on the basis of representational mental states such as beliefs (Gopnik & Wellman, 1992). Researchers have also speculated about the processes underpinning change in children’s theories about the mind, and indeed other aspects of their world; candidate processes include both informal experimentation and the detection of statistical information about event contingencies (Gopnik & Wellman, 2012).

In contrast, simulation theorists argued that the ability to understand others hinges upon being able to apply first-hand experience in order to imagine (or simulate) what another is feeling or thinking (Harris, 1989). That is, rather than resorting to theorizing about the relations between mental states and behavior, children and adults

could use a “like me” analogy to make an imaginative leap into the minds of others based on the mental states they themselves experienced every day (Harris, 1989; 1991; Meltzoff, 2007). Within this perspective, improvements in performance on false-belief tasks reflect children’s growing ability to override their own mental states, to imagine states of affairs that do not correspond to those at hand, and to detect regularities in their experiences of mental states in order to run more complex simulations (Harris, 1991).

During the 1980s and 1990s, simulation theory and theory theory (or some hybrid of the two) were, for most philosophers (and indeed many developmental psychologists), the only games in town (e.g., Carruthers & Smith, 1996). However, as new data about the theory-of-mind impairment in autism emerged, support grew for a modular account of theory of mind (Leslie, 1991; Baron-Cohen, 1995). In contrast to the constructivist position espoused by some theory theorists and simulation theorists, the modular account proposed that the ability to reason about mental states is an innate, domain-specific skill (Leslie, 1991). That is, it proposed that children and adults are hard-wired to track the mental states of others and improvements in understanding mind emerge as a series of specialised, possibly innate modules (capable of processing different types of mental states) come online with age (Baron-Cohen, 1995). From this perspective, the peripheral demands of traditional false-belief tasks mask children’s early emerging ability to reason about mental states (Carruthers, 2013), whereas the failure of children with ASD on such tasks provides evidence for a domain-specific module for mental-state reasoning (Leslie, 1991).

Despite voluminous data on the acquisition of false-belief understanding, the polemical debates about theory theory, simulation theory, and modularity theory have yet to be resolved (e.g., Moses, 2001; Scholl & Leslie, 2001). As we will see later, interest in modular accounts (or at least the early emergence perspective) of theory of mind has remained strong (e.g., Carruthers, 2013). In contrast, some theorists have criticized theory theory and simulation theory on the grounds that the core claims of these accounts, that individuals use either first-person experience or appeal to a theoretical framework when reasoning about others’ mental states, are notoriously difficult to test using behavioral methods (e.g., Hughes, 2011).

Individual Differences in Theory of Mind

Broadly speaking, individual differences in theory of mind can be viewed in two different ways. On the one hand, this variation may simply reflect delays or precocities in

the *onset* of understanding mental state concepts (e.g., Slaughter & Repacholi, 2003). This account hinges on the assumption that “late starters” will eventually “catch up” with their peers and that variation in performance will not differentiate people beyond early childhood (Bartsch & Estes, 1996; Wellman et al., 2001). On the other hand, individual differences in theory of mind may reflect genuine qualitative variation between individuals in their sensitivity, motivation, or capacity to explicitly reason about others’ mental states (Apperly, 2012; Bartsch & Estes, 1996; Hughes, 2011). In support of this “genuine variation account,” individual differences in theory of mind show remarkable longitudinal stability in the preschool and early school years (e.g., Astington & Jenkins, 1999; Hughes et al., 2011) and across middle childhood (Banerjee et al., 2011; Caputi, Lecce, Pagnin, & Banerjee, 2012; Lecce, Zocchi, Pagnin, & Palladino, 2010). Moreover, evidence is accumulating that these individual differences are not trivial and show consistent associations with different aspects of cognition and social adjustment.

Emerging Accounts of the Development of Theory of Mind

As noted earlier, Onishi and Baillargeon (2005) used the violation-of-expectations paradigm to construct a nonverbal variant of the standard false-belief task and found that 15-month-old infants looked reliably longer when an actor reached for an object in a location in which it had not previously been seen. Subsequently, Southgate, Senju, and Csibra (2007) demonstrated that 24-month-old children’s anticipatory looking indicated an awareness of an actor’s mistaken beliefs. Using a variety of looking-based measures and active helping paradigms, numerous studies of infants and young toddlers have revealed similar findings (e.g., Buttelmann, Carpenter, & Tomasello, 2009; Scott & Baillargeon, 2009) that collectively present a paradox: Infants seem to understand others’ false beliefs, whereas preschool children do not.

Despite long-standing criticisms about the appropriateness of looking paradigms for investigating higher-level cognition (e.g., Haith, 1998), these findings have injected new life into previous theoretical debates. The literature in this field can be divided into four camps that highlight: (1) early competence, (2) behavior rules, (3) distinctions between implicit and explicit forms of knowledge, and (4) dual systems. According to early competence theorists, the findings from traditional tasks are, quite simply, misleading and mask a much earlier genuine competence in mindreading (Baillargeon et al., 2010; Carruthers, 2013).

Baillargeon et al. (2010) proposed the “response account” to explain the discrepancy between the performance of infants and preschoolers. According to this hypothesis, standard false-belief tasks require children to: (a) represent another’s false belief, (b) access this representation to select a response, and (c) inhibit their own knowledge about the true state of affairs. In contrast, new minimally verbal looking tasks, or “spontaneous response tasks,” require only the first of these processes to achieve success. This account does not necessarily support a nativist position (Luo & Baillargeon, 2010). Like Baillargeon et al. (2010), Carruthers (2013) explains the gap between infancy and preschool in terms of the demands imposed upon children by traditional measures of theory of mind. For Carruthers (2013) however, early competence on spontaneous response tasks provides compelling support for the modular account of theory of mind and more specifically for an innately specified mindreading mechanism.

The second “behavior rules” camp offers a much leaner interpretation of findings from the new generation of tasks in which success on spontaneous response tasks does not require the ability to represent others’ mental states. Instead, children can rely on causally shallow behavior rules (e.g., people look for objects where they last saw them) that capture statistical regularities in behavior without having to consider mental states as mediators of behavior (Low & Perner, 2012; Perner, 2010; Perner & Ruffman, 2005). Thus performance on spontaneous response tasks reflects early emerging subconscious awareness of behavioral contingencies whereas performance on standard tasks reflects a later developing genuine understanding of mental states (Perner, 2010). Support for the idea that these two types of task tap into distinct abilities comes from the finding (from several different cultures) that 3- to 4-year-olds pass diverse false-belief tasks at the same time and so display considerable flexibility in mental-state reasoning (Perner & Ruffman, 2005). Until studies adopting a within-subjects design can demonstrate a similar flexibility in infants, many existing results can be interpreted quite parsimoniously using behavioral rules (Low & Perner, 2012; San Juan & Astington, 2012).

Within the third camp, the discrepancy in performance between infants and preschoolers on spontaneous response tasks and standard false-belief tasks illustrates a distinction between two distinct *forms* of knowledge: an implicit, tacit sensitivity on the one hand and an explicit, conscious understanding on the other (Clements & Perner, 1994; Perner & Roessler, 2012). For example, Perner and Roessler (2012) have argued that infants’ and toddlers’ performance on

indirect tasks reflects an implicit understanding of belief based upon keeping track of what agents perceive using an experiential record, which is triggered by the agent’s return to the scene. In contrast, experiential records are insufficient for success on standard tasks, which require children to make a deliberate shift to a different perspective.

The fourth and final account builds upon theories from other aspects of cognitive development (e.g., numerical cognition) by positing a two-system solution (Apperly & Butterfill, 2009). That is, separate cognitive mechanisms are held to underpin infants’ performance on spontaneous response tasks and older children’s (and adults’) performance on traditional measures of theory of mind (Apperly, 2011). Specifically, early-emerging, automatic but inflexible processes could underpin success on spontaneous response tasks, but later-emerging, flexible and effortful processes are needed for success on standard measures of theory of mind (Apperly & Butterfill, 2009).

Currently, there is sparse direct empirical evidence available to test these four emerging theoretical accounts, highlighting the close interplay between method and theory. In particular, the hegemony of the false-belief task led to a narrow focus on the preschool years. By expanding the repertoire to include new indirect measures for assessing mental state understanding in infancy and toddlerhood on the one hand and complex or “advanced” measures of theory of mind for school-aged children, adolescents, and adults on the other hand, researchers have opened up the field for testing the validity of existing theoretical accounts across different stages of the life span as well as developing new theoretical accounts that encompass processes underpinning the *use* of theory of mind as well as the acquisition of theory of mind (e.g., Apperly, 2011).

SOCIAL INFLUENCES ON THEORY OF MIND

Two early lines of evidence supported a nativist perspective of theory of mind. First, children with (highly heritable) ASD were found to show marked delays in their understanding of false belief (Baron-Cohen et al., 1985). Second, early experimental studies indicated that typically developing preschoolers make rapid improvements in their understanding of false belief, supporting a “watershed” model in which cognitive structures come “on-line” with little to no support from social factors. However, subsequent studies indicated that different mechanisms are likely to underpin false-belief task performance in atypical

and typically developing preschoolers: although both deaf children and children with ASD often fail false-belief tasks but pass false-photo tasks (which assess children's understanding of nonmental representations by asking them to point out the location of an object in an unseen photograph taken before the object was moved), performance on the false-photo and false-belief tasks is concordant for typically developing preschoolers (Peterson & Siegal, 1998). In addition, over the past two decades, researchers have developed tasks suitable for a wide age range (from infancy through to late adulthood) and the results from this work suggest a much more gradual and protracted pattern of developmental change in children's understanding of mind (e.g., Devine & Hughes, 2013). Together, these findings challenge an entirely nativist account of theory of mind acquisition, such that there is now growing interest in the possibility of social influences on typically developing children's understanding of mind.

In this section, we use the metaphor of the seven pillars of wisdom from the Book of Proverbs to argue that advances in the rigor and scope of research in this field have led to seven lines of evidence that support the importance of social experiences for the development of and individual differences in children's understanding of mind. Before presenting each of these "pillars" it is worth noting that early optimism within research into genetic influences on individual differences has been followed by decades of disappointing results, such that theorists (e.g., Joseph, 2012) have begun to challenge the wisdom of searching for elusive genes, rather than improving the rigor with which environmental influences are investigated. As argued by Bronfenbrenner (1979), development occurs within a nested system of interacting environments extending out from the person's immediate setting (e.g., home, preschool) to the larger cultural milieu. We will demonstrate how research on individual differences in theory of mind has begun to elucidate how these various levels of environmental influence might shape children's understanding of others' minds. Before making developmental claims about the links between children's social environments and the emergence of theory of mind, it is first worth considering the type of evidence needed to make causal claims about development. As argued by Bryant (1990), testing a developmental account about the relation between any two measurable constructs requires both longitudinal data (to assess naturally occurring but not necessarily causal links between earlier and later constructs) and experimental training data (to establish causal but not necessarily naturalistic links between two constructs). On

this account, cross-sectional data alone provide insufficient evidence to make a causal developmental claim and longitudinal and training data can each provide only partial support for a developmental account. However, converging evidence from these three sources can provide a compelling case to support a causal developmental theory. With this point in mind, we will now consider the seven lines of evidence for links between children's social environments and theory of mind.

First, whereas early studies typically administered just one or two tasks to small homogeneous samples, since the year 2000 studies have focused on individual differences by administering task batteries to larger and more diverse samples, including samples of twins. As a result, researchers have been able both to demonstrate striking variation in children's performance on tests of theory of mind and to investigate directly the relative salience of genetic and environmental influences on this variation in performance (e.g., Hughes et al., 2005). *Second*, studies comparing deaf children born to hearing parents versus deaf parents have shown that the former group (but not the latter group) are also markedly delayed in acquiring a concept of false belief. This finding provides compelling evidence that early conversational environments can facilitate children's mastery of an explicit representational understanding of mind (Peterson & Siegal, 1995). *Third*, researchers have begun to conduct training studies that examine the effects of social experiences (such as mental-state discourse) on theory of mind. *Fourth*, the recognition of variation in children's understanding of mind provided a platform for integrating research on socio-cognitive development (with its emphasis on developmental milestones) and research on children's attachment relationships with caregivers (with its emphasis on individual differences). This led to a useful cross-fertilization of ideas—for example, regarding how constructs such as maternal sensitivity might contribute to variation in children's understanding of mind has produced a refinement in our understanding of what is meant by maternal sensitivity, resulting in a new focus on mothers' reflective functions (e.g., Fonagy & Target, 1997) or "mind-mindedness" (Meins et al., 2003). The adoption of longitudinal designs using cross-lagged analyses has permitted researchers to tease apart the direction of effects of these variables on theory of mind (Ensor & Hughes, 2008; Ruffman, Slade, & Crowe, 2002). *Fifth*, the original debate between theorists who adopted observational versus experimental approaches to assessing children's understanding of mind (characterized as a debate between "boosters" versus "scoffers"—Chandler, Fritz, & Hala, 1989) has

been replaced by research in which these two approaches are integrated, providing clear evidence of robust links between variation in children's understanding of mind and individual differences in their relationships with other family members, notably siblings (Dunn, Brown, & Beardsall, 1991; Hughes, Marks, Ensor, & Lecce, 2010) and in the content and quality of family conversations (Jenkins, Turrell, Kogushi, Lollis, & Ross, 2003). *Sixth*, although numerous studies have explored how developments in theory of mind might facilitate children's interactions with friends and peers (e.g., Hughes et al., 2011), a small but growing body of research has investigated how friends and peers may contribute to children's understanding of mind. *Seventh*, early studies were largely restricted to the Western world, but the past decade has seen a marked growth in studies of non-Western populations that suggest significant cultural contrasts in the timing (and perhaps the sequence) of milestones in children's understanding of mind (e.g., Liu et al., 2008).

Before considering each of the above pillars, two theoretical points deserve mention. First, sociocultural perspectives on theory of mind have a long history (Gauvin, 1998). The phrase "folk psychology" was actually coined by Wundt (1900/1921), who argued that higher order functions (e.g., remembering, reasoning, learning—*völkerpsychologie*) emerge from group experiences. Moreover, in their landmark paper outlining the "epistemic triangle" between child, social partner, and object of knowledge and calling on researchers to focus on the social aspects of young children's social understanding, Carpendale and Lewis (2004) drew on the work of three classical theorists: Piaget, Vygotsky, and Wittgenstein (e.g., Piaget, 1928; Vygotsky, 1978; Wittgenstein, 1958). Similarly, in a seminal paper that applied an attachment theory perspective to simulation theorists' accounts of how children acquire a concept of mind, Fonagy and Target (1997) both drew on Cooley's (1902) early work on children's developing sense of self and work conducted in the late 1970s on attachment and children's expectations of behavior (e.g., Lamb, 1981). Second, although researchers have, for many years, focused heavily upon interactions with caregivers (and, more specifically, mothers), there are good grounds for attending to children's interactions with other social partners; in particular, with children both within and outside the family. Again, this approach has a long pedigree, resting as it does on Piaget's (1932) work on children's disagreements with peers as a source of moral development. However, advances in assessing mental state awareness in middle childhood have allowed theorists to begin to

consider whether, as children grow up, relationships with other children come to eclipse relationships with parents as a source of influence on their understanding of mind (Humfress, O'Connor, Slaughter, Target, & Fonagy, 2002). Reflecting this view, the sections below begin with experimental work that provide good evidence for social influences on children's understanding of mind and then, reflecting an ecological systems approach (Bronfenbrenner, 1979), consider evidence not only for maternal influences but also for influences of siblings, friends, and culture.

Studies of Environmental and Genetic Influences on Theory of Mind

Comparing identical and fraternal twins for similarity in any given trait serves as a simple natural experiment for assessing the relative magnitude of genetic and environmental effects. However, within this field of research at least two caveats deserve note. First, environmental influences are often nonlinear in their effects and so the power of a twin study to detect environmental influences depends on type as well as size of sample (e.g., is the bottom end of the scale sufficiently well represented?). This is important because the contrast between neglectful/abusive versus adequate environments is much more important than that between adequate versus high quality environments ("good enough" parenting is, by definition, just that). Second, twin studies provide only a snapshot picture: The same sample may yield different estimates of genetic and environmental influences at different points in development (e.g., if contact with other children is important for children to develop an understanding of mind, then social influences may well increase in magnitude following the transition to school). Together, these factors help to explain why the first two twin studies of theory of mind yielded contrasting results.

Specifically, Hughes and Cutting (1999) gave a battery of theory-of-mind tasks to a volunteer sample of 119 pairs of same-sex 3.5-year-old twins and reported a heritability estimate of .67, suggesting strong genetic influence on variation in task performance. In a later study involving a much larger (and socially much more diverse) sample of 1,116 same-sex pairs of 5-year-old twins, Hughes et al. (2005) found that nongenetic factors accounted for 93% of the variance in total scores. The simplest explanation for this contrast is that the first study was underpowered. However, later findings suggest that the between-study contrast in sample age may also have been important.

Specifically, in a large study of over 5,000 twin pairs followed at ages 2, 3, and 4 years, Ronald, Happé, Hughes, and Plomin (2005) found that individual differences in parent-reported mentalizing (i.e., ratings of behaviors such as joking or lying that require mental-state awareness) showed moderate genetic influence (heritability estimate ranged from .25 to .57). In contrast, a much smaller study ($N = 388$ same-sex twin pairs) of 9-year-olds who completed the Strange Stories test of theory of mind (Happé, 1994) showed that environmental factors accounted for 88% of the variation in task scores (Ronald, Viding, Happé, & Plomin, 2006). Viewed together, the findings from these studies show interesting points of convergence and contrast. For example, the two studies of school-aged children involved different tasks and samples of different ages and yet both showed a robust effect of environment on individual differences in understanding of mind among typically developing children.

Alongside developmental shifts in the relative salience of genetic and environmental influences on children's understanding of mind, it is worth noting that twin studies are open to several different lines of external criticism. Although researchers involved in behavior genetic studies typically rebut some critiques (notably, the assumption that identical and fraternal twins share equally similar environments), there are some limitations that are generally accepted even by behavior geneticists. In particular, twin studies are not informative with regard to the exact processes involved and assume an additive relationship between genetic and environmental influences. This assumption is significant as there is now substantial evidence for genotype–environment interactions (e.g., Caspi et al., 2003). These limitations have led researchers to move beyond twin studies by adopting a molecular genetic approach in order to identify DNA polymorphisms to conduct more detailed examinations of genetic and environmental influences on individual differences in a wide range of traits and abilities (Plomin, DeFries, McClearn, & McGuffin, 2008). As yet however, molecular genetic research in the field of theory of mind is thin on the ground. In one study, Lackner, Sabbagh, Hallinan, Liu, and Holden (2012) found that children with the shorter allele for the dopamine D4 receptor gene (DRD4) outperformed children with the longer allele and so suggested that DRD4 polymorphisms may underpin genetic influences on theory of mind. Challenging this view, however, findings from a separate study indicate that ASD is associated with a polymorphism of the serotonin transporter promoter region but not of the DRD4 gene (Yirmiya et al., 2001). Molecular genetic

research opens up the possibility of examining whether specific functional polymorphisms moderate the effects of environmental experiences on individual differences in theory of mind. Functional polymorphisms in the dopamine receptor gene (DRD4) and the serotonin transporter gene (5-HTTLPR) have been implicated as genetic moderators of parenting and childcare influences on a variety of outcomes in childhood (e.g., behavior problems, internalizing symptoms) (Belsky et al., 2009). It is therefore conceivable that such genetic polymorphisms might result in differential susceptibility to the effect of mental-state talk on individual differences in theory of mind, for example. In seeking to explain how polymorphisms of the DRD4 gene might contribute to individual differences in theory of mind, Lackner et al. (2012) proposed that dopaminergic pathways might regulate children's ability to learn from social experiences. Indirect support for this proposal comes from a study in which children's ability to adapt to a non-social task (smoothly lifting a deceptively heavy object) was found to predict theory-of-mind performance, even when effects of age and executive function were controlled (Sabbagh, Hopkins, Benson, & Flanagan, 2010), suggesting that variations in children's domain-general abilities to revise conceptual structures in response to experience contribute to individual differences in theory of mind.

In sum, studies that have adopted genetically sensitive designs have produced complex findings. First, the relative salience of genetic and environmental influences on theory of mind appears to shift with development. Evidence for environmental influences on theory of mind is stronger in studies of older children. One explanation for this might be that individual differences in social experiences become more marked as children grow up and widen their social horizons. Note also that children's early social experiences are often restricted to interactions with family members, such that genetic and environmental influences co-vary; in contrast, as children spend more time with friends and peers, these two sources of influence become more distinct. Second, although very few studies have examined the molecular genetics of theory of mind, extant findings suggest that distinct genetic influences contribute to normative variation in theory of mind and ASD. This biological contrast adds to the between-group contrast (noted earlier) in profiles of performance on false-photo and false-belief tasks and indicates that researchers should be cautious in extrapolating findings from ASD to typically developing children. Below we turn to another atypical group: children with hearing impairments.

Deafness and Theory of Mind

About one in every 1,000–2,000 children in the United Kingdom is born with a hearing impairment: 96% of these deaf children are born to hearing parents (“DoH”), but a minority are born to deaf parents (“DoD”) who are fluent signers (Mitchell & Karchmer, 2004). Just as twin studies provide a natural experiment for assessing the magnitude of genetic and environmental influences, a comparison of these two groups of deaf children, with their markedly different linguistic experiences, provides an intriguing natural experiment for studying the effects of conversational exposure on children’s understanding of mind. Before reviewing this literature, it is worth noting that delayed mentalizing skills have also been reported for children with *visual* (rather than hearing) impairments (e.g., Minter, Hobson, & Bishop, 1998). However, the literature in this area is much sparser, reflecting the much lower prevalence of congenital visual impairments (e.g., the estimated prevalence in the United Kingdom is 0.1 per 1,000; Gilbert, Anderton, Dandona, & Foster, 1999). It is probably sufficient to note that, although research on deafness provides a valuable spotlight on the importance of conversational influences, nonverbal processes (e.g., initiation of or response to joint visual attention; displays of affect) are also likely to be key contributors to the social scaffolding of children’s understanding of mind but have, with a few exceptions (e.g., Erek-Stevens, 2008; Lillard & Witherington, 2004), received very little research attention to date.

As reviewed elsewhere (see Corina & Singleton, 2009), several studies have shown that, while native-signing DoD children do not differ from typically developing controls in their acquisition of a theory of mind (Schick, De Villiers, De Villiers, & Hoffmeister, 2007), late-signing DoH children are profoundly delayed in their ability to understand false beliefs (e.g., De Villiers & De Villiers, 2000; Peterson & Siegal, 1995). Moreover, even once effects of child age and language are controlled, variation in mothers’ mental-state talk is moderately related to individual differences in DoH children’s theory-of-mind performance (Moeller & Schick, 2006). Together, these three findings support the view that access to rich and fluent conversation (either oral or signed) facilitates children’s understanding of mind. The developmental scope of this work has been extended in two directions.

First, several research groups have begun to examine whether DoH children are also impaired in early appearing milestones in understanding of mind—a question that is of direct relevance for the development of effective

interventions. For example, using an anticipatory looking paradigm designed to investigate awareness of mental states in infancy (described earlier), Meristo et al. (2012) found that DoH toddlers (aged 17–26 months) performed less well than toddlers with no hearing impairments. Conversely, a study by Ketelaar, Rieffe, Wiefferink, and Frijns (2012) has shown that DoH children who receive cochlear implants early in life lag behind peers with normal hearing in their understanding of desire and belief, but show no impairment in their understanding of intentions. Together, these findings suggest that, although conversational access matters even for very early milestones in understanding of mind, early implants of hearing aids reduces the adverse effects of hearing loss (at least with regard to children’s understanding of simple mental states, such as intentions). In addition, extending a previous study demonstrating the same five-step developmental sequence in both DoH and hearing children (Peterson, Wellman, & Liu, 2005), Peterson and Wellman (2009) have reported that the understanding of pretense emerges at an earlier stage in the sequence for DoH children than for their hearing counterparts (for an extension of this work that demonstrates similar divergence in much later milestones for children with ASD, see Peterson, Wellman, & Slaughter, 2012). Thus, providing young DoH children with experience of shared pretense, or structured tasks that elicit pretence, may help to reduce delays in the acquisition of a theory of mind. Related to this finding, De Villiers and De Villiers (2012) have reported that: (a) deaf children who are delayed (relative to hearing peers) in their understanding of false belief show intact performance on deception games; and (b) performance on these two types of task show distinct correlates (in both deaf and hearing children). Specifically, false-belief understanding was more strongly related to syntax than to inhibitory control, whereas deception showed the opposite pattern. Together these findings highlight the value of a fine-grained approach in which distinct aspects of theory of mind (i.e., intentions, pretense, deception, false belief) are treated as separate components of a multifaceted construct.

Second, researchers have also begun to consider whether continuing access to linguistically enriched environments, including school-based opportunities to engage in mental-state discourse, may also contribute to developments in understanding of mind among older children with hearing impairments. Confirming this view, Meristo et al. (2007) not only replicated the contrast between DoH and DoD children in an international study (involving deaf children from Italy, Estonia, and Sweden), but also showed

that variation in theory-of-mind success within the DoD group was related to contrasts in conversational experience at school. Specifically, DoD children attending bilingual schools (i.e., schools that employed both sign and spoken language) outperformed those attending monolingual (i.e., spoken language only) schools. Tomasuolo, Valeri, Di Renzo, Pasqualetti, and Volterra (2013) have reported that deaf children at bilingual primary schools outperformed both deaf children *and* hearing children at monolingual schools. Results from a study of hearing bilingual children (Kovács, 2009) suggest that improvements in executive control may partially mediate the advantage of bilingualism in deaf children; longitudinal work is needed to test this proposal. Further support for the sustained importance of conversational access comes from a study by Pyers and Senghas (2009) who compared two cohorts of deaf adults in Nicaragua: the first cohort (mean age = 27 years) learned a nascent form of Nicaraguan Sign Language (NSL) during childhood, whereas the second cohort (mean age = 18 years) learned a later, more developed form of NSL. Both cohorts attended the same school for the same number of years and had similar-sized social networks. However, when given video clips involving mistaken beliefs and a low-verbal false-belief task, a large group difference was found, with the (younger) second cohort outperforming the first cohort on a series of false-belief tasks and giving more mental state terms in response to the video clips.

In sum, a range of different methods and samples have been used to demonstrate that the mentalizing skills in individuals with hearing impairments show robust associations with the quality of their conversational environments. Whereas the minority of deaf children who are born to deaf parents (who are fluent users of sign language) show intact theory-of-mind performance, deaf children born to hearing parents show delays of similar magnitude to those displayed by children with ASD, but can benefit from exposure to enriched environments (e.g., schools that use both oral and signed language). Although these findings appear to translate very simply to typically developing children, there are also interesting contrasts to note, both in the sequence with which specific milestones are reached and in the likely contribution of other cognitive abilities to children's understanding of mind.

The Effect of Discourse on Theory of Mind: Training Studies

Children with hearing impairments provide interesting opportunities to conduct "natural experiments" on the

impact of conversational environments on children's developing understanding of mind but researchers have also begun to apply direct experimental methods to assess whether enriching children's conversational environments leads to accelerated progress in this domain. These studies are important not only because such interventions provide a real-life application of research that may be valuable for educational practitioners but also, as we noted earlier, because training studies provide particularly compelling evidence for a direct causal impact of conversational input. Correlations between frequencies of family mental-state talk and children's later performance on theory-of-mind tasks can be interpreted in a number of different ways. In particular, children are active conversational partners, such that mothers are likely to adjust their use of mental-state talk for specific children (Jenkins, Rabash, & O'Connor, 2003); as a result, correlations between maternal talk and children's later theory-of-mind performance may reflect stable within-child characteristics rather than causal relations between maternal talk and children's socio-cognitive development.

Thus far, training programs generally involve relatively short (e.g., 2-week) interventions administered to preschoolers who failed standard false-belief tasks at pretest. All studies included in this review included a language-based training and an active control condition, which minimizes the "Hawthorne effect" (i.e., gains accrued via general social contact with experimenters; Landsberger, 1958). Most of the studies examined improvements not just on tasks similar to those used in the intervention but also on related novel tasks. In one of the first training studies, Appleton and Reddy (1996) presented 23 preschoolers with video sequences of a child's display of surprise following the unexpected transfer of an object, followed by a discussion that was designed to provide positive elaboration of children's answers rather than to provide negative feedback as counter-evidence. Relative to the control group, the intervention group performed better on measures of false-belief understanding at posttest and follow-up. At least two further training studies of preschool children have also shown that participation in conversations about mental states can produce moderate gains in false-belief task performance (Lohmann & Tomasello, 2003; Ornaghi, Brockmeier, & Gavazzi, 2011).

In what is, to our knowledge, the only non-Western theory-of-mind training study to date, Lu, Su, and Wang (2008) identified 55 Chinese preschoolers who performed poorly on a pretest battery of false-belief and deception tasks and over an 8-day period gave them four 10-minute

storytelling sessions involving a story with a surprise ending and invitation to retell the story. At the end of each session, half the children (the training group) were asked about the story characters (without any specific mention of mental states) and half received questions about physical aspects of the story (control group). Just 16% of the control group but 58% of the training group showed improved scores at posttest, 3 days later (these children were, on average, older than those in the training group who did not improve their scores). In discussing these findings, Lu et al. (2008) suggested that, for Chinese children, talking about others may serve as a substitute for mental-state discourse as a vehicle for facilitating children's understanding of mind.

The above studies all involved direct training (i.e., children received feedback) and most involved tasks that were structurally quite similar to the false-belief task used at posttest, so that the results show near rather than far transfer. However, in another study, Gola (2012) simply asked preschoolers to watch a series of video clips in which 128 mental verb utterances were presented in conditions that varied in form (statement or question), referent (first person or other person), or style (overheard or direct). Although limited by ceiling effects (many of the children could already pass the pretest theory-of-mind tasks), this study did demonstrate large gains in false-belief understanding for children who simply overheard talk about someone else's mental states. Thus fostering children's attention to differing perspectives appears to be an effective scaffold for theory-of-mind development. The use of simple exposure via video rather than corrective feedback is helpful in at least three ways: (1) it enables training to be administered in a standardized fashion, (2) it does not require experienced adults to administer, making it accessible to a wide range of children, and (3) it provides a useful bridge between the results from training studies and studies involving naturalistic observations of family conversations, which also highlight the benefits of being able to "eavesdrop" on discourse about mental states (Jenkins et al., 2003).

All of the training studies discussed above involved preschool samples, but research has begun to extend this approach to assess whether training can also facilitate social understanding beyond the preschool years. For example, Lecce and colleagues (Lecce, Bianco, Devine, Hughes, & Banerjee, 2014) conducted an intervention study in which groups of 9-year-olds (matched for age, verbal ability, SES, and initial performance on tests of both theory of mind and executive function) were given

either mentalistic or physical vignettes (based on Happé's [1994] Strange Stories task) to discuss in sessions led by a trained researcher. Their results showed that the large posttest group difference (of about one standard deviation) was maintained over 2 months. In a separate study (Goldstein & Winner, 2012), quasiexperimental comparisons of SES- and age-matched groups were used to test the hypothesis that training in acting (which involves "stepping into others' shoes") is more effective at improving empathic accuracy than training in visual arts or music. The predicted group difference was found for adolescents, who completed a more intensive acting program than the younger children (5–9 hours a week, versus 90 minutes a week), suggesting a dosage effect. Together, these two studies suggest that theory-of-mind skills remain plastic well beyond the preschool years.

In sum, although conversation-based training studies remain rather scarce, their findings are consistently positive. Adopting a variety of different training paradigms and involving samples that differ in age (from preschool to adolescence) and cultural background, these studies highlight the benefits of discourse about mental states for children's growing awareness of the representational (and therefore fallible) nature of belief. However, there are still a number of methodological challenges to overcome. In particular, relatively few studies directly compare pre- and posttest performance, or include either a later follow-up or tasks that help to establish the nature of what has improved (e.g., are gains specific to mental state awareness or more general understanding of narratives?) or recruit sufficiently large samples to examine the factors that may moderate the impact of training.

Longitudinal Studies of Parent–Child Conversation

Although the above training studies demonstrate that it is possible to promote children's understanding of mind through exposure to and engagement in rich conversations about mental states, the artificial nature of these studies limits conclusions about whether "real life" conversations about mental states also facilitate children's understanding of mind. Before reviewing naturalistic longitudinal research on predictive relations between linguistic environments and children's understanding of mind, a number of landmark studies deserve mention. In the first of these, Bretherton and Beeghly (1982) used maternal reports to document the emergence of children's conversational references to desires, beliefs, and thoughts within young children's expressive lexicons. This study demonstrated

just how early in life children begin to attend to and reflect on their own and others' mental states, and so set the stage for later experimental research. In a second classic study, Bartsch and Wellman (1995) analyzed more than 200,000 everyday conversations recorded from 10 children in the CHILDES study between the ages of 2 and 5 years and demonstrated that the sequence of emergence of children's talk about these specific mental states closely mirrored the age milestones identified in experimental research. The third landmark study sparked interest in children's *exposure* to talk about mental states; this direct observational research, conducted by Dunn and colleagues (e.g., Dunn, Brown, Slomkowski, et al., 1991), showed that family discourse about mental states predicted children's later success on tests of false belief and emotion understanding over and above effects of child verbal ability and total family talk. The fourth key study, conducted by Ruffman et al. (2002), applied separate (lab-based) measures of mother-to-child and child-to-mother talk about mental states within a cross-lagged design in order to elucidate whether exposure to family talk about mental states independently predicted children's later theory of mind. Individual differences in mothers' mental state discourse were stable across 12 months and children with mothers who frequently referred to mental states at earlier time points scored more highly than their peers on theory-of-mind tasks at the last time-point; the effect size for this relation remained large, even when associations with nonmental discourse were taken into account.

The findings from the separate studies conducted by Dunn and by Ruffman provided compelling evidence for a causal relation between maternal mental-state talk and children's social understanding and led the way for a rapidly growing body of research on this topic—a review (Pavarini, de Hollanda Souza, & Hawk, 2013) noted at least 30 different studies. For reasons of space, we shall focus on a handful of studies that stand apart from the field in various ways. Indeed, a number of studies have shown that maternal references to cognitions are a particularly consistent correlate of children's false-belief understanding (Ensor & Hughes, 2008; Slaughter, Peterson, & MacKintosh, 2007). For example, Ensor, Devine, Marks, and Hughes (2014) have shown that individual differences in the frequencies of mothers' references to cognitive states in their conversations with their children at Age 2 ($N = 105$) were stable across a 4-year period and, even when across-time continuities in both mothers' cognitive references and children's mentalizing skills were taken into account, showed a modest but significant predictive relation with

children's false-belief understanding at Age 6. A subgroup of this sample ($N = 77$) were followed up at Age 10 and again mothers' talk about cognitive states at Age 2 was a modest but significant predictor of children's mentalizing skills—as indexed by success on the Strange Stories task (Happé, 1994). The 8-year span of this predictive relation is a striking illustration of the enduring impact of early conversational environments on children's sociocognitive development.

Findings from earlier time-points in the study described by Ensor et al. (2014) also contribute to an understanding of the nature of conversational influences on children's understanding of mind. For example, by assessing not only conversational *content* (e.g., talk about distinct mental states) but also conversational *quality* (i.e., connected, initiatory, failed, and conflictual turns), these authors (Ensor & Hughes, 2008) were able to examine both the independence and interplay between these two conversational measures at Age 2 as predictors of gains in children's theory of mind from Age 2 to Age 4. Consistent with the findings from Jenkins, Turrell, et al. (2003) study, talk about cognitive states (rather than desire states) was particularly strongly related to children's performance. Interestingly, however, cognitive talk also occurred especially frequently within connected turns, suggesting that it may be the quality (rather than the specific content) of such talk that is the key ingredient. In testing this proposal Ensor and Hughes (2008) found that cognitive talk and connected talk each independently but weakly predicted gains in task performance, but there was also a significant interaction: Connected mother–child conversations about cognitive states appeared particularly fertile as a context for facilitating children's understanding of mind. This finding suggests that the benefits of mental-state talk are maximized when the child has a salient matching internal experience.

This emphasis on the connectedness of mothers' talk to their children's own talk (or actions, more generally) echoes ideas that have emerged from attachment accounts of how children acquire a concept of mind. Specifically, Fonagy and Target (1997) have argued that "the social processes which accelerate the mentalizing quality of self-organization are the very same as those which ensure security of attachment" (p. 687). In turn, this proposal drew on Cooley's (1902) work on the "looking glass self." In describing young children's ability to read other people's minds, Fonagy and Target (1997) offered the term "reflective function," which, they argued: (a) enables children to organize their experiences of their own and others'

behavior in terms of mental states; and (b) is underpinned by caregivers' abilities to communicate an understanding of their children's intentional stance.

Indirect support for the first of the above claims comes from the finding that children who, as infants, were securely attached to their caregivers, typically outperform their less securely attached peers on tests of understanding of false belief and emotion (for a review, see Pavarini et al., 2013). However, the effect sizes in this literature are modest and, when effects of verbal ability are taken into account, the contrast between secure and insecure infants typically only remains significant for tests of emotion understanding). Evidence to support the second claim, namely that maternal "mind-mindedness" (i.e., the propensity for mothers to attribute intentions and goals to their children's activities) facilitates young children's growing mental-state awareness comes from the work of Meins and colleagues. For example, Meins et al. (2003) reported that individual differences in mothers' appropriate comments on their 6-month-old infants' mental states provide the earliest known social predictor of individual differences in theory of mind (explaining 11% of variance in performance at Age 4, even when the 16% accounted for by children's concurrent verbal skills were taken into account). That is, mothers' appropriate comments on their infants' mental states may serve as a linguistic and conceptual scaffold in which infants' attention is drawn to the existence and functional significance of mental states (Meins et al., 2003). By contrast, attachment security at 12 months showed no such independent predictive effect, suggesting that maternal "mind-mindedness" may underpin the association between attachment security and children's theory of mind. That said, findings from another, relatively large ($N = 108$) study highlight the variety of ways in which mothers help infants develop an awareness and understanding of themselves as beings with thoughts and feelings. Erek-Stevens (2008) found that a composite measure of mothers' nonverbal play interactions (e.g., mindful facilitation, joint attention commenting, pacing, and affect catching) with their 10-month-olds, but *not* their mind-related comments, strongly predicted children's understanding of false beliefs at 54 months.

Research has expanded this field in several directions, leading to clear practical implications. For example, Lundy (2013) has shown that preschoolers' success on theory-of-mind tasks shows equally strong associations with *fathers'* mind-mindedness. This finding is open to at least two distinct interpretations. First, what appears to be an environmental effect may well be at least partially

explained by genetic factors (see Sabbagh & Seamans, 2008). Second, given that fathers typically spend much less time than mothers interacting with their infants, this finding suggests that (as for attachment security) it is quality rather than quantity of interaction that matters. This point highlights the need for future research to include parallel observations of children's interactions with fathers (as well as mothers), because fathers are increasingly participating in childcare (e.g., Bianchi, 2011) and appear to differ from mothers in their style of interactions with children (e.g., LaBounty, Wellman, Olson, Lagattuta, & Liu, 2008; Wilson & Durbin, 2013).

Other studies have considerably expanded the developmental scope of this work. For example, arguing that the emotional connections that enable children to draw meaning from their interactions with caregivers are, at least in part, made possible by caregivers' abilities to reflect on their own attachment relationships, Steele, Steele, and Johansson (2002) have reported a strong association between how pregnant women responded in adult attachment interviews about their own childhood and their children's responses to emotional dilemmas 11 years later. Children's responses to these dilemmas were also associated with maternal concurrent beliefs about nurturance, but were unrelated to children's verbal IQ or security of infant attachment (to either mothers or fathers). These results challenge "critical period" models of early interactions and instead support a model in which primary caregivers have an ongoing influence that involves processes beyond attachment security (e.g., family talk about feelings in the postinfancy years).

A third new direction for research in this field concerns interventions for at-risk groups. Meins, Centifanti, Fernyhough, and Fishburn (2013) have found that the relation between low socioeconomic status and preschool problem behaviors is attenuated in the context of high maternal mind-mindedness such that interventions that promote mind-mindedness may help to buffer children from the risks of social adversity. Moreover, Pawlby et al. (2010) have found that, whereas mothers with depressive mood disorders were less likely than healthy controls to make appropriate comments about their infants' mental states, mothers with schizophrenia showed no such impairment. This finding is important because it challenges the assumption that mothers with severe mental illness are necessarily impaired in their interactions with their babies. That said, although other studies have also reported poor theory-of-mind performance among women with depressive disorders (e.g., Lee, Harkness, Sabbagh, &

Jacobson, 2005), moderately *enhanced* theory-of-mind performance has been reported for women with dysphoria (Harkness, Jacobson, Sinclair, Chan, & Sabbagh, 2012) and both depressed and nondepressed women whose own mothers suffered from depression (Harkness, Washburn, Theriault, Lee, & Sabbagh, 2011). These contrasting findings suggest a complex interplay between mental health and mental-state awareness that will require much more work to unravel.

In sum, substantial progress has been made in demonstrating that individual differences in caregivers' propensity to view their children as agents with thoughts and feelings and to engage them in conversations about mental states are robust predictors of later individual differences in children's theory-of-mind performance (even across extended periods of 8 to 11 years). However, existing findings are restricted to Western samples and may not be applicable to other cultures in which parental practices and socialization goals are likely to be quite different. In addition, the specific processes underpinning these associations have yet to be fully elucidated; one challenge for future research is to integrate theory-driven studies of normative samples with studies of at-risk groups that provide both a valuable testing ground for competing theories and the potential for developing evidence-based interventions. Another challenge is to include genetically sensitive designs (e.g., comparisons of the similarity between children and their biological versus adoptive parents or stepparents) to test whether links between parental mind-mindedness or mental-state talk and individual differences in children's theory of mind could reflect shared heredity.

Theory of Mind and Children's Relationships With Siblings

As noted earlier, Piaget's (1932) work on children's moral development highlighted the cognitive benefits of disagreements with peers and set the stage for investigations into whether interactions (and arguments!) with siblings foster children's understanding of minds. Interestingly, however, the first empirical study to note the potential contribution of sibling relationships to young children's understanding of mind focused on *cooperative* interactions between siblings. Specifically, Dunn et al. (1991) found that 33-month-olds who enjoyed frequent cooperative interactions with an older sibling outperformed their peers at 40 months on tests of emotion and false-belief understanding. As these authors acknowledged, this longitudinal association did not allow one to draw any

causal conclusions as early mental state awareness could both foster cooperative interactions with siblings and predict good performance on theory-of-mind tasks. However, the issue of causal direction was resolved in a later study that showed that, on average, children with one or more siblings passed false-belief tasks at least 6 months earlier than children without siblings (Perner, Ruffman, & Leekam, 1994). Subsequent studies have replicated this finding (McAlister & Peterson, 2007; Ruffman, Perner, Naito, Parkin, & Clements, 1998) and identified several distinct potential underpinning processes, including both negative and positive sibling interactions (i.e., siblings as rivals or allies), shared pretend play, and indirect effects of siblings on family interactions.

The juxtaposition of love and hate is a common (and rather unique) feature of sibling relationships. As noted in a review by Hughes (2011), both dimensions might foster early understanding of mind, because the ability to understand mistaken beliefs is central to a variety of social situations, including repairing misunderstandings, avoiding blame, taunting, teasing, and sharing jokes. Citing as an example a 7-year-old's mocking appraisal of her younger sister's play ("Yeah it's stretching; really, really, interesting. You know in fact I am amazed, I wonder if I'll ever, ever, see this again. No I don't think I will because it's just so, so rare, so amazing. Wow I think I'm going to faint"), Hughes (2011) observed that even negative interactions can be rich in reference to mental states and convey a clear contrast between literal and intended meaning; two conversational features that are likely to boost a child's understanding of mental states.

Shared pretend play is also frequently seen in siblings and is likely to show a particularly close association with mental-state awareness, for at least two reasons. First, as noted by Leslie (1987), pretend play and false belief show a striking "structural isomorphism" in their logic of non-entailment (i.e., to know *or* to pretend that X is Y does not entail that that X really is Y, or even that X exists). Second, sustaining a shared pretense narrative requires that children juggle different representations of reality (e.g., is this upturned table a pretend ship or a pretend house?) and so is likely to provide a fertile context for developing and refining an understanding of mind. Observational findings offer indirect support this view: 4-year-olds refer to mental states more often both within pretend than nonpretend interactions (e.g., Hughes & Dunn, 1997) and developmental changes in children's ability to engage in joint pretend play with other children coincide with a developmental shift (between the ages of

33 and 47 months) in preferred conversational partners, such that talk with siblings (and friends) comes to eclipse talk with mothers (Brown, Donelan-McCall, & Dunn, 1996). This shared enjoyment of pretend play is a powerful motivator for children to align their viewpoints in order to initiate or maintain joint pretend play. Although often glad to enter children's imaginary worlds, adults are also quick to tire when the same pretend scenario is enacted time after time, whereas children often relish opportunities for repeat performances. This opportunity to rehearse and practice pretend scenarios may well be an important arena for children's growing mentalizing skills. However, direct attempts to assess the association between individual differences in theory of mind and frequencies of pretend play (usually between peers rather than siblings) have typically produced disappointing results (for a review, see Lillard, 1993). In addition, studies involving socially diverse samples (e.g., Cole & Mitchell, 1998) have typically reported much weaker (and even nonsignificant) associations between number of siblings and false-belief comprehension than those based on middle-class samples. One simple explanation for the inconsistent results in this field is that the quality of sibling interactions matters at least as much as the quantity, and interactional quality is an emergent property of the relationship (i.e., the whole is greater than the sum of its parts). Note that this point applies both directly (e.g., siblings who are very different in age are unlikely to share very similar interests) and indirectly, in that sibling conflict is associated with marital discord (e.g., Stocker & Youngblade, 1999) and negative parent-child interactions (e.g., Volling & Belsky, 1992).

This point brings us to a fourth set of processes that may contribute to the accelerated mentalizing skills shown by children with siblings, namely indirect effects mediated by children's interactions with other family members. For example, having a sibling on whom one can pin the blame may well encourage young children to attempt to deceive their parents. Equally, the presence of a sibling (and perhaps especially an older sibling) provides young children with a valuable opportunity to eavesdrop on conversations between other family members. Importantly, these conversations are often about salient and familiar topics (e.g., discussion of sibling disputes, or shared past events) that fall within their "zone of proximal development" (Vygotsky, 1978) and so are likely to contribute to younger siblings' accelerated development in theory of mind (Ruffman et al., 1998). For example, in the study by Jenkins, Turrell, et al. (2003) noted earlier, children with an older sibling both

produced and overheard more talk about cognitive states (e.g., thoughts, beliefs) than did children without an older sibling. Moreover, cognitive and feeling talk by family members at the first time point predicted change in younger children's cognitive and feeling talk (respectively) 2 years later, after controlling for initial levels of younger children's talk and general language ability.

In sum, it is clear that a variety of processes (both direct and indirect, positive and negative) are likely to moderate the "sibling effect" on individual differences in theory of mind. For example, just as hostile sibling interactions only predict later conduct problems among children who also experience harsh or rejecting parenting (Garcia, Shaw, Winslow, & Yaggi, 2000), the mixed findings from studies of sibling influences on children's understanding of mind indicate that variations in the quality of parent-child relationships may amplify or attenuate the benefits of sibling interactions for children's understanding of mind. It is also worth noting that the evidence for this effect of siblings appears stronger for children from affluent families than for less advantaged children and has yet to be reported for non-Western samples. Indeed, for Chinese children, frequent contact with other children in the family (typically cousins) appears to predict *worse* performance on false-belief tasks (Lewis, Huang, & Rooksby, 2006); in addition, children from Hong Kong (who are much more likely to have at least one sibling) have been reported to perform less well than children from mainland China (Liu et al., 2008). These contradictory findings are both a salutary reminder of the need to adopt an international multicultural perspective and an opportunity to refine theoretical accounts of the exact processes through which the presence of siblings may help children to learn about others' minds.

Friends, Peers, and Theory of Mind

As described above, research into social influences on children's understanding of mind has focused almost entirely on family processes. Although in part explained by the focus on the preschool years, this restricted focus is nevertheless curious, given that early theoretical and observational work (e.g., Murphy, 1937; Piaget, 1932, 1959) clearly highlighted the importance of peer interactions for children's moral and cognitive development. Moreover, research conducted by Dunn and colleagues (Dunn & Cutting, 1999; Hughes & Dunn, 1998) confirmed the potential significance of children's interactions with friends as a fertile context for developing insights into

others' thoughts and feelings. For example, as noted earlier, talk about mental states occurs more frequently within 4-year-olds' conversations with siblings or friends than in their conversations with mothers (Brown et al., 1996).

In a separate study involving a low-income sample of 25 pairs of friends (50% Black) living in London, England, and filmed at three time-points over a 12-month period, Hughes and Dunn (1998) showed that, even with effects of verbal ability taken into account, age-related increases in the frequency and quality of children's references to mental states in their conversations with friends were closely associated with gains in their understanding of belief and emotion. A larger parallel study of preschool friends ($N = 64$ pairs) conducted by Dunn and Cutting (1999), showed remarkable similarity between friends' sociolinguistic skills and behavioral adjustment, suggesting homophily and/or mutual socialization. Each of these sets of measures was also positively associated with cooperative shared pretend and successful communication, providing a direct parallel for the findings (described earlier) from studies of mother-child interactions.

At a theoretical level, the above findings have been influential. For example, Carpendale and Lewis (2004) noted that successful peer interactions might mediate the association between infant attachment security and children's later mentalizing skills. Specifically, the "secure base" provided by the attachment figure may enable children to engage in a variety of social interactions (e.g., shared pretend play, conversations about thoughts and feelings, interactions within peer groups) that are likely to promote theory of mind. Consistent with this view, several studies have reported modest but statistically significant associations between peer status and performance on tests of understanding belief. These studies have involved preschoolers (e.g., Cassidy, Werner, Rourke, Zubernis, & Balaraman, 2003; Slaughter, Dennis, & Pritchard, 2002), school-age children (Banerjee et al., 2011; Devine & Hughes, 2013), and preadolescents (Bosacki & Astington, 1999). Importantly, findings from the only study among these to adopt a longitudinal design demonstrated that (in a sample of 71 children aged 6 years and 138 children aged 9 years followed over 2 school years) there was a reciprocal relationship between sociocognitive skills (indexed by children's understanding of faux pas) and peer status (Banerjee et al., 2011). Later, we outline the evidence that early mastery of theory of mind predicts children's later peer success; here, we summarize findings from another longitudinal study that also suggests a causal influence of peers on children's understanding of mind.

In this study, Dunn, Cutting, and Fisher (2002) adopted a quasi-experimental design that exploited naturally occurring changes in friendship dyads across the transition to school to distinguish the effects of preschool friends from within-child continuity in mental-state awareness. Their results indicated that, over and above within-child associations between preschool theory of mind and insight into the thoughts and feelings of new friends at school, children's insights into their new friends were also associated with the sociocognitive maturity of their preschool friends. This finding suggests that preschool interactions with socially mature peers foster children's understanding of others' thoughts and feelings.

In sum, the findings summarized in this section support three conclusions. First, the similarity in results from studies of preschoolers and older children suggest that interactions with friends and peers are closely related to individual differences in children's understanding of mind across a broad developmental period. Second, although this association appears bidirectional, more longitudinal work is needed to elucidate the nature and magnitude of social influences of friends and peers on children's understanding of mind. Third, existing research has paid very little attention to the potential interplay between social influences within and outside the family on children's understanding of mind. Bridging this gap in future research is important for elucidating how the nature of social influence varies both with age (e.g., with peer influence increasing and perhaps eclipsing parental influence as children move through middle childhood) and with culture (e.g., with differences in parental practices leading to distinct forms of social support).

Cultural Variation in Theory-of-Mind Performance

Having considered some of the more proximal social influences on individual differences in theory of mind, we now examine the ways in which a more distal aspect of the social environment—culture—might shape children's understanding of others' minds. Cross-cultural studies provide an opportunity to test the universality of theories of theory of mind. Early work, including studies of children from China (Flavell, Zhang, Zou, Dong, & Qi, 1983) and Japan (Gardner, Harris, Ohmoto, & Hamazaki, 1988) and from the indigenous and preliterate Baka community in the Cameroon (Avis & Harris, 1991) indicated that mastery of false belief and perspective taking emerges at very similar ages in children from very different cultural backgrounds. Confirming this view, another study (Callaghan et al.,

2005) has reported remarkable synchrony in the developmental trajectory of false-belief understanding across five different countries, namely Canada, India, Peru, Samoa, and Thailand.

However, methodological limitations (concerning both samples and tasks) mean that the above findings need to be viewed with caution. In particular, the early studies in this field did not actually involve any direct comparisons between children in different cultures. In addition, although Callaghan et al. (2005) did compare performance across different groups, the samples were not matched for either language ability or socioeconomic status, which, as noted earlier, are two key predictors of individual differences in task performance. Findings from two further studies highlight the importance of sample effects. In a separate study of children in the Cameroon (involving Mofu rather than Baka children), Vinden (2002) reported that, although all the children showed poor understanding of false belief, those receiving schooling did moderately better than their unschooled counterparts on a task that required understanding evidence for a true belief. In a study involving a large ($N = 300$) sample of Samoan children (ranging in age from preschool to preadolescence), Mayer and Träuble (2013) found that most children younger than 8 (and one third of 10- to 13-year-olds) failed a change of location task and concluded that the ability to use mistaken belief to predict behavior is markedly delayed in cultures in which mental states are not appropriate objects for conjecture.

The early studies that reported similar performances in children from different cultures each also relied on a single task; this factor alone may have limited their sensitivity to variations in performance. Task effects are clearly illustrated in the findings from several other studies. For example, in Vinden's (1996) Peruvian study, while 4- to 8-year-old Junín Quechua children all performed poorly on standard false-belief tasks, the older children performed relatively well on appearance-reality tasks. In addition, challenging their earlier account of synchronous development across diverse cultures, Callaghan, Rochat, and Corbit (2012) have reported that Canadian 5-year-olds (but not 4-year-olds) were more likely to pass a picture-book false-belief task than their age-matched counterparts from either Peru or India.

Findings from the first meta-analysis in this field showed marked international variation in the age at which children acquire an understanding of belief (Wellman et al., 2001). Specifically, compared with children from the United States and the United Kingdom, children from Australia performed somewhat better on the false-belief

task (with 69% of 44-month-old Australian children passing compared to 50% of British and American children) whereas children from Japan performed significantly worse (with 40% of 44-month-old children passing). In a second meta-analysis of studies from China and Hong Kong, Liu et al. (2008) found that children from Hong Kong showed a delay of approximately 2 years in their understanding of false belief, when compared with children from Canada and the United States. Interestingly this lag was not evident among children from mainland China, suggesting that the East–West contrast cannot be explained in terms of simple factors such as China's one-child policy or a Confucian emphasis on the group rather than the individual (Hong, Morris, Chiu, & Benet-Martínez, 2000).

Researchers have begun to adopt comprehensive batteries of false-belief tasks to examine potential East–West differences directly and in more detail. These studies reveal similar contrasts in the ages at which children from the United Kingdom as opposed to Asian countries such as Japan and Korea succeed on false-belief tasks (Hughes et al., 2014; Lewis et al., 2009). Task batteries also allow researchers to adopt a latent variable approach in which “true” scores are estimated by partitioning out measurement error (e.g., Hughes et al., 2011; Devine & Hughes, 2013). In turn, this approach enables researchers to assess (via multiple-groups confirmatory factor analysis) whether contrasts in mean latent factor scores between children from different countries reflect genuine differences in underlying abilities, rather than unrelated factors such as differing response styles, reflecting differences in social norms, inappropriate translations, or contrasts in the definition or meaning of a concept (Byrne & Campbell, 1999; Chen, 2008). Two cross-national comparisons of theory-of-mind performance (Fujita, 2013; Hughes et al., 2014) have assessed measurement invariance, with contrasting results that may reflect a developmental increase in the coherence of theory-of-mind understanding. Specifically, in a study comparing 5- to 6-year-old children from the United Kingdom, Italy, and Japan ($N = 270$), individual differences in the understanding of first- and second-order false belief (and emotions based on false belief) could be indexed by a single latent factor that showed across-country measurement invariance (Hughes et al., 2014). In contrast, a single latent factor showed very poor fit in a separate study of 3- to 6-year-olds from the United Kingdom and Japan ($N = 230$) that included tests of diverse desires, diverse beliefs, knowledge access, and hidden emotions, indicating that these are distinct milestones that do not necessarily cohere as a single construct (Fujita, 2013).

Related to this point, other research groups have begun to examine whether there is across-culture variation in the *nature* of mental state awareness; for example, regarding the importance of mind, the characteristics of mind, and what children understand about the content of the mind (Lillard, 1998). In particular, Wellman and colleagues (Shahaeian, Peterson, Slaughter & Wellman, 2011; Wellman, Fang, Liu, Zhu & Liu, 2006) have conducted a set of investigations that suggest that children from different countries may master distinct aspects of theory of mind in a different sequence. For example, Wellman et al. (2006) reported that children in China and children in the United States and Australia differed in the order in which they succeeded at tasks tapping *thinking* (diverse beliefs) and *knowing* (knowledge access). Specifically, as might be predicted from the greater emphasis placed within collectivist cultures on gaining knowledge, respecting adults, and avoiding conflict, Chinese children understood knowledge access before they understood that different people might hold divergent beliefs. Replicating this finding in another collectivist culture, Shahaeian et al. (2011) found that Iranian (but not Australian) children understand knowledge access before they understand the subjective nature of belief.

Thus existing evidence supports both etic perspectives (which emphasize the cultural universality of milestones in children's understanding of mind) and emic perspectives (which emphasize cultural specificity, both in the nature of mental-state concepts and in social influences upon children's concepts of mind). How should these cultural contrasts be explained? Previously, we have discussed how linguistic factors (e.g., specific wording of questions) can affect children's performance. Although this point holds force with regards to cultural effects (e.g., languages often differ in lexical explicitness of reference to the falsity of a belief), to avoid repetition of material we shall focus on (a) differences in social norms (e.g., with regard to deference to adults); and (b) socialization practices both within and outside the family.

With regards to the potential influence of discrepant social norms, a series of experiments have shown that Japanese children are not simply delayed in their success on false-belief tasks, but actually adopt a different explanatory framework for interpreting human behavior (Naito & Koyama, 2006). Specifically, when asked to justify the behavior of a character that either deliberately or inadvertently changed location, Japanese children often referred to general situational cues, rather than to the person's beliefs or desires. Likewise, in a study of Chinese 3- to

7-year-olds, Wang, Zhu, and Shi (2011) concluded that children's judgments were guided by knowledge of social norms rather than information about beliefs or desires, reflecting the strong emphasis within Chinese culture on obedience to rules and submission to authority.

Contrasting social norms mean that familial influences are also likely to differ between cultures. For example, although (as discussed earlier) numerous Western studies have reported that children with siblings show accelerated success on false-belief tasks, cultural differences in the nature of the sibling relationship mean that this effect may not be evident in non-Western samples. In particular, whereas children in the West often display high levels of playful rivalry toward their siblings and so may be motivated to hone their skills in deception and provocation (Hughes, 2011), siblings in many other parts of the world assume important caregiving responsibilities, constraining opportunities for these kinds of playful interactions. Consistent with the view that the sibling advantage may be specific to Western countries in which children's interactions with siblings are quite distinct from their interactions with other family members, the results from a study conducted in Greece and Cyprus (Lewis, Freeman, Kyriakidou, Maridaki-Kassotaki, Berridge, 1996) support a "general apprenticeship" model in which daily interactions with extended adult kin are as effective as sibling interactions in promoting children's understanding of false belief. Interestingly, in a later study, Lewis et al. (2006) found that for children in China (who typically do not have any siblings) contact with other children (e.g., cousins) actually appeared to be *negatively* related to false-belief task performance. This negative association is surprising and may reflect confounding effects of other family variables (e.g., socioeconomic status), but serves as a useful reminder of the likely complexity of social influences. Moreover, even in Western cultures, the benefit associated with having a sibling appears much weaker (or non-significant) for low-income samples (e.g., Cole & Mitchell, 1998). Overall, the impact of contact with other children in the family (siblings, cousins) appears to depend on the quality of interactions, which is likely to vary markedly from culture to culture.

Are other family influences on children's understanding of mind also culture-specific? Although (as described earlier) mother-child interactions are a key predictor of children's false-belief understanding and are known to differ widely across cultures (e.g., Bornstein, 1995), cross-cultural studies of theory of mind have yet to examine directly children's interactions with mothers. However,

a few research groups have examined links between children's performance on diverse theory-of-mind measures and parenting within different ethnic groups living in the United States. In the first of these studies, Korean American and Caucasian American mothers' responses to a Parenting Attitudes Inventory revealed culturally specific links between parental style and children's false-belief understanding (i.e., authoritarian parenting was negatively associated with false-belief understanding in Anglo American but not Korean American children). Doan and Wang (2010) compared children's ability to generate specific situations that would elicit particular emotions and maternal mental-state talk during shared reading of a picture book at home for European American and Chinese American mother-child dyads. Their study showed that European American mothers made more references to mental states (but fewer references to behaviors) than Chinese American mothers. In addition, children's ability to describe situations likely to provoke particular emotions (e.g., sadness) was more advanced in European American children than in Chinese American children and this large contrast was at least partially explained by the group difference in the mothers' emphasis on mental states.

Other researchers have examined the relation between maternal "mind-mindedness" and children's theory-of-mind skills in non-Western samples. For example, in a small-scale longitudinal study of 38 Japanese mother-child dyads, Shinohara (2011) found that maternal mind-mindedness at 6 months weakly predicted children's understanding of mind at Age 4. However, this association was nonlinear and so differed from that reported in a study of British mother-child dyads (Meins, Fernyhough, Russell, & Clarke-Carter, 1998). Specifically, superior emotion understanding in children was associated with moderate (but not either low or high) levels of maternal mind-mindedness. Fujita (2013) has conducted a comparison of British and Japanese mothers' speech samples ($N = 226$) coded for mind-mindedness. Echoing earlier findings reported by Meins and colleagues (1998), maternal mind-mindedness was associated with children's false-belief understanding in the British but not the Japanese sample, suggesting that maternal influences on children's theory-of-mind performance may be culturally specific.

Interestingly, evidence is also emerging for between-country differences in theory-of-mind performance *within* Western cultures. For example, at least two studies (Hughes et al., 2014; Lecce & Hughes, 2010) have shown that Italian children lag behind their British counterparts in their

performance on a battery of theory-of-mind tasks. This (weak) group difference appears, at first glance, rather surprising, but may reflect differences in the age at which children begin formal schooling (between 4 and 5 in the United Kingdom, and around Age 6 in Italy). Formal schooling offers both increased contact with peers and exposure to pedagogical situations that encourage reflective self-awareness and so may be important to theory-of-mind development. Here it is worth noting that Japanese children, like children in Italy, start formal schooling later than children in the United Kingdom. Thus a viable alternative to accounts of cultural differences that focus on general cultural attitudes (e.g., individualism versus collectivism) is that contrasts in pedagogical experiences contribute to cultural differences in children's acquisition of a theory of mind.

Finally, there is clear scope to expand cross-cultural research into children's understanding of mind in two further directions: By going beyond false belief to consider children's understanding of other mental states, particularly emotion; and by going beyond the preschool years to establish whether the lag between children from collectivist as opposed to Western cultures is also evident among older children. With regard to the first of these points, cross-cultural contrasts in children's understanding of emotion appear complex. For example, relative to their Western peers, children from non-Western cultures appear more advanced in certain domains, such as recognizing emotions from facial expressions (e.g., Markham & Wang, 1996), but less advanced in other domains, such as predicting an emotion based on a false belief (e.g., Vinden, 1999).

With regard to the second point, whereas studies of preschoolers' understanding of mind suggest a robust "East-West" contrast that favors children from the West, evidence from studies of older children (involving paradigms that indirectly assess children's awareness of false belief by examining their propensity to tell lies in order to conceal a transgression) is much more equivocal (Evans, Xu, & Lee, 2011; Talwar, Gordon, & Lee, 2007). As children develop, their social horizons widen considerably, such that family influences are likely to decline in importance. Thus cultural contrasts among older children and adults may be quite different from those evident in preschool children. Support for this view comes from at least two studies of adults' perspective taking. In the first of these studies, conducted in the United States, (bilingual) Chinese-American adults appeared more likely than Caucasian-American adults to take another

person's perspective; in that they were less likely to focus on an distractor object that was occluded from the view of a person giving instruction (Wu & Keysar, 2007). In the second study, conducted in Hong Kong, Chinese–English bilingual adults made substantially fewer errors when interpreting game instructions under Chinese rather than Western primes (Luk, Xiao, & Cheung, 2012). Together, these findings provide a striking contrast with the delayed performance on theory-of-mind tasks reported for preschoolers and so highlight the importance of combining developmental and cross-cultural perspectives.

In sum, although findings from several early studies of non-Western samples highlighted universalities in children's understanding of mind, closer inspection reveals a number of methodological issues that constrain the conclusions that can be drawn from this work. Later studies that have adopted a more rigorous approach (e.g., involving task batteries or larger samples matched for verbal ability) converge with meta-analytic reviews in demonstrating contrasts in the rate at which children from different cultures acquire an understanding of mind. That said, this research remains very restricted in its developmental scope, such that more work is needed both with infants (using the new generation of indirect measures described earlier in this chapter) and with older children (to assess whether catch-up effects attenuate the delays reported for non-Western children). However, the most obvious gap in existing cross-cultural research is the scarcity of direct measures of children's environments: To date, very few studies have attempted to address this issue and even these exceptional studies have relied on nonobservational measures (e.g., questionnaires or speech samples). A clear direction for future cross-cultural research is therefore to integrate experimental assessments of theory of mind with direct observations of children's interactions with other children and with adults, both within and outside the family.

Social Influences on Theory of Mind: Converging Themes

These seven strands of research encompass a very broad set of findings, such that it is worth reflecting on whether there are any overarching themes that might draw these distinct bodies of work together. One such theme is the *cumulative* nature of social influences: Although even very short interventions have produced positive gains (e.g., Lohmann & Tomasello, 2003), at least some training studies (e.g., Goldstein & Winner, 2012) reveal dosage effects

(both of quantity of training and of exposure to distinct sources of discourse); likewise enhanced theory of mind has been reported for both typically developing and deaf children growing up in bilingual environments (either two oral languages or oral plus sign). This cumulative effect may explain why studies with genetically sensitive designs suggest stronger environmental influences on theory of mind among older children (who are in regular contact with a broader array of social partners, each of whom may contribute to children's awareness of mind in different ways) than among younger children. Second, findings highlight both the stability of individual differences in theory of mind across an extended developmental period and the similarity of social influences across this broad developmental span, such that a second overarching theme is *continuity*. For example, in early and middle childhood, enhanced performance on tests of theory of mind appears associated with exposure to rich discourse about thoughts, feelings, and intentions.

Alongside these two themes are a few emerging new directions. These include: (a) a focus on social influences on the nature of theory of mind rather than simply on the rate of acquisition (both for typically developing children from different cultures and for children with perceptual impairments); (b) the adoption of more sophisticated statistical methods (e.g., use of confirmatory factor analyses to test for measurement invariance before making comparisons between different groups); and (c) investigations of genotype–environment interactions as a means of elucidating how children play an active part in shaping their environments. As shown in the next section, two cognitive domains have received considerable attention in studies of the correlates of theory of mind—executive function and language.

COGNITIVE CORRELATES OF THEORY OF MIND

As noted, the “second wave” of theory-of-mind research focused on identifying the predictors, correlates, and consequences of individual differences in children's understanding of mind (Dunn, 1999). In this section, we examine two cognitive correlates of theory of mind—executive function and language—and evaluate competing developmental theories about the links between each of these domains and theory of mind. In doing so we also consider how executive function and language might act as a bridge between children's social experiences and individual differences in theory of mind.

Executive Function and Theory of Mind

Research on executive function originated from neuropsychological studies of the functions of the adult prefrontal cortex, which typically involved complex problem-solving tasks. Over the past two decades, new, simplified tests of executive function have been designed, enabling researchers to investigate the development of executive function in the preschool years and across childhood and adolescence (e.g., Garon, Bryson, & Smith, 2008).

Defining Executive Function and Evidence for Links With Theory of Mind

As discussed elsewhere (e.g., Best, Miller, & Jones, 2009), researchers have, over the past few decades, hotly debated whether executive function should be conceived as a unitary construct or as a set of separate but related constructs. The three most widely recognized components of executive function are: (1) inhibitory control (the ability to override a prepotent but maladaptive response; Carlson, Moses, & Breton, 2002); (2) working memory (the ability to hold something in mind in order to guide future action; Baddeley, 2007); and (3) set shifting (the ability to switch from one set of rules for action to another; Garon et al., 2008). Studies using confirmatory factor analysis (CFA) have confirmed the validity of this three-factor model of executive function in middle childhood, adolescence, and adulthood (Huizinga, Dolan, & Van Der Molen, 2006; Miyake, Friedman, Emerson, Witzki, & Howerter, 2000). However, CFAs on data from preschoolers suggest that a unitary model provides the best fit for younger children (e.g., Wiebe, Espy, & Charak, 2008).

Key catalysts for early interest in the relation between executive function and theory of mind were: (a) their striking developmental synchrony, with both domains showing protracted development and notable gains in the preschool years (e.g., Carlson, Moses, & Hix, 1998); and (b) the claim that executive dysfunction rather than meta-representational difficulties might underpin the theory-of-mind deficits displayed by children with autism (e.g., Ozonoff, Pennington, & Rogers, 1991). Following initial work by Russell, Mauthner, Sharpe, and Tidswell (1991) on the relations between inhibitory control and false-belief task performance, a series of studies sought to examine more closely the relation between executive function and theory of mind. This work revealed that, for typically developing children, the association between theory of mind and executive function was independent of maturational variables such as age or verbal ability (e.g.,

Hughes, 1998). In a review of 10 studies, Perner and Lang (1999) reported evidence for a strong correlation between children's executive function and theory of mind (mean $r = .47$). Cross-cultural data from China and the United States suggested that the association between these two constructs was similar across cultures (Sabbagh, Xu, Carlson, Moses, & Lee, 2006); however, subsequent findings have contradicted this claim (e.g., Lewis et al., 2009).

In an effort to synthesize over 20 years of research on the relations between executive function and theory of mind, Devine and Hughes (2014) conducted a meta-analysis of the data from 102 studies from 15 different countries (representing 9,934 children aged 3 to 6) that showed a moderate but geographically stable correlation ($r = .38$) between theory of mind and executive function. This correlation remained significant when effects of age and verbal ability were controlled and did not vary across different measures of executive function. However, the strength of the association between executive function and theory of mind varied according to the type of theory-of-mind task used. Specifically, indirect measures of false-belief understanding exhibited significantly weaker associations with executive function than standard direct measures (which did not differ from each other). Just 10 of the studies in the meta-analysis included longitudinal data, which when pooled in the meta-analysis indicated an asymmetric link: Early individual differences in executive function modestly predicted later theory of mind (even controlling for previous theory-of-mind scores and individual differences in verbal ability) but the reverse correlation was not significant. To explain these meta-analytic findings, we now discuss the competing theoretical accounts of the relation between executive function and theory of mind.

Theories of the Relation Between Executive Function and Theory of Mind

In Shakespeare's *The Merchant of Venice* (c. 1596/2005a), Portia's father sets her suitors a challenge in which they must choose between three sealed boxes of lead, silver, and gold in order to win her hand in marriage. We too are faced with a choice of three possible options to explain the relation between executive function and theory of mind. According to Perner and Lang (1999) the three main accounts (described in more detail below) claim that: (1) there is a peripheral role for executive components within theory-of-mind tasks; (2) executive function is necessary for the development of theory of mind; and (3) theory of mind is a necessary precursor to executive function.

Early theorists (e.g., Russell et al., 1991) noted that success on the classic change-of-location false-belief task hinges on children's ability to track the location of the object, hold in mind the beliefs of the absent character, and override their own correct knowledge in order to attribute a false belief to the character. Thus executive task demands make it difficult for young children to *express* their conceptual understanding of mental states (e.g., Moses, 2005). By this account, the correlation between performance on theory-of-mind and executive function tasks reflects common demands for inhibitory control or working memory but not overlapping conceptual content.

Prima facie, this *expression* account of the link between theory of mind and executive function makes intuitive sense. More importantly, it provides testable hypotheses. Perner, Lang, and Kloo (2002) reasoned that, if the correlations between executive function and theory of mind were simply due to the executive demands of theory-of-mind tasks, then these correlations should attenuate or disappear once the executive demands were reduced or removed. Moreover, the expression account also predicts that children with superior executive function performance should outperform their peers on measures of theory of mind (Moses, 2005). Existing research evidence presents several challenges to the expression account. Firstly, at least two separate studies revealed no difference in the magnitude of the correlation between executive function and performance on the false-belief prediction task (thought to place considerable demands on a child's inhibitory control) and the false-belief explanation task (which conceivably places no such demand on participants) (Hughes, 1998; Perner et al., 2002). Secondly, cross-cultural studies have indicated that, despite superior performance on measures of executive function, children from China showed no gains in theory of mind over age-matched participants from the United States (Sabbagh et al., 2006).

In their meta-analytic review, Devine and Hughes (2014) reported a significant omnibus effect of theory-of-mind task type (i.e., change of location, unexpected contents, second order and indirect false-belief tasks) on the strength of correlation between executive function and theory of mind. Providing some support for the expression account, post hoc analyses revealed that the correlation between executive function and performance on standard direct false-belief tasks was greater than that between executive function and performance on indirect or spontaneous theory-of-mind tasks. That said, as we have noted earlier, precisely what indirect false-belief tasks actually measure remains hotly contested.

How else might the correlation between children's performances on tests of executive function and theory of mind be explained? Several theorists (e.g., Perner & Lang, 2000; Russell, 1996) have proposed a functional relation in which one construct is necessary for the development of the other. Given that, as noted above, just 10 of the studies included in the meta-analysis reported by Devine and Hughes (2014) were longitudinal in design (i.e., included measures of both executive function and theory of mind at two or more time points) it is clear that this research field remains "stubbornly cross sectional" (Bryant, 1990, p. 40). Moreover, to date, there have been just three published training studies focused on the link between executive function and theory of mind (Benson, Sabbagh, Carlson, & Zelazo, 2013; Fisher & Happé, 2005; Kloo & Perner, 2003) and only one of these has tested the causal direction of the relations between executive function and theory of mind in typically developing children. With these gaps in the literature in mind, we now examine the claims of the two functional accounts concerning the relation between executive function and theory of mind.

For some theorists (e.g., Carruthers, 1996; Perner & Lang, 1999, 2000), theory of mind is a necessary precursor to the development of executive function. In his early work, Perner (1991) speculated that gaining an understanding of their own and others' desires would facilitate children's development of self-control. In his later work, Perner (1998) hypothesized that children with a "deficient theory of mind" (p. 278) would experience difficulties with executive function. Elaborating this hypothesis, Perner and Lang (1999, 2000) proposed that, by acquiring an insight into the nature of mental states as entities that cause behavior ("meta-representation"), children develop improved executive function (or "meta-representational control"). That is, the ability to exert greater control over one's thoughts and actions is founded upon a representational understanding of the mind (Pellicano, 2007).

In contrast, others have proposed that executive function is a necessary foundation in the development of an understanding of mental states. This hypothesis was derived from the work of Hughes and Russell (1993) who first argued that, even if the executive demands of theory-of-mind tasks were stripped away, children with autism (who had difficulty with standard theory-of-mind tasks) would still not exhibit a normal conception of the mind because early difficulties with executive function would disrupt the acquisition of mental state understanding. From this perspective, insofar as it contributes to increasing self-reflection and control over one's thoughts

and attention, executive function may be necessary for the *emergence* of theory of mind (Russell, 1996, 1997). That is, executive function provides the foundation for the development of an understanding of mental state concepts (Wellman et al., 2001).

In an effort to investigate the direction of the developmental relation between executive function and theory of mind, Hughes (1998) proposed that longitudinal cross-lagged analyses could be used to assess the strength of the predictive association between individual differences in theory of mind and executive function. Specifically, if theory of mind drives the development of executive function, then early individual differences in theory of mind should predict later performance on measures of executive function. Alternatively, if executive function is implicated in the development of theory of mind, then early individual differences in executive function will predict later performance on measures of theory of mind. In their analysis of the existing longitudinal evidence, Devine and Hughes (2014) found that initial individual differences in executive function modestly predicted later theory of mind (controlling for initial theory of mind and verbal ability) but that the reverse was not true. Interestingly, Pellicano (2010) has found a similar pattern of relations between executive function and theory of mind in a landmark longitudinal study of the relations between these constructs in children with autism. Together, these findings appear to support the emergence hypothesis, that is, that early advances in executive function seem to aid the development of theory of mind in the preschool years.

Are these findings enough to construct a developmental account of the relations between executive function and theory of mind? There are at least two challenges to the longitudinal evidence in favor of the emergence account. First, it may be unreasonable to assume that false-belief tasks provide the only means of measuring children's theory of mind (Perner & Lang, 1999). Meta-analytic data suggest that an understanding of others' desires precedes the awareness of others' beliefs (Wellman & Liu, 2004). It is therefore possible that early advances in understanding desires might underpin the emergence of later executive function. This possibility has not been examined in longitudinal research and thus remains a research priority for proponents of the emergence account. Second, findings from a training study conducted by Kloo and Perner (2003) were equivocal: Training in a rule-shifting task led to gains in both executive function and theory of mind, whereas training in the theory-of-mind condition led to gains in executive function but not theory of mind. These results

can be interpreted as favoring either the metarepresentation account or as providing evidence of a reciprocal relation between these two constructs. No further training studies have directly examined whether a cause-effect relation exists between executive function and theory of mind.

Unlike the choice facing Portia's suitors in the three-caskets lottery, our three choices for explaining the link between executive function and theory of mind are not necessarily mutually exclusive. Instead, longitudinal and meta-analytic evidence from research in the preschool years points to a hybrid account in which executive function is implicated in both the emergence and expression of theory of mind (Carlson & Moses, 2001). Evidence from training studies will provide a further test of the hypothesized developmental relation between executive function and theory of mind. That said, the restricted focus of existing research on the preschool years limits the claims we can make about the relations between theory of mind and executive function beyond this period.

Executive Function and Theory of Mind Beyond the Preschool Years

There is a growing interest in the nature and development of theory of mind in adolescence (e.g., Dumontheil et al., 2010) and adulthood (Apperly et al., 2009). Support for a continued link between executive function and theory of mind beyond the preschool years comes from two sources. First, findings from a series of studies with older adults (e.g., German & Hehman, 2006; Philips et al., 2011) point to a moderate correlation between individual differences in performance on a range of complex theory-of-mind tasks and measures of working memory, inhibitory control, and set shifting. Second, findings from dual-task experiments also indicate a clear association between executive function and theory of mind in adults (e.g., Lin, Keysar, & Epley, 2010; McKinnon & Moscovitch, 2007). Although this evidence from adults provides a useful opportunity to reevaluate theories about the relations between theory of mind and other aspects of cognition (Apperly et al., 2009), its cross-sectional nature precludes any further analysis of *how* these two constructs are related. As for the preschool years, this relation could be developmental (i.e., gains in one predict change in the other) or nonfunctional (i.e., reflecting shared peripheral task demands).

Addressing both the need for longitudinal work and the dearth of research on theory of mind in the period between the preschool years and adolescence, Devine (2013) conducted a 4-year longitudinal study of 137 children who completed batteries of executive function and

theory-of-mind tasks at Ages 6 and 10. Individual differences in theory of mind and executive function were moderately correlated at each of these time-points. However, across-time analyses revealed that, once the substantial temporal stability in each construct was taken into account, longitudinal associations between executive function and theory of mind were not significant. These findings suggest that developmental links between these two constructs do not appear to persist beyond the preschool period. In other words, relations between executive function and theory of mind appear to shift in nature with age, from “emergence” (in the preschool years) to “expression” (in middle childhood).

Note, however, that the lack of a cross-lagged association between executive function and theory of mind in middle childhood does not render the cross-sectional association between these two constructs trivial. In this sense at least, classifying theoretical accounts as “functional” and “nonfunctional” may be misleading. Although further gains in executive function may have no payoff in terms of theory of mind, executive function may nevertheless be an essential component of theory-of-mind performance. Apperly (2011) has argued that executive function may be an integral element of theory of mind, underpinning any or all of the processes of attributing a mental state to another. These processes include inferring what someone else thinks (“inference”), holding this in mind (“storage”), and making a judgment or prediction about that person’s behavior (“use”). In order to disentangle these separate processes, Apperly, Back, Samson, and France (2008) devised a noninferential false-belief task in which adult participants were told about the target character’s mental state and were not required to make a judgment about behavior. Such tasks are valuable in that they open up the possibility of examining the contributions of executive functions to specific processes involved in theory of mind.

In sum, despite more than 20 years of research on the relations between executive function and theory of mind, the links between these constructs have yet to be fully explained and may alter in nature over the course of development. Specifically, executive function appears to be implicated in the *development* of theory of mind in the preschool years and in the *use* of theory of mind beyond the preschool years. Further training studies are needed to test claims about the developmental relations between executive function and theory of mind in the preschool years. Of course, designing an appropriate false-belief training condition presents a number of challenges. For example, as noted by Moses and Tahiroglu (2010), it is difficult to

disentangle whether improvements in task performance or executive function reflect executive or conceptual aspects of training. In addition, more work focusing on middle childhood, adolescence, and adulthood is needed both to confirm whether there is indeed a shift in the nature of the relations between executive function and theory of mind (i.e., from “emergence” to “expression”) and to test Apperly’s (2011) hypothesis about how executive function is involved in our later *use* of theory of mind (e.g., are individual differences in executive function related to some or all of the processes—*inference*, *storage*, *use*—involved in mature mental state reasoning?).

Theory of Mind and Language

Echoing Astington and Baird’s (2005) distinction between individual linguistic ability and linguistic environment, our discussion of relations between language and theory of mind are divided between two sections in this chapter. Earlier, we examined the links between variation in children’s linguistic environments and individual differences in theory of mind. Here, we focus on whether there is a developmental relation between individual differences in language capacity and theory of mind.

Theories of the Relation Between Language and Theory of Mind

Researchers studying language capacities often differentiate between semantics (i.e., lexical knowledge) and syntax (i.e., mastery of grammatical conventions for combining words) (Milligan, Astington, & Dack, 2007). The question of whether theory of mind is related to one, both, or some combination of these aspects of language has preoccupied researchers in the field for almost two decades. In a meta-analysis integrating 104 studies of English-speaking children ($N = 8,891$) Milligan et al. (2007) reported a moderate association ($r = .43$) between multiple measures of language and theory of mind. This association held even after controlling for individual differences in age ($pr = .31$).

That said, the *nature* of the association between language and theory of mind remains a matter of controversy, open to at least three distinct theoretical accounts that directly mirror the explanations for the link between executive function and theory of mind. The first “non-functional” account (analogous to the expression account of the relation between executive function and theory of mind) proposes that a correlation between measures of language ability and theory-of-mind tasks arises quite simply because language might act as “a simple crutch” (De Villiers, 2005, p. 187)

for performance on the false-belief task. This perspective posits no causal relation between an early-emerging, possibly innate theory of mind and the language abilities required to pass the false-belief task (Astington & Baird, 2005; Astington & Jenkins, 1999). In contrast, the next two accounts posit a functional (i.e., causal) developmental relation between theory of mind and language, but differ in the direction of influence. Specifically, the second account proposes that the development of semantic knowledge or syntactic abilities (or indeed both) provides a necessary foundation for understanding mental states (Astington & Baird, 2005; Astington & Jenkins, 1999), while the third account proposes that aspects of language development actually depend upon having a theory of mind (Astington & Jenkins, 1999). Below, we ask: What is the evidence for each of these three accounts?

First, it is generally agreed that standard false-belief tasks do place heavy linguistic demands upon children and it is entirely possible that these demands may mask their early competence in theory of mind. However, a key prediction from the expression account is that reducing or eliminating the linguistic demands of false-belief tasks should attenuate the association between language and theory of mind and “unmask” early competence in theory of mind (Perner & Roessler, 2012). Evidence from three separate meta-analyses challenges this proposal. First, in an early meta-analysis (largely restricted to Western samples) Wellman et al. (2001) reported that neither the phrasing of the false-belief task question (i.e., whether the question used the word “think,” “believe,” “know,” “look,” or “say”) nor the inclusion of a temporal marker (e.g., “first”) in the false-belief question appeared to enhance young children’s ability to pass the false-belief task. Second, a meta-analysis of data (from English-speaking children) on relations between language and theory of mind showed that the strength of the association between theory of mind and language did not alter according to the type of theory-of-mind task used despite the varying linguistic demands of the different tasks (Milligan et al., 2007). Third, a meta-analysis of false-belief task performance among children from China and Hong Kong (Liu et al., 2008) provides an interesting counterpoint to data from Western studies because, unlike English, Mandarin and Cantonese include alternative terms that vary with regard to the veracity of someone’s belief (i.e., neutral versus “think falsely”). Liu et al. (2008) found that, although children tested using the neutral verb form performed less well than those tested using the “think falsely” form, the verb form did not enhance overall performance relative to

children from North America nor did it interact with age. Thus removing one source of linguistic ambiguity from the false-belief task did not affect the age-related improvement in performance. Together, these findings challenge the notion that the relation between language and theory of mind is only skin-deep.

Nevertheless, a growing body of findings from comparative and developmental psychology have led researchers to question the necessity of language for theory of mind and inspired a resurgence of interest in the expression account. For example, researchers have begun to demonstrate that nonlinguistic species are capable of performing tasks that appear to involve being able to reason about the minds of other organisms (e.g., Western scrub jays re-cache food in a way that reduces the chances of it being taken by potential pilferers; Dally, Emery, & Clayton, 2010). In addition, the development of new measures that use children’s eye gaze rather than speech or gesture to assess children’s understanding of others’ minds (discussed earlier) has led some researchers to claim that infants as young as 9 months may have an appreciation of others’ beliefs (e.g., Baillargeon et al., 2010). Given that infants and young children have only limited linguistic abilities, these findings challenge functional accounts of the links between language and theory of mind and bolster the expression account. Related to these points, Milligan et al. (2007) acknowledged that, in their meta-analysis, they were unable to identify any studies that examined the relations between performance on nonverbal false belief tasks and language ability. Since then, Low (2010) has reported that performance on a minimally verbal anticipatory looking false-belief task in preschool children was unrelated to measures of semantic knowledge or syntactic ability.

In raising questions about the necessity of language for theory of mind, the above findings are not without controversy. Specifically, as noted previously, it is, at present, difficult to establish exactly how one should interpret indirect measures of theory of mind in studies of infants and nonhuman animals. Crucially, without clear evidence regarding how individual differences in performance on such measures are related to (or independent from) individual differences in either language ability or in performance on standard theory-of-mind tasks, it is hard to establish whether success on indirect or nonverbal false-belief tasks reflects an early awareness of mental states, an awareness of behavioral rules, or the operation of a separate mindreading system.

Setting aside these controversies, we now return to research findings based on standard measures of theory

of mind in order to examine the evidence for explanatory accounts that posit a causal, developmental relation between language and theory of mind in young children. In their meta-analysis, Milligan et al. (2007) integrated findings from several longitudinal studies to show that the relation between early language ability and later theory of mind ($r = .56$) was significantly stronger than that between early theory of mind and later language ($r = .36$). This asymmetric longitudinal association provides initial support for a developmental association between these two constructs and suggests that theory of mind development builds upon language ability. Researchers are divided over what aspects of language ability might be causally implicated in the development of children's ability to explicitly reason about mental states. To address this issue, Milligan et al. (2007) examined whether the relation between language and theory of mind was specific to any one aspect of language (i.e., general language measures that involve semantic and syntactic subtests, measures of receptive vocabulary, measures of syntactic ability, and measures of complementation syntax). Their findings revealed that, although the correlation between theory of mind and receptive vocabulary was lower than that between theory of mind and general language, each aspect of language ability was associated with theory-of-mind task performance. However, these cross-sectional findings reveal little about the developmental relations between theory of mind and specific aspects of language. Longitudinal and training studies have revealed a rather different set of findings.

One prominent developmental account of the relations between language and theory of mind places central importance on children's mastery of syntax, more specifically, the syntax of mental-state verbs (De Villiers, 2005). Mental-state verbs and verbs of communication are unique (in English) in the kinds of complements they take because the embedded clause can be false while the whole sentence remains true (De Villiers, 2007). Take, for example, the following sentences about some of the events in Shakespeare's *King Lear* (c. 1605/2005b):

1. Edmund said that Edgar wrote the letter.
2. Gloucester believed that Edgar conspired against him.
3. Gloucester was blinded because Cornwall and Regan plucked out his eyes.

In sentences (1) and (2), the proposition in the lower clause (underlined) may be true or false without altering the veracity of the sentence as a whole. In contrast, if the lower

clause in sentence (3) is false, the whole sentence is false. Sentences (1) and (2) contain verbs of communication ("said") and mental states ("believed"), which take tensed complements. According to the "linguistic determinism account" of theory-of-mind development, mastery of the syntax of tensed complements (such as those in sentences (1) and (2)) enables children to represent mental states (De Villiers, 2005, 2007). From this perspective, rather than simply being a crutch for success on theory-of-mind tasks, language is fundamentally implicated in the development of the capacity to reason about mental states (De Villiers, 2005; Hale & Tager-Flusberg, 2003).

In their meta-analytic review, Milligan et al. (2007) reported a robust correlation ($r = .60$) between measures of complementation syntax and performance on false-belief tests. Both training and longitudinal methods have been used to test the causal hypotheses arising from the linguistic determinism account. Training studies were discussed in a previous section of this chapter, but two studies deserve particular mention here because they aimed to establish whether training in sentential complementation is sufficient to improve preschoolers' performance on false-belief tasks. In the first of these studies, Hale and Tager-Flusberg (2003) trained 72 preschool children in one of three conditions: a false-belief task, sentential complementation, and relative clauses. Importantly, none of these conditions involved the use of mental state verbs. Children in both the false-belief and sentential complementation training groups (but not those in the relative clauses group) improved in their false-belief performance, but only children in the sentential complementation training group improved their performance on the sentential complementation task. In a separate study aimed at disentangling the effects of sentential complementation training versus experiences of deception, Lohmann and Tomasello (2003) trained 138 preschoolers in one of four conditions: full training (i.e., the experimenter first showed the child an object that appeared to be a flower but was really a pen and then discussed its deceptive appearance using mental state language and sentential complements), sentential complementation training (i.e., the experimenter discussed an object without referencing its deceptive appearance), discourse-only training (i.e., the experimenter highlighted the deceptive aspects of the object without using mental-state language or sentential complements), and a no-language training condition (i.e., the experimenter highlighted the deceptive qualities of the object with minimal language input). At posttest, although the full training group outperformed all other groups, training in sentential complementation

syntax (without deceptive experience) was sufficient to facilitate false-belief understanding.

Taken together, then, the findings from these two studies offer partial support to De Villiers' (2005) linguistic determinism account, in that they indicate that training in sentential complementation is *sufficient but not necessary* to produce change in false-belief task performance. Other findings that suggest that the mastery of the syntax of mental state verbs is not *necessary* for false-belief task performance come from two longitudinal studies in which mastery of sentential complementation syntax did not predict Time 2 false-belief task performance once effects of age and Time 1 false-belief task performance were controlled (Farrant, Maybery, & Fletcher, 2012; Tardif, So, & Kaciroti, 2007).

Further criticism of the linguistic determinism account comes from studies of non-English speaking children. Meta-analytic evidence shows that English-speaking children come to understand volitional mental states (e.g., desires, intentions) before epistemic mental states (e.g., beliefs, knowledge) (Wellman & Liu, 2004). This finding has been replicated in studies of Mandarin-, Cantonese-, and German-speaking children (Perner, Sprung, Zauner, & Haider, 2003; Perner, Zauner & Sprung, 2005; Tardif & Wellman, 2000). Unlike epistemic mental-state verbs such as "believe" and "think," English verbs denoting volitional mental states (e.g., "want") take an infinitival complement (not a tensed sentential complement), for example: (4) *Edmund wants to take Edgar's land and inheritance.* The linguistic determinism theory originally accounted for the developmental delay between understanding volitional and epistemic mental states in terms of children's ability to use tensed sentential complements, which emerged later than the ability to use infinitival complements (Perner et al., 2003). Unlike English, German verbs of desire must take a "that" complement (Perner et al., 2005). Across two experiments, Perner et al. (2003) demonstrated that despite requiring a "that" complement, German-speaking children performed better on tasks designed to measure the complements of desire statements ("want") than on the complements of verbal communications ("say") and epistemic mental states ("think"). This finding suggests that, in German, the mastery of tensed sentential complements is not a sufficient condition for understanding epistemic mental states.

Whereas linguistic determinism theory privileges the specific role of the syntax of mental-state verbs in the development of theory of mind, others have proposed a more general developmental account in which both

syntactic and semantic aspects of language foster children's growing understanding of mind (Ruffman et al., 2002; Slade & Ruffman, 2005). This assertion is supported by evidence from both cross-sectional and longitudinal research. Specifically, in one cross-sectional study of English-speaking and Cantonese-speaking children, performance on a measure of complementation syntax was no longer correlated with false-belief task performance when individual differences in general language ability were accounted for (Cheung et al., 2004). Longitudinal studies of English-speaking and German-speaking children also demonstrate that no one aspect of language (semantics or syntax) exerts greater influence on false-belief task performance than another (Lockl & Schneider, 2007; Ruffman et al., 2002). This position is undermined somewhat, however, by findings from the training studies reported earlier. Recall that training in relative clause structures (Hale & Tager-Flusberg, 2003) and training that involved discourse about a deceptive object without the use of mental-state verbs or sentential complements (Lohmann & Tomasello, 2003) produced no effect on false-belief task performance. Clearly, further training studies are required to support the claim that general linguistic ability (and not just sentential complementation) plays a causal role in the development of theory of mind.

Language and Theory of Mind Beyond the Preschool Years

Much like the research on executive function and theory of mind, the bulk of what is known about the links between language and theory of mind is derived from research on preschool children. A few studies focused on middle childhood have identified a moderate correlation between measures of language ability and performance on complex theory-of-mind tasks (Banerjee et al., 2011; Devine & Hughes, 2013), but without longitudinal or training evidence it is difficult to determine what role language plays in the development of mental-state reasoning during middle childhood and adolescence.

Several adult experimental studies have begun to shed light on the possible role of language in the fully developed theory of mind. In one study, A. M. Newton and De Villiers (2007) used a dual-task approach to examine the extent to which adults required language to perform a simple nonverbal false-belief task. Simultaneous performance of a verbal shadowing task had a large and negative effect on false-belief task performance when compared to a nonverbal rhythmic tapping task. However, Dungan and Saxe (2012) have argued that this contrast may reflect the

greater working memory demands imposed by the verbal shadowing task because, when working memory load was matched across conditions, performance on the nonverbal false belief was equivalent in both dual-task conditions. Further, in a case study, Apperly, Samson, Carroll, Hussain, and Humphreys (2006) demonstrated that an adult with severe grammatical impairments following stroke (including the inability to use complementation syntax) performed at above chance levels on nonverbal first- and second-order false-belief tasks. This case study raises the possibility that adults with impaired language abilities can reason about others' mental states. Additional work with typically developing adults is needed to elucidate the ways in which language remains part of the fully developed ability to reason about mental states.

In sum, although the evidence reviewed in this section makes it clear that language provides a foundation for the development of false-belief understanding in early childhood, the exact nature of this foundation (e.g., syntax or semantics or some combination of these) remains to be established. Data from longitudinal studies suggest that general language ability, rather than separate aspects of language, is necessary for later theory-of-mind development, but data from training studies suggests that mastery of syntactic complementation is sufficient (but not necessary) to produce change in false-belief task performance. Further work is needed to establish whether language continues to aid the development of theory of mind beyond the preschool years or whether it remains an important aspect of theory-of-mind use. In addition, replication studies within different linguistic contexts are needed to test the universality of specific relations between language and theory of mind. A further promising direction for future work is to test the emergence account by establishing whether language skills are also related to performance on *nonverbal* false-belief tasks.

Theory of Mind, Executive Function, and Language: A Social Perspective?

Our review of the developmental links between theory of mind and two cognitive domains: Executive function and language has been useful in identifying three key lacunae within existing research. Specifically, although the abundance of cross-sectional correlation studies focused on preschool children has been useful in identifying the links between individual differences in theory of mind and other cognitive abilities, progress in testing developmental theories has been constrained both by the scarcity of

longitudinal and training studies and by the narrow focus on the preschool years.

Second, existing studies have typically focused on *either* executive function *or* language ability as a correlate of theory of mind, with only limited attempts to integrate findings from these two strands of research. Because associations between theory of mind and both executive function and language are consistently moderate in magnitude, neither executive function nor language is likely to be a sufficient foundation for the development of theory of mind. That is, although existing theoretical accounts of the development of theory of mind consider the role of language ability and executive function separately, neither construct is likely to show a simple direct causal relation with individual differences in theory of mind. Instead, there is likely to be an interesting interplay between individual differences in these three constructs. One obvious interplay is that language skills foster children's executive function, which in turn promotes the development of theory of mind. This possibility is supported by Vygotsky's (1978) theory predicting that the capacity for language permits children to develop higher-order cognitive processes involved in the control of thought and action (i.e., executive functions). An alternative possibility is that improvements in executive function enable children to engage in more complex forms of discourse that in turn boost their understanding of others' minds. That is, for both language and executive function, the association of one construct with theory of mind may be mediated by the other.

The third obvious gap within existing research is that associations between theory of mind, executive function, and language have typically been examined in a social vacuum. This omission is surprising given the extensive bodies of literature that exist concerning social influences on (a) theory of mind (discussed earlier in this chapter) and (b) both language (e.g., Hoff, 2006) and executive function (e.g., Bernier, Carlson, & Whipple, 2010) as well as a growing body of work demonstrating differential susceptibility to environmental influence (discussed earlier). That is, just as genetic variation has been shown to moderate the impact of both positive and negative environments on diverse child outcomes (Belsky et al., 2009), it is reasonable to suppose that variation in children's language and executive function will also play a moderating role in the association between social environments and children's theory of mind. Reflecting this possibility, Benson et al. (2013) found that individual differences in executive function were a strong predictor of how much preschool children benefited from a short intervention designed

to promote false-belief understanding. Thus the relation between other aspects of children's social environments such as the frequency of parental mental-state talk and individual differences in theory of mind may be greatest for children who are more advanced in their executive functions (and so are better able to control their perceptual experiences). Focusing on the interplay between social and cognitive influences on children's understanding of mind is, we think, an exciting challenge for future research that might act to integrate the various competing theoretical perspectives on the development of theory of mind and elucidate the processes by which social experiences effect individual differences in theory of mind.

THEORY OF MIND: SOCIAL AND ACADEMIC OUTCOMES

In this final section, we turn the tables to examine a central tenet of the "social individual differences" perspective on theory of mind (Apperly, 2012), namely that individual differences in children's understanding of mind matter for children's social lives (e.g., Hughes, 2011). First, we consider links with children's later social competencies and peer relationships because these are not only important outcomes in their own right but also influence children's academic success. Next, we consider four further pathways that may mediate the association between theory of mind and academic success: peer relationships, child-teacher relationships, children's self-perceptions, and meta-cognition.

Theory of Mind: Social Outcomes

More than 30 years of research have produced remarkably few direct tests of whether and how mind-reading matters for everyday social interaction and existing studies have focused heavily on atypical groups. We therefore begin with a brief review of this literature on atypical groups.

Theory of Mind, Social Adjustment, and Atypical Populations

There is now considerable evidence that children with ASD have difficulty with tasks designed to measure theory of mind. Just over 10 years after Baron-Cohen et al.'s (1985) seminal study, a meta-analysis of data from 22 separate studies indicated that performance on such measures was, on average, almost 1 standard deviation ($d = .88$) lower in children with ASD than in typically developing children

(Yirmiya, Erel, Shaked, & Solomonica-Levi, 1998). Challenging earlier views that theory of mind was the crucial and unique defining deficit in ASD, similar findings have also emerged in the field of schizophrenia research. A meta-analytic review of 29 separate studies confirmed that adults with schizophrenia typically performed over 1 standard deviation below ($d = 1.25$) unaffected adults on measures of theory of mind (Sprong et al., 2007). These findings have led some theorists (e.g., Baron-Cohen, 1995; Corcoran et al., 1995) to claim that impairments in theory of mind underpin the social impairments that characterize both ASD and schizophrenia. For children with ASD, this view has at least partial empirical support from studies that have applied parental and teacher ratings of everyday social functioning to distinguish between "interactive" social skills that require mind reading (e.g., ability to respond to hints and indirect cues, or to initiate conversations of interest to others) and nonmentalistic "convention-based" social skills (e.g., sharing, following rules in a game) to compare children who passed or failed false-belief tasks (e.g., Fombonne, Siddons, Achard, Frith, & Happé, 1994; Frith, Happé, & Siddons, 1994; Hughes, Soares-Boucaud, Hochmann, & Frith, 1997). According to Frith et al. (1994) the weakness of the observed association between task performance and everyday social functioning for individuals with ASD may reflect their use of alternative non-theory of mind or "hacking" strategies on false-belief tests. Consistent with this view, two training studies (Hadwin, Baron-Cohen, Howlin, & Hill, 1997; Ozonoff & Miller, 1995) have shown that improvements in the performance of individuals with ASD on false-belief tasks do not lead to improvements in parent- and/or teacher-rated social adjustment.

However, it should be noted that, although all three studies confirmed that group differences were restricted to interactive social skills, effects of verbal ability were not considered in the study by Frith et al. (1994) which attenuated the group differences observed in the other two studies. Adopting a more fine-grained approach, Peterson, Slaughter, and Paynter (2007) reported that, for both children with ASD and typically developing controls, overall scores on a battery of false-belief tasks were moderately related to teachers' ratings of social skills, even when effects of age and verbal ability were taken into account. However, none of these predictors remained significant when diagnostic status was included in the model, indicating that group differences in social skills could not be explained by age, verbal ability, or theory of mind.

Theory of Mind, Social Adjustment, and Typically Developing Preschoolers

Earlier in this chapter, we identified seven strands of research that support the view that social environments influence children's understanding of mind. Far fewer studies have focused on the potential social *consequences* of individual differences in theory of mind (Dunn, 1995; Hughes & Leekam, 2004). The extant evidence suggests only qualified support for the view that theory-of-mind skills matter for our everyday social lives. Addressing this issue, Astington (2003) has argued that theory of mind is sometimes necessary but never sufficient for explaining social competence, highlighting the importance of other factors, such as language and social context. Likewise, Apperly (2011) has argued that, rather than constantly deploying a theory of mind, people often rely on social scripts, behavioral cues, and narratives to guide their behavior in social situations. In a stronger version of this account, Ratcliffe (2007) has proposed that *most* social interactions can be successfully navigated by relying on social norms and roles rather than the attribution of mental states. Below, we outline the evidence that theory of mind contributes to children's social functioning and discuss why different studies have led to contrasting findings.

In one of the earliest studies in this field, Lalonde and Chandler (1995) adopted a similar methodology to that applied in early studies of children with ASD, distinguishing between teachers' ratings of "conventional" and "interactive" (i.e., mentalistic) social behaviors and demonstrating that only the latter were (moderately) related to performance on false-belief tasks in typically developing 3-year-olds. However, a direct replication study (Astington, 2003) that took account of individual differences in verbal ability produced no significant findings and also highlighted the difficulty in reliably distinguishing between conventional and interactive social behaviors. Likewise, although two separate studies (of 5- and 6-year-olds) have reported weak associations between false-belief understanding and teachers' ratings of social skills (Hughes, 2011; Watson, Nixon, Wilson, & Capage, 1999), at least two other studies (E. Newton & Jenvey, 2011; Weimer & Guajardo, 2005) have failed to detect any significant association between theory of mind and social functioning. The evidence then is, at best, mixed.

Findings from the first study to address the issues of causal direction suggest that peer interactions reflect rather than influence children's understanding of mind. At three time-points over a 7-month period, Jenkins and Astington

(2000) gave 20 Canadian preschoolers a set of false-belief tasks and filmed them in dyadic play with a friend. These play sessions were transcribed and coded for quantity and quality of pretend play (e.g., joint planning, explicit role assignment); cross-lagged analyses showed that prior false-belief performance predicted children's joint planning and role assignment during later sessions (even with effects of age, concurrent child language, and prior pretend play taken into account). In contrast, there was no evidence that early social behaviors predicted children's later theory of mind. That said, findings from other studies do suggest a reciprocal association (e.g., Razza & Blair, 2009).

One possible explanation for the inconsistent association between false-belief task performance and adult-ratings of social skills is that the ability to attribute mental states is a socially neutral tool, which can be applied to both prosocial goals (e.g., helping, comforting, explaining) and antisocial goals (e.g., deceiving, manipulating, excluding). This perspective suggests that researchers need to consider potential moderating influences. For example, in a study involving a sample of 120 pairs of same-sex 40-month-old twins, girls' good performance on a battery of false-belief tasks was weakly associated with harmonious and cooperative mother-child interactions, whereas for boys, success on the same battery of false-belief tasks was moderately associated with greater use of parental discipline, suggesting gender differences in *how* children apply their understanding of others' minds (Hughes, Deater Deckard, & Cutting, 1999). Replicating this gender difference, Walker (2005) examined theory-of-mind performance in 111 children aged 3 to 5 years and found that the associations with teachers' ratings of aggressive or disruptive behavior were moderately stronger for boys than for girls.

Differences in how social skills are conceptualized and measured might also contribute to the mixed findings reported in the literature. Whereas some studies have focused on complex or "interactive" social competence skills (e.g. Lalonde & Chandler, 1995; Peterson et al., 2007), others have assessed social adjustment through ratings of prosocial behavior (Cassidy et al., 2003) or peer acceptance (Slaughter et al., 2002).

In addition, as argued by Astington (2003), conclusions regarding the link between theory of mind and social skills are also constrained by the heavy reliance on cross-sectional research. In one exceptional study involving 101 children who completed batteries of false-belief tasks at Ages 3 and 6, Hughes et al. (2011) applied latent variable analyses to demonstrate that individual differences

in false-belief understanding were stable across this 3-year period and showed both distal and proximal associations with frequencies of children's mental-state talk to friends at Age 6. Importantly, this model included both children's overall talk and friends' mental state talk, such that the findings indicate specific and independent longitudinal and cross-sectional associations between children's understanding of false-belief tasks and the frequency of their conversational references to their own and their friends' thoughts and feelings. One possible explanation for these findings is that achieving an early understanding of mind gives children an advantage in forming and maintaining friendships, which in turn leads to greater intimacy and mental-state awareness within these friendship interactions.

Theory of Mind, Social Adjustment, and School-Aged Children

As children grow up, their relationships with friends and peers come to eclipse the importance of family relationships and so one might expect a particularly robust association between individual differences in understanding of mind and peer relationship quality among school-aged children. To date however, findings have been limited by the scarcity of developmentally appropriate tasks for assessing individual differences in older children's understanding of mind. In addition, the findings from the few studies that have investigated this association are rather complex and highlight the importance of informant effects. For example, Bosacki and Astington (1999) found that variation in preadolescents' theory-of-mind skills, although unrelated to teachers' ratings of social competence, was moderately correlated with peers' ratings of social competence even when effects of age and verbal ability were controlled. Here it is worth noting that, by preadolescence, children are taught by a variety of teachers who are therefore less likely than teachers of younger children to be in tune with the social lives of their students.

Rater effects are also apparent in the findings from another much larger study involving 600 pairs of 9-year-old twins who completed Happé's Strange Stories (a series of text-based vignettes in which an actor says something that is not literally true and the child is asked to explain the actor's motives). Scores on this task showed uniformly modest correlations with self-, parent-, and teacher-ratings of children's social and communicative skills (on a checklist for symptoms of ASD) (Ronald et al., 2006); however, only the correlation with self-ratings remained significant once effects of language ability were taken into account. In another study involving 230 children aged 8 to 13 years,

Devine and Hughes (2013) administered both the Strange Stories task and a novel measure of theory of mind (in which children watched brief clips from Harold Lloyd's classic silent film "Safety Last" and were then asked questions about the characters' thoughts and feelings). In this study, poor performance on both tasks was associated with children's self-reported loneliness and social dissatisfaction, even when effects of age, gender, verbal ability, and socioeconomic status were taken into account. These associations were more robust than those reported by Ronald et al. (2006); two possible explanations for this difference are that the two studies adopted different measures (a checklist for symptoms of ASD in Ronald et al.'s [2006] twin study versus a measure of normative variation in loneliness and social dissatisfaction in Devine and Hughes' [2013] study) and involved samples that differed in age range (9-year-olds in the first study, as compared with 8- to 13-year-olds in the second study).

To date, just three studies of the relation between theory of mind and social competence in school-aged children have adopted a longitudinal design. First, Banerjee et al. (2011) used a cohort sequential longitudinal design to follow 210 British children across a 2-year period and reported a weak bidirectional link between individual differences in theory of mind (indexed by performance on a faux pas task) and peer rejection. Second, in a study involving 70 Italian children, Caputi et al. (2012) demonstrated that variation in prosocial behavior (from Ages 5 to 6) mediated the association between theory of mind at Age 5 and peer acceptance at Age 7.

In the third study, Devine (2013) followed up a sample of 137 children who completed batteries of theory-of-mind tasks at Ages 6 and 10; each time point also included child, parent, and teacher ratings of social adjustment. Theory of mind at Age 6 predicted social adjustment at Age 10 (as rated by children, parents, and teachers) even when Age-6 social adjustment and verbal ability were controlled. Interestingly, echoing the findings of Jenkins and Astington's (2000) study of preschoolers, this relation was asymmetric: Early social adjustment did not predict later theory of mind. The similarity of results from two samples of different ages suggests that theory of mind contributes to the success of children's social interactions across a broad developmental span.

In sum, while numerous cross-sectional studies (involving different age groups and diverse measures) have reported associations between theory of mind and various indices of social adjustment, the findings from a small but growing number of longitudinal studies indicate that this

association is asymmetric, with effects of theory of mind on later social success being stronger than the effects of early social competence on children's theory of mind skills. Moreover, this conclusion applies equally across a broad range of ages. However, the reported effect sizes range from weak to moderate in strength. Together, these findings provide some support for the social individual differences hypothesis although the relatively small effect sizes underscore that unqualified assertions about the centrality of theory of mind to children's social lives are unwarranted. Instead, the data support the more nuanced perspective on the relation between social adjustment and theory of mind proposed by Astington (2003). Viewed alongside the positive results from training studies described earlier in this chapter, the findings indicate that improving theory-of-mind skills may be a simple yet effective means of improving children's social adjustment. Thus, an obvious next step for future research is to investigate whether training studies can produce improvements in theory of mind that have a measurable impact on the quality of children's interactions with peers. The mixed findings discussed earlier suggest that this impact may be more evident in the quality and content of children's conversations with friends than in more general markers of behavior.

Theory of Mind: Academic Outcomes

Educational perspectives on children's understanding of others' minds are long overdue such that there is scant data available on the implications of both developmental changes and individual differences in theory of mind for children's real-life experiences at school (Astington, 2003). As a result, we can offer only speculative suggestions for pathways that might link theory of mind to children's academic success. The first of these concerns children's relationships with peers, the second concerns their relationships with teachers, the third concerns children's self-concepts, and the fourth concerns children's meta-cognitive abilities.

Peer Relationships, Theory of Mind, and Academic Success

As well as being important outcomes in their own right, positive peer relationships provide a foundation for children's engagement and motivation at school (e.g., Pianta & Stuhlm, 2004) and so are likely to be important mediators of any relation between theory of mind and children's academic success. For example, in a short-term longitudinal study of 200 kindergarteners, Ladd, Birch, and Buhs (1999)

showed that children's cognitive maturity contributed to their participation and achievement both directly and indirectly, via interactions with peers and teachers. The same research group applied structural equation modeling to longitudinal data on children followed from kindergarten through to fifth grade and reported similar findings. Specifically, teacher-rated chronic peer exclusion mediated the association between early (self-rated) peer rejection and later (teacher-rated) classroom participation, whereas (self-rated) victimization from peers mediated the association between teachers' ratings of early peer exclusion and later engagement in classroom activities (Buhs, Ladd, & Herald, 2006). Viewed alongside the peer problems among children with poor theory of mind described above, these findings suggest that peer relationships play a key mediating role in any associations between early theory of mind and later academic success.

Child-Teacher Relationships, Theory of Mind, and Academic Success

Understanding that other people have thoughts leads very easily to reflecting (and perhaps even ruminating) about the contents of those thoughts, and in particular, about what other people think of you. Thus, just as enhanced theory of mind has been reported for adults with dysphoria (Harkness et al., 2012), it may be that early awareness of others' minds may come at a price. Consistent with this view, findings from at least three separate longitudinal studies demonstrate that early mind-reading predicts later sensitivity to criticism.

The catalyst for this work was a longitudinal study of 46 Pennsylvanian preschoolers, which showed that false-belief understanding at 40 months was a moderately strong predictor of children's ratings of negative experiences in school 2 years later (Dunn, 1995). In a later London-based study, Cutting and Dunn (2002) told 141 preschoolers a puppet story involving a teacher who either praised or criticized a child's attempts at a task (drawing/arithmetic). Children were asked to imagine themselves as the child and to rate their ability and feelings. When effects of age and verbal ability were controlled, sensitivity to teacher criticism (i.e., ratings of low ability and negative feelings in the criticism condition) remained strongly correlated with both concurrent and prior false-belief performance. Similar findings have emerged from studies in which the same puppet paradigm was administered to children in Cambridge (United Kingdom) and Pavia (Italy). In the Cambridge study, Hughes (2011) found that sensitivity to teacher criticism at Age 6

was related to concurrent (but not prior) theory-of-mind performance. Echoing the gender-specific social correlates for theory of mind reported earlier, this association was stronger for girls than for boys. Importantly, however, false-belief performance and sensitivity to teacher criticism were each inversely related to both teachers' and children's ratings of dependency on teachers. Thus despite its negative connotations, sensitivity to teacher criticism may actually reflect a positive aspect of the child–teacher relationship. For example, as noted by Cutting and Dunn (2002): “Children who are more sensitive to criticism may be in a better position to learn from constructive criticism than those who are less affected by critical remarks” (p. 857). Support for this view comes from findings from a mediation analysis conducted in a longitudinal study of 60 Italian children. Specifically Lecce, Caputi, and Hughes (2011) have reported that sensitivity to criticism at Age 6 was a moderately strong mediator of the association between theory of mind at Age 5 and teacher-rated academic success at Age 7. Thus, rather than simply being a “cost” of early mind-reading, sensitivity to criticism may actually drive children's efforts to enhance their academic performance.

A further challenge to the idea that early mind-reading ability may have negative consequences (e.g., leading children to worry about what others think of them) is provided by the finding, reported in two separate studies (Banerjee, 2008; Broeren & Muris, 2009) of a weak inverse relationship between false-belief performance and social anxiety. On balance, then, early mind-reading appears unlikely to adversely affect children's well-being, but may facilitate their grasp of teachers' intentions (Ziv, Solomon, & Frye, 2008) and enable them to form responsive interactions with their teachers (e.g., Garner & Waajid, 2008). This is an important goal, as evidence from a large-scale NICHD study (of 1,304 children followed from birth to 11 years) indicates that child–teacher relationship quality both strongly predicts later achievement and buffers children from the adverse effects of insecure maternal attachment on academic achievement (O'Connor & McCartney, 2007).

Are the above findings limited to studies of young school-aged children, or might individual differences in theory of mind also be associated with variation in the quality of adolescents' relationships with teachers (and hence with their academic performance)? This question has yet to be addressed directly, but the few findings that are available for older children and adolescents are encouraging. For example, at least one study has shown that

preadolescents demonstrate marginally better mental-state awareness when answering questions about hypothetical scenarios involving teachers they like rather than teachers they do not like (O'Connor & Hirsch, 1999); to our knowledge, however, this (weak) contrast has yet to be replicated.

Self-Perceptions, Theory of Mind, and Academic Success

Theorists (e.g., Rutter, 1989) have long argued that children's self-perceptions (e.g., evaluations of their own academic potential) shape their behavior and developmental trajectories. Empirical support for this view comes from longitudinal evidence for a moderate reciprocal association between achievement and academic self-concept (e.g., Marsh, Ellis, & Craven, 2002). That is, while academic success obviously influences children's academic self-concept, a positive academic self-concept predicts academic gains, especially in mathematics (Marsh & Yeung, 1997).

To our knowledge, no published study has directly investigated the relation between theory of mind and children's academic (rather than social) self-concept. However, at least two studies have demonstrated links between theory-of-mind performance and children's global self-worth. One of these studies involved 3-year-old children and demonstrated an interesting interplay between the predictive effects of theory of mind and mother–child relationship quality on children's self-worth. Specifically, the (weak to moderate) association between theory of mind and self-worth was positive for children who enjoyed high levels of maternal warmth, but negative for children exposed to low levels of maternal warmth (Cahill, Deater Deckard, Pike, & Hughes, 2007).

Likewise, in a study of preadolescents, Bosacki (2000) found that, even when variation in language ability was taken into account, the sophistication of participants' accounts of vignettes involving beliefs about beliefs (used as an index of their theory-of-mind skills) showed a moderate to strong association with their justifications for statements about the self. Whereas Bosacki (2000) interpreted this finding from a sociocultural perspective (that is, that the understanding of self emerges through interaction with others), others have offered a more biological view. Specifically, in a review of evidence from neuroimaging studies and from experimental studies of both typically developing children and children with ASD, Happé (2003) has argued that “self-reflection may

be, in one sense, an epiphenomenon—an extraordinary side effect of the crucial ability to read other minds" (p. 142). To date, however, this proposal has yet to be tested. The earlier-described findings of an association between positive self-concept and academic achievement suggest that future research to elucidate the nature of associations between theory of mind and self-concept may be important not just theoretically, but also at a practical level, in developing new strategies to promote children's academic success. That is, interventions that successfully promote theory of mind may also enhance children's self-perceptions and thus indirectly foster their academic achievement.

Meta-Cognition, Trust, Theory of Mind, and Academic Success

According to Harris (2007, 2012), much of what children learn about the world comes from others' testimony. Experimental comparisons of 3-year-old children's attention to visual and verbal information indicate that preschoolers show a specific bias to trust testimony (Jaswal, Croft, Setia, & Cole, 2010). Moreover, an ingenious series of investigations (described below), has shown that young children display selective trust, acting preferentially on information provided by: (a) familiar rather than unfamiliar adults; (b) in-group rather than out-group (e.g., as defined by racial features) adults; (c) adults whose previous testimony has been accurate and reliable; and (d) adults whose previous testimony is endorsed by bystanders.

Interestingly, the above strategies for filtering information vary with children's age and attachment security. Specifically, whereas younger preschoolers show a global preference for information from familiar rather than unfamiliar speakers (Corriveau, Pickard, & Harris, 2011), older preschoolers can moderate this preference according to the accuracy of the speakers' previous statements (Corriveau et al., 2009). Likewise, Corriveau et al. (2009) have shown that securely attached children prefer to act on information provided by a caregiver than by a stranger when no external cues are available, but reverse this preference if the stranger is likely to be better informed; in contrast, insecurely attached children are less flexible and judicious in their preferences for informational sources. Although this research is typically used in accounts of the social origins of children's concepts of mind, it also provides a platform for investigating whether age-related changes in children's understanding of mind contribute to their growing success in learning about the world more generally.

The educational implications of this proposal are clear, making this a valuable direction for future research. For example, it is possible that children with more advanced or fluent mind-reading skills are more likely to attend to information from informed and reliable sources and are, in this way, at an advantage in learning about the world around them.

Links between theory of mind and meta-cognitive skills may also provide another clue to how individual differences in children's understanding of mind might relate to academic outcomes. Take, for example, meta-knowledge about reading strategies (e.g., understanding the benefits of both skim-reading and rereading a text). As argued by Lecce et al. (2010), this meta-knowledge hinges on understanding that texts, like mental states, are representational in nature and can be interpreted in different ways by different people; in addition, understanding that text has an intended meaning is likely to help children understand that texts (like human intentions) can be misinterpreted. To test this proposal and establish the specificity of relations between theory of mind and meta-knowledge of reading, Lecce et al. (2010) conducted two studies of school-aged children (total $N = 277$) that examined whether children's understanding of cognitive states and emotion states predicted children's later meta-knowledge of reading. Their findings demonstrated a weak but specific link between variation in children's understanding of cognitive states and their later meta-knowledge about reading, even controlling for prior meta-cognition scores.

In sum, although the scarcity of research in this field means that we can only offer speculations rather than conclusions, several lines of investigation suggest that early individual differences in theory of mind may contribute to children's academic success via a number of routes. These include the fostering of social skills needed to form and maintain positive relationships with peers; the ability to understand teachers' intentions, enabling children to engage in constructive dialogue when teachers provide feedback on their work; the development of a positive and well-articulated sense of self that motivates children to strive to achieve their full potential; and the ability to reflect on others' perspectives in order to identify reliable sources of information or to reflect on one's own knowledge or cognitive abilities. Much more work is needed, both to draw these different strands of research together in order to test mediation models and to expand the developmental scope of this research in order to examine developmental shifts in the relative salience of each of these putative pathways.

CONCLUSIONS AND FUTURE DIRECTIONS

Each section in this chapter finished with an interim summary of research findings; thus our goal here is to offer a few key conclusions and suggestions regarding useful avenues for future research.

Individual Differences in Theory of Mind Are Not Trivial

Rather than simply reflecting a delay in the emergence of an area of knowledge (with no further consequences for development once acquired) individual differences in theory of mind appear both stable and meaningful. Although much more longitudinal work is needed to construct a life-span perspective on children's understanding of mind and address questions about developmental processes, findings from existing longitudinal studies demonstrate that individual differences in children's understanding of mind exhibit relative stability, even when different tasks are used at time-points that are several years apart.

What is less clear, however, is just what underpins these stable individual differences. Existing studies have controlled for the effects of other cognitive abilities (e.g., language, executive function) and family background, but have not, to our knowledge, controlled for effects of variation in child temperament or personality—some children may be more accurate in their reading of other minds than other children for the simple reason that they are more interested and hence more motivated to understand others. Conversely, contrasts in the ease with which children are able to “tune in” to others' minds may actually lead to individual differences in children's motivation to understand others. Teasing these two competing accounts apart requires designs that enable researchers to distinguish between children's performance and their competence (e.g., studies that give children attractive rewards for successful mind-reading, or assess changes in social orientation following training in mind-reading skills).

Although, as discussed in this chapter, researchers have made considerable headway in extending the developmental scope of investigations both below and above the preschool years, this research has typically involved individual tasks. Thus another important challenge is the development of reliable task batteries that can capture variation in mental-state understanding for use with very young children, or with school-aged children and adolescents. Several new infant paradigms have been developed but these have yet to be applied together as a battery that

might be sensitive to individual differences. Although there are obvious challenges in administering several tasks to infants, the availability of a wide variety of paradigms (e.g., violation of expectation, anticipatory looking, active helping, imitation) should enable researchers to sustain the interest of both infants and caregivers. Equally however, given that infants' attention is a precious resource, an urgent challenge for future studies is to assess the reliability and validity of existing measures. This psychometric work is an important prerequisite for testing competing theoretical accounts of why infants appear able to display an awareness of mental states in their spontaneous behaviors long before they succeed on traditional theory-of-mind tasks.

There is also a variety of paradigms available for older children and adolescents, but these do not share a common focus. Instead, some tasks measure perspective-taking skills (e.g., Dumontheil et al., 2010), whereas others focus on understanding epistemic mental states (e.g., Happé, 1994) or emotion (Baron-Cohen, Jolliffe, Mortimore, & Robertson, 1997). Addressing the lack of convergence in how we define theory of mind beyond the preschool years is a clear challenge for researchers trying to develop task batteries that, combined with the use of statistical modeling, can be used to clarify the structure of individual differences in theory of mind in school-aged children, adolescents, and adults. This modeling approach has already been applied successfully in research on the components of executive function, revealing an interesting contrast between the global or unitary structure of executive function in preschool children (Hughes et al., 2011; Wiebe et al., 2008) and the fractionated structure of executive function in adulthood (e.g., Miyake et al., 2000). Achieving a similar understanding of developmental continuity or change in the structure of theory of mind is important for assessing whether existing theories of young children's developing understanding of mind (e.g., executive accounts, linguistic accounts) can be applied at later stages in the life span.

Individual Differences in Theory of Mind Reflect a Complex Interplay of Social and Cognitive Influences

One impressive feature of existing research on potential social influences upon variation in children's theory of mind is the sheer range of different research strategies that have been adopted. As outlined in this chapter, these include: genetically sensitive designs; quasi-experimental studies of children with hearing impairments growing

up in different communicative environments; training studies involving typically developing children across a broad range of ages; longitudinal cross-lagged analyses of relations between measures of family discourse and children's success on diverse measures of theory of mind; observational studies of children's interactions with siblings, friends, and peers; and cross-cultural comparisons to investigate the potential impact of children's wider social environments. So far, however, these distinct strategies have typically been employed in separate studies. Integrating these diverse perspectives will enable future studies to increase both the rigor of existing research and the variety of questions addressed. For example, applying observational paradigms within cross-cultural studies would enable one to assess (rather than assume) cultural contrasts in specific social influences and therefore test competing hypotheses about the processes that contribute to children's emerging understanding of mind (e.g., cultural contrasts in parental socialization goals or practices versus contrasts in children's pedagogical experiences).

Our review of studies of the social and cognitive correlates of theory of mind highlighted twin limitations: Whereas studies of social influences often fail to consider child-driven effects, studies of cognitive influences often appear to have been conducted within a social vacuum. A second key challenge for future research is therefore to examine the complex interplay that is likely to exist between social and cognitive correlates of theory of mind. For example, as discussed earlier, impairments in executive function or in language development are each likely to constrain children's participation in the kinds of social interactions that might be expected to foster advances in children's understanding of mind (i.e., links between theory of mind and each of these cognitive domains may be socially mediated). Equally, there is growing evidence that family factors (e.g., quality of parent-child relationships, engagement in stimulating activities) contribute to variations in the rate at which children develop both executive function and language skills; thus each of these cognitive abilities might mediate associations between variation in children's social environments and in their understanding of mind. Alongside these bidirectional mediation effects, moderation effects are also worth exploring. For example, the extent to which children benefit from exposure to conversations about mental states is likely to depend both on their executive skills (e.g., to hold information in mind and shift attention in order to track the conversations that they overhear) and on their language skills (e.g., understanding lexical ambiguity is likely to facilitate

both children's awareness of contrasts between literal and intended meaning).

Individual Differences in Theory of Mind May Underpin Variation in Social and Academic Outcomes

Understandably, studies of the social impact of theory of mind have focused on atypical groups (such as adults with schizophrenia or children with ASD) for whom social interactions are often very difficult. For normative variation in theory of mind, associations with social success appear modest in size and are often inconsistent across different studies. One challenge for future research is therefore to identify which dimensions determine the salience of theory-of-mind skills. Two obvious candidates are familiarity and complexity: Whereas attempts to deceive or manipulate unfamiliar others place obvious demands on theory-of-mind skills, simple routine interactions with familiar others may require very little in the way of mind-reading (e.g., Ratcliff, 2007). To test these proposed nuanced relationships between theory of mind and social behavior, future studies could incorporate paradigms from game theory and economics (e.g., tasks that invite children to share rewards in situations that either do or don't involve material consequences) and systematically vary the familiarity and identity of the other protagonist (e.g., Guth, Shmittberger, & Schwarze, 1982). This approach might also be useful in elucidating potential cultural contrasts in children's understanding of mind. For example, in a comparison of young school-aged children from the United Kingdom, Italy, and Japan, we found that Italian children were particularly unwilling to accept a vignette in which a mother was trying to keep her son's birthday gift a surprise; many of these Italian children stated categorically that mothers always tell the truth (Hughes et al., 2014).

Also adding to the complexity of findings in this field is the likelihood of developmental shifts in how theory of mind affects social interactions. Among preschoolers, for example, variation in understanding of mental states may be most salient for individual differences in joint pretend play, or in the ability to appreciate simple humor, whereas among school-aged children understanding mental states is likely to be a prerequisite for negotiating complex group interactions or for developing intimacy within friendships (e.g., underpinning children's ability to appreciate the unspoken significance of an utterance). Elucidating developmental shifts in the social functions of theory of mind is an important goal, both in its own right

and as means to constructing more effective interventions for clinical groups who experience difficulties in reading others' minds. In this way training studies can provide us with useful insights for applied psychological work in community and clinical samples.

The modest and fluctuating relation between theory of mind and social behavior is likely to reflect not just moderation effects (such as those outlined above) but also mediation effects. Here, our review highlighted the paucity of direct empirical studies but also outlined four possible mediation paths. These included mediating effects of children's social relationships within the classroom (with both peers and teachers), their self-concepts and their meta-cognitive skills. The time has come for the field to make a concerted effort to use *developmental* research designs to test causal hypotheses about the antecedents and consequences of theory of mind across the life span.

In sum, we hope this chapter has convinced the reader that individual differences in theory of mind: (a) are stable and can be reliably measured across a broad range of ages; (b) reflect a complex interplay of social and cognitive factors; and (c) show meaningful associations with a variety of both social and academic outcomes. We also hope that this chapter has demonstrated the value (for both theory and practice) of expanding both the developmental and conceptual scope of existing research on theory of mind.

REFERENCES	645

Prosocial behavior—voluntary behavior intended to benefit another—is of obvious importance to the quality of dyadic and group interactions and was a popular topic of research in the 1970s and 1980s. Then attention to the topic declined dramatically for over a decade. However, research on prosocial behavior and related emotional responses (e.g., empathy) has been reenergized in the past decade, in part due to a growing interest in topics such as: (a) the biological correlates and bases of prosocial behavior and empathy-related responding, including heredity; (b) the neurological bases for understanding and responding to others' affective states; (c) the development of sociocognitive skills that play a role in the early emergence of prosocial behavior

and empathy-related responding; and (d) empathy and helping in bullying contexts.

Prosocial behaviors can be performed for a host of reasons, including egoistic ones (Eisenberg, 1986). Of particular importance to the study of prosocial behavior in many (but perhaps not all) cultures is the subgroup of prosocial behaviors labeled altruism, sometimes defined as intrinsically motivated voluntary behavior intended to benefit another—acts motivated by concern for others or by internalized values, goals, and self-rewards rather than by the expectation of concrete or social rewards or the avoidance of punishment (Eisenberg, Fabes, & Spinrad, 2006). However, because it is often impossible to

differentiate between altruistic actions and those prosocial behaviors based on other motives, it is necessary to focus on the broader domain of prosocial behaviors.

Empathy-related emotions frequently are viewed as contributing to the performance of other-oriented prosocial behaviors. Definitions of *empathy* vary; we define it as an affective response that stems from the apprehension or comprehension of another's emotional state or condition, and which is identical or quite similar to what the other person is feeling or would be expected to feel (Eisenberg et al., 2006). Empathy often is differentiated from related vicarious emotional responses, including sympathy and personal distress.

Sympathy is an affective response that frequently stems from empathy, but can derive directly from perspective taking or other cognitive processing including retrieval of relevant information from memory. It consists of feeling sorrow or concern for the distressed or needy other (rather than feeling the same emotion as the other person is experiencing or is expected to experience). *Personal distress* also may stem from exposure to another's state or condition; however, it is a self-focused, aversive emotional reaction to the vicarious experiencing of another's emotion (e.g., discomfort, anxiety; see Batson, 1991). Because empathy and sympathy have been strongly implicated in prosocial development and action, they are discussed throughout the chapter.

In the initial section of this chapter, we briefly present a general framework for integrating factors that contribute to prosocial responding (see Eisenberg [1986] and Eisenberg & Fabes [1998] for a review of relevant philosophical theories and grand theories in psychology). Then the empirical literature related to the development of prosocial behavior, with an emphasis on the emerging literature on early development and development during adolescence, is reviewed. In the following section, we review literature on the origins of prosocial responding, including potential biological, cultural, familial, and peer/school factors. Next we address sociocognitive correlates of prosocial responding and the relations of both temperamental/personality and social-behavioral individual differences (e.g., aggression) to prosocial behavior and/or empathy-related responding. Because there have been relatively few recent studies on the role of situational factors such as cost and benefits, situational skills, or mood inductions on prosocial behavior, these topics are not reviewed (see Eisenberg & Fabes, 1998). In the final sections of the chapter, gaps in the field and future directions for scholarship and research are discussed.

Due to space constraints, we often build on previously published reviews and focus more on recent than older publications (see Eisenberg & Fabes, 1998, and Eisenberg et al., 2006, in prior editions of the *Handbook* for older citations). We focus disproportionately on topics of central importance to prosocial development and issues that have been foci of interest in the decade prior to the time of this writing. Furthermore, we have confined our coverage to a somewhat narrow definition of prosocial responding. For example, the literature on cooperation, personality agreeableness, or the allocation of rewards generally is not emphasized. In addition, although people can empathize with others' positive emotions, we focus primarily on empathy with others' negative emotions or conditions of need because such empathy-related responding with negative emotions is of greater conceptual relevance to prosocial behavior.

A HEURISTIC FRAMEWORK

In our view, there are several major ways to approach the study of prosocial development: (a) examining normative developmental change in relevant behaviors and affect, (b) studying factors that might affect relatively enduring individual differences in prosocial responding (e.g., genetics, culture, socialization in the home or school), (c) delineating processes underlying the unfolding of prosocial action (or the lack thereof) in context, and (d) examining the role of contextual factors in situational prosocial behavior or empathy-related responding. All of these are represented to some degree in the heuristic model in Figure 15.1.

In Figure 15.1, we propose that prosocial action in a given context (or the lack thereof) is indirectly affected by individual differences in biology; socialization in the culture, family, and community; and in individuals' sociocognitive and dispositional (temperamental/personality) characteristics, along with antecedent temporary affective states and specific characteristics of a given situation (e.g., costs, who is the recipient). Specifically, such factors influence individuals' attention and how they interpret specific situations, if they identify helping actions and believe they are capable of engaging in relevant prosocial actions, how they make choices among conflicting goals in a specific situation, the intention to benefit another, and engaging in prosocial behavior. However, aspects of individuals' biology, socialization, and sociocognitive/dispositional

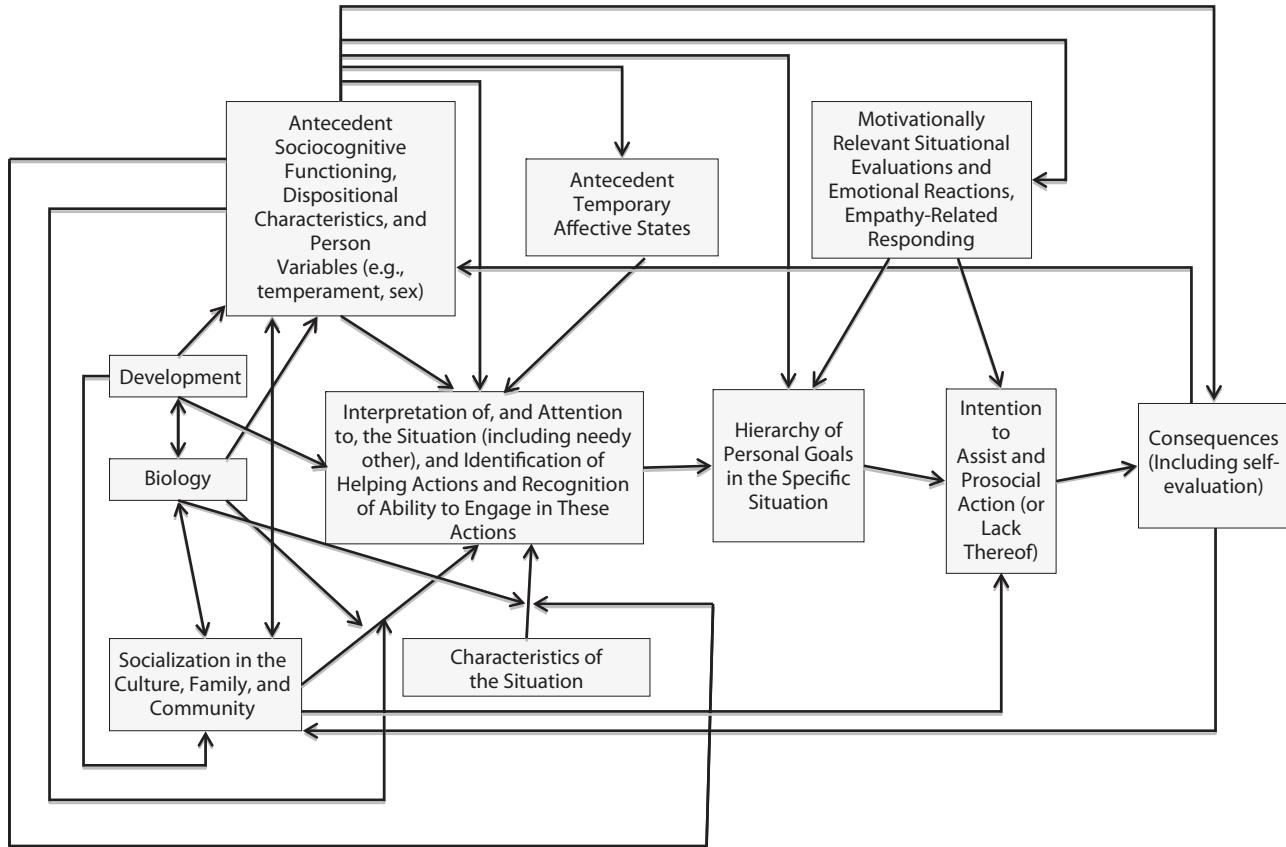

Figure 15.1 Heuristic model of prosocial behavior.

Source: Adapted from *Altruistic Emotion, Cognition, and Behavior*, by N. Eisenberg, 1986, Hillsdale, NJ: Erlbaum.

characteristics are likely to affect one another. Moreover, biological factors such as heredity, as well as antecedent sociocognitive and dispositional differences, likely interact with both *socialization within culture/family/community* and *characteristics of a given situation* in predicting behavior in a specific contexts. In addition, environmental and internal self-evaluative consequences of acting (or not acting) in a prosocial manner are expected to affect dispositional characteristics and socialization over time. Furthermore, development can affect antecedent sociocognitive/dispositional characteristics, biology, socialization, and interpretation of, and attention to, the situation.

Research focused on processes involved in the execution of prosocial behavior in context was popular and especially characteristic of the research in the 1970s and 1980s (see Eisenberg, 1986; Eisenberg & Fabes, 1998). However, such a focus has been more in the domain of social psychologists than developmentalists in the past two decades (with the exception of some work on situational factors that affect infants' abilities to perform prosocial actions). Thus,

in this chapter, we focus primarily on normative development as well as sociocognitive and dispositional factors that might affect individual differences in prosocial behavior and emotions (e.g., empathy/sympathy). We suggest that these factors jointly predict, at least to some degree, individual differences in prosocial behavior, albeit perhaps only certain types of prosocial behavior and prosocial emotion, depending on the relevance of the sociocognitive/dispositional variable for the specific aspect of prosocial functioning.

THE DEVELOPMENT OF PROSOCIAL TENDENCIES

As is evident in Figure 15.1, we believe development plays a multifaceted role in prosocial development. Prosocial behavior and empathy emerge early in life. Hoffman (2000) was one of the first theorists or researchers to discuss this process in depth. He argued that young infants have not acquired a sense of self-other differentiation and

cannot differentiate their own distress from that of another; thus, they tend to experience self-distress in response to another's distress, as evidenced in their reactive crying in response to the sound of another's cry (viewed as a simple form, or precursor, of global empathy). He further argued that, beginning around the end of the first year of life, infants begin developing a sense of self as separate from others; however, they cannot fully differentiate between their own distress and that of another so they often respond to empathic and self-related distress situations in the same way (labeled *egocentric empathic distress*). As a consequence, infants are thought to seek comfort for themselves when exposed to others' distress.

Hoffman (2000) further proposed that, in the second year of life, toddlers clearly differentiate between self and other, although they still do not distinguish well between their own and another's internal states. Nonetheless, toddlers can experience empathic concern for others (labeled *quasi-egocentric empathic distress*), rather than solely seek comfort for themselves. They sometimes try to comfort other people, but such prosocial behavior is likely to involve giving the others what the toddlers themselves find comforting. In Hoffman's theory, in the second and third years of life, as children become increasingly aware of other people's feelings and are capable of understanding that other people's perspectives and feelings can differ from their own, prosocial actions reflect an awareness of the other person's needs and they experience *veridical empathic distress*. Moreover, with the development of language, children are able to empathize and sympathize with a wider range of emotions than previously, but younger children's empathic responses are restricted to another's immediate, or situation-specific, distress.

Hoffman's (2000) theory has been helpful in identifying some of the early limitations in children's empathy and prosocial behavior and some of the skills that contribute to the development of prosocial responding. However, it is evident from other research that infants have more sophisticated empathic and sociocognitive capacities than suggested by Hoffman. This body of work can appear contradictory but is more consistent if one differentiates between the affective and top-down (higher-level) cognitive components of empathy-related responding and between empathy and prosocial behavior.

Infancy and Toddlerhood: Empirical Findings

The affective component of empathy appears to emerge quite early. Newborn infants exhibit what might represent

a rudimentary capacity for global empathy: They often exhibit more distress (reactive crying) in response to another infant's crying than to their own crying (Dondi, Simion, & Caltran, 1999). At around 6 months of age, infants sometimes respond to the spontaneous cry of another infant by crying, but they more typically orient toward the crying peer without showing self-distress (Hay, Nash, & Pederson, 1981). In a study of 8- and 10-month-olds, Roth-Hanania, Davidov, and Zahn-Waxler (2011) documented modest levels of affective and cognitive concern (i.e., hypothesis testing) for others, but the infants exhibited virtually no helping behavior in the first year of life. Infants' affective responses increased only gradually (nonsignificantly) into the second year; in contrast, their prosocial behaviors and cognitive attempts to understand others' states increased from 8 to 16 months of age. Accordingly, Davidov, Zahn-Waxler, Roth-Hanania, and Knafo (2013) argued that during the first year of life, infants' empathic repertoire includes not only self-distress, but affective concern for others that is based on simply comprehending that another person is upset or unwell rather than a more sophisticated understanding of the other's predicament. They further suggested that this early affective core of empathy does not change much with age (albeit others report change in the early years; see below), although cognitive empathy and prosocial behavior do.

Consistent with Hoffman's (2000) theory, researchers often have found that toddlers who demonstrate self-recognition—often on a mirror self-recognition task administered in the latter part of the second year of life—tend to be relatively empathic and prosocial in the early years (Bischof-Köhler, 2012; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). Nonetheless, other research suggests that rudimentary self-other differentiation develops prior to success on the typical mirror self-recognition task (see Davidov et al., 2013), which would allow for the emergence of empathy in the first year. For example, Rochat and Striano (2002) found that 4-month-olds smiled more and looked longer at the mirror image of someone imitating them than at a mirror image of themselves, indicating that they discriminated between self and other. Moreover, the level of self-other differentiation required for mirror self-recognition has not been found to relate to prosocial behavior in India, suggesting that cultural views on the self may affect the relation between self-conceptions and prosocial responding (Kartner, Keller, & Chaudhary, 2010).

Other work indicates that infants consider others' motives, intentions, and internal states, which supports the capacity for self-other differentiation and empathy.

For example, Hamlin and colleagues found that infants as young as 3 months of age preferred a helpful puppet over a nonhelpful one (e.g., Hamlin & Wynn, 2011; Hamlin, Wynn, Bloom, & Mahajan, 2011) and were more likely to direct positive behavior toward the helpful puppet in the second year of life (Hamlin et al., 2011) or toward someone who intentionally helped another (Dunfield & Kuhlmeier, 2010). Moreover, 18- and 25-month-olds are more likely to express concern for and to help someone who has been harmed than someone who has not, even if the harmed individual did not express any emotion, suggesting that children sometimes can sympathize with a victim in the absence of overt emotional cues of distress (Vaish, Carpenter, & Tomasello, 2009). Furthermore, toddlers' understanding of internal state words and self-understanding (as reported by mothers) have been associated with their prosocial behavior with nonfamilial adults (Brownell, Iesue, Nichols, & Svetlova, 2013; Brownell, Svetlova, & Nichols, 2009).

Given the early development of empathy-related responding, it should not be surprising that children can perform simple prosocial behaviors early in life, especially if emotional cues of distress or need are very clear and the behaviors are simple. Empathy and sympathy, as well as empathy- or need-based prosocial behavior, appear to increase over the second year of life (e.g., Knafo, Zahn-Waxler, Van Hulle, Robinson, & Rhee, 2008; Liew et al., 2011; Zahn-Waxler, Radke-Yarrow, et al., 1992), at least for some potential recipients (e.g., for empathy directed at parents; van der Mark, van IJzendoorn, & Bakermans-Kranenburg, 2002), and such prosocial behavior also increases from 2 to 4 years of age (Dunfield & Kuhlmeier, 2013). In addition, even 12-month-olds frequently share objects with parents in their interactions (which do not usually involve empathy) and release objects they are holding to peers (see Hay & Cook, 2007). Such sharing seems to emerge around 8 months of age and is increasingly evident during the next year (Hay & Rheingold, 1983).

Moreover, 14-month-olds can provide simple instrumental helping (handing objects to a nonfamilial adult who was unsuccessfully reaching for the objects), but do not help reliably in situations involving more complex goals (Warneken & Tomasello, 2007). By 18 months of age, infants often perform a variety of simple helping behaviors, even when an adult does not verbally ask for help (Warneken & Tomasello, 2008; also see Brownell, Svetlova, Anderson, Nichols, & Drummond, 2013; Svetlova, Nichols, & Brownell, 2010). A high percent of children provide simple instrumental help by 2 years of age—so

many that instrumental helping does not improve from 2 to 4 years of age (Dunfield & Kuhlmeier, 2013). Such instrumental helping does not require encouragement or external motivation (Warneken & Tomasello, 2008).

Helping behaviors that require an understanding of subtle cues take time to develop. Svetlova et al. (2010) found that helping requiring inferences regarding specific helping acts needed to meet an adult's needs (e.g., giving a woman a hairclip when the woman was upset by hair in her eyes or handing the woman a blanket when she exhibited signs of being cold) was unlikely among 18-month-olds without extensive prompts but was more frequent and required less communication by 30 months. Eighteen-month-olds tend to require more explicit cues regarding an adult playmates' need for toys or food than do 24- or 25-month-olds (Brownell et al., 2009; Brownell, Iesue, et al., 2013). Moreover, Svetlova et al. (2010) found that sharing of one's own possessions (e.g., a toy or the child's blanket) in the situations discussed above (requiring complex inference) was uncommon at both 18 and 30 months of age, and giving up material objects is infrequent even in 2- and 4-year-olds (Dunfield & Kuhlmeier, 2013). Thus, both the degree of cognitive processing required and cost to the self seem to affect toddlers' sharing behavior.

Some discrepancies across studies in regard to age of performing prosocial behaviors may be due to differences in the recipients. For example, toddlers are more likely to help and show concern for their mothers than strangers (Knafo, Zahn-Waxler, Van Hulle, Robinson, & Rhee, 2008; Spinrad & Stifter, 2006; van der Mark et al., 2002). Toddlers and preschoolers (Caplan & Hay, 1989; Howes & Farver, 1987) are relatively unlikely to respond with concern and prosocial behavior to the distress of peers, perhaps because young toddlers evidence very little understanding of peers' emotions or affective messages (Nichols, Svetlova, & Brownell, 2010). Thus, both the nature of the task and the recipient's identity may moderate relations of age to empathy-related responding and prosocial behavior.

Childhood and Adolescence: Empirical Findings

At least some types of prosocial behaviors increase in frequency across the preschool and childhood years. Eisenberg and Fabes (1998), in a meta-analysis, found significant increases in prosocial behavior within both the infant (less than 3 years) and the preschool years (3 to 6 years). There was no difference between the infancy and preschool periods, due perhaps to the small number of relevant studies. However, children (7 to 12 years) and adolescents (13 to

17 years) were higher in prosocial behavior than preschoolers, and adolescents were higher than children.

Despite general increases in prosocial responding in the early years, Hay and Cook (2007) argued that prosocial behaviors become more selective during the preschool years because they are increasingly governed by display rules, gender roles and norms, and friendships. Consistent with their general argument, Hepach, Vaish, and Tomasello (2012) showed that 3-year-old children tended to sympathize with a person when their distress was justified (e.g., a lid closes on the experimenter's fingers) but not when the distress was unjustified (e.g., a lid closes on the experimenter's sleeve). Similarly, young children showed more concern and prosocial behavior toward a person who was harmed than toward an unharmed victim, even when the victim did not express negative emotion (Vaish et al., 2009). Children also have been found with age to increasingly favor prosocial behavior directed at members of the in-group rather than the out-group (Weller & Lagattuta, 2013; see Eisenberg & Spinrad, 2014). Thus, it is likely that, in some circumstances, children become more discriminating with age about whom to help and show declines in rates of helping. At the same time, due to growth in sociocognitive understanding, older children may perceive more opportunities to act prosocially.

Although Eisenberg and Fabes (1998) found a general increase in prosocial behavior across childhood to early adolescence, this was not true for all types of prosocial behaviors. For example, adolescents tend to be higher in prosocial behavior than children aged 7 to 12 years on sharing/donating, but not instrumental helping or comforting. Age changes in prosocial behavior also may vary as a function of the cost of the behavior. In a study of allocation behavior by children in six cultures (House et al., 2013), including Los Angeles and five traditional hunting/gathering, horticultural, and/or marine foraging cultures, allocation choices that benefited another but did not cost the child anything increased in a similar linear manner from 3 to 14 years of age in all cultures. However, when there was a cost to the child of giving the other person more, prosocial choices declined from 3 years to approximately 7 to 9 years in all six cultures and then increased considerably to 14 years in most, but not all, cultures.

Moreover, findings appear to differ based on the informant (see Eisenberg et al., 2006). For example, teacher-reported prosocial behavior has been found to be relatively stable or to decline from 6 to 12 years of age, at least at schools in Canada (Côté, Tremblay, Nagin, Zoccolillo, & Vitaro, 2002; Kokko, Tremblay, Lacourse, Nagin, & Vitaro,

2006). Teachers also report a decline in prosocial behavior from 10 to 14 or 15 years of age for Canadian boys and for girls and boys in Italy. However, mothers' reports and self-ratings of prosocial behavior evidence primarily mean-level stability rather than declines (Nantel-Vivier et al. 2009). Veenstra et al. (2008) found that teachers and parents used different criteria for rating children's prosocial behavior. Academic performance and the quality of peer relationships were related to teachers' judgment of prosocial behavior whereas problems at home were related to mothers' ratings; these associations might be due to causal relations between these aspects of functioning and prosocial behavior or could reflect a halo effect.

In meta-analyses, there is little evidence of change in mean level of prosocial behavior in adolescence (Eisenberg & Fabes, 1998), although personality agreeableness, which includes prosocial tendencies, appears to increase from early to later adolescence (Klimstra, Hale, Raaijmakers, Branje, & Meeus, 2009). However, only a few investigators have examined change in adolescence with longitudinal data. Using growth-curve modeling, Carlo, Crockett, Randall, and Roesch (2007) found that the self-reported prosocial behavior of adolescents significantly declined on average beginning in 7th grade (12–13 years of age), although there was a small increase in 12th grade (17–18 years of age). Kanacri, Pastorelli, Eisenberg, Zuffianò, and Caprara (2013) obtained a quadratic growth curve for Italian adolescents' self-reported prosocial responding, with a decline from 13 years of age to approximately 17 years and a slight rebound until 21 years of age. Eisenberg, Cumberland, Guthrie, Murphy, and Shepard (2005) found that self-reported helping increased from 15–16 to 17–18, decreased from 17–18 to 21–22, was stable from 21–22 to 23–24, and increased from 23–24 to 25–26 years. Using cross-sectional data, Soto, John, Gosling, and Potter (2011) reported a decline in the altruism facet of personality agreeableness from 10–12 to 13–17 years of age but an increase from 13–17 to 18–25 years of age (for both sexes). In contrast to the aforementioned nonlinear patterns, Jacobs, Vernon, and Eccles (2004) found an increase in volunteering behavior in adolescence. In regard to sympathy, Taylor, Barker, Heavey, and McHale (2012) reported no change in self-reported sympathy from 17 to 19 years of age, Eisenberg et al. (2005) found no change from 15–16 to 25–26 years, and Davis and Franzoi (1991) found an increase from 10th grade to 12th grade (approximately 16 to 18).

Thus, the findings are inconsistent with regard to age-related changes in adolescents' prosocial responding.

However, it appears that, with the exception of volunteering, prosocial behavior (but not sympathy) declines in adolescence but starts to rebound somewhat in late adolescence or early adulthood. Developmental level and associated experiences or hormones may be more closely associated with sympathy in early adolescence than is age. Masten, Eiesenberger, Pfeifer, Colich, and Dapretto (2013) found that pubertal development from 10 to 13 years of age was related to increases in empathic concern and personal distress. In addition, they reported that increases in self-reported sympathy and personal distress from 10 to 13 years of age were related to greater activity in neural regions linked to both mentalizing and affective pain activity. (Masten et al.'s [2013] findings did not change when controlling for sex.)

Sociocognitive Processes and Age-Related Change in Prosocial Responding

For some theorists, the primary source of the increase in prosocial and altruistic behavior across age is sociocognitive development. Indeed, it is commonly assumed that perspective-taking skills increase the likelihood that individuals will identify, understand, and sympathize with others' distress or need (e.g., Eisenberg, 1986; Hoffman, 2000; see Figure 15.1). Information about others' internal states can be obtained by imagining oneself in another's position or through processes such as accessing stored knowledge, mental associations, and social scripts or deduction. Children also may have "theories" about others' internal states that they use to infer how others feel that are relevant to morality (e.g., theory of mind; Lane, Wellman, Olson, LaBounty, & Kerr, 2010).

Throughout infancy and childhood, children develop an increasingly refined understanding of others' emotional states and cognitive processes and are better able to decode other people's emotional cues, and such perspective taking and related sociocognitive skills are associated with prosocial responding. Moreover, with age, children are more likely to have the social experience necessary to perceive another's need in social contexts where overt cues of distress are ambiguous or subtle. Research, reviewed above, supports the role of advances in young children's socioemotional skills in their prosocial development (e.g., Brownell et al., 2009; Brownell, Iesue, et al., 2013), and research concerning associations between perspective-taking/emotional understanding and prosocial responding is discussed shortly.

Moreover, numerous researchers have suggested that the quality of children's motivation for assisting others changes with age. Bar-Tal (1982) proposed that children's helping behavior develops through six stages that differ in quality of motivation. The first three stages involve helping behaviors that are compliant and in which the child anticipates the gain of material rewards (or the avoidance of punishment). The next two stages involve compliance with social demands and concern with social approval and generalized reciprocity. The final stage represents true altruism in which helping is an end in itself. Although it is unclear whether all their proposed stages actually emerge in the specified order (see Eisenberg, 1986), researchers generally have found a decrease with age in self-oriented, hedonistic reasons for helping and an increase in other-oriented, internalized, and altruistic motives and reasons for prosocial behavior (see Bar-Tal, 1982; Eisenberg, 1986).

Age-related changes in children's evaluative processes and prosocial-relevant goals and motives are also reflected in changes in children's prosocial moral reasoning (i.e., reasoning about moral dilemmas in which one person's needs or wants conflict with those of others in a context where authorities, laws, rules, punishment, and formal obligations play a minimal role). In research on prosocial moral reasoning, individuals typically are presented with hypothetical moral conflicts (e.g., about helping an injured child rather than going to a party) and their reasoning about resolving the conflicts is elicited.

Based on cross-sectional and longitudinal research, Eisenberg and colleagues (e.g., Eisenberg, Carlo, Murphy, & Van Court, 1995; Eisenberg et al., 2005; Eisenberg, Miller, Shell, McNalley & Shea, 1991; Eisenberg et al., 1987; see Eisenberg, 1986) identified an age-related sequence in children's prosocial reasoning. Preschool and early elementary school children tend to use primarily hedonistic reasoning or needs-oriented (primitive empathic) prosocial reasoning. Hedonistic reasoning decreases sharply in elementary school and increases slightly in adolescence, especially for males, declining again in early adulthood for men. Needs-oriented reasoning increases until mid-childhood, declines somewhat in adolescence, and is stable in early adulthood. In elementary school, children's reasoning begins to reflect concern with others' approval and enhancing interpersonal relationships, as well as the desire to behave in stereotypically "good" ways. However, approval-oriented reasoning during interviews appears to fluctuate somewhat in adolescence and then stabilizes, although adolescents and young adults tend

to clearly reject approval-oriented reasoning on pencil-and-paper measures of prosocial moral reasoning. When using interview measures, stereotypic reasoning peaks and then declines somewhat (at least proportionally) in adolescence, but shows a modest increase in proportional use in the 20s (Eisenberg et al., 1995; Eisenberg, Hofer, Sulik, & Liew, 2013).

Beginning in late elementary school (approximately 12 years of age or older) or thereafter, children begin to express reasoning reflecting abstract principles, internalized affective reactions (e.g., guilt or positive affect about the consequences of one's behavior for others or living up to internalized principles/values), and self-reflective sympathy and perspective taking (e.g., explicitly acknowledging concern or perspective taking), although such reasoning generally is not the dominant mode (Eisenberg et al., 1995, 2005). Some of these more sophisticated modes of moral reasoning tend to increase across adolescence and appear to stabilize across the 20s (Eisenberg et al., 1995, 2005, 2013). Specific trends differ somewhat across studies, depending on the index of prosocial moral reasoning (frequency of reasoning in a category versus proportional use of a given category) and measure of reasoning (interview versus pencil-and-paper measure).

As discussed later, individual differences in prosocial moral reasoning—an aspect of socio-cognitive functioning (in Figure 15.1)—are associated with prosocial and empathy-related responding. Thus, the processes reflected in children's moral reasoning likely play some role in the age-related changes in the quantity and quality of prosocial behavior (Eisenberg, 1986).

Summary

Although prosocial behavior seems to increase with age from infancy until adolescence (with no consistent pattern in adolescence), the results vary considerably across studies, samples, measures, and other study features. Nonetheless, even though Eisenberg and Fabes (1998) found that type of prosocial behavior (instrumental help, sharing/donating, comforting, aggregated across multiple types) was related to effect sizes for age prior to controlling for a variety of study characteristics, effect sizes for age were not affected by type of prosocial measure after doing so. However, Eisenberg and Fabes (1998) did not differentiate, for example, between teachers' and mothers' reports of prosocial behavior. Nor did they differentiate between variables such as costliness of the prosocial behavior for the

child, which may be at least as important a consideration as the type of behavior (see Eisenberg & Fabes, 1998). Thus, a task for future work is to delineate the developmental trajectories of various modes of prosocial behavior that vary in cost, recipient, cognitive complexity, and other important characteristics, as well as the source of the data (teacher report, observations, etc.). Moreover, there is a need to identify the reasons for the apparent decline in prosocial behavior in adolescence in certain settings (e.g., school as reported by teachers) and for certain kinds of prosocial behavior.

The developmental factors involved in age-related changes require more attention, including sociocognitive development. As noted by Hoffman (2000), the development of perspective taking must play a role in prosocial development. Moreover, although children and adolescents sometimes verbalize immature modes of reasoning, children's moral reasoning becomes more abstract, somewhat less self-oriented, and increasingly based on values, moral principles, and moral emotions with age, at least into the 20s. The next wave of research might include studies devoted to identifying when and how age-related changes in sociocognitive capabilities, in combination with the skills needed to act on one's social understanding (e.g., a sense of efficacy, regulation; see below), jointly affect or predict prosocial responding, especially after the first few years of life (considerable work on this topic has been conducted with infants). Moreover, although a number of the studies cited have been conducted outside of North America, more research is needed in non-Western cultures to determine whether results obtained in Western societies are generalizable to non-Western groups.

ORIGINS OF PROSOCIAL RESPONDING

Dispositional prosocial tendencies appear to be affected by heredity and related biological processes, cultural values and practices, parenting, peers, and experiences at school (see Figure 15.1). Findings related to their potential influences are discussed in turn.

Genetic and Biological Influences on Prosocial Tendencies

Evolutionary Perspectives

Prosocial actions have frequently been noted among nonhuman animals (e.g., E. O. Wilson, 2004). Social insects often

sacrifice their own lives to protect their nest. Similarly, costly helping and rudimentary forms of empathy have been observed in rodents (Bartal, Decety, & Mason, 2011; Langford et al., 2006), and consoling and helping appear in chimpanzees and bonobos (e.g., Warneken & Tomasello, 2009). Such behaviors, as well as very early signs of prosocial tendencies in human infants (Hamlin & Wynn, 2011), are unlikely to rely on direct socialization or moral considerations and require a biological explanation. Such explanations may then be extended to human behavior, although humans differ from other animals in the nature and extent of prosocial behavior (reviewed by Silk & House, 2012).

To explain how prosociality evolved despite the evolutionary price accrued by sharing or helping, several approaches have been proposed, most notably direct reciprocity, indirect reciprocity, network reciprocity, kin selection, and group selection (Nowak, 2006). Reciprocity explains the evolution of altruism to the extent that the behavior is reciprocated, either directly or through reputation. Toddlers' prosocial behavior involves both direct and indirect reciprocity (Vaish & Tomasello, 2014).

In kin selection, through self-sacrificing or cooperative actions, the prosocial animal increases the probability that its relatives, who share its genes, will survive and reproduce (E. O. Wilson, 2004), and evolution promotes altruism through promotion of genes, not survival of individuals. Humans share more resources with those genetically close to them, and are more willing to risk their lives for relatives (e.g., Graziano, Habashi, Sheese, & Tobin, 2007), although it is hard to distinguish between closeness based on genetic relatedness, geographic proximity, or emotional closeness, which often co-occur.

Group selection approaches posit that altruism among group members may benefit the survival of the group (D. S. Wilson, 1975). This idea has been hotly debated (e.g., Pinker, 2012), although there is evidence that highly cooperative groups survive better than do other groups (Bowles, 2006). The idea of multilevel selection implies that although evolution at the individual level (within groups) favors nonaltruists, selection at the group level favors altruism (Nowak, 2006).

The competing group-level and individual-level selection forces may be one reason for diversity in behavior within groups. Similarly, because empathy and prosocial behavior provide benefits to the person performing them, but also increase the likelihood they will be taken advantage of (Nettle, 2007), variation in genes related to individual differences in prosociality should emerge.

Importantly, although evolutionary principles explain ultimate, long-range causation, they do not directly explain the behavior of each individual. Human empathy may have evolved as a mechanism promoting infant–mother bonds (de Waal, 2008), but it can now be extended to other conspecifics and even to pets. At the group level, altruism may be seen as a tool for outperforming other groups (Choi & Bowles, 2007), but such consideration of group needs can be extended to overall, within-group cooperation (Vaish & Tomasello, 2014).

Genetic Effects on Individual Differences

Research estimating the genetic contribution to individual differences in prosocial responding (heritability) typically relies on the twin design. In this design, if the covariance between scores on prosocial responding is higher for identical (monozygotic) twins than for fraternal (dizygotic) twins, the difference is attributed to genetic effects to the degree that common environmental sources are assumed to be shared to roughly equal degrees by the two types of twins.

Most twin studies involving adults' self-reported prosocial tendencies have found that genetic factors accounted for a substantial portion of the variance in altruism, empathy, and nurturance (typically, 40%–60%). Most of the remaining variance was accounted for by idiosyncratic differences in the environments of the twins (nonshared environment) rather than by their shared environment (see Knafo & Israel, 2009, for review). Despite this consistency, the estimated contribution of genetics and the environment varies from study to study, reflecting the diversity in measures and conceptualizations of prosociality (see Fortuna & Knafo, 2014, for review). Studies using experimental measures of prosocial behavior are few and tend to show lower heritabilities. For example, in a Swedish twin study, moderate but significant heritability (22%) was found for donations to a charity, with a small (9%) shared environment effect on giving (Cesarini, Dawes, Johannesson, Lichtenstein, & Wallace, 2009).

Most genetically informative studies of prosocial behavior and empathy in children have used parents' reports of children's behavior; sometimes teachers' and self-reports have been used as well. These studies tend to converge on substantial heritability estimates and meaningful nonshared environment contributions, whereas shared environment estimates vary by age, measure, and culture (see Knafo & Israel, 2009). For example, American adolescents' self-reported empathy showed moderately significant heritability (.28) and no shared environment effects (Davis, Luce, & Kraus, 1994). Using parents' reports of prosocial behavior,

a South Korean study of 2- to 9-year-old twins reported 55% heritability and no shared environment effects (Hur & Rushton, 2007). A cross-cultural (United Kingdom, South-Korea, and Israel) comparison of parent-reported prosocial behavior found similar heritability estimates, accompanied by differences in the importance of shared environment effects (Knafo & Israel, 2009). Among German preadolescents, values focusing on the welfare of others as opposed to the self showed substantial (49%) heritability and no shared environment effects (Knafo & Spinath, 2011).

Only a handful of studies have tested genetic and environmental effects on empathy and prosocial behavior using observational measures. One small study (91 pairs of 7-year-old Dutch twins) found a strong (45%) shared environment effect, but no heritability for willingness to donate to a charity (Van IJzendoorn, Bakermans-Kranenburg, Pannebakker, & Out, 2010). In a study of 3.5-year-old Israeli twins, Knafo, Israel, and Ebstein (2011) estimated heritability at 34% for a combined set of three experimentally observed compliant prosocial behaviors, and at 43% for a set of three self-initiated prosocial behaviors; they found no shared environment effects.

The other observational studies of empathy and prosocial behavior all relied on twins' reactions to others' simulated distress. Among American twins (aged 19–25 months) watching their mother feign distress, monozygotic correlations were higher for hypothesis testing (the cognitive aspect of empathy) and empathic concern, but not for helping behavior, and evidence for shared environment effects was also found (Volbrecht, Lemery-Chalfant, Aksan, Zahn-Waxler, & Goldsmith, 2007). A study of 3.5-year-old Israeli twins showed a small, nonsignificant genetic effect for empathic concern towards an examiner (19%) and a significant effect for hypothesis testing (44%). No evidence for shared environment effects was found and the nonshared environment and error accounted for the rest of the variance (Knafo, Zahn-Waxler, et al., 2009).

The largest genetic study of children's empathy involved 400 pairs of Colorado twins tested at 14, 20, 24, and 36 months of age, reacting to their mothers' and an experimenter's simulated distress. Empathy toward an examiner showed modest heritability at 14 and 20 months, but a common empathy factor (combining mother and examiner observations) showed no heritability at 14 and 20 months. At 24 months, a genetic effect on the common factor (34%) emerged, which increased to 47% at 36 months. In contrast, shared environment effects on the common factor were very large at 14 months (69%) and decreased steadily to 0% at 36 months (Knafo et al., 2008).

This pattern of heritability increasing with age accompanied by decreasing shared environment effects was found in a meta-analysis of twin studies of empathy (Knafo & Uzefovsky, 2013). In a large British twin study (Knafo & Plomin, 2006a), heritability of mother-reported prosocial behavior increased from 26% for girls and 37% for boys at 2 years of age, to 60% and 62%, respectively, at 7 years of age (teacher reports at 7 years also showed high heritability estimates, 51% for girls and 72% for boys). In contrast, shared environment effects decreased from 43%–50% to 0%–6% during this period. Another British study of teacher-rated prosocial behavior found a similar pattern when comparing (cross-sectionally) 5- to 10-year-old and 11- to 16-year-old twins (Scourfield, John, Martin, & McGuffin, 2004), although a longitudinal British twin study using self-reports did not report a further increase from 13–17 to 14–19 years (Gregory, Light-Hausermann, Rijsdijk, & Eley, 2009). One reason for this increase in heritability is that novel genetic effects emerge with age (Knafo et al., 2008), perhaps reflecting maturation or adjustment to the changing social environment. However, genetic effects also contribute to stability (Knafo & Plomin, 2006a).

A process of evocative gene–environment correlation, in which children's genetically influenced behavior affects the input they receive from the environment (Scarr & McCartney, 1983), can account in part for this increase in heritability. For example, maternal negativity (puniteness, negative emotions) correlated negatively with prosocial behavior, an effect accounted for in part by an overlap with the genetic effects on prosocial behavior (Knafo & Plomin, 2006b). When children's genetically influenced behavior (e.g., low prosociality) affects their environment (e.g., parental negativity), the environment can feed back to the child, further affecting their behavior, and thus the environmental input can increase the observed heritability (Beam & Turkheimer, 2013).

One way to control for the presence of evocative gene–environment correlations in understanding parents' influence on children is by comparing monozygotic twins. In a study involving only monozygotic preschool-age twins, Deater-Deckard et al. (2001) obtained evidence of the role of nonshared environment (e.g., twin differences in maternal supportive and punitive behaviors) in predicting children's prosocial behavior. Thus, although genetics appear to contribute to children's prosocial tendencies, genetically informed studies also provide evidence for the role of the environment in the origins of prosocial behavior.

Although the role of genetics in prosocial behavior has been established, direct evidence for specific genes has

started to accumulate in the past decade, mainly for genes involved in dopamine, serotonin, oxytocin, and vasopressin activity (see Fortuna & Knafo, 2014). Several studies have focused on a variation in the third exon (coding region) of the dopamine receptor D4 gene (DRD4-III). DRD4-III predicted young adults' self-reported altruism (Anacker, Enge, Reif, Lesch, & Strobel, 2012; Bachner-Melman, Gritsenko, Nemanov, Zohar, & Ebstein, 2005), and twin children's observed sharing with their siblings, although not with their peers (DiLalla, Elam, & Smolen, 2009). Two other experimental studies also did not find that DRD4-III related to children's prosocial behavior outside the family (Bakermans-Kranenburg & Van IJzendoorn, 2011; Knafo, Israel, et al., 2011). Thus, this polymorphism may relate to prosocial behavior in age-specific ways, and may also interact with situational and environmental factors, as noted below (see Figure 15.1).

Research on the genetics of empathy and prosocial behavior has largely focused on genes related to vasopressin and oxytocin, two neuropeptides involved in social behavior (Ebstein, Knafo, Mankuta, Chew, & Lai, 2012). Knafo, Israel, et al. (2008) found that the length of the promoter region of the arginine vasopressin 1A receptor (AVPR1A) gene related to university students' money donations in the dictator game (in which participants decide how to split a fixed amount of money between themselves and a stranger) and self-reported altruism. In a similar task, 3.5-year-old Israeli twins donated fewer stickers if they were carriers of the 327-bp allele of this gene (Avinun et al., 2011). Poulin, Holman, and Buffone (2012) did not find a main effect of AVPR1A but did find that this gene (and the oxytocin receptor gene) interacted with perceived threat to predict adults' prosocial behavior.

In two studies, variation in the oxytocin receptor gene (OXTR) related to empathy, either self-reported or indexed by a test involving the identification of emotional expressions (Chakrabarti et al., 2009; Rodrigues, Saslow, Garcia, John, & Keltner, 2009). The same OXTR single-nucleotide polymorphism (SNP, a variation of one base pair in the DNA) reported by Rodrigues et al. (2009) for empathy predicted adults' prosociality as rated by observers (Kogan et al., 2011). Other OXTR SNPs predicted dictator game donation and self-reported prosocial preferences in two Israeli adult samples (Israel et al., 2009), but not in a Swedish twin sample (Apicella et al., 2010).

Several additional studies have linked genes to prosocial behavior (e.g., the COMT gene [Reuter, Frenzel, Walter, Markett, & Montag, 2010]; the serotonin transporter gene [Stoltenberg, Christ, & Carlo, 2013]) and other

genes might also be important. The results often do not replicate, perhaps reflecting the use of different populations and methods across studies. Additionally, different variants of a specific gene may have diverse impacts in different populations or ages (as in the AVPR1A studies described above). Moreover, genetic contributions to the normal-range variance often reflect the accumulative, additive, and interactive contributions of many polymorphisms, each with small effects (Benjamin et al., 2012).

One important limitation to genes' effects concerns the need to consider gene–environment interactions (G × E). Most of the relevant G × E research has pertained to variation in the DRD4-III polymorphism as a moderator of the association between environmental variables and prosociality. In DRD4-III, individuals differ in the number of repeats of the same sequence. Four repeats are the most common, and two and seven repeats often show increased susceptibility to environmental influences (Jiang, Chew, & Ebstein, 2013). Among DRD4-III 7-repeat carriers, but not among other individuals, a negative correlation was found between maternal negativity and preschoolers' observed empathy towards an examiner (Knafo & Uzefovsky, 2013), and prosocial behavior related positively to secure attachment and positive parenting (Bakermans-Kranenburg & van IJzendoorn, 2011; Knafo, Israel, et al., 2011; but see DiLalla et al., 2009).

To summarize, there is substantial evidence for heritability of empathy and prosocial behavior, which varies by measurement and probably increases with age. All twin studies demonstrate the importance of the environment, especially the environment not shared by children growing up together. There is evidence for the involvement of specific genes, although these results do not always replicate. Genes, and environmental variables such as parenting, do not operate in isolation. More research on gene–environment correlations and interactions is needed to understand their combined contributions.

Neurophysiological Underpinnings of Prosocial Responding

Panksepp (1986) asserted that all mammalian helping behavior arises from the “nurturant dictates of brain systems that mediate social bonding and maternal care” (p. 44). This view is consistent with that of MacLean (1985), who argued that the basis for altruism lies in maternal behavior, affiliation, and play, which are mediated in part by the limbic system of the brain. MacLean further suggested that the prefrontal neocortex, which developed

relatively recently in evolution and is most distinctive in humans, provides the basis for concern for others and a sense of responsibility and conscience.

There has been an explosion of neuroscientific studies on empathy, and to a lesser extent prosocial behavior and prosocial motivations. Most of these studies were performed on adults (for reviews, see Bernhardt & Singer, 2012; Zaki & Ochsner, 2012; for a developmental perspective, see Hastings, Miller, Kahle, & Zahn-Waxler, 2014; for a meta-analysis, see Fan, Duncan, de Grecq, & Northoff, 2011).

Most brain studies of empathy focused on reaction to others' distress, particularly pain. There is no single "empathy" brain region; rather, empathizing with others' pain involves a network of several regions also involved in the experience of pain to the self: anterior midcingulate cortex (aMCC), anterior insula (aINS), supplementary motor area (SMA), and periaqueductal gray (PAG) (Decety & Knafo, *in press*). These regions are activated when children (7–12 years) watch others in pain (Decety, Michalska, & Akitsuki, 2008). This overlap in networks for self-pain and other-pain suggests that empathy involves experiences shared by the person in distress and the perceiver (e.g., Bernhardt & Singer, 2012), providing a strong signal that can promote empathic concern. It has been proposed that vicariously experiencing emotions other than pain, such as disgust and anxiety, also activates the aINS and the cingulate cortex, with aINS involved in perception of positive emotions in others (Bernhardt & Singer, 2012).

The overlap in neural systems involved in experiencing and empathizing has been proposed to reflect mirroring processes at the single-cell level, which involve mirror neurons (Iacoboni, 2009). The role of the mirror-neuron system has been debated, and although its involvement in simulation of others' emotions is referred to as the basis for empathy (Oberman & Ramachandran, 2007), it has been pointed out that mirror neurons have been found only for actions, not emotions (Decety, 2010a), and that there is little overlap in brain regions involved in experience as compared to perception of emotion (see meta-analysis by Wager et al., 2008). There is a debate whether self–other overlap in brain activation reflects only the intersection of adjacent and partially distinct processes or also the actual activation of identical neural populations (Bernhardt & Singer, 2012; Morrison & Downing, 2007).

Much research on the neuroscience of empathy has differentiated between emotion-sharing processes involved in the more affective aspects of empathy, and other processes involved in mentalizing, or the cognitive aspects

of empathy (Fan et al., 2011). Lesion studies show a link between dorsolateral frontal system lesions and deficits in cognitive aspects of empathy, whereas lesions in the orbitofrontal system relate to deficits in the more emotional aspects (Eslinger, Eastin, Grattan, & Van Hoesen, 1996). In experimental designs designed to distinguish between affect sharing and mentalizing, the latter involves a different brain network (e.g., temporoparietal junction, temporal pole, posterior cingulate cortex, precuneus, and the medial prefrontal cortex), although there are reasons to expect overlap of the two processes in more naturalistic settings because the cognitive and affective aspects of empathy are correlated (Zaki & Ochsner, 2012).

Despite the early appearance of certain aspects of empathy, the brain processes involved in emotional sharing, empathic concern, and prosociality continue to develop throughout childhood, adolescence, and possibly beyond (Decety, 2010b). For example, one study showed that early adolescents (10–12 years old), mid-adolescents (14–16), and young adults (19–23) all show increased activation in the posterior superior temporal sulcus when trying to infer emotions from photographed eyes. However, only early adolescents also showed involvement of the medial prefrontal cortex, the inferior frontal gyrus, and the temporal pole (Moor et al., 2012). Another study exposed 7- to 40-year-olds to situations involving either a person whose pain was accidentally caused (referred to as empathy-eliciting, leading to feeling as the other) or a person whose pain was intentionally inflicted by another (sympathy-eliciting, increasing concern for the other). In empathy situations, age was negatively correlated with neural responding in the amygdala, SMA, and posterior insula activation, and positively correlated with activation in the left inferior and right superior frontal gyri. In contrast, in sympathy-eliciting situations, younger age was associated with greater medial orbitofrontal and fusiform gyrus activity. Within the same region, activity changed with age, such that with age, activity in the medial orbitofrontal cortex decreased, whereas orbitofrontal cortex activity increased (Decety & Michalska, 2010).

Another developmental study examined age changes in response to intentional versus accidental harm in participants aged 4 to 37 years (Decety, Michalska, & Kinzler, 2012). In all participants, perceiving intentional harm to people (as opposed to accidental harm) was associated with increased activation in brain regions such as the right posterior superior temporal sulcus (pSTS), which are sensitive to the perception, prediction, and interpretation of others' intentions. Furthermore, increased activation was found in

regions known to process the affective consequences of these actions, namely, the insula, ventromedial prefrontal cortex (vmPFC), and amygdala. Participants' personal distress in response to harmful actions was correlated with increased activity in the amygdala. Age was negatively correlated with empathic sadness for the victim of harm, with the youngest participants exhibiting the greatest personal sadness. Ratings of sadness for the victim correlated with increased activity in the insula and subgenual prefrontal cortex, the latter part of which has extensive connections with circuits implicated in emotional behavior and response to stressors (Decety et al., 2012).

This differential activity of brain regions therefore depends on the situational context in which others' suffering happens. Brain empathic responses vary in amplitude also by the intensity of the displayed emotion, and by characteristics of the suffering person (e.g., perceived fairness, relationship with victim; Hein & Singer, 2008). In addition, prosocial motivation and behaviors involve separate processes, and although they have been studied to a lesser extent than empathy, it is safe to say that the former involves a different neural system whose activity overlaps with cognitive and affective aspects of empathy (Zaki & Ochsner, 2012). For example, the subjective value of adults' voluntary donations to charity correlated with activation of the vmPFC (Hare, Camerer, Knoepfle, O'Doherty, & Rangel, 2010). This activity overlapped with that of regions encoding for reward value, suggesting the involvement of the brain's reward system in donations (see also Harbaugh, Mayr, & Burghart, 2007). Similarly, vmPFC activity correlated with other networks, such as the aINS and posterior superior temporal cortex, that are thought to be involved in social cognition (Hare et al., 2010), thus showing further connection between different aspects of empathy and prosociality at the neural level.

In addition to the central nervous system, the autonomic nervous system (ANS) is important for empathic response. Sympathetic and parasympathetic responses (e.g., blood pressure, heart rate, skin conductance, pupil dilation, respiration) are important not only because they are indicators of a person's affective state (e.g., accelerated heart rate indicates change in arousal), but also because they could serve as clues for self-perceiving one's emotion states, in a bottom-up feedback process (e.g., a person learns about their affective state from their autonomic reactions).

Most studies show that heart-rate deceleration accompanies empathic reactions (e.g., Zahn-Waxler, Cole, Welsh & Fox, 1995; see Eisenberg et al., 2006). It is important to note that some studies do not support this association, and

that results vary by situation (Eisenberg et al., 1990). This could be due to different processes, including self-distress, arousal, and caring for others, each potentially associated with a different physiological response, all operating simultaneously (Hastings et al., 2014) and measuring heart rate across different time periods (e.g., right at an especially evocative moment versus across a longer time period).

It is also important to distinguish between global processes affecting all normally developing children and those implicated in individual differences. For example, in one study, researchers exposed 7-year-old children to two episodes designed to elicit feelings of empathy/sympathy (a child losing his dog and a mother upset over the child's grandfather's illness). Based on maternal interviews and structured observations of children's reactions to others' pain, children were classified as (a) showing concern, (b) showing passive disregard (little or no concern), and (c) active disregard (anger/hostility and antisocial behavior). All groups showed deceleration of heart rate when exposed to others' distress, but there were no between-group differences, indicating a global change in ANS activation involved in empathizing, rather than individual differences. Such individual differences were evident as the active disregard group showed lower heart rate than the other two groups (Van Hulle et al., 2013). However, all three groups showed deceleration of heart rate when exposed to others' distress, indicating a global change in ANS activation involved in empathizing.

Considerable research on children's ANS in relation to empathy has involved skin conductance and respiratory sinus arrhythmia (RSA, indexing heart rate variability). This research tends to show mixed results, depending on children's age and sex, as well as aspects of the situation (e.g., home versus lab; Hastings et al., 2014). Both skin conductance and RSA tend to show different patterns of association with the more emotional aspects of prosociality, that is, empathic concern, and more behavioral aspects such as prosocial behavior (reviewed by Hastings et al., 2014). This, again, attests to the need to view prosociality with all its complexity, with different, sometimes competing, biological substrates operating on various components of prosociality.

The activity of the brain regions and the ANS system involved in empathy and prosociality is affected by the neurotransmitters and hormones carrying messages between adjacent neurons and between parts of the neurophysiological system. Of particular interest are dopamine, oxytocin, and vassopressin. For example, brain regions in the reward system (e.g., ventral striatum, periaqueductal gray)

are characterized by enhanced presence of dopamine, oxytocin, and vasopressin receptors (Hastings et al., 2014). One hormone showing meaningful relations with prosociality is testosterone. Both correlational and experimental studies suggest that this masculine sex hormone is associated with reduced prosociality (e.g., Hermans, Putman, & van Honk, 2006).

The role of two neuropeptides, oxytocin and vasopressin, is increasingly acknowledged. These two closely related molecules have been shown in animal studies to control social behaviors (Donaldson & Young, 2008). In human mothers, naturally occurring oxytocin levels related to infant–mother bonding (Feldman, Weller, Zagoory-Sharon, & Levine, 2007) and increasing oxytocin levels (e.g., following watching emotional video clips) were positively associated with empathy, especially for women (Barraza & Zak, 2009). Intranasal administration of oxytocin is reported to increase generosity, cooperation, and affective empathy (Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005; Zak, Stanton, & Ahmadi, 2007). However, oxytocin does not increase positive interpersonal behavior indiscriminately. For example, it has been shown to increase in-group favoritism and, perhaps also out-group derogation (De Dreu, Greer, Van Kleef, Shalvi, & Handgraaf, 2011). The effect of oxytocin depends both on contextual factors such as prior contact with the other person, and on individual differences in prosocial motivation (Declerck, Boone, & Kiyonari, 2014). There is great need for oxytocin research on children, in order to understand the developmental role it plays in empathy and prosociality. One study of 6-year-olds found that salivary oxytocin levels correlated positively with children's social engagement (e.g., social gaze, positive affect, and creative-symbolic play; Apter-Levy, Feldman, Vakart, Ebstein, & Feldman, 2013). In this study, affective resonance to others' distress, an aspect of empathy, related positively to children's oxytocin levels (Ruth Feldman, personal communication, August 28, 2013).

Vasopressin has received less attention, but it may also play a role in prosocial development. Evidence from animal studies (Donaldson & Young, 2008) shows the important role of vasopressin in social behavior. Research on humans, thus far, has concentrated on adults. Men and women may be differently affected by vasopressin administration (reviewed by Hastings et al., 2014), although there is too little research to draw conclusions.

In summary, a surge in research on the neurophysiological components of prosocial responding has yielded a vast amount of data, and the challenge now is to better

conceptualize how different aspects of prosociality (e.g., empathy and prosocial behavior) are associated with these neurophysiological factors. There is still a need to integrate research on central and autonomous nervous system on empathy and prosociality. In addition, there is a need to distinguish between factors involved in the prosociality and empathy of humans, as a species, and those involved in individual differences. The role of vasopressin and oxytocin in empathy and prosocial behavior suggests a good place to start in studying the influence of genes on prosociality.

Summary

Both the overall human tendency for prosocial behavior and empathy and individual differences reflect biological characteristics. Some of these characteristics may be common to humans and other species. Biological influences are meaningful at the genetic, brain, and physiological levels, although research combining these different levels is scarce. In addition, neuroscientific research on empathy and prosociality has largely focused on adults, but the existing evidence from this research and from the genetic research suggests that processes may be age-dependent, and a stronger developmental approach is needed. The effects of these biological factors likely vary across situations and interact with other social factors. More studies from non-Western cultures are needed to establish the role of culture as a potential moderator of the biological substrates of prosociality and empathy.

Cultural Determinants of Prosocial Behavior

Research on the cultural bases of prosocial responding provides insight into the role of the social environment in prosocial development. People in different cultures may differ somewhat genetically from one another, but these differences are unlikely to fully account for any large cultural differences found in human social behavior.

Prosocial Behavior and Empathy-Related Responding

Research in non-Western cultures suggests that societies vary greatly in the degree to which prosocial and cooperative behavior are normative. In ethological studies of individual cultures, writers have described societies in which prosocial and communal values and behaviors are (or were in the past) especially valued and usually common, such as the Aitutaki (a Polynesian island people; Graves & Graves, 1983) and the Javanese (e.g., Williams, 1991; see de Guzman, Do, & Kok, 2014; Eisenberg & Fabes, 1998, for reviews).

In one of the few cross-cultural studies involving observational data, Whiting and Whiting (1975) found that prosocial behavior—operationalized as offering helping (including food, toys, and helpful information), offering support, and making helpful suggestions—was more frequently observed among children in Kenya, Mexico, and the Philippines than in Okinawa, India, and the United States. In prosocial cultures, people tended to live together in extended families, women made major contributions to the economic status of the family, work was less specialized, the government was less centralized, and children tended to be assigned chores and responsibilities for the welfare of family members and their economic well-being at an early age (also see Graves & Graves, 1983).

It is possible that children in the more traditional societies would not have been higher in prosocial behaviors directed toward strangers or people that the child did not know well. In a study of adults in 23 countries, those in cultures that regard the family or extended in-group as the key social unit were less likely to provide low-cost helping to strangers than were those in cultures that view the autonomous person as the key social unit (Knafo, Schwartz, & Levine, 2009). Moreover, children from the Philippines generally were more prosocial toward relatives whereas U.S. children, especially those 5.5 to 10 years of age (rather than less than 5.5 years), generally were more prosocial toward people who were not relatives (de Guzman, Carlo, & Edwards, 2008). It was not clear if the absolute amount of helping of nonrelatives differed across the two groups.

Much of the work on cross-cultural and subcultural variation in prosocial behavior is embedded in the research on cooperation, competition, and reward-allocation behavior. Researchers generally have found that children from traditional rural and semiagricultural communities and from relatively traditional subcultures/cultures (e.g., Mexican American children), in comparison to children from urban or Westernized cultures, are more cooperative and tend to give more to peers on tasks involving the distribution of objects when sharing does not change the child's own yield (Graves & Graves, 1983; see Eisenberg & Fabes, 1998; Knight & Carlo, 2012). However, this has not always been found, especially when children are asked to help in noncompetitive contexts or simply share objects (see Eisenberg et al., 2006). For example, House et al. (2013) found no difference between 3- to 14-year-old children from Los Angeles and from more traditional cultures in prosocial allocation of rewards to another person when there was no cost to the child. When there was a cost, the number of prosocial choices declined from 3 years of age

to about 7 to 9 years of age in all groups, and increased for some groups thereafter. The children from Los Angeles and the Aka from Africa were the groups that showed the most dramatic increase in early adolescence and made the most prosocial choices at the older ages.

In studies of cross-national or cross-cultural differences in sharing or helping that do not use allocation tasks, few consistent differences have been found among Western, industrialized countries (e.g., Russell, Hart, Robinson, & Olsen, 2003; Yagmurlu & Sanson, 2009), although some minor differences have been found (Kumru, Carlo, Mestre, & Samper, 2012). In contrasts between Western and Asian cultures, findings differ considerably across measures of prosociality. A common view is that Asian children are more likely to engage in prosocial behavior than are Western Caucasian children due to the greater focus on maintaining good relationships with group members in at least some Asian cultures. Moreover, Stevenson (1991) and others have argued that Chinese and Japanese societies generally put great emphasis on socializing children to be responsible and prosocial toward others in their group (e.g., the family, the classroom, and the society). Consistent with that view, several researchers have found that East Asian elementary school children, compared to Western counterparts, were more likely to donate gifts for participating in the study to other children (S. M. Stewart & McBride-Chang, 2000), share food with a peer (Rao & Stewart, 1999), or spontaneously share an attractive toy with peers (French et al., 2011; also see Suzuki & Greenfield, 2002). Moreover, Stevenson (1991) found that the observed incidence of sharing, comforting, and helping was lower in kindergarten classes in the United States than in Taiwanese or Japanese classes (albeit relatively high in all groups).

However, there is some evidence that Asian children may be lower in prosocial behavior in emotional (and possibly empathy-inducing) contexts and more distressed by others' distress and sadness than are Western children. Trommsdorff (1995) did not find a difference between German and Japanese 5-year-olds' prosocial behavior with a distressed peer and Kartner et al. (2010) found no difference between Delhi and Berlin toddlers' prosocial behavior in response to an adult's sobbing. However, Trommsdorff, Friedlmeier, and Mayer (2007) found that preschoolers from Indonesia and Malaysia displayed more self-focused distress and less prosocial behavior than children from Germany and Israel in response to an adult's sadness; there were no differences in sympathy, which was infrequent. Similarly, Friedlmeier and Trommsdorff (1999) reported that 2-year-old Japanese girls displayed more distress and

were less able to regulate their distress reaction than were their German peers (they did not code sympathy). In a study of high school and undergraduate students in western Canada (mean age of 19), those born in Asia and with an Asian identity reported higher levels of personal distress and lower sympathy than their Western peers. Bicultural Asians (born in Canada but identified with an East Asian ethnicity) did not differ from Asian-identified youth in personal distress (but differed from Westerners) and were between Asian-identified youth and Western youth in sympathy (and did not differ from either group; Cassels, Chan, Chung, & Birch, 2010). Trommsdorff et al. (2007) suggested that the stronger self-focused distress observed in Asian children could be the result of a higher overarousal due to culturally based differences in shyness with adults and the greater acceptability of inhibited behavior in Asian cultures than in the West. However, this explanation would not seem to fully explain the self-reported differences for adolescents and young adults.

A growing body of work on subcultural differences in the United States has examined the role of acculturation and cultural variables in prosocial behavior. Researchers have found that Mexican American immigrant children are more cooperative and prosocial than Mexican Americans born in the United States (Knight & Carlo, 2012), suggesting that acculturation is associated with a decline in prosocial tendencies. Consistent with the latter finding, de Guzman and Carlo (2004) found that acculturation was negatively related to Latino-American adolescents' self-reported prosocial behavior. Moreover, Mexican American children with a stronger ethnic identity have been found to display more concern with others' outcomes on allocation tasks that can involve a cost to the self (Knight, Cota, & Bernal, 1993; also see Schwartz, Zamboanga, & Jarvis, 2007). However, in a study of Latino-American adolescents, both acculturation and a Latino-American orientation (perhaps indicating biculturalism) were positively related to higher levels of youths' self-reported prosocial behavior (Schwartz et al., 2007). Some scholars have argued that traditional values in the Mexican culture (e.g., familism; being *acomendidola*, defined as alert to surrounding events and ready to contribute spontaneously to the group) foster some forms of Mexican American children's prosocial behavior (e.g., helping within the family or community; see Knight & Carlo, 2012; Lopez, Najafi, Rogoff, & Mejía-Arauz, 2012). Participation in the community involves collaboration and helping and children in traditional Mexican communities are expected to contribute to the group and are provided with opportunities to do so (Lopez et al., 2012).

Moral Reasoning, Values, and Beliefs

About Social Responsibility

It is assumed that cultural values and norms in regard to issues such as the importance of interpersonal harmony and interdependence contribute to observed differences across groups in prosocial responding. Clearly, there are some differences in cultural beliefs and values related to prosocial behavior. For example, J. G. Miller and Bersoff (1992) found that Hindu Indians held a broader and more stringent duty-based view of social responsibility than did people in the United States. Hindu Indians, school-age and adult, tended to focus more than North Americans on responsiveness to others' needs when discussing moral conflicts, and viewed interpersonal responsibilities as at least as important as justice-related obligations. In contrast, consistent with a focus on individual rights and autonomy, people in the United States tended to view interpersonal responsiveness and caring as less obligatory and more of a personal choice, particularly if the other's need was moderate or minor, or if friends or strangers (rather than parents and children) were potential recipients (J. G. Miller, Bersoff, & Harwood, 1990).

Cross-cultural comparisons are difficult because cultures differ in the degree that they value various types of prosocial action. Hindu Indians view prosocial behavior performed because of reciprocity considerations as more moral than do American adults (J. G. Miller & Bersoff, 1994). Further, Jacobsen (1983) found that Middle Eastern third graders (7–8-year-olds) in Israel seemed to value requested acts of consideration more, and spontaneous acts less, than did Israeli Jewish children of Western heritage. Thus, Westerners may value prosocial acts based on endogenous motivation more than do people from traditional cultures whereas people from traditional cultures value prosocial actions that reflect responsiveness to others' stated needs and reciprocal obligations.

Summary

Culture appears to affect how much, when, and with whom children experience empathy or sympathy and engage in prosocial behavior. Cultures seem to vary in which types of prosocial behaviors they value most and may differ in regard to beliefs about who is deserving of help and caring. Before we can truly understand the cultural differences, more information on the types of prosocial behaviors most valued and to whom they are extended (e.g., in-group versus out-group members) is needed. Moreover, how such differences are inculcated in different cultures is an important question to address in the future.

Socialization in the Family

Consistent with Figure 15.1, although there is a substantial genetic contribution to children's prosocial behavior, there is a large body of work suggesting that socializers play an important role in fostering prosocial behavior. In this section, the associations between parental socialization styles or practices and children's prosocial behaviors and empathy/sympathy are reviewed. Due to space constraints, we do not cover the associations between prosocial behavior and demographic features of families, and we cite primarily references since 2006 (see Eisenberg et al., 2006, for more in-depth review and older references).

Parental Socialization Style and Practices

The majority of research on socialization has focused on mothers' potential influence on children's prosocial behaviors and empathy-related responding, although researchers have begun to include fathers in their research (Attili, Vermigli, & Roazzi, 2010; Garner, 2012; Hastings, McShane, Parker, & Ladha, 2007; Nickerson, Mele, & Princiotta, 2008). Findings generally suggest that mothers contribute more to children's prosocial behaviors and empathy than do fathers (Hastings et al., 2007; Nickerson et al., 2008; Padilla-Walker & Christensen, 2011), but examining how mothers and fathers differentially predict children's and adolescents' prosocial behaviors is an area for further research. Moreover, the contributions of mothers' and fathers' parenting to children's prosociality may be interconnected. For example, in one investigation, coparenting practices (i.e., behaviors used by parents to support or undermine each other's parenting) predicted children's affective discomfort, a measure that included empathy (Groenendyk & Volling, 2007).

Parental Warmth and Quality of the Parent–Child Relationship. Parental warmth and the quality of the parent–child relationship are thought to promote children's sense of connection to others. Consistent with this notion, a positive relation between maternal warmth or support (often versus negativity) and prosocial or empathic/sympathetic responding has been obtained in childhood and adolescence (e.g., Carlo, Mestre, Samper, Tur, & Armenta, 2011; Kuppens, Grietens, Onghena, & Michiels, 2009; Miklikowska, Duriez, & Soenens, 2011). However, a number of investigators have found no (or negative) relations between parental warmth (or rejection) and children's prosocial behaviors or empathy/sympathy (e.g., Davidov & Grusec, 2006;

see Eisenberg et al., 2006) or findings that vary depending on the type of analysis performed (Soenens, Duriez, Vansteenkiste, & Goossens, 2007). Sometimes the relation of parental warmth to children's prosocial responding has been weak and only significant through mediation by other parenting factors such as parental expressivity (see Eisenberg et al., 2006).

Similar to the construct of warmth and nurturance, parental responsiveness, reflecting sensitive, child-centered, and emotionally available parenting, has been found to predict children's empathy/sympathy or prosocial behavior (Bronstein, Fox, Kamon, & Knolls, 2007; Davidov & Grusec, 2006; Moreno, Klute, & Robinson, 2008; Newton, Laible, Carlo, Steele, & McGinley, 2014; Spinrad & Stifter, 2006; Tong et al., 2012). Moreover, several other related constructs have been shown to predict children's prosocial behaviors and empathy. For example, a construct dubbed "evolved developmental niche," reflecting maternal responsiveness as well as other practices such as breastfeeding, constant touch, and cosleeping, has been found to predict mothers' reports of children's empathy/prosocial behavior in a Chinese sample (Narvaez et al., 2013). Parenting that reflects high parental involvement and parent–adolescent connection also has directly predicted prosocial behaviors toward family members, as well as prosocial behaviors toward strangers and friends, through children's self-regulation and empathy (Padilla-Walker & Christensen, 2011). In a long-term longitudinal study, Feldman (2007a, 2007b) showed that mother–infant synchrony in the first year of life predicted empathy in Israeli adolescents. Bidirectional relations between children's prosocial behavior and maternal sensitivity also have been found (Newton et al., 2014).

There is also evidence that children and adolescents with secure attachments to parents are more sympathetic and/or prosocial (Diamond, Fagundes, & Butterworth, 2012; Ma, Cheung, & Shek, 2007; Nickerson et al., 2008; Padilla-Walker, Harper, & Jensen, 2010; Yoo, Feng, & Day, 2013). Because securely attached children tend to have sensitive and warm parents, these findings provide some indirect support for an association between parental warmth and children's prosocial development. Further, the relations between parent–child relationship quality and children's prosocial behaviors or sympathy have been found to be mediated by factors such as emotion-regulation abilities (Padilla-Walker et al., 2010; Panfile & Laible, 2012), emotional expressiveness (Laible, 2007), or emotion understanding (Ensor, Spencer, & Hughes, 2011).

It is likely that the degree of association between prosocial behavior and parental warmth/attachment is

moderated by a number of factors (Eisenberg et al., 2006). Padilla-Walker and Nelson (2010) found that high maternal attachment was related to prosocial behavior for boys lower on fear, demonstrating that for fearless boys, the quality of the relationship with mothers may be particularly important. In a sample of children and mothers in China, mothers' encouragement of connectedness (behaviors supporting emotional closeness and proximity) predicted later helping and sharing for children who displayed high initial connectedness but not for children who were low in connectedness (Liu, Chen, Zheng, Chen, & Wang, 2009). Moreover, other socialization practices, such as discipline strategies, control, and modeling, have been shown to moderate the relations between parental warmth and children's prosocial behavior, and such moderation may partly account for the inconsistent findings regarding parental warmth (see Eisenberg et al., 2006).

Inductions and Preachings. A disciplinary practice of particular importance to prosocial behavior is parental inductions, characterized as attempts to provide explanations or reasons for requiring the child to change his or her behavior, and a focus on another's emotional reactions or on the consequences of the child's behavior. Parental inductions are thought to induce an optimal level of arousal for learning (i.e., elicit the child's attention, but are unlikely to disrupt learning; Hoffman, 2000). Over time, these messages are believed to be internalized by children because they play an active role in processing the information and the focus is on one's own action and its consequences rather than on the parent as the disciplinary agent.

There is support for an association between parental use of inductions and children's prosocial behavior and sympathy (Carlo, Knight, McGinley, & Hayes, 2011; Hastings et al., 2007; Laible, Eye, & Carlo, 2008; see Eisenberg et al., 2006). Parenting that encourages perspective taking seems to enhance children's perspective-taking abilities, which are associated with prosocial behavior (Farrant, Devine, Maybery, & Fletcher, 2012; see below). Furthermore, parental inductions have been positively related to sympathy and to various types of prosocial behavior (i.e., dire, compliant, public) in adolescents in Mexican American and European American families (Carlo, Knight, et al., 2011).

Relations between inductive discipline and empathy-related responding or prosocial behavior may depend on various factors such as the children's sex, age, or socio-economic status, the tone in which inductions are delivered, and whether such practices co-occur with other parenting

practices (Eisenberg et al., 2006). For example, inductions delivered with no affect or high degrees of anger may be ineffective or may be associated with low prosocial behavior (Denham, Renwick-DeBardi, & Hewes, 1994). Similarly, the effectiveness of inductions may be reduced when parents also use power-assertive strategies (see Eisenberg et al., 2006).

In addition to inductive discipline, adults' preachings about why one should assist those in need in nondisciplinary contexts have been studied. Although findings for preachings have been somewhat inconsistent, depending on who is preaching (i.e., adults with or without direct power over the children), empathy-inducing preachings that emphasize the emotional consequences for recipients of aid have been found to enhance children's prosocial behaviors, whereas preachings that simply state norms for giving have not (see Eisenberg et al., 2006).

Power-Assertive, Punitive Techniques of Discipline.

Power-assertive practices are thought to evoke fear of punishment resulting in children's overarousal and self-focus (Hoffman, 2000). Researchers generally have found that socializers' use of power-assertive techniques, such as physical punishment or deprivation of privileges, are negatively related to children's prosocial behavior, empathy, or sympathy (Cornell & Frick, 2007; Knafo & Plomin, 2006b; Laible et al., 2008), although no relations also have been reported (Garner, 2012; see Eisenberg et al., 2006). It is possible that the association between such parenting practices and children's empathy-related outcomes varies by age. That is, negative relations may increase with age as children develop more cognitive skills and understanding of the meaning of such messages (Garner, 2012). At the extreme level of parental negative control, physical abuse of children has been linked to low levels of children's empathy and prosocial behavior (Anthonysamy & Zimmer-Gembeck, 2007; see Eisenberg et al., 2006).

Although power assertion and punitive discipline may induce immediate compliance with socializers' expectations, these practices are generally thought to be problematic styles of parenting in relation to children's prosocial behaviors over the long term. However, this assertion may be less true in non-Western cultures, particularly for those in which punitive or controlling practices are considered normative. For example, Yagmurlu and Sanson (2009) found that parental obedience-demanding behavior was related to higher prosocial behavior in Turkish preschool-aged children living in Australia, but a similar relation was not found in Anglo-Australian children.

Further, the relations of harsh parental discipline strategies to empathy or prosocial behavior may differ depending on children's temperamental characteristics. For example, Cornell and Frick (2007) reported that inconsistency in parental discipline (e.g., threaten to punish child but do not actually punish child) was negatively related to parent-reported empathy for behaviorally uninhibited children, but not for inhibited children. Moreover, there appears to be more detrimental effects of parental power assertion on fearful children's moral self (a construct that includes empathy) than for children who are relatively fearless (Kochanska, Aksan, & Joy, 2007). This finding is consistent with Hoffman's (2000) notion that children need to experience optimal arousal levels for effective socialization messages.

Further complexities may be found when considering both parents' discipline style. Garner (2012) reported that maternal power assertion was negatively related to children's sympathy only at high levels of paternal power assertion, suggesting that when both parents use such disciplinary strategies, children are at greater risk than when receiving harsh discipline from just one parent. Thus, parental negative control tends to be related (albeit somewhat weakly) to low levels of children's empathy and prosocial behavior, but these relations are likely moderated by aspects of children's temperament and some aggravating family factors.

Appropriate Versus Inappropriate Parental Control. Perhaps the critical issue when thinking about parental punishment and control is whether the degree of power asserted by the parent is excessive and arbitrary rather than reasonable. Parental demands and expectations for socially responsible and moral behavior (often as expressed in an authoritative parenting style) have been associated with socially responsible and prosocial behavior (Frensch, Pratt, & Norris, 2007; Hastings et al., 2007; Kuppens et al., 2009; Padilla-Walker, Carlo, Christensen, & Yorgason, 2012; Soucie, Lawford, & Pratt, 2012; S. M. Stewart & McBride-Chang, 2000) and moral affect (Laible et al., 2007). For example, parental monitoring has been associated with relatively high prosocial behavior in 10- to 15-year-olds (Elgar, Mills, McGrath, Waschbusch, & Brownridge, 2007).

Parental Emphasis on Prosocial Values. Parents who hold prosocial values would be expected to teach and model prosocial behavior to their children. Indeed, children's and adolescents' perceptions of their parents' prosocial values have been associated with adolescents'

prosocial behavior (Eisenberg et al., 2006), sometimes through adolescents' own prosocial or personal values (Hardy, Carlo, & Roesch, 2010; Padilla-Walker, 2007). Parent-child discussions about moral issues that emphasize values of compassion and empathy have been found to predict relatively high sympathy in adolescents, and in turn, high prosocial behavior (Carlo, McGinley, Hayes, Batenhorst, & Wilkinson, 2007). Some investigators, however, have found no relations between parental prosocial values and children's prosocial behavior or empathy or have found mixed or positive relations (see Eisenberg et al., 2006).

There is no question that cultural differences in prosocial values are substantial. Indeed, European American parents have been shown to attribute less importance to altruistic behaviors and compassion than do Mexican American, African American, or Chinese American parents (Suizzo, 2007). A related value of familism (a value of importance on the family, including responsibilities for one another) central to Latino-American families is thought to foster helping and prosocial behaviors (Knight & Carlo, 2012). Despite the likelihood of mean differences in prosocial values across cultures, researchers need to examine whether culture moderates the relations between such values and children's prosocial behaviors.

Modeling. Numerous researchers have examined whether children's prosocial behavior varies as a function of exposure to prosocial models. Much of the research in this domain involves laboratory studies in which children earn prizes by winning a game, view or do not view a model, and then are provided an opportunity to donate to needy children. In general, researchers have shown that children who view a generous model or helpful model are more generous or helpful than those exposed to a control condition (Williamson, Donohue, & Tully, 2013; see Eisenberg & Fabes, 1998).

Investigators have also examined whether children appear to model real-life socializers, such as parents. For example, McGinley, Lipperman-Kreda, Byrnes, and Carlo (2010) found that parental encouragement and modeling of volunteer work predicted adolescent volunteering, and this relation was mediated by adolescents' sympathy and helpfulness. Parents who model relatively high levels of sympathy or empathy are likely to have children who are sympathetic and willing to help others (Eisenberg et al., 2006; Farrant et al., 2012). In addition, children model adults' prosocial behaviors, such as volunteerism, helping,

and political activism, although most research in this area is correlational and often retrospective (Eisenberg et al., 2006). There are limited longitudinal data on the impact of modeling on children's prosocial behavior, and the relations between parental prosocial behaviors or empathy and children's prosocial behaviors may be due to parents' general parenting style rather than modeling per se.

Prompts, Directives, and Reinforcement for Pro-social Behavior. Children who are instructed or prompted to help or share tend to do so, although evidence suggests such simple, direct requests often may not be needed, even for very young children (Svetlova et al., 2010; Warneken & Tomasello, 2006). There is some debate regarding whether parents should reinforce children's prosocial behaviors. Based on social learning ideas, praising and reinforcement should increase children's sharing and helping; however, it is possible that offering such rewards undermines children's intrinsic motivation to behave prosocially and in turn, induces extrinsic motivation for engaging in prosocial activities. In a series of experimental studies with toddlers, Warneken and Tomasello (2013) showed that reinforcements (i.e., parental presence, parental/adult encouragement) are unnecessary to promote instrumental helping (i.e., helping an adult obtain an out-of-reach object) in young children, and material rewards for helping may deter future prosocial behavior (Warneken & Tomasello, 2008). Consistent with this view, Carlo, McGinley, and colleagues (2007) showed that when parents used material and social rewards to promote prosocial behavior, their adolescents were less likely to report altruistic behaviors and more likely to report public prosocial behaviors (when others are watching), supporting the notion that rewards undermine intrinsic motivation to help others (see Eisenberg et al., 2006, for further review).

Other studies have shown that nonmaterial reinforcements increase children's prosocial behavior, at least in the immediate context (Hastings et al., 2007; see Eisenberg et al., 2006). In a sample of African American preschoolers, mothers' social approval and praise, but not material rewards, were positive predictors of prosocial behavior (Garner, 2006). It is likely that the impact of reinforcement varies as a function of age and type of reinforcement, such as rewards, communication of internal versus external attributions for prosocial behaviors, and praise. For example, children are likely to behave prosocially when provided with internal attributions (a type of verbal praise) for their prosocial behavior (see Eisenberg et al., 2006).

Learning by Doing (and the Foot-in-the-Door Effect). Simply participating in prosocial activities appears to foster future prosocial behavior (see Eisenberg et al., 2006). Indeed, Carlo, McGinley, and colleagues (2007) found that parents who provide hands-on experience and involvement in prosocial activities have adolescents who report higher sympathy and prosocial behaviors. Further, youths' participation in organized youth activities has been linked to their contribution to families and communities (Zarrett et al., 2009).

Researchers have argued that participation in prosocial activities fosters a sense of responsibility and social identity. Telzer and Fuligni (2009) found that adolescents who provided assistance to their families (e.g., household chores, caring for siblings) reported relatively high levels of happiness and a sense of role fulfillment. Further, Grusec, Goodnow, and Cohen (1996) found that routine (but not requested) participation in household chores was related to 9- to 14-year-olds' prosocial behavior in the family, but primarily for older youth and girls. Routine participation in chores was not related to helping strangers. Thus, if chores benefit a delimited group of individuals, any prosocial tendencies fostered may not extend to those beyond that group.

Recall that Whiting and Whiting (1975) found that children were more prosocial in cultures in which they were expected to contribute to the welfare of the family. The degree to which adolescents are involved in household helping undoubtedly varies by culture. Asian American and Latino American adolescents spend more time helping and assisting their families than do their European American counterparts (Hardway & Fuligni, 2006). In some cultures, children are socialized into prosocial activities through what is known as "learning through intent community participation" (see Lopez et al., 2012; Rogoff et al., 2007). Using examples from children from indigenous and indigenous-heritage communities of Mexico, Lopez and colleagues (2012) argued that helpfulness and collaboration are the norm in such communities. Children are thought to learn prosocial skills and goals through their participation in every-day activities in their community.

Participation in both voluntary as well as school-required community service also provides experiences that appear to promote a sense of civic responsibility and contribution (see Eisenberg et al., 2006). Hart, Donnelly, Youniss, and Atkins (2007) reported that participation in community service in high school, as well as participating in extracurricular activities, predicted volunteering in communities and in youth organizations as young adults (8 years after

high school). Thus, it appears that even mandatory service participation increases prosocial responding (see Eisenberg et al., 2006).

Emotion Socialization and Prosocial Tendencies

Parental practices that help children to cope with their negative emotion in a constructive fashion tend to be associated with children's sympathy (rather than personal distress) and prosocial behavior. Presumably, this is partly because children who cannot adequately cope with their emotions tend to become overaroused and, consequently, experience a self-focused, aversive response (i.e., personal distress) when confronted with another's distress (Eisenberg et al., 1996, 2006).

In particular, parental expression of emotion is likely to teach children when it is acceptable to experience and express emotions and can provide opportunities for learning about others' needs. Parental expression of positive emotion and shared positive affect tend to be positively correlated with children's prosocial tendencies in U.S. (Lindsey, Colwell, Frabutt, Chambers, & MacKinnon-Lewis, 2008; Michalik et al., 2007) and Chinese samples (Wang, Chen, Chen, Cui, & Li, 2006), a finding that is consistent with the modest associations between prosocial behavior and parental support and warmth. The expression of positive emotion has been mostly unrelated to children's sympathy, possibly due to quadratic relations in the early years (Valiente et al., 2004) or potential moderating factors, such as temperament and culture (see Eisenberg et al., 2006). Culture may moderate the relation between parental expression of positive emotion and children's sympathy such that the relation is positive only in cultures that value the expression of relatively intense positive emotions (Eisenberg, Liew, & Pidada, 2001).

The relations of parental negative expressivity to children's sympathy and prosocial behavior have been somewhat mixed (Eisenberg et al., 2006). In a number of studies, negative expressivity has been related to lower prosocial behaviors and sympathy (Eisenberg et al., 2006; Eisenberg et al., 2001). For example, parental negative behavior, reflected in parents' use of criticizing, hostility, and ignoring, has been negatively related to prosocial behavior (Attili et al., 2010). Similarly, Michalik and colleagues (2007) showed that observed negative expressivity when interacting with children predicted low prosocial behavior in adolescence. However, in the same study, parental reports of negative expressivity (negative dominant emotion) in the home more generally were negatively related to boys', but not girls', sympathy in childhood

and were unrelated to boys' sympathy in adolescents. There was a positive relation between parents' reports of negative expressivity in childhood and girls', but not boys', sympathy in adolescence. These findings might indicate that some exposure to negative dominant emotions in the home, if not excessive, may foster daughters' awareness of and attention to negative emotions. Further, the relation between parental expression of negative emotion in the family and young schoolchildren's sympathy appears to be quadratic (a moderate level was associated with their sympathy) and also moderated by children's regulation; negative relations have been found only for children low in regulation (Valiente et al., 2004).

When anger is directed at the child, negative emotionality is perhaps most likely to be detrimental to children's prosocial development. Consistent with the findings of Michalik et al. (2007), Batanova and Loukas (2012) reported that for middle-school-aged (mean age of about 11 to 12 years) girls, but not boys, parent-child conflict predicted a decline in empathic concern across a 1-year period.

Reviewing research on troubled families (i.e., depressed mothers, marital distress), Zahn-Waxler and Van Hulle (2012) discussed "pathological altruism" in children, particularly girls. In such troubled families, children may be likely to engage in comforting and prosocial behaviors toward family members. Such prosocial behavior may serve to minimize self-related negative emotional (and physical) consequences of conflict but likely does not foster the capacity for sympathy or other-oriented (rather than self-oriented) prosocial behavior beyond that directed toward family members. Indeed, prosocial behavior toward playmates is lower for children exposed to maternal depression and conflict involving one or both parents (see Zahn-Waxler & Van Hulle, 2012). McCoy, Cummings, and Davies (2009) demonstrated that, even after controlling for prior levels of children's prosocial behavior, destructive marital conflicts (i.e., those that are hostile and angry) predicted lower prosocial behavior through children's lower emotional security.

In addition to parental expression of emotions, the socialization of emotion involves parental responses to children's emotions. Mothers' appropriate responses to their children's negative emotions have been related to children's sympathy, prosocial behavior, and personal distress reactions (Garner, 2006; see Eisenberg et al., 2006). For example, Davidov and Grusec (2006) found that maternal responsiveness to children's distress was positively associated with empathy and prosocial behavior, and, as predicted, this relation was mediated by children's

ability to regulate their negative affect. Eisenberg, Fabes, Schaller, Carlo, and Miller (1991) found that parents (mostly mothers) who emphasized to their sons the need to control their own negative emotions (i.e., sadness and anxiety) had sons who showed facial and physiological signs of distress when viewing a sympathy-inducing film but were likely to report experiencing no distress in reaction to the film. On the other hand, when boys had parents who encouraged their children to deal with emotions in instrumental ways, they were likely to experience sympathy rather than personal distress. Interestingly, when same-sex parents restricted emotional displays that could be hurtful to others (i.e., gasping at a disfigured person), children tended to show relatively high levels of dispositional and situational sympathy. Thus, parents' restrictiveness may foster prosociality when in regard to the display of hurtful emotions but may undermine it for the display of children's own experiences of emotion.

Emotion socialization also involves parental discussion of emotion. Mothers' discussions of their own and their children's emotions appear to relate positively to children's vicarious emotional responding and prosocial behaviors (Brownell, Svetlova, et al., 2013; Garner, Dunsmore, & Southam-Gerow, 2008). However, the positive association between mothers' discussion of emotion and prosocial tendencies has not been found in all studies and may be dependent on the manner in which mothers talk about emotional events (see Eisenberg et al., 2006). Moreover, little is known about differences in mothers' and fathers' discussion of emotions and their effects.

Siblings

The role of the sibling relationship in children's prosocial behaviors and empathy-related responding has received surprisingly little attention. Because siblings spend considerable time together and are familiar and relatively uninhibited with one another, they would be expected to play a considerable role in the development of children's social understanding and social skills. In fact, even young children show relatively high levels of comforting behaviors to their distressed siblings, although they are less likely to show such behavior with peers (see Eisenberg et al., 2006).

Positive sibling relationships may provide children with opportunities to learn about others' needs and how to care effectively for others, and such relationships are likely to provide a buffer from stress and negative emotionality. Sibling warmth/low conflict was related to higher empathy over time in a sample of young adolescents (Lam, Solmeyer, & McHale, 2012). Similarly, sibling affection

was positively related to prosocial behavior, even after controlling for the impact of parent-child relationship quality, and this relation was mediated by children's self-regulation skills (Padilla-Walker et al., 2010). Morgan, Shaw, and Olino (2012) reported that although sibling relationship quality did not directly predict boys' social skills (a composite that included some indices of prosocial behavior/cooperation), higher destructive sibling conflict related to lower social skills for boys high (but not low) in negative emotion (girls were not studied). Thus, children's temperament may moderate the impact of the sibling relationship on their social behavior.

The child's ordinal position in the sibling dyad likely affects opportunities and expectations for prosocial behavior. Older children are more likely to enact prosocial behaviors directed toward younger siblings, and younger siblings accept reciprocal roles by displaying high rates of compliance and modeling (see Eisenberg et al., 2006). In one of the few studies to consider the role of sibling composition in adolescents' empathy, Tucker, Updegraff, McHale, and Crouter (1999) found that young adolescents' (10–12 years old) empathy was positively associated with their younger sisters' (2–3 years younger) empathy, whereas older brothers' empathy was positively related to younger brothers' empathy, indicating that younger siblings may model their older siblings' behavior.

Because sibling relationships are embedded in the family, it is not surprising that mothers' behaviors are linked to prosocial behavior between siblings. For example, when mothers discussed their newborn's feelings and needs with an older sibling, the older child was more nurturing toward the infant. Furthermore, friendly interest in the infant persisted and predicted prosocial behavior toward the younger sibling 3 years later (Dunn & Kendrick, 1982). Thus, sibling interactions are clearly an important context for learning caregiving behaviors, perspective taking, and social skills, although little is known about ways in which the larger familial context, children's characteristics, and culture moderate the relations of prosocial development to aspects of the sibling relationship.

Summary

A number of parenting practices and beliefs, as well as the emotional climate of the home and sibling relationships, are related to prosocial development. The findings are generally consistent with the notion that the development of prosocial behavior and empathy/sympathy is enhanced by a sense of connection to others (i.e., attachment, exposure to parental warmth), positive discipline and guidance, and

participation in prosocial activities. Furthermore, the ways in which parents respond to and teach about emotions have been related to children's sympathy and prosocial behaviors. Sibling relationships also provide a context for learning and practicing prosocial capacities.

Researchers typically ignore the role of children's characteristics in the socialization process. Yet, as was demonstrated by Padilla-Walker and colleagues (2012), youth are as likely to influence parenting as the reverse. Moreover, as is illustrated in Figure 15.1, relations of parenting behaviors to children's prosocial development undoubtedly are affected and/or moderated by a number of factors, including culture, children's age and sex, sex of the parent (although there is little research on fathers), children's dispositional characteristics, and other parenting behaviors. Relatedly, children's heredity likely affects the degree to which they are responsive to socialization efforts, what kinds of socializing behaviors they respond to, and the socialization-relevant behaviors they evoke from family members.

Extrafamilial Socialization

Of course, people and institutions outside the family are potential socializers of children's prosocial actions. Research on the role of nonparental influences is still limited, and researchers seldom have simultaneously studied multiple family socializers or multiple types of potential socializers (e.g., peers and the school context).

Peer Influences on Prosocial Development

Peers are likely important and unique socializing agents for children. Being affiliated with prosocial peers appears to encourage prosocial and positive behaviors in youth, perhaps through modeling. Adolescents who are prosocial or who volunteer are likely to have friends who also engage in these activities (Barry & Wentzel, 2006). In one of the few studies with young preschool and kindergarten-aged children, Fabes, Hanish, Martin, Moss, and Reesing (2012) found that greater affiliation with prosocial peers was related to enhanced positive emotional responding and a decrease in negative emotionality in subsequent peer interactions, even after controlling for earlier levels of emotionality and classroom-level prosocial behavior.

Peers can also reinforce prosocial behaviors. Fujisawa, Kutsukake, and Hasegawa (2008) showed that Japanese preschoolers tended to reciprocate prosocial behaviors in dyads. Peers may also promote adolescents' prosocial behavior when they communicate expectations for

prosocial behaviors (Wentzel, 2014; Wentzel, Baker, & Russell, 2012; Wentzel, Battle, Russell, & Looney, 2010). Indeed, in one study, peers' expectations about prosocial behavior predicted adolescents' prosocial behavior, and this relation was mediated by adolescents' personal prosocial values (Padilla-Walker & Carlo, 2007).

Furthermore, warm and close relationships with peers might offer opportunities to develop reciprocal relationships that involve empathy and prosocial behavior. Children tend to behave more prosocially toward friends than nonfriends (Fujisawa et al., 2008) and having at least one reciprocated friendship (rather than having no such friendship) has been related to higher levels of prosocial behavior (Wentzel, Barry, & Caldwell, 2004). In addition, Sallquist, DiDonato, Hanish, Martin, and Fabes (2012) reported that mutual positive expressivity among preschool-aged peers, but not children's overall positive expressivity, was positively related to children's social adjustment—a construct that included cooperation and prosocial behavior with peers. Thus, the quality of peers' relationships may foster perspective taking and empathy, even in early childhood.

Research with adolescents also supports an association between quality of peer relationships and prosocial tendencies. Attachment security with peers in adolescence has been related to higher prosocial behavior and sympathy, even after controlling for attachment with parents (Laible, 2007), and adolescent empathy has been related to higher friendship quality (Soenens et al., 2007). Moreover, adolescents' sympathy has been related to the quality of their friendships (e.g., intimacy and conflict management; Chow, Ruhl, & Buhrmester, 2013; de Wied, Branje, & Meeus, 2007). Of course, quality of peer relationships could affect prosocial tendencies or vice versa, or both may stem from a third variable.

Peer social status (being liked by peers) also has been positively related to empathy and prosocial behavior (Caputi, Lecce, Pagnin, & Banerjee, 2012; Gorman, Schwartz, Nakamoto, & Mayeux, 2011; Mouratadis & Sideridis, 2009; see Eisenberg et al., 2006). Kuppens et al. (2009) found that elementary school children's prosocial behavior predicted boys' (but not girls') social status 2 years later when controlling for initial social status; there was less evidence of the reverse relation. Also suggesting an association, Closson (2009) found that members of perceived popular cliques were relatively prosocial toward their friends, whereas unpopular cliques were characterized by lower levels of prosocial behavior toward clique members. Similarly, centrality in peer groups has been

found to predict prosocial behavior (Ellis & Zarbatany, 2007). However, some researchers have found no relations between peer social status and sympathy/prosocial behavior (e.g., Ellis, Dumas, Mahdy, & Wolfe, 2012).

Teachers and Schools

Based on the literature on the role of parents as socializers of prosocial behavior and empathy, it is not surprising that teachers play an important role in children's social behaviors (see Jennings & Greenberg, 2009; also see subsequent section on school-based interventions). Teachers' warmth has been positively associated with children's empathy/sympathy and prosocial behavior (Eisenberg et al., 2006; Luckner & Pianta, 2011). Further, teacher-child relationship quality (high closeness and low conflict) has been positively related to prosocial behavior (Palermo, Hanish, Martin, Fabes, & Reiser, 2007). The majority of the work in this area has focused on early childhood settings; further research is needed on these associations with older children (Bergin, 2014). Longitudinal and experimental research also is needed to identify the likely direction of causality.

In addition, aspects of the school and classroom may be important considerations. For example, school connectedness (e.g., a sense of belonging to school) may promote involvement and prosocial activities. Indeed, Batanova and Loukas (2012) found that school connectedness was related to increases in males', but not females', sympathy and perspective taking over 1 year. Similarly, Barr and Higgins-D'Alessandro (2007) reported that positive perceptions of the school culture were related to relatively high levels of adolescents' sympathy. Youths' perceptions of experiences of cooperative learning in the classroom also have been positively related to their prosocial behaviors (Choi, Johnson, & Johnson, 2011).

Experiences outside of the classroom also could facilitate prosocial skills. Youths who participate in after-school sports and youth development programs, such as 4-H, YMCA, Boys & Girls Clubs, as well as youths who participate in sports and religious-based youth groups, report higher positive youth development than do students who are not involved in such activities (Zarrett et al., 2009). Thus, school settings likely play an important role in fostering children's positive social development.

School-Based Interventions

Based on the previously described literature concerning the socialization of prosocial attitudes and behavior, some investigators have attempted to design school-based programs for fostering prosocial responding. For example,

Solomon, Watson, Delucchi, Schaps, and Battistich (1988) implemented a whole-school intervention program designed to promote prosocial values and positive teacher-child relationships. Teachers were trained in child-centered approaches (e.g., inductive discipline), students participated in rule setting and decision making and mutual problem solving, and the program provided children with opportunities to participate in collaborative activities, such as rule-setting and engaging in different roles in the classroom. The program was implemented for 5 consecutive years (kindergarten through Grade 4, or approximately 5–6 years of age to 9–10 years of age). Evaluation of the program indicated improvements in spontaneous prosocial behavior and observed friendly and helpful behavior (Solomon et al., 1988). It appears, however, that the impact of the program on children's sympathy was not long-term. One report indicated that by middle school (in grades 6 to 8, typically 11–12 years to 13–14 years of age), even for the subsample of schools that implemented the program well, there were no differences between children in the program and control groups in concern for others (Battistich, Schaps, & Wilson, 2004).

A number of smaller programs (in few schools) targeting prosocial behavior and/or empathy/sympathy appear to have had some positive results. Caprara et al. (2014) focused on prosocial behavior and reported effects of the *Promoting Prosocial and Emotional Skills to Contrast Externalizing Problems* curriculum directed to middle-school students (mean age of about 12). The program was designed specifically to promote prosocial skills by addressing perspective taking, emotion regulation, and the promotion of prosocial actions. Those in the intervention group increased in helping and decreased in physical and verbal aggression across three time points (6 months apart) and also got higher grades than the children in the control group.

In a small study of preschool-aged children, Ramaswamy and Bergin (2009) trained teachers in Head Start classrooms to use "victim-centered" inductive discipline when students misbehaved (involving teaching students to focus on others' well-being), reinforcements for prosocial behavior (e.g., hug, pat, compliment), or both induction and reinforcements. Although teachers only modestly changed their behaviors, the children's prosocial behavior significantly increased from pretest to posttest in all interventions groups, but particularly for students who were in the induction-only group.

Another program designed specifically to improve prosocial behavior is the *Roots of Empathy* program (ROE).

This program, directed to fourth- through seventh-grade classrooms (nearly 9 to nearly 13 years old, with a mean age of 10 to 11 years), involved monthly classroom visits by an infant and his or her parent(s) and bimonthly visits from a program instructor who provided lessons designed to foster empathy, emotional understanding, and sensitivity. The students were also required to engage in lessons designed to benefit the infant (e.g., create a recording of nursery rhymes and songs for the infant), with the goal of promoting altruism and prosocial values. Children in the ROE group, compared to control children, increased on peer-nominated prosocial behaviors (i.e., sharing, cooperating, helping others) and decreased in teacher-rated aggression (Schonert-Reichl, Smith, Zaidman-Zait, & Hertzman, 2012).

A number of other intervention programs have not focused specifically on prosocial skills but have measured them, often in combination with other positive behaviors. In one program, emotional skills were integrated into literature teaching by using “affective teaching” to encourage fifth- and sixth-grade students (typically 10–11 and 11–12 years; age was not specified) to think about characters in stories, and teachers asked “feeling questions” about the characters and their own personal experiences. Students in the program group improved in their positive behavior (which included prosocial behavior) and were more supportive of each other than were children in traditional teaching classrooms (Shechtman & Yaman, 2012).

The *Second Step* program was designed as a violence prevention program that involved lessons about anger and emotional management, empathy, and impulse control for third- and fourth-grade children, typically 8–9 and 9–10 years old (Cooke et al., 2007). In addition to the school-based curriculum, there also were components aimed at involving parents and other members of the community in modeling and reinforcing children’s positive behavior. Students’ self-reported caring/cooperative behavior and self-reported consideration of others significantly improved from pre- to posttest; however, observed prosocial behaviors did not increase.

The *Fast Track Project* involved multiple components, including parents and schools to improve social skills for children at-risk for antisocial behavior. Children in the intervention group engaged in more prosocial activities with peers and showed more improvement in aggressive-disruptive behavior than did children in the control group (Conduct Problems Prevention Research Group, 1999, 2002).

Another school-based intervention program, the *Social Aggression Prevention Program*, was designed to improve

girls’ social problem solving and social skills. This program was delivered to small groups of 5th grade girls (mean age of 10.5 years) and involved social-skills training and activities designed to enhance emotional awareness. For girls with relatively high social aggression at baseline, this training was linked to increases in teachers’ ratings of prosocial behavior and marginally higher ratings of empathy. There were no differences between the intervention and control group in peers’ prosocial ratings (Cappella & Weinstein, 2006).

Many of the aforementioned programs focus on the importance of building social and emotional skills. In a meta-analysis, Durlak, Weissberg, Dymnicki, Taylor, and Schellinger (2011) found that such programs have small but positive effects on positive social behavior. It is important to note, however, that these programs tend to focus on general positive and socially competent behaviors and do not necessarily focus specifically on improvements in prosocial behavior or empathy. Further, many of the interventions emphasize reducing negative behaviors rather than focusing on positive behaviors.

Summary

Extra-familial socializers probably influence children’s prosocial development. In particular, high-quality relationships with peers and teachers are likely to promote children’s prosocial behavior and empathy/sympathy. In brief, peer interactions seem to provide unique opportunities for prosocial behavior, and peer responses in such contexts might influence the type and degree of potential prosocial responses. However, the direction of relations between peer competence and prosocial behavior is not clear (although prosocial tendencies likely affect peer status and quality of friendships); longitudinal research controlling for initial levels of prosocial behavior is needed. Further, little is known about the degree to which the effects of peers are moderated by other variables (e.g., the nature of interactions with other socializers and characteristics of the child, the peer group, or the context) or the exact processes that underlie potential peer influences.

School-based programs designed to enhance prosocial values, behaviors, and attitudes in children can be effective (albeit not always are) in fostering children’s prosocial attitudes and behaviors. However, these programs are often difficult for schools to implement given their cost and a number of policies in the U.S. educational system that require teachers to focus on academic testing, rather than on socioemotional learning. Additional research is needed to examine the types of programs that are most effective and who should be targeted in such interventions.

SOCIOCOGNITIVE CORRELATES OF PROSOCIALITY

As already discussed, the emergence of sociocognitive skills appears to be correlated with the emergence of sympathy and prosocial behavior. In addition, theorists have frequently argued that sociocognitive skills such as perspective taking and moral reasoning foster prosocial responding (Batson, 1991; Eisenberg, 1986; Hoffman, 2000). Because cognitive abilities may underlie the ability to discern others' needs or distress as well as the capacity to devise ways to respond to others' needs, it would be logical to also expect some relation between measures of intelligence and prosocial responding, particularly prosocial behavior involving sophisticated sociocognitive skills.

Indeed, often investigators have obtained modest to moderate positive correlations between measures of intelligence (e.g., IQ, vocabulary or reading skills, language development, developmental level) or grades and prosocial behavior or sympathy (e.g., Carlo, Hausmann, Christiansen, & Randall, 2003; Moreno et al., 2008; Rhee, Boeldt, et al., 2013; van der Mark et al., 2002; see Eisenberg et al., 2006). The contribution of these cognitive skills probably is partly through their contribution to sociocognitive abilities, which might have a more direct relation to empathy/sympathy and prosocial behavior. However, prosocial behavior and sympathy might also affect cognitive and academic outcomes (e.g., Romano, Babchishin, Pagani, & Kohen, 2010) due to their effects on variables such as relationships with peers and teachers at school and children's liking of school (Palermo et al., 2007). Moreover, prosocial behavior and sociocognitive development may be associated due to environmental variables (e.g., life events, neighborhood environment, parenting quality) contributing to both variables.

Understanding of Others' Cognitions and Emotion

Numerous investigators have examined the decoding of others' emotions and an understanding of others' mental states as predictors and correlates of children's prosocial behavior and empathy-related responding. For convenience, and because it generally is difficult to identify the processes underlying performance on perspective-taking and related tasks, the term *perspective taking* is used to refer to the ability to engage in any of these processes when they result in knowledge about others' internal states.

Researchers often but not always have found a positive association between perspective taking (broadly defined)

and prosocial behavior (including defense of victims of bullies and empathy/sympathy) (e.g., Caputi et al., 2012; Caravita, Di Blasio, & Salmivalli, 2010; Eggum et al., 2011; Ensor et al., 2011; Espelage, Green, & Polanin, 2012; Nichols, Svetlova, & Brownell, 2009; see Carlo, Knight, McGinley, Goodvin, & Roesch, 2010; Eisenberg et al., 2006), as well as young children's other-oriented prosocial moral reasoning (e.g., Lane et al., 2010). In a meta-analysis, Carlo et al. (2010) found relatively larger associations in studies involving comforting behavior (rather than volunteering or donating/sharing), school children (including adolescents) as opposed to older or younger individuals, and affective (rather than social/cognitive or visual/spatial) perspective-taking measures (overall weighted mean correlation was 0.22). This association does not seem to be due merely to the correlations between age and both perspective taking and prosocial behavior; sometimes the age range of study participants was narrow or findings were maintained when age was controlled (e.g., Nichols et al., 2009; see Carlo et al., 2010). The relation is stronger when there is greater similarity between the type of perspective-taking skills assessed and the type or level of understanding likely to promote prosocial behavior in the given context (e.g., when both require an awareness of another's emotional state, the target is similar in the two tasks) and/or the level of assessment (global versus specific) is similar. Children with specific perspective-taking skills are likely to apply those same skills when engaging in prosocial tasks that prime or activate cognitive, affective, or motivational scripts similar to those required in the perspective-taking tasks (Carlo et al., 2010).

In some circumstances, perspective-taking skills may be unimportant because prosocial actions are enacted in a relatively automatic fashion due to either their low cost or the compelling, crisis-like nature of the situation (Eisenberg, 1986). Moreover, in some contexts, prosocial behavior is likely motivated by factors other than knowledge of another's internal states. Furthermore, contexts vary in the degree of sociocognitive skills required to help, which can affect the relation between such skills and prosocial behavior. Knafo, Steinberg, and Goldner (2011) found that children with low levels of affective perspective-taking ability (but not general cognitive skills) had difficulty inferring the need for prosocial action and were low in self-initiated prosocial behavior when there were relatively subtle social cues, but did not differ from their peers when specific social cues or requests were provided by adults.

Because sociocognitive skills can be used for good or ill (Eisenberg, 1986; Sutton, Smith, & Swettenham, 1999),

it is not surprising that their relation to prosocial behavior sometimes has been mediated or moderated by other morally relevant variables. In one study, for example, children who donated money to help a child who had been burned were those who not only evidenced relatively sophisticated perspective-taking skills, but also were sympathetic and understood units and value of money (Knight, Johnson, Carlo, & Eisenberg, 1994). In another investigation, there was no direct relation between perspective taking and prosocial behavior, only mediated relations through sympathy or prosocial moral reasoning (Eisenberg, Zhou, & Koller, 2001).

In summary, sociocognitive skills related to understanding of others' internal states of situations may be involved in discerning others' needs, evoking the affective motivation for prosocial action (i.e., sympathy, empathy, or guilt), and providing sensitive help. Consistent with this argument, children with higher perspective-taking skills generally are somewhat more prosocial, particularly if their perspective-taking abilities are relevant to the prosocial task. However, it is also likely that children with well-developed perspective-taking abilities have more opportunities to be prosocial (e.g., parents may be more likely to allow children to care for and assist their younger siblings if they are relatively advanced in perspective taking; R. B. Stewart & Marvin, 1984).

Moral Reasoning and Attributions

If, as argued by Eisenberg (1986), moral reasoning reflects the hierarchy of an individual's values, needs, goals, and motives in a given situation, within the constraints of the individual's cognitive and sociocognitive capabilities (which may be limited due to age), one would expect some relation between moral reasoning and prosocial tendencies. Of course, prosocial actions can be motivated by a range of considerations, including altruistic, pragmatic, and even self-oriented concerns; nonetheless, prosocial behavior motivated by a particular type of factor (e.g., sympathy) is likely to be correlated with the types or levels of reasoning reflecting that factor, although not necessarily with an individual's overall level of reasoning. Similarly, one would expect moral attributions regarding one's own and others' moral behaviors to reflect individuals' values, needs, and motives.

Moral Reasoning

Children's prosocial behavior has been inconsistently related to aspects of Piaget's (1965) scheme of moral judgment (e.g., intentionality, distributive justice), but

generally (albeit not consistently) positively related to Kohlberg's (1981) prohibition- and justice-oriented moral reasoning (or modified versions thereof) (see Eisenberg, 1986; Eisenberg & Fabes, 1998). Moreover, in general, children's moral reasoning about dilemmas involving helping or sharing behavior has been modestly associated in the predicted manner with at least some measures of prosocial behavior, within and outside North America (e.g., Carlo, Mestre, et al., 2011; Eisenberg et al., 1995; Eisenberg, Zhou, et al., 2001; Kumru et al., 2012; S. M. Stewart & McBride-Chang, 2000; see Eisenberg, 1986, and Eisenberg & Fabes, 1998, for reviews). In addition, types of reasoning that reflect an other- versus self-orientation or are developmentally mature for the age group are most likely to predict prosocial responding, whereas immature types of reasoning (e.g., hedonistic reasoning) tend to be negatively related (e.g., Carlo et al., 2003; Carlo & Randall, 2002; Eisenberg et al., 1995; Eisenberg, Miller, et al., 1991; Kumru et al., 2012; see Eisenberg et al., 2006).

The degree and valence of the relation between prosocial moral reasoning and prosocial behavior vary with the type of prosocial behavior. Higher-level, self-reported internalized prosocial moral reasoning tends to be positively correlated with adolescents' reports of altruistic prosocial actions and helping in emotional and anonymous situations, whereas lower-level reasoning (i.e., approval-oriented or hedonistic) tends to be related positively to reported public helping (only for approval) and/or negatively to altruism or helping in emotional or dire circumstances (Carlo et al., 2003; see Carlo, Knight, et al., 2011, for a weaker pattern, especially for Mexican American youth). In laboratory studies, prosocial moral reasoning more frequently has been associated with prosocial actions that incur a cost (e.g., donating or volunteering time after school) than with those low in cost (e.g., helping pick up dropped paper clips; Eisenberg et al., 1987; Eisenberg & Shell, 1986). In observational studies, higher prosocial moral reasoning most often has been positively related to preschoolers' spontaneous sharing behaviors in comparison to helping behaviors (which, in these studies, generally entailed little cost) or prosocial behaviors performed in compliance with a peer's request (Eisenberg-Berg & Hand, 1979), although spontaneous and compliant prosocial preschool behaviors relate to different types of moral reasoning in adulthood (more needs-oriented for the former and stereotypic or internalized for the latter; Eisenberg et al., 2013).

Other variables sometimes moderate the relation between moral judgment and prosocial behavior. For example, P. A. Miller, Eisenberg, Fabes, and Shell (1996) found that preschoolers who reported sympathy for hospitalized

children and who also were relatively high in use of needs-oriented reasoning were especially likely to help hospitalized children at a cost to themselves. Affective motivation such as sympathy (and perhaps guilt) often may be necessary to spur the individual to action. Thus, it is important to identify other moderators and mediators of the relation between moral reasoning and prosocial responding.

Moral Emotion Attributions

Children's attributions of emotions such as guilt, remorse, or happiness when considering situations involving moral transgressions or prosocial acts also have been associated with individual differences in prosocial behavior. In a typical study, children are presented with vignettes in which some morally relevant behavior is performed and are asked how the story protagonist or they would feel. Malti and Krettenauer (2013) argued that individual differences in moral emotion attributions reflect morally relevant behavioral dispositions. Consistent with this argument, in a meta-analysis, they found a modest overall relation between emotion attributions (e.g., attributing guilt or sadness to a story protagonist or the self) and prosocial behavior (.26). This relation was not moderated by age. Although various characteristics of coding and study design did moderate the size of the association, overall the findings supported the view that how children think they or others feel when they behave in morally relevant ways is relevant to their prosocial behavior in other contexts.

Summary

Research on moral reasoning, especially prosocial moral reasoning, and attributions about moral behaviors and emotions tend to be modestly related to children's prosocial behavior, suggesting that moral cognitions often contribute to prosocial behavior. However, moral reasoning/attributions may simply reflect motives, values, goals, and needs that contribute to moral reasoning/attributes and to prosocial behavior, and engaging in prosocial behavior may help to shape moral cognitions (Laible, McGinley, Carlo, Augustine, & Murphy, 2014). Longitudinal research examining potential causal pathways and experimental research manipulating development or availability of particular levels of moral judgments or cognitions would be useful in identifying causal pathways.

THE RELATION OF PROSOCIAL BEHAVIOR TO EMPATHY-RELATED EMOTIONAL RESPONDING

A causal relation between empathy or sympathy and prosocial behavior has been presumed to exist both within

specific contexts and at the dispositional level (i.e., people with a dispositional tendency toward empathy/sympathy are expected to be relatively altruistic in general). Empathy may often evoke sympathy, and sympathetic concern is expected to motivate other-oriented behavior, including altruism (e.g., Batson, 1991; Eisenberg, 1986; Hoffman, 2000). In contrast, personal distress is viewed as involving the egoistic motivation of alleviating one's own distress; therefore, it is expected to motivate prosocial behavior only when the easiest way to reduce one's own distress is to reduce the other's distress (e.g., when one cannot easily escape contact with the empathy-inducing person; Batson 1991).

In a meta-analytic review of the literature, Eisenberg and Miller (1987) found significant positive associations with prosocial behavior for a variety of measures of empathy-related responding; however, some types of measures were infrequently used prior to 1987 (e.g., facial and physiological measures) and one commonly used measure appeared to lack validity. Moreover, in the early studies of empathy, investigators often did not differentiate among empathy, sympathy, and personal distress.

Since the 1980s, it has become clear that it is essential to differentiate among empathy-related emotional reactions. Consistent with his theorizing, Batson (1991), in laboratory studies with adults, found that sympathy is more likely to be positively associated with helping than is personal distress when it is easy for people to escape contact with the person needing assistance. In a series of studies, Eisenberg, Fabes, and their colleagues (see Eisenberg & Fabes, 1998; Eisenberg et al., 2006) obtained similar findings with children, using facial and physiological measures, as well as self-reports of sympathy and personal distress. In regard to physiological measures, Eisenberg et al. (1989) argued that people tend to experience personal distress when they are physiologically overaroused, whereas they feel sympathy when they experience moderate vicarious arousal. Thus, they hypothesized that in evocative empathy-inducing contexts (but not less evocative ones), high levels of autonomic arousal would be associated with personal distress, whereas the reverse would be true for sympathy (although, in response to a mildly evocative stimulus, low arousal could be an index of no empathy-related responding). In addition, heart rate deceleration tends to occur when individuals are oriented to information in the environment outside the self, so they predicted an association between experiencing sympathy and heart rate deceleration at the time of the sympathetic response. Across studies in which children were shown empathy-inducing videotapes, children who exhibited facial or physiological (i.e., heart

rate deceleration or lower skin conductance) markers of sympathy tended to be relatively prosocial when given an opportunity to assist someone in the film or people similar to those in the film (e.g., hospitalized children). In contrast, children who exhibited evidence of personal distress (higher heart rate or skin conductance) tended to be less prosocial. Self-report measures in these studies were less consistently related to children's prosocial behaviors (e.g., Eisenberg et al., 1989; Eisenberg et al., 1990; see Eisenberg et al., 2006, for a review).

Other investigators have found an association between expressions of empathy/sympathy and prosocial behavior in observational studies (e.g., Zahn-Waxler, Robinson, & Emde, 1992; Knafo, Zahn-Waxler, et al., 2008; Trommsdorff & Friedlmeier, 1999; Trommsdorff et al., 2007; Vaish et al., 2009), although self-distress in reaction to another's emotion has been inconsistently related to young children's prosocial behavior (Liew et al., 2011; Zahn-Waxler, Radke-Yarrow, et al., 1992; Zahn-Waxler, Robinson, et al., 1992; also see Trommsdorff, 1995). Consistent with Eisenberg's work, Zahn-Waxler et al. (1995) found children's heart rate deceleration during exposure to sadness (at the peak interval) was associated with three of four measures of prosocial responding, and behavioral/facial measures of concerned attention were positively related to prosocial behavior directed toward the target of concern. Gill and Calkins (2003) found that heart rate acceleration was positively related to toddlers' empathy, but they used mean level of heart rate rather than looking at change in heart rate during a short evocative episode.

Consistent with the findings in studies of situational sympathy, questionnaire measures of empathy or sympathy frequently have been found to be positively related to diverse measures of prosocial behavior (Malti, Gummerum, Keller, & Buchmann, 2009; see Eisenberg et al., 2006), including helping victims of bullies (e.g., Bellmore, Ma, You, & Hughes, 2012; Caravita et al., 2010; Espelage et al., 2012). Relations between dispositional sympathy and prosocial behavior seem to be most consistent for self-reported or relatively costly prosocial behavior (Eisenberg, Miller, et al., 1991; Eisenberg et al., 1987). Findings for self-reported empathy (rather than sympathy) are not highly consistent (e.g., see Eisenberg et al., 2006). However, empathy questionnaires often contain items that may reflect personal distress or sympathy in addition to empathy. Preschoolers' personal distress reactions have been positively related to the children's tendency to engage in compliant, requested prosocial behaviors (Eisenberg et al., 1990; Eisenberg, McCreathe, & Ahn, 1988). However,

self-reported personal distress tends to be inconsistently and often unrelated to prosocial behavior (e.g., Eisenberg, Miller, et al., 1991; Eisenberg et al., 1995), although relations consistent with expectations have been found in early to mid-adolescence in some (Carlo, Eisenberg, & Knight, 1992; also see Eisenberg et al., 2002) but not all (e.g., Eisenberg et al., 1995) studies. It may be that questionnaire measures of personal distress, which have been adapted from work with adults, are not optimal for children.

In summary, research findings are consistent with the conclusion that sympathy and sometimes empathy (depending on its operationalization) are positively related to prosocial behavior. In contrast, personal distress, particularly when assessed with nonverbal measures in an evocative situation, is negatively related to prosocial behavior (and often unrelated for self-reported personal distress). Moreover, children with a sympathetic disposition appear to be somewhat more prosocial in general than are other children. Because there is evidence that the relation of sympathy to prosocial behavior is moderated by dispositional perspective taking (Knight et al., 1994) and moral reasoning (P. A. Miller et al., 1996), it is important to identify other dispositional and situational factors that influence when and whether empathy-related situational reactions and dispositional characteristics are related to prosocial behavior.

RELATIONS OF PROSOCIAL RESPONDING TO TEMPERAMENT/PERSONALITY CHARACTERISTICS AND DISPOSITIONAL DIFFERENCES IN SOCIAL BEHAVIOR AND VALUES

Although findings differ considerably across measures of prosocial responding, there is evidence of modest consistency across situations and stability across time (see Eisenberg & Fabes, 1998). Nonetheless, distinct types of behaviors (helping versus sharing) tend to be at best weakly interrelated and consistency in general likely increases with age (Eisenberg et al., 2006). Given the diversity of motives likely to be associated with prosocial and empathy-related responses, it is impressive that investigators frequently have found significant relations across situations or time, even if many are modest in size. These associations suggest that there are individual differences in children's prosocial tendencies that can be predicted by variables related to children's temperament, aspects of personality (besides prosociality), and characteristic styles of behavior.

In this section, we briefly review some dispositional and behavioral individual differences that have been examined as predictors/correlates of prosocial tendencies.

Self-Regulation

In studies involving adult-reported or behavioral measures of self-regulation (often defined in terms of processes involved in modulating one's own emotional states and behaviors), prosocial children tend to be relatively well-regulated (e.g., Beauchaine et al., 2013; Carlo, Crockett, Wolff, & Beal, 2012; Laible, Carlo, Panfile, Eye, & Parker, 2010; Padilla-Walker & Christensen, 2011; Padilla-Walker et al., 2010; Yagmurlu & Sanson, 2009, for Australian but not Turkish children; see Eisenberg et al., 2006). Similarly, sympathy has been associated with high levels of children's self-regulation (Eisenberg et al., 1996; Eisenberg, Liew, et al., 2001; Eisenberg et al., 2007; Trommsdorff & Friedlmeier, 1999) whereas personal distress sometimes has been associated with low regulation (Geangu, Benga, Stahl, & Striano, 2011; Ungerer et al., 1990; Valiente et al., 2004). Relations between regulation and sympathy sometimes have been found when controlling for sex (e.g., Valiente et al., 2004) or in a single-sex sample (e.g., Eisenberg et al., 1996; Trommsdorff & Friedlmeier, 1999), suggesting that this relation is not due solely to girls being higher on both self-regulation and sympathy.

The association between regulation and prosociality is not surprising because engaging in prosocial actions likely often requires controlling one's own negative emotion, sustaining attention (Dickert & Slovic, 2009; Trommsdorff & Friedlmeier, 1999), controlling the tendency to focus on one's own wants and needs, and suppressing tendencies to avoid contact with distressed or needy others (see discussion of sociability and shyness, below). However, it is also possible that the same socialization practices that foster self-regulation also foster prosocial behavior and sympathy.

There is also some supportive evidence from physiological data for an association between self-regulation and prosocial behavior. For example, Telzer, Masten, Berkman, Lieberman, and Fuligni (2011) found that neural regions associated with self-control tended to be recruited during prosocial behaviors directed at family members. In addition, baseline RSA, a measure of parasympathetic influence on the heart that is often viewed as an index of physiological emotion regulation, frequently (but not always; e.g., Gill & Calkins, 2003) has been positively related to sympathy or prosocial behavior. Findings for RSA suppression (change in RSA in response to an evocative event) are less consistent

and suggest a positive relation for helping behaviors but not sympathy (Beauchaine et al., 2013; see Hastings et al., 2014, for a review). In some situations, greater suppression followed by augmentation (less RSA)—a pattern of flexible responding to task demands—has been associated with helping behavior (Hastings & Miller, 2014).

Emotionality

Children's positive emotionality or intensity of positive emotions has been positively associated with sympathy (e.g., Eisenberg et al., 1996), empathy with positive emotions (Sallquist, Eisenberg, Spinrad, Eggum, & Gaertner, 2009), and prosocial behavior (Fabes et al., 2012; Volbrecht et al., 2007). These relations may, however, be confounded with children's general social competence.

The data pertaining to negative emotionality are somewhat mixed. In general, children's negative emotionality has been negatively associated with sympathy (Bandstra, Chambers, McGrath, & Moore, 2011; Carlo, Crockett, et al., 2012; Eisenberg et al., 1996) or prosocial behavior (e.g., Laible et al., 2010; Liew et al., 2011). However, positive or nonsignificant relations between negative emotionality or anxiety and sympathy or prosocial behavior have also been found (Broeren, Muris, Diamantopoulou, & Baker, 2013; Laible et al., 2008, 2010; Panfile & Laible, 2012). In studies with toddlers, temperamental fear has been positively associated with personal distress reactions (Liew et al., 2011; Spinrad & Stifter, 2006), but fear also has sometimes positively predicted sympathy reactions in very young children (Spinrad & Stifter, 2006).

In addition, the intensity of the emotion may be related to whether people experience sympathy or personal distress; that is, some degree of negative emotionality may be important in predicting appropriate responses to others' distress (Carlo, Crockett, et al., 2012). If people can maintain their emotional reactions within a tolerable range, perhaps they are more likely to vicariously experience the emotion of needy or distressed others, but are relatively unlikely to become overwhelmed by the emotion and, consequently, self-focused. In contrast, people who are overaroused by vicarious negative emotion are expected to experience that emotion as aversive and as a distressed, self-focused reaction (personal distress). Based on this line of reasoning, the combination of a tendency to experience at least moderate negative emotionality and effective emotion-regulation abilities is thought to contribute to the experience of sympathy and, hence, relate to prosocial behavior. Although the evidence to support this notion has

been complex (see Eisenberg et al., 2006), children who are emotionally reactive but well-regulated are especially sympathetic (e.g., Eisenberg et al., 1996).

Current work on the role of temperamental emotionality in children's empathy and prosocial behavior is limited by the tendency of researchers not to differentiate between different negative emotions (i.e., anger, sadness, fear) and to ignore potential nonlinear relations between prosocial tendencies and emotionality. Moreover, the interaction between regulation and emotionality when predicting empathy-related responding might vary as a function of age, type of negative emotion, and evocativeness of an empathy-inducing stimulus.

Sociability and Shyness

Sociability and shyness appear to influence if and when children assist others. In preschool and beyond, children who are sociable and low in shyness, social anxiety, or social withdrawal are somewhat more empathic/sympathetic and likely to help than are other children (Broeren et al., 2013; Findlay, Girardi, & Coplan, 2006; Howes & Farver, 1987; Inglés, Hidalgo, Mendéz, & Inderbitzen, 2003; Russell et al., 2003; see Eisenberg et al., 2006; contrast with Batanova & Loukas, 2011). Moreover, behavioral inhibition and shyness in toddlerhood have been associated with lower empathy and prosocial behavior toward someone in distress/need, especially strangers (Liew et al., 2011; Young, Fox, & Zahn-Waxler, 1999), whereas social anxiety has been positively correlated with youths' dispositional personal distress but not sympathy (Davis & Franzoi, 1991).

Sociability is particularly likely to be associated with the performance of prosocial behaviors that are spontaneously emitted (rather than in response to a request for assistance; Eisenberg, Cameron, Tryon, & Dodez, 1981; Eisenberg, Pasternack, Cameron, & Tryon, 1984; Eisenberg-Berg & Hand, 1979) or directed toward an unfamiliar person in an unfamiliar setting (rather than a familiar person at home; Stanhope, Bell, & Parker-Cohen, 1987; Young et al., 1999)—situations involving social initiative and social interaction. For example, extroversion (which includes an element of sociability) was related to elementary school children's helping in an emergency when another peer was present (but not when the child was alone) and to helping that involved approaching the other person; introverts tended to help in ways that did not involve approaching the injured individual (Suda & Fouts, 1980). The association between prosocial behavior and both sociability and

shyness can account for part of the genetic influence on prosocial behavior (Knafo & Israel, 2012).

Consistent with the findings for shyness, assertive children (e.g., those who issue commands or defend their possessions) are relatively high in sympathy as opposed to personal distress reactions (Eisenberg et al., 1990) and prosocial behavior (Inglés et al., 2003; Larrieu & Mussen, 1986), particularly spontaneously emitted (unrequested) prosocial behavior (Eisenberg et al., 1984). In contrast, nonassertive, nondominant children tend to be prosocial in response to a request, probably because they receive more requests than their peers and therefore, apparently due to compliance and lack of assertion, respond to a higher frequency (but not proportion) of requests (Eisenberg et al., 1981, 1984, 1988).

Social Competence and Aggression/Externalizing Problems

Because sympathy and prosocial behavior are socially appropriate in many contexts, it is not surprising that children's prosocial behavior and sympathy are related to indexes of socially appropriate behavior, including reports of socially appropriate behavior, peer status and high-quality peer relationships, and coping and problem-solving skills (Caputi et al., 2012; Caravita et al., 2010; Carlo, Mestre, et al., 2012; Gorman et al., 2011; Lansu, Cillessen, & Bukowski, 2013; Malti, Gummerum, Keller, Chaparro, & Buchmann, 2012; Rodkin, Ryan, Jamison, & Wilson, 2012; see Eisenberg et al., 2006). Degree of social competence or peer status may also affect the types of prosocial behavior children prefer to perform (or vice versa). Hampson (1984) found that popular prosocial adolescents tended to engage in peer-related prosocial behavior, whereas less popular helpers preferred non-peer-related tasks.

Especially when considering studies without problematic measures of empathy (see Eisenberg & Miller, 1987), children who are prosocial and/or sympathetic tend to be low in aggression (including bullying) and other externalizing problems (Carlo, Mestre, et al., 2012; Jolliffe & Farrington, 2011; see Eisenberg et al., 2006). Moreover, children's observed disregard for others at 14–36 months in empathy-inducing contexts predicted antisocial behavior in childhood and adolescence (Rhee, Friedman, et al., 2013). Also suggesting an association between low empathy-related responding and externalizing problems, juvenile offenders with psychopathic traits tend to exhibit atypical neural dynamics of pain empathy processing (Cheng, Hung, & Decety, 2012; Lockwood

et al., 2013) and children/youth with disruptive problems or conduct disorders tend to exhibit reduced physiological responding when viewing empathy-inducing stimuli (see Anastassiou-Hadjicharalambous & Warden, 2008; de Wied, van Boxtel, Matthys, & Meeus, 2012). In longitudinal research, aggression/externalizing and empathy or sympathy predict each other over time (e.g., Stavrinides, Georgiou, & Theofanous, 2010), although studies examining bidirectional relations or controlling for prior levels of both variables are difficult to find.

In a meta-analysis, Card, Stucky, Sawalani, and Little (2008) found that, although both direct aggression (physical and overt verbal aggression) and indirect aggression (damaging the target's social position through indirect or covert means; e.g., gossip) were negatively related to prosocial behavior (e.g., helping, sharing, cooperation), when controlling for the effect of the other kind of aggression, the unique relation of direct aggression was negative whereas the unique relation of indirect aggression was positive. Thus, when controlling for level of direct aggression, children and adolescents who tended to use indirect aggression were also those who were more prosocial than other children. This may reflect a high degree of social skills involved in both indirect aggression and prosocial behavior.

The relation between aggressiveness and prosocial behavior is more complex in the early years than at older ages. Gill and Calkins (2003) found a positive relation between aggression and empathy/sympathy in 2-year-olds. The lack of regulation reflected in aggression may allow young children to approach and exhibit concern toward an unfamiliar adult (the measure of concern used in the study). Moreover, Yarrow et al. (1976) found a positive correlation between prosocial and aggressive behavior for preschool boys (but not girls) below the mean in exhibited aggression, and a negative relation for boys above the mean in aggression. For young children who are relatively nonaggressive overall, aggression often may be indicative of assertiveness rather than hostility or the intent to harm another. In contrast, Rhee, Friedman, et al. (2013) found no relation between sympathy at 13–36 months and antisocial behavior in childhood and adolescence, suggesting that early sympathy may not be very predictive of later aggression.

The negative relation between aggression (especially direct aggression) and prosocial tendencies may consolidate with age. Although Hastings, Zahn-Waxler, Robinson, Usher, and Bridges (2000) did not find a relation between concern for others and the behavior problems of 4- to 5-year-olds, children with clinical behavior problems

decreased in their concern and were reported to be relatively low in concern by 6 to 7 years of age. Moreover, greater concern at 4 to 5 years predicted a decline in the severity of externalizing problems over the 2 years.

The inverse relation between prosocial tendencies and externalizing problems found after the early years may reflect, in part, an overlap in the variables contributing to both. Consistent with this possibility, Waldman et al. (2011) found an overlap between the genetic influences on conduct disorder and prosocial tendencies.

Values and Goals

An important component of the self is one's values. Hart and Fegley (1995) found that adolescents who demonstrated exceptional commitments to care for others were particularly likely to describe themselves in terms of moral personality traits and goals and to articulate theories of self in which personal beliefs and philosophies were important (see Walker, 2014, for similar findings). Moreover, adolescents who were more actively involved in community helping activities reported closer agreement with parents about the importance of moral values for the self 2 years later than did their less-involved peers (Pratt, Hunsberger, Pancer, & Alistat, 2003).

More generally, there is evidence that prosocial behavior is positively associated with measures of moral functioning, including other-oriented values and beliefs, social responsibility, guilt or need for reparation, and low levels of moral disengagement (Barry, Padilla-Walker, Madsen, & Nelson, 2008; Cornell & Frick, 2007; Hyde, Shaw, & Moilanen, 2010; Silfver, Helkama, Lönnqvist, & Verkasalo, 2008; see Eisenberg et al., 2006). Furthermore, adolescents sometimes cite moral values and responsibility for others as reasons for enacting prosocial behaviors (e.g., Carlo et al., 1992; Eisenberg et al., 1995). Thus, it appears that older children and adolescents who have internalized moral (including altruistic) values and who view morality as central to their self-concept are particularly likely to be altruistic.

Summary

In general, aspects of temperament/personality and individual differences in social behavior and values are somewhat consistently related to children's and adolescents' prosocial behavior and empathy-related responding. Although associations frequently have been found, they are not

highly consistent and are probably moderated by numerous factors, including type of prosocial behavior (e.g., compliant, spontaneous, egoistically motivated, or altruistic) or empathic response (sympathy, empathy, or personal distress), the context (i.e., the particular situation and recipient, as well as cultural features), other characteristics of the child (e.g., age, sociocognitive abilities, sex), and socialization history. Much more research is needed to delineate both moderating and mediating processes and how they change with age. Moreover, the associations that have been identified may not always be causal; heredity and environmental factors (e.g., parenting, experiences with peers) may affect both children's prosocial tendencies and their functioning in other domains. Future work with genetically sensitive and/or experimental designs is needed to better understand the reasons for these associations.

SEX DIFFERENCES IN CHILDREN'S PROSOCIAL BEHAVIOR

Based on stereotypic gender roles, females generally are expected and believed to be more responsive, empathic, and prosocial than males, whereas males are expected to be relatively independent and achievement oriented. Eisenberg and Fabes (1998), in a large meta-analysis, found a modest sex difference in prosocial behavior favoring girls. Sex differences were greater when prosocial responding was measured with self-reports or reports from others than with observational methods, and were larger for indices reflecting kindness/consideration than for indices reflecting instrumental help, comforting, or sharing. Instrumental help was less predictive of sex differences in prosocial behavior than were other types of prosocial indices when controlling for other study variables. Although sex differences in prosocial behavior tended to get larger with increasing age, this effect was eliminated once other study qualities were controlled.

Gender differences continue to be found in numerous studies since 1998 (e.g., Bellmore et al., 2012; Carlo, Crockett, et al., 2012; Carlo, Mestre, et al., 2012; Malti et al., 2009; Nantel-Vivier et al., 2009; Padilla-Walker & Christensen, 2011; Padilla-Walker et al., 2010; see Eisenberg et al., 2006) and have been found across diverse cultures (e.g., Whiting & Edwards, 1973). To some degree, sex differences in self- and other-reported prosocial responding may reflect people's conceptions of what boys and girls are supposed to be like rather than how they actually behave. Peers, parents, and teachers may tend

to perceive girls as more prosocial than behavioral data indicate (e.g., Shigetomi, Hartmann, & Gelfand, 1981). Moreover, Zarbatany, Hartmann, Gelfand, and Vinciguerra (1985) argued that measures used to evaluate children's prosocial tendencies include a disproportionate number of sex-biased items (pertaining to feminine activities) favoring girls. Nonetheless, there is a modest sex difference favoring girls even in observational studies of prosocial behavior (Eisenberg & Fabes, 1998), so there likely is some truth to the stereotype.

In three separate meta-analyses, investigators found an overall gender difference in empathy/sympathy favoring girls (Chaplin & Aldao, 2012; Eisenberg & Fabes, 1998; Eisenberg & Lennon, 1983), although, as for prosocial behavior, findings vary as a function of method. In the two meta-analyses that examined effect sizes by method (Eisenberg & Fabes, 1998; Eisenberg & Lennon, 1983), large differences favoring girls were found for reports by adults and self-report measures of empathy/sympathy, especially questionnaire indices. No gender differences were found when the measure of empathy was either physiological or unobtrusive observations of nonverbal behavior in experimental contexts (also see Michalska, Kinzler, & Decety, 2013). In work in which sympathy and personal distress have been differentiated, investigators have also found differences in observational studies, many of which involved young children (e.g., Knafo, Zahn-Waxler, et al., 2008; Rhee, Friedman, et al., 2013; see Eisenberg & Fabes, 1998). Eisenberg and Lennon (1983) suggested that the pattern of results was due to differences among measures of empathy in the degree to which both the intent of the measure was obvious and people could control their responses. Thus, when gender-related stereotypes are activated and people can easily control their responses, they may try to project a socially desirable image to others or to themselves. Sex differences in reported empathy increase with age (Eisenberg & Fabes, 1998), as children become more aware of, and are perhaps more likely to internalize, gender-role stereotypes and expectations into their self-image (a finding consistent with the emergence of sex differences in prosocial moral reasoning in adolescence; Eisenberg, Miller, et al., 1991).

In summary, although girls appear to be more prosocial than boys, it is difficult to determine the degree to which the sex difference reflects a difference in moral factors or an other-orientation versus other factors (e.g., self-presentation). Moreover, it seems likely that sex differences change with age for only some aspects and/or measures of prosocial and empathic responding. In future

research, there is a need to better assess the developmental trajectories of the sex differences and to investigate the origins of sex differences in different modes of prosocial responding.

CHALLENGES AND FUTURE DIRECTIONS

There is now considerable research on antecedents and correlates of children's prosocial responding. This research has provided a rudimentary understanding of the factors that may foster prosocial action, although for most environmental influences (with the exception of some experimental interventions), it is premature to confidently assume causation. Many questions remain and the existing body of research cannot adequately address a number of the critical issues regarding development and change in prosocial tendencies.

Many of the deficiencies in the research on prosocial development noted in 1998 and 2006 still exist. Although there is much more research on some topics than a decade ago (e.g., the early emergence of prosocial responding; genetic contributions and the neurological correlates of empathy), the field would benefit from more attention to longitudinal methods and conceptual frameworks, including issues related to process and moderating variables.

Content Areas in Great Need of Attention

A number of content areas require much more attention. For example, researchers' understanding of the role of siblings and peers, as well as the role of the family as a unit involving multiple individuals, is rudimentary. Moreover, mothers, rather than fathers, have usually been studied, so little is known about the role of fathers in prosocial development. In addition, the inconsistent findings on normative trajectories of development for prosocial behaviors and empathy/sympathy indicate that much more work is needed to chart the development of different aspects of prosocial responding and how they vary with the method of assessment. Further work on the earliest indications of empathy or sympathy in infancy is also needed. In addition, although a number of the studies cited in this chapter were from outside North America, there is a need to test the generalizability of many of the findings in non-Western cultures and to identify influences on prosocial development that might be unique to different cultures.

A topic that we believe is of particular importance but has been neglected is the boundary conditions for the

enactment of prosocial behavior or the experience of prosocial emotion and factors that affect these boundaries. There are individual differences in the degree to which various prosocial behaviors and empathy/sympathy are extended to people one knows and cares about, people one does not like, strangers, people in one's social in-group (i.e., groups someone belongs to), and/or people not in the in-group. Eisenberg (1983) reported that elementary school children and adolescents who verbalized higher-level prosocial moral judgment were less likely to differentiate among potential recipients of aid in regard to whom they thought should be helped when in need. Moreover, the motives for prosocial behaviors extended to various groups may differ; for example, prosocial actions directed to members of an out-group or disliked others might tend to be more motivated by internalized moral values (although they could also be motivated by self-protective, reciprocity, and other reasons) than are prosocial behaviors directed at family members and friends. For example, in one study, adolescents' sympathy was related to helping friends and strangers, but not to helping family members, which was related only to supportive mothering (Padilla-Walker & Christensen, 2011). In addition, as was discussed, cultures may differ in their tendencies to help in-group versus out-group members (Knafo, Schwartz, & Levine, 2009).

Although in-group–out-group distinctions in prosocial responding have frequently been examined in social psychology research (see Eisenberg & Spinrad, 2014), there is much less relevant research with children. There is research suggesting that an in-group bias in regard to prosocial behavior increases from 3 to 8 years of age (Fehr, Bernhard, & Rockenbach, 2008) and that 5- to 13-year-olds believe that other children feel more positive about, and more obligation to help, in-group members (Weller & Lagattuta, 2013). Thus, it seems important to examine the early emergence of these biases and factors that affect the degree to which children extend their prosocial tendencies to people beyond the in-group.

Conceptual Models and Methodological Issues

Generally, there is a need to differentiate among different types of prosocial behaviors that involve different motivations and also may differentially rely on empathy, sympathy, or moral values. It only makes sense that the antecedents, sequelae, and correlates of prosocial behaviors that vary in motivation will differ. As one example, although prosocial actions that involve a positive affective response to an individual and those not motivated by

personal gain tend to be negatively related to adolescents' reports of aggression (and their belief that aggression is acceptable), reports of prosocial actions performed for personal gain have been positively related to reported aggressive actions and the acceptance of aggression (Boxer, Tisak, & Goldstein, 2004). Moreover, there is evidence that different modes of prosocial behavior relate differently to different socialization practices (e.g., Carlo, Knight, et al., 2011; Carlo, McGinley, et al., 2007; see Eisenberg & Spinrad, 2014) and differentially predict sympathy, costly prosocial behaviors, and prosocial values across decades (Eisenberg et al., 1999, 2002, 2013). In addition, not all prosocial behaviors are socially appropriate or result in benefits for recipients; indeed, some types of prosocial behavior may even be pathological (e.g., Zahn-Waxler & van Hulle, 2012). Thus, there is a need to better identify the motives, affective states, and values associated with various types of prosocial behaviors, as well as examine the origins, correlates, and consequences of different modes of prosociality.

In this chapter, we discussed a few of the mediators and moderators of relations of various predictors to measures of prosocial responding obtained in the empirical literature. However, as noted in the 2006 chapter of this *Handbook* (Eisenberg et al., 2006), a greater focus on mediation would enhance the field's understanding of the processes related to prosocial development and behavior. For example, little is known about factors that mediate the relations between parental inductions or assignment of responsibilities to children and the children's prosocial behavior or empathy-related responding. Consistent with Hoffman's (2000) thinking, inductions may affect perspective taking and empathy, which then foster prosocial action. Additionally, certain types of interactions with peers or teachers may enhance children's understanding of others' emotions and mental states which, in turn, fosters sympathy. Dispositional emotionality and regulation, or perhaps agreeableness, may mediate the relation between socialization or genetic predispositions and children's sympathy and, hence, their other-oriented prosocial behavior. Examination of such mediational processes requires that investigators refine their conceptual explanations and go beyond looking at global associations to focus on process-oriented explanations.

In contrast, a focus on moderation forces investigators to think about the ways in which predictors of prosocial responding interact in their potential influence. As discussed, genetic contributions to prosocial tendencies are likely often moderated by environmental factors such as

parenting or supportiveness of the social environment more generally. The strength of many predictors of prosocial responding (e.g., perspective taking or parental use of inductions) probably varies depending on factors such as sex, age, general parenting style, cultural experiences, personality predispositions, or children's susceptibility to experience empathy or sympathy. Prosocial behavior in specific situations and even more generally is undoubtedly determined by numerous additive and interacting factors. In addition, it is important to go beyond moderational models to examine the ways in which configurations of numerous variables (e.g., childrearing practices, several personality traits) predict prosocial outcomes.

Most of the research on prosocial development continues to be correlational. To better examine issues of causality, longitudinal designs and structural equation modeling can be used to provide stronger tests of causal hypotheses (although structural modeling with longitudinal data does not prove causality). Longitudinal data are especially important for testing mediated relations. Furthermore, experimental research designs could be used more frequently to test causal assumptions. Although experimental designs usually (but need not) require relatively artificial laboratory situations, researchers have tended to shy away from experiments in the past decade or two. Yet experiments, especially those performed in more natural settings (e.g., at school), can be valuable in testing ideas about causality. Experimental interventions and prevention programs provide a rigorous test of causal relations, and implementing programs that are both cost-effective and impactful is an obvious goal for researchers and policy makers.

A multimethod approach in the design of studies is necessary because different methods address somewhat different questions, including questions about causality. Moreover, all methods of measurement have limitations, but these differ for different measures. Thus, the convergence of findings across methods increases one's confidence in the veracity of the findings. In addition, as illustrated by the results of the Eisenberg and Fabes (1998) meta-analyses, certain types of methods tend to be used with certain ages of children, and this may undermine researchers' ability to understand the development of prosocial behavior.

As illustrated in this chapter, advances in the neuroscience and in genetics are beginning to provide novel methods and data that can inform the field's understanding of prosocial development. Developments in brain-scanning procedures are providing new venues for studying emotion, attention, and decision making and, hence, processes

related to sympathy and prosocial behavior. This technology may provide new insights into the role of emotion and attentional processes in prosocial decision making. Research on the neuroscience and genetics of prosocial behavior and empathy has developed in two separate, almost parallel strands. As genetic effects on prosociality are likely to operate through individual differences in brain structure and function, and possibly also differences in ANS activity, studies combining these methods are highly desirable. For example, in a study of adults' thinking about others' emotions, variation in the gene ZNF804A related to neural activity in the medial prefrontal cortex and left temporoparietal cortex (Walter et al., 2011).

Similarly, it would be important to study the biological aspects of prosocial and empathic responding from an early age, due to the accumulating evidence for the early emergence of relevant behaviors (e.g., Hamlin et al., 2011; Roth-Hanania et al., 2011). There is little developmental research on the neural bases of such behaviors, and we located no longitudinal study covering meaningful developmental ground on the topic. The developmental changes in genetic effects on prosocial behavior and empathy reviewed above also suggest the need to pay attention to different genetic variables and how they affect behavior directly or in conjunction with environmental variables at different stages.

Finally, although the study of prosocial responding has broadened in the last decade in terms of its outreach to related topics in psychology (e.g., peer relationships, the study of regulatory processes) and also neuroscience and genetics, more attention to related domains of study would enrich developmental research on the topic. In addition, investigators studying other issues (e.g., psychopathology, information processing, peer relationships, academic success) would benefit from attending to processes involving prosocial behavior and empathy/sympathy. The broader field of developmental sciences would profit if the boundaries among content areas, as well as across disciplines, were more permeable.

OVERVIEW

Work on the development of children's achievement motivation and engagement has flourished since the sixth edition of this *Handbook*. In this chapter we update and extend Wigfield, Eccles, Schiefele, Roeser, and Davis-Kean's (2006) chapter on motivation in that edition, adding a particular focus on student engagement. Due to space limitations, we focus on the developmental processes involved in motivational changes in diverse groups of

children and include relatively little on the current theories of achievement motivation; for discussion of these theories see Harris, Graham, and Urdan (2012); Wentzel and Wigfield (2009); and Wigfield, Eccles, et al. (2006).

Broadly, motivational psychologists study what moves people to act and why people think and do what they do. Motivation is most directly observable in the level of energy in individuals' behaviors, as well as in the intensity of their engagement. Historically, drives, needs, and reinforcements were proposed as the primary sources

of this energy (see Eccles, Wigfield, & Schiefele, 1998; Schunk, Meece, & Pintrich, 2014), and both needs and related emotions continue to be prominent in some current motivational theories and research. Much current theory and research on motivation, however, focuses on individuals' beliefs, values, and goals as primary influences on motivation (Eccles & Wigfield, 2002; Wigfield, Eccles, et al., 2006). This implies that some of the processes influencing motivation are cognitive, conscious, affective, and often under control of the individual. Due to limited space, we focus primarily on these aspects of motivation. We note in the conclusion of this chapter that there is increasing interest in the biological underpinnings of motivation, and also on unconscious aspects of it; these topics will likely be more prominent in the next edition of this *Handbook*. Because much of the work on motivation in the developmental and educational psychology fields has focused on achievement motivation, we emphasize that in this chapter. Achievement motivation refers specifically to performance on tasks at which one could objectively succeed or fail.

Children and adolescents' motivations relate to their choices about which tasks and activities to do in school and other achievement settings (sports, music, social, etc.), the persistence with which they pursue those activities, the intensity of their engagement in them, and their performance on them. Depending on their motivation, some individuals approach activities in different areas with great persistence and enthusiasm, whereas others seek to avoid these activities. Once engaged in an activity, motivation can influence how diligently the activity is pursued, and the ways in which it is pursued. Fundamentally, then, many achievement motivation theorists and researchers work to understand the motivational predictors of choice, persistence, effort, and engagement on achievement-related tasks and activities (Eccles et al., 1998).

There are important changes in children's motivation as they grow up. The prevailing pattern of change with respect to achievement motivation for many children around the world is a decline with increasing age in children and adolescents' motivational beliefs and values. We discuss the reasons for this decline in this chapter, and also discuss new work showing that the decline varies across different groups of children and do not occur for all children. There are also important individual and group differences in the development of achievement motivation, which we summarize, paying particular attention to the new work on culture, ethnicity, and motivation. Finally, we also summarize work on the influences of different socialization agents, such as parents and teachers, and various contexts on the

development of achievement motivation. Indeed, there has been increasing concern for how different contexts influence motivation or even determine it (Nolen & Ward, 2008).

In the first major section, we focus on the development of different aspects of achievement motivation, primarily focusing on the belief, value, interest, and goal constructs prominent in many current models of motivation (Eccles & Wigfield, 2002). The next section considers gender, cultural, and ethnic differences in motivation, with a special focus on the importance of looking within different groups, as well as how motivational processes in the groups may differ. The next two sections summarize how children's motivation is socialized in the home and school. We conclude with a brief assessment of the field and make suggestions for future research. Because of the large volume of work in the field and the restricted length of this chapter, this review is selective.

Our own theoretical perspective is expectancy-value theory (EVT), particularly the expectancy-value model of achievement choice developed by Eccles and her colleagues (Eccles, 2005, 2009; Eccles-Parsons et al., 1983; Wigfield & Eccles, 2000). This model focuses on the cultural, social, and other influences on the development of children's achievement motivation and its impact on choice, performance, and persistence. The model is presented in Figure 16.1. We assume that the positive and negative components of expectancies and values directly influence performance, persistence, and task choice. We also assume that expectancies and values are influenced by task-specific beliefs such as perceptions of competence, perceptions of the difficulty of different tasks, and individuals' goals and self-schema. We assume that these social cognitive variables are, in turn, influenced by individuals' perceptions of other peoples' attitudes and expectations for them, and by their own interpretations of their previous achievement outcomes and affective reactions to them. Finally, we assume that individuals' task-perceptions and interpretations of their past outcomes are influenced by the socializers' behavior and beliefs, contextual factors, cultural milieu, and unique historical events.

We believe this model provides a strong conceptual framework for thinking broadly about the development of achievement motivation and engagement for the following reasons. First, it includes many of the belief, values, and goal variables that are included in a variety of theories in the field. Second, it focuses directly on how different socializers, such as parents and teachers, influence the development of achievement motivation. Third, broad cultural influences are an essential part of the model, affecting both the processes of the socialization of motivation as

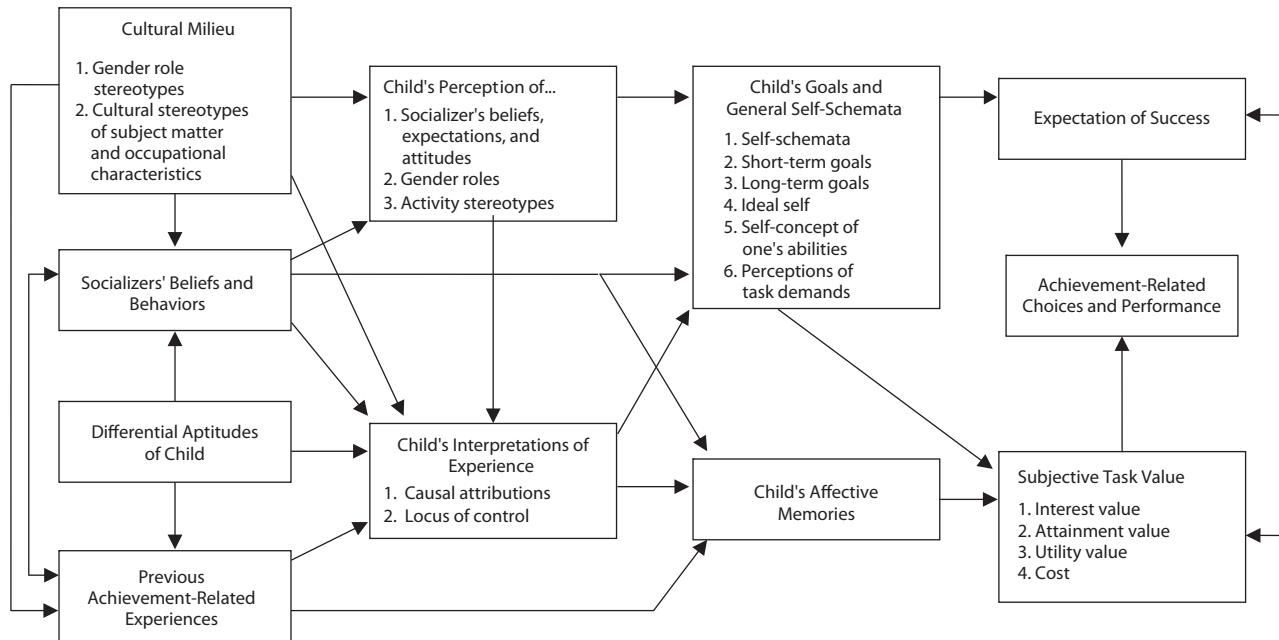

Figure 16.1 Eccles and colleagues' motivational model of achievement performance and choice.

Eisenberg (Ed.), 2006, Vol. 3 of the *Handbook of Child Psychology*, W. Damon and R. M. Lerner (Eds.-in-Chief), 6th ed., Hoboken, NJ: Wiley.

well as how individuals' beliefs, values, and goals develop over time and affect performance and choice.

Along with expectancy-value theory, many current social-cognitive achievement motivation theories emphasize children's beliefs, values, and goals as prominent influences on achievement motivation in academic, physical, and social domains (Eccles et al., 1998; Wentzel & Wigfield, 2009; Wigfield, Eccles, et al., 2006). Central constructs of interest to motivation theorists include self-efficacy, expectancies for success, and other competence-related beliefs; the goals (both specific and general) children have for learning and other activities; children's interest and intrinsic motivation for learning; and children's valuing of achievement (Bandura, 1997; Eccles, 2005, 2009; Maehr & Zusho, 2009; Schiefele, 2009). Although the study of beliefs, goals, and values remains strong, both Eccles and the Self-Determination theorists continue to emphasize the role of the basic psychological needs of competence, autonomy, and relatedness and how they influence motivation (Deci & Ryan, 2012; Eccles, 2009; R. M. Ryan & Deci, 2009). As noted above, there also has been a greater emphasis on contextual influences on motivation; that is, on how children's motivation is affected by different classroom and school environments (Nolen & Ward, 2008). We believe our expectancy-value framework provides a good perspective from which to discuss these issues.

As Eccles et al. (1998) and Wigfield, Eccles, et al. (2006) did, we organize our discussion of the development of motivation around three broad motivation-related questions children can ask themselves: “Can I do this task?” “Do I want to do this task and why?” and “What do I have to do to succeed on this task?” The first two questions are primarily motivational and reflect the ability beliefs, values, and goals in expectancy-value theory and other major motivation theories. The third question merges cognitive and motivational variables crucial to the regulation of achievement behavior.

Competence-related beliefs, including individuals' beliefs about their competence, self-efficacy, and expectancies for success; attributions for success and failure; and beliefs about intelligence relate directly to the question "Can I Do This Task?" and remain prominent in theory and research on achievement motivation in different domains of achievement (e.g., Wentzel & Wigfield, 2009). In general, when children answer this question affirmatively, they try harder, persist longer, perform better, and are motivated to select more challenging tasks.

Although theories dealing with competence-related beliefs provide powerful explanations of individuals' performance, they do not address the second question: Do I want to do this task or activity? Even if people are certain they can do a task, they may not want to engage in

it, and so they may not be strongly motivated to approach it (E. Anderman & Wolters, 2006; Eccles-Parsons et al., 1983; Fredricks, Blumenfeld, & Paris, 2004). Furthermore, individuals often have different purposes or goals for doing different activities, which also affect their motivation for doing so (Maehr & Zusho, 2009). The primary constructs researchers have studied reflecting this question are subjective task values, achievement goals and goal orientations, intrinsic motivation, and interest (Wigfield, Eccles, et al., 2006).

The question “What do I have to do to succeed?” deals with how motivation is translated into action and how individuals’ regulate their achievement behavior (Zimmerman & Schunk, 2011). This work has integrated motivation and cognition to a greater extent than before (Kreitler, 2012). A related topic is how children become engaged or disengaged in their schoolwork or other activities; we present work on that topic after discussing self-regulation. We begin the chapter with discussion of the various components of motivational beliefs, values, and goals and their development. We then discuss the social influences on the development and expression of achievement motivation in both home and school environments.

THE DEVELOPMENT OF ACHIEVEMENT MOTIVATION

Psychologists studying children and adolescents’ motivation examine how the achievement related beliefs, values, and goals develop and differ due to growth and maturation in cognitive and emotional processes, and both individual and group characteristics (such as the, gender, cultural, and ethnic groups to which the individual belongs). Some also focus on socially mediated developmental changes resulting from systematic age-related changes in the social contexts children experience at home, in school, and among peers¹ as they grow up; and socially mediated influences that differ across individuals and contexts. Many researchers take a domain-specific approach in their work, studying the development of children’s beliefs, values, and goals in different achievement domains. We organize our discussion of both the development of achievement motivation and individual differences in achievement motivation and engagement around these broad categories of influence. We begin with a brief discussion of how

very young children begin to evaluate their achievement outcomes in different areas.

Very Early Development of Self-Evaluation in Achievement-Related Activities

How do young children react to accomplishments and failures? It was originally believed that preschoolers would not react to failures in the same way as older children. However, although children younger than 22 months were neither concerned with others’ evaluation of their performance nor self-reflective in their evaluations, they did show positive emotional reactions to accomplishing a task and negative emotions when they did not (Stipek, Rechchia, & McClintic, 1992). At 2 years of age, children do react to success and failure by both seeking approval when they do well and turning away when they do poorly. At 3, preschool children are able to evaluate their successes and failures without adult confirmation and react more strongly to winning and losing than do younger children. Furthermore, Dweck and her colleagues (see Dweck, 2002; Dweck & Master, 2009, for reviews) have shown that some preschool children react quite negatively to failure and suggest that reactions reflect exposure to overly harsh and controlling parenting that includes excessive personal criticism of children when they do not do well. Dweck (2002) argued that children do not have a clear sense of ability as a characteristic that determines outcomes during the preschool years and into kindergarten even though they react emotionally to success and failure. Instead, Dweck and her colleagues (e.g., Heyman, Dweck, & Cain, 1992) found that children believe that success and failure reflect the actions of a good or bad person in a moral sense, arguing that conceptions of goodness and badness rather than competence and incompetence are primary at this time. These early reactions to success and failure can set children on different motivational pathways moving forward.

Competence-Related Beliefs: Can I Do the Task?

Competence Beliefs, Performance, and Choice

Studies in Asia, Europe, and the United States show that children’s competence-related beliefs predict their subsequent performance in different areas as well as their choice of activities to pursue, their levels of engagement, and their persistence (Bong, 2001; Denissen, Zarrett, & Eccles, 2007; Simpkins, Davis-Kean, & Eccles, 2006). Children’s ability beliefs are often a stronger predictor of actual performance than are children’s values, at least in the relatively short term (Meece, Wigfield, & Eccles, 1990;

¹Due to space limitations we do not discuss peer influences on motivation; see A. M. Ryan and Shim (2012) and Wentzel, Baker, and Russell (2009) for reviews of relevant research.

Spinath, Spinath, Harlaar, & Plomin, 2006). Furthermore, differences in these beliefs measured in elementary school predict school course, college major, and occupational choices made many years later (Eccles, Vida, & Barber, 2004; Musu-Gillette, Wigfield, Harring, & Eccles, 2014; Simpkins, Davis-Kean, & Eccles, 2006).

Change in the Mean Level of Children's Competence-Related Beliefs

A hallmark of work since the previous edition of this *Handbook* is the use of advanced longitudinal data analytic approaches such as growth curve modeling to examine change in children's competence beliefs, values, goals, and interests. Generally, current and earlier work show that children's competence beliefs for different tasks decline across the middle childhood and early adolescent years (see Wigfield, Eccles, et al., 2006). On average, young children (Ages 2–8) from many different Western industrialized countries are quite optimistic about their competencies in a wide range of skills; this confidence declines, beginning around Age 7 or 8, on average. In part, these declines reflect increasing realism (that is, stronger correlations with objective indicators of one's relative performance levels) and in part the declines reflect a growing pessimism among children of all abilities levels (Fredericks & Eccles, 2002; Jacobs, Lanza, Osgood, Eccles, & Wigfield, 2002; Spinath & Spinath, 2005; Watt, 2004). Finally, researchers in the United States have found a second period of steep average levels declines at the transition from elementary to middle school at around 10 to 11 years of age (Wigfield, Eccles, Mac Iver, Reuman, & Midgley, 1991).

There are four important caveats about this general "optimism early and realism later" pattern. First, as noted earlier, some preschoolers react quite negatively to failure. The connection between these reactions and children's level of ability beliefs likely begins to develop early in the school years (Ages 4–6), and children reacting negatively to failure early on may be more likely to be pessimistic about their abilities later. Second, there are both individual and group differences in the patterns of change in children's competence beliefs with stronger rates of general decline among those children who perform the most poorly. However, in some studies, low math performers' math self-concepts actually went up when they moved at around Age 12 into tracked math classes in the seventh grade, whereas the math self-concepts of the high performers went down (e.g., Marsh, Trautwein, Lüdtke, Baumert, & Köller, 2007; Wigfield et al., 1991; see Chmielewski, Dumont, & Trautwein, 2013, for similar patterns across school transitions throughout the world). Archambault, Eccles, and Vida (2010)

found seven different trajectories of change in students' competence beliefs in reading. Although these trajectories generally indicated decline in children's competence beliefs, they were markedly different and some showed increases across the high school years. Students whose literacy competence beliefs declined most strongly included boys and lower-SES students. Third, there are cultural differences in change in children's competence beliefs. For example, looking across the middle-school transition (around Age 12), Q. Wang and Pomerantz (2009) found declines in early adolescent American students' but not in Chinese students' beliefs. Fourth, Eccles (2014) reported that finer-grained analyses of the changes show many different patterns, including increases for some children.

In summary, many children's competence beliefs continue to show a pattern of decline. However, there is more variation in this pattern than was once believed. The major processes involved in the changes include the following:

1. Because older children become much better at understanding, interpreting, and integrating the evaluative feedback they receive, and engage in more social comparison with their peers, children become more accurate or realistic in their self-assessments, leading many to become relatively more negative (see Eccles et al., 1998; Nicholls, 1984; Wigfield, Byrnes, & Eccles, 2006).
2. Because school environments in the United States, Europe, and Asia change in ways that make evaluation more salient, frequent, and significant, and competition between students more likely, some children's self-assessments decline as they get older due to increased rates of negative evaluations of their competence (see Wigfield, Byrnes, & Eccles, 2006). Such school environments also lead children to conclude that individual differences in achievement-related abilities are stable, leading children to develop more entity-like beliefs about their own abilities (Dweck, 2006b). These beliefs can lead these children to give up hope of success when they start having difficulty mastering their school work. In school environments where such changes do not occur, children's competence beliefs can remain more positive (we discuss some of these school environment differences later).
3. Because school and home environments differ across cultural groups, the rates of these changes vary across different cultural groups. More research is badly needed to understand these cultural differences.

Another important developmental issue is how stable children's competence beliefs are. Longitudinal studies in

both Germany and the United States looking at relations of children's competence beliefs over time also show that these beliefs become increasingly stable as children get older (e.g., Eccles et al., 1989; Spinath & Steinmayr, 2008; Wigfield et al., 1997). Even by middle childhood, children's competence beliefs correlate quite highly across a 1-year period, with the correlations reaching as high as .74. Thus by early adolescence these beliefs are quite stable, making interventions more difficult. In addition, children's competence-related beliefs correlate more strongly with their achievement as they get older (Wigfield, Byrnes, & Eccles, 2006).

***Changes in Children's Understanding
of Competence-Related Beliefs and the Causes
of Success and Failure***

Several developmentalists have proposed and studied developmental changes in children's understandings of the concept of achievement-related ability (e.g., Dweck, 2006b; Nicholls, 1978). Nicholls and his colleagues (Nicholls, 1978; Nicholls & Miller, 1984) studied children in New Zealand and the United States and were the first to document a developmental progression between Ages 5 and 12 with respect to children's beliefs about ability, effort, and performance. They found four relatively distinct levels of reasoning: At level one (Ages 5 to 6), effort, ability, and performance are not clearly differentiated in terms of cause and effect. At level two (Ages 7 to 9), effort is seen as the primary cause of performance outcomes. At level three (Ages 9 to 12), children begin to differentiate ability and effort as causes of outcomes, but they do not always apply this distinction. Finally, at level four, adolescents clearly differentiate ability and effort, and understand the notion of ability as capacity. They also believe that ability can limit the effects of additional effort on performance, that ability and effort are often related to each other in a compensatory manner, and, consequently, that success requiring a great deal of effort likely reflects limited ability. Folmer et al. (2008) replicated many of these findings in a study of children's understanding of effort and ability when they experience negative outcomes (see also Stipek & Gralinski, 1996). Heyman and her colleagues (Heyman & Compton, 2006; Heyman, Gee, & Giles, 2003) studied how preschool children understood the relations between ability, effort, and task difficulty. They found that even the 3-year-olds could make some inferences about others' ability if given information about how hard they tried, how difficult the task was, or both. Thus Nicholls' (1978) levels may underestimate children's understanding

of ability. The universality of these developmental patterns is not known, and so more studies of them are needed in different countries.

Inherent in Nicholls' (1978) levels of ability is the notion that a developmentally mature view of ability is characterized by the belief that individual differences in abilities represent stable capacities that individuals bring to the task at hand (although see Nicholls, 1984, for discussion of how ego versus task-focused achievement situations can impact children's views of ability). Dweck and colleagues (Dweck, 2006b; Dweck & Master, 2009) argue that this notion of ability (or intelligence, in their terminology) represents only one of two potential views of the essence of ability, one that is fixed and entity-like. They argue that there is another equally mature view of intelligence—one that assumes that current levels of intelligence are changeable. Dweck (2006b) further argued that children and adolescents' motivation to persist at difficult achievement-related tasks, like schoolwork, would depend on how modifiable they believed their current intelligence level is. Children who believe that intelligence can continue to grow and that they can control this growth through their own efforts will persist on achievement tasks even when they are not doing well at the moment. In contrast, children who believe that a particular ability, like math, reflects a stable personal characteristic or entity are likely to give up when they start to experience difficulty succeeding at tasks requiring this ability (see Pomerantz & Saxon, 2001, for a similar argument). An interesting question for future research that would add theoretical clarification in this area is whether children of different ages define "intelligence" and "ability" as the same thing.

Closely related to Dweck's (2006b) distinction between entity and incremental beliefs about one's intelligence is the work on causal attributions. According to attribution theory, people try to explain the causes of their achievement-related successes and failures and these explanations determine their subsequent emotional reactions and success expectations. Attributing one's success to ability and effort and failure to lack of effort are adaptive attributions in that they foster high expectations for future success and feelings of pride in the moment (Graham & Williams, 2009). In contrast, attributing one's failures to lack of ability is particularly debilitating to children's motivation, particularly if one believes that it is impossible or very difficult to increase one's ability level so that one does not continue to fail.

Attribution theorists classify causal attributions into three dimensions—stability, controllability, and internality—and argue that variations on these dimensions

influence the impact of the attributions on subsequent motivation (Graham & Williams, 2009; Weiner, 1985). If individuals attribute their failures to stable, internal, and uncontrollable causes, then their expectations for future success should go down and their motivation for engaging in the tasks on which they are failing should drop. As proposed by Dweck (2006b), the belief that academic abilities are entities could lead to just this type of causal attribution and its associated motivational consequences. In contrast, attributing one's academic failures or difficulties to unstable, internal but controllable causes (like lack of sufficient effort) coupled with a belief that academic abilities are incremental and modifiable (similar to Dweck's mastery-oriented mind-set) should lead to continued efforts to master the material.

Two important developmental questions emerge within this framework, as well as within Dweck's (2006b) framework: Do children's views of the nature of intelligence change with age and do the causal attributions children make for their successes and failures change with age? Both Flammer and Schmid (2003) and Normandeau and Gobeil (1998) found evidence of both types of developmental changes. For example, Normandeau and Gobeil (1998) found that 7-, 9-, and 11-year-old children differ in their understanding of different attribution categories. Eleven-year-olds saw effort and strategy as more internal, controllable, and less stable than did younger children (a result that appears to go against the work showing that young children see effort and ability as less stable).

In sum, work on children's understanding of ability shows that younger and older children have different ideas about the nature of ability and its relations to effort and performance. As noted above, these changes in children's understanding of ability help us understand the negative changes in ability beliefs. One methodological implication of this work is that using the same questionnaire to measure perceived ability at different ages may be problematic given the apparent differences in how younger and older children understand ability.

Development of Self-Efficacy Beliefs

Closely related to beliefs about one's competence are self-efficacy beliefs (Schunk & Pajares, 2009). Over the past 10 years, greater attention has been paid to different types of self-efficacy beliefs (e.g., general self-regulatory efficacy beliefs versus specific skill-mastery efficacy beliefs, etc.). Researchers have found declines in self-regulatory efficacy beliefs. Deatrick et al. (2013) studied the confidence of children in middle childhood and early adolescence in both

their ability to perform certain math skills and their ability to self-regulate their engagement in math learning tasks. Only the latter declined with age; Caprara et al. (2008) obtained similar results in a study of Italian adolescents. These results are similar to results from work on ability beliefs reviewed above, and likely are explained by the same processes. It is unfortunate that aspects of students' self-efficacy decline, but intervention studies have shown that self-efficacy can be increased and positively affect students' academic performance (Schunk & Pajares, 2009).

Usher and her colleagues (e.g., Usher, 2009; Chen & Usher, 2013) studied the information sources children and adolescents use to form their self-efficacy in different subject areas, and also examined how it relates to other constructs. Their findings indicate that the four sources initially defined by Bandura (1997) as determining self-efficacy (previous performance, vicarious experience, verbal persuasion, physiological reactions) are prominent in both children's and adolescents' self-efficacy, with previous performance or mastery relating most strongly to self-efficacy.

At all ages, self-efficacy is a strong predictor of children's and adults' persistence, effort, and self-regulation of their achievement activities. It also predicts performance on different kinds of tasks, and choices of activities to pursue. Klassen and Usher (2010) reviewed evidence showing that self-efficacy also enhances the use of deep cognitive strategies, which can foster students' engagement. However, there are age differences in self-efficacy's relations to performance; the correlations are higher for older than younger children, as is the case for competence beliefs more generally (Davis-Kean et al., 2008).

Schunk and Pajares (2009) discussed processes influencing the development of self-efficacy. These include early mastery experiences that foster a rudimentary sense of personal agency, the growing sense of the self as causing outcomes, and the evaluative information children receive in school and other places. Parents are especially important in fostering mastery experiences and a sense of agency. Schunk and Pajares (2009) stressed the importance of school environments for developing and supporting a high sense of efficacy, or possibly undermining it if support is not provided. We return later in the school influences on achievement motivation section to a discussion of how this can occur.

In summary, important advances over the past 10 years in the understanding of changes in children's competence beliefs and self-efficacy include the discovery that there are different patterns of change in different groups of children, and that children and adolescents utilize the same sources of information to judge their self-efficacy. Researchers

need to understand further changes in competence-related beliefs in children from different cultures, in order to see whether the pattern of decline found in many studies is culture specific or general.

Subjective Task Values: Do I Want to Do the Task?

Values, Performance, and Choice

Students' subjective task values refer to their desire to do different tasks (Eccles-Parsons et al., 1983; Wigfield & Eccles, 2000). Eccles and her colleagues distinguished four value components: interest, importance, utility, and cost (see Eccles-Parsons et al., 1983, and Wigfield & Eccles, 2000, for detailed discussion of these components). Consistently, children's expectancies and values have been shown to predict their performance and choice on different activities; values often predict intentions and choice more strongly than performance (see Wigfield, Eccles, et al., 2006). The most important findings concerning these relations are that values (and competence beliefs) measured when children are young predict their choices much later. Durik, Vida, and Eccles (2006) found that 10-year-old children's values and self-concepts of ability in reading predicted these same beliefs and values in middle adolescence as well as how adolescents' engagement in leisure-time reading and plans to have careers that involve much reading. Similarly, in Simpkins, Davis-Kean, and Eccles' (2006) study, students' math values and ability beliefs measured at Age 11 predicted these beliefs and values at Age 17, as well as the students' enrollment in advanced high school math courses.

Wigfield, Eccles, et al. (2006) concluded from their review of extant research that children's ability beliefs are more predictive of subsequent performance, whereas children's values are predictive of task choice. Subsequent studies looking at these relations over time show that both constructs predict both performance and choices. The relations of values and performance begin quite early: Viljaranta, Lerkkanen, Poikkeus, Aunola, and Nurmi (2009) found that 5- and 6-year-old Finnish children's interest in math early in the school year predicted math achievement measured in the following spring. The relationship was reciprocal: Higher performing children early in the school year reported higher math interest later in the year.

Trautwein and his colleagues (Nagengast et al., 2011; Trautwein et al., 2012) have examined the effects of expectancies, different aspects of values, and the interaction of expectancies and values on the math and English performance of a large sample of German high school students. Both expectancies and the different aspects of value

(interest, attainment, and utility) predicted performance. When students' values were entered into the model after expectancies, values were no longer a significant predictor of performance. However, the expectancies by values interaction term was a significant predictor in both models with value increasing the positive effect of expectancies (although the interaction effects generally are small in size). Nagengast et al. (2011) found this same interaction in studies of students' engagement in science and intentions to pursue science careers, in a sample of nearly 400,000 students from 57 countries. The findings generalized across the countries.

Another important aspect of values is the anticipated cost of engaging in any particular activity. Cost includes anticipated negative emotional experiences as well as the loss of time and energy to undertake other activities. For example, choosing one major in college means that other majors cannot be pursued. Conley (2012), in a study of variables from expectancy-value theory and goal-orientation theory, found that cost differentiated students with positive motivation patterns from those with negative patterns. Other work showed that cost negatively predicts adolescents' achievement, plans to take AP courses, and plans to pursue science careers (Kirkpatrick, Chang, Lee, Tas, & Anderman, 2013; Safavian, Conley, & Karabenick, 2013). These findings show the power of cost in predicting different outcomes.

Anxiety is the most commonly studied psychological cost associated with academic learning tasks. Both general anxiety and test anxiety interfere with children and adolescents' learning and performance in evaluative situations, with these findings occurring across the world (Zeidner, 2007; Zeidner & Matthews, 2011). The problem of anxiety gets worse as evaluation and accountability become more emphasized in schools (Deci & Ryan, 2002b; Zeidner, 2007). Furthermore, anxiety increases across the school years as children and adolescents face more frequent evaluation, social comparison, and (for some) experiences of failure (Deci & Ryan, 2002b; Zeidner, 2007; Zeidner & Matthews, 2011). Interventions to alleviate anxiety focus on either the emotional/physiological part of anxiety, the cognitive or worry part, or both (Zeidner & Matthews, 2011). Programs focused on emotionality utilize relaxation and desensitization techniques. Those focused on worry work to alleviate the negative, self-deprecating thoughts of anxious individuals and replacing them with more positive, task-focused thoughts. This latter kind of program has been more successful both in lowering anxiety and improving performance than those focused solely on emotionality (Zeidner, 2007).

Mean Level Change in Subjective Task Values

As with competence-related beliefs, studies done in the United States, Australia, and Germany generally show age-related decline in children's valuing of certain academic tasks. Jacobs et al. (2002) found that children's valuing of the domains of math, language arts, and sports declined. As was the case for competence beliefs, children's valuing of language arts declined most during elementary school and then leveled off. By contrast, children's valuing of math declined the most during high school (see also Fredericks & Eccles, 2002, and Watt, 2004). Researchers have begun to address different patterns of change in students' valuing of activities in different domains. Archambault et al. (2010) found seven different trajectories of change in students' valuing of reading; all trajectories showed decline, although the patterns were markedly different.

The Relation of Subjective Task-Value Beliefs and Competence Beliefs

An important developmental question is how children's developing competence beliefs relate to their developing subjective task values. According to both Eccles-Parsons et al.'s (1983) expectancy-value model and Bandura's (1997) self-efficacy theory, ability self-concepts influence the development of task values. Bandura (1997) argued that interests emerge out of one's sense of self-efficacy and that children should be more interested in challenging than in easy tasks. Taking a developmental perspective, Wigfield (1994) proposed that initially young children's competence and task-value beliefs are likely to be relatively independent of each other. This independence would mean that children might pursue some achievement activities in which they are interested regardless of how good or bad they think they are at the activity. Over time, particularly in the achievement domains, children may begin to attach more value to activities on which they do well. One important process here is that children may lower the value they attach to activities that they have difficulty with in order to maintain positive ability beliefs and self-esteem (Covington, 2009; Eccles, 2005; Harter, 2012). In support of this view, Jacobs et al. (2002) found that changes in competence beliefs predicted changes in children's valuing of the activities, accounting for as much as 40% of the variance in change in children's valuing of the activities (see Denissen et al., 2007, for similar results). These results suggest that the causal direction in this relation goes from competence beliefs to values, but more longitudinal work is needed to assess the strength of these relations. Indeed, longitudinal studies in Germany by Spinath and Steinmayr (2012) show that competence

beliefs and intrinsic motivation relate positively to one another at each measurement point but do not show causal relations over time. This work is especially important for understanding how beliefs and values may work together to affect motivation, and how children's competence beliefs potentially are the driving force in this relationship.

Children's Understanding of the Components of Task Value

It seems likely that a 6- or 8-year-old will have a different sense of what it means for a task to be "useful" than an 11-year-old does. Further, it also is likely that there are differences across age in which components of achievement values are most dominant. Wigfield and Eccles (1992) suggested that interest value may be especially salient during the early school grades with young children's activity choices being most directly related to their interests (see also Hidi & Renninger, 2006). Young children likely will try many different activities for a short time each before determining which activities they enjoy the most. As children get older the perceived utility and personal importance of different tasks likely become more salient, especially for achievement activities that have implications for their futures and also as they develop more stable self-schema and long-range goals and plans. Eccles (2009) has argued repeatedly that processes related to identity formation and enactment are directly related to the relative subjective value of various activities. Because identity processes become more salient during adolescence and early adulthood, these aspects of subjective task value should become more important determinants of task choice and engagement during these years (see Oyserman & Fryberg, 2006, for a similar argument). Unfortunately, researchers have not addressed changes in children's understandings of the components of task value identified by Eccles-Parsons et al. (1983) and thus these developmental predictions need to be tested.

Interest

Closely related to the idea of subjective task value is the idea of interest. Much of the research on interest development has focused on age-related changes in the specificity and the sources of interest. In general, this work (done primarily in the United States and Germany) suggests that young children have quite general or universal interests that become more specific relatively quickly as they mature (see Eccles et al., 1998; Schiefele, 2009). This early differentiation eventually leads to individual differences in interests in a variety of different activities.

The next phase of interest development—between 3 and 8 years of age—is characterized by the formation

of gender-specific interests. The acquisition of gender identity leads to gender-specific behaviors, attitudes, and interests. Children strive to behave consistently with their gender identity, and, thus, evaluate activities or objects consistent with their gender identity more positively than other activities or objects. As a consequence, boys and girls develop gender-role stereotyped interests (see Eccles, 1994, 2013; Ruble, Martin, & Berenbaum, 2006).

At the next stage (Ages 9–13), the emerging self-concept is assumed to be linked more directly to social group affiliation and cognitive ability, leading to occupational interests consistent with one's social class and ability self-concepts. The final stage (occurring after Age 13 or 14) is characterized by an orientation to the internal, unique self leading to more differentiated and individualized vocational interests, based on abstract concepts of self (e.g., of personality). Thus, the development of vocational interests is a process of continuous elimination of interests that do not fit the self-concepts of one's gender, social group affiliation, ability, and personal identity (Eccles, 2009). This process is assumed to depend both on the general cognitive development as well as shifts in social roles, scripts, and demands.

It is also likely that changing needs or motives across the life span can influence the development of interests. A good example is early adolescents' increasing interest in biology and psychology during puberty. The need to know oneself and to cope with rapid bodily and psychological changes seems to foster interest in biological and psychological domains of knowledge at this age.

Hidi and Renninger (2006) and Renninger and Su (2012) proposed a model that addresses the development of specific interests. First, like others (Schiefele, 2009), they distinguish between situational or short-term interests and personal or well-developed and long-term interests. They posited that the development of such interests occurs over four phases. The first phase, *triggered situational interest*, is a state of heightened attention, curiosity, and positive affect. Typically, situational interest is initiated by aspects of the learning environment (e.g., an exciting lesson in which the teacher conveys novel and surprising information). The second phase, *maintained situational interest*, involves the repeated and increasingly persistent experience of situational interest. Personally meaningful and involving tasks, for example, facilitate this phase of interest development. The third phase, *emerging individual interest*, is the initial phase of a relatively enduring individual interest. Based on the emerging formation of stored valence beliefs, the person tends to reengage

with particular tasks or topics. Finally, the fourth phase, *well-developed individual interest*, is characterized by stronger valence beliefs and higher amounts of knowledge than an emerging interest. According to Hidi and Renninger, individuals with a well-developed interest more often than others choose interest-related activities, sustain long-term constructive and creative endeavors, and persist when interest-related tasks or activities are difficult; thus there are strong parallels in this work and expectancy-value theory. A crucial point related to our overall discussion of change in motivation, of course, is what kinds of personal interests grow in children, and how many of them relate to school and academic performance?

In summary, as with competence-related beliefs, research in the past 10 years has established that there are different patterns of change in children's achievement values. We also have learned more about how children's competence beliefs influence their values, an important process that has implications for their self-esteem. As we noted above, value and interest are related constructs, and Hidi and Renninger (2006) discussed how children's personal interests lead them to do valued tasks. Theoretically it would be interesting to define more clearly the interplay between these two constructs.

Intrinsic Motivation Versus Extrinsic Motivation: Why Do I Want to Do the Task?

There is a fundamental distinction in the motivation literature between *intrinsic* motivation and *extrinsic* motivation. When individuals are intrinsically motivated, they do activities for their own sake, based on their own volition and out of personal interest in the activity. When extrinsically motivated, individuals do activities for instrumental or other reasons, such as receiving a reward (see R. M. Ryan & Deci, 2009). A great deal of research in motivation, particularly in the area of Self-Determination Theory (SDT), has focused on the relative benefits and costs of these two different motivational orientations.

SDT is a comprehensive theory of motivation and well-being; reviews of its many different aspects can be found in Deci and Ryan (2002a, 2012) and R. M. Ryan and Deci (2009). These authors have proposed that humans have three basic needs that are universal: autonomy, competence, and relatedness. When these needs are met, children and adolescents have a stronger sense of well-being. Both parents and teachers can help children meet their needs by supporting them as they try to do things autonomously, helping them develop a sense of competence, and helping

them build relations with others. Various researchers have studied specific ways in which parents can support children; see Grolnick, Gurland, Jacob, and Decourcey (2002) and further discussion below in the section on socialization of motivation in the family for what the research says about positive parenting practices for meeting children's needs. Similarly, the ways teachers relate to students can help them fulfil their needs, or impede their development, depending on the ways instructional practices are structured. The claim that needs are universal has, of course, led to research exploring whether they indeed are; this research often has focused on the need for autonomy because it is not clear whether that need is as prevalent in cultures defined as collectivist (Markus & Kitayama, 2003). To date, the research has shown that each need is prevalent in a wide variety of countries, but may be expressed somewhat differently (see Chirkov, Ryan, & Sheldon, 2011, for review).

Intrinsic and extrinsic motivation are major aspects of the theory that are most directly relevant to this chapter. Deci and Ryan (2012) stated that extrinsic and intrinsic motivation lie on a continuum rather than comprising a dichotomy. At one end of the continuum are amotivation and externally regulated motivation (motivation controlled by rewards), and at the other, intrinsic motivation. R. M. Ryan and Deci (2009) proposed that healthy development involves moving from extrinsic to intrinsic motivation. This model is not explicitly developmental because individuals can cycle through the motivation continuum at different points and on different activities, but R. M. Ryan and Deci (2009) argued that being intrinsically motivated relates strongly to well-being, and so is an important developmental outcome. When individuals are intrinsically motivated, they are in control of their own actions (autonomous), believe they can accomplish things (competence), and are connected to others (relatedness). Thus satisfaction of the needs ties directly to becoming intrinsically motivated.

Unfortunately, studies of the developmental course of intrinsic motivation suggest that it declines as children grow up. In a longitudinal study of children in the United States, Gottfried and Gottfried found a general pattern of decline in children's intrinsic motivation for math and general school from Ages 10 to 17 (Gottfried, Fleming, & Gottfried, 2001; Gottfried, Marcoulides, Gottfried, Oliver, & Guerin, 2007; see also Corpus, McClintic-Gilbert, & Hayenga, 2009). Interestingly, this decline is less pronounced for higher achievers (Gottfried et al., 2007; Marcoulides, Gottfried, Gottfried, & Oliver, 2008). Further,

the decline in intrinsic motivation predicted declines in academic attainment. Another important finding research is that children's intrinsic motivation is quite stable in children aged 13 and above; Gottfried et al., 2001). The greater stability means that the decline in children's intrinsic motivation likely becomes more difficult to change as children get older.

Similar patterns have been shown in longitudinal European studies, particularly for the natural sciences and mathematics (e.g., Hedelin & Sjöberg, 1989) and particularly during the early adolescent years. Researchers have explained these findings by pointing to particular aspects of instruction such as high achievement pressure and low levels of clarity of presentation, classroom management, supportive behavior, and cognitively stimulating experiences that may contribute to declining interest in school subjects (e.g., Eccles & Midgley, 1989; Kunter, Baumert, & Köller, 2007; Wigfield, Eccles, et al., 2006).

SDT researchers also have extensively studied and debated the effects of rewards on intrinsic motivation, noting conditions under which rewards actually undermine intrinsic motivation. Due to space limitations we cannot discuss that work here; see Deci, Koestner, and Ryan (1999) and Wigfield, Eccles, et al. (2006) for reviews. Overall, we concur with their conclusions about the detrimental effects of some kinds of external rewards on intrinsic motivation.

Achievement Goal Orientations: Why Am I Doing the Task?

Goal orientations refer to the approaches students take to their learning. Researchers initially defined three primary goal orientations: mastery orientation, performance orientation, and work-avoidant orientation (Maehr & Zusho, 2009). Mastery goals reflect an orientation focused on learning material and seeking improvement. Performance goals involve the demonstration of ability; students who are performance-oriented want to show they are able and (in some views of performance goals) that they can outperform others. Researchers have distinguished approach and avoid goals for both of these types of goal orientations. Performance approach goals refer to the demonstration of one's ability and (in some views of this construct) the desire to outperform others; whereas performance avoid goals are the desire to not appear incompetent (Elliot & Murayama, 2008; Hulleman & Senko, 2010; Murayama, Elliot, & Friedman, 2012). Mastery approach goals involve learning and improvement; mastery avoid goals involve working to

avoid losing abilities, and perfectionism. Work-avoidant goals are the desire to do as little as possible in school. Elliot, Murayama, and Pekrun (2011) reconceptualized the extant goal-orientation models to distinguish between the standards of information people use to judge their competence under mastery and performance orientations. They distinguished self standards, or individuals' sense of how their performance relates to the trajectory of their competence growth; task standards that come from characteristics of the tasks being done; and other standards, or how one's performance compares to that of others. There are approach and avoidance aspects of each of these information standards. The model is therefore a three (standard of evaluation) by two (approach/avoid) model of goal orientations. Ongoing research is assessing this model.

The association of mastery, performance, and work avoidance goal orientations with motivation and achievement has been researched extensively over the past 25 years (see Hulleman & Senko, 2010; Maehr & Zusho, 2009, for reviews). There is growing evidence of the positive consequences of mastery orientation (particularly mastery approach goals) for self-efficacy, use of deeper cognitive strategies, and intrinsic motivation to learn (Hulleman & Senko, 2010). It is less clear, however, if mastery approach goals relate to achievement; they do in studies of U.S. children aged 5 to 17, but not as much in college students (Keys, Conley, Duncan, & Domina, 2012). Interestingly, in Senko and Miles' (2008) study, mastery-oriented college students got lower grades than other students in part because they focused on their own interests in the course rather than the course requirements.

The evidence regarding performance goals also depends on whether performance approach or performance avoid goals are assessed. By and large, performance avoid goals have strong negative consequences for student motivation and learning, relating to poorer performance, willingness to cheat, higher anxiety, and so on (e.g., A. H. Anderman & Murdock, 2007; Middleton & Midgley, 1997; see Hulleman & Senko, 2010; and Murayama et al., 2012, for review). In contrast, performance approach goals relate positively to academic self-concept, task value, and performance (Harackiewicz, Barron, Pintrich, Elliot, & Thrash, 2002; Murayama et al., 2012; Senko, Hulleman, & Harackiewicz, 2011). Finally, work avoidant goals relate negatively to other aspects of motivation and performance (Meece & Miller, 2001; Wigfield, Cambria, & Ho, 2012; Wigfield & Guthrie, 1997).

Short-term longitudinal studies done primarily in the United States show low to moderate stability in children's

mastery and performance goals from Ages 11 to 16 (Meece & Miller, 2001; Wolters, Yu, & Pintrich, 1996), with less stability across the elementary to middle school transition (Ages 10 to 11) than during the last year of elementary school, which occurs around Age 10 for most students in the United States (E. M. Anderman & Midgley, 1997; Meece & Miller, 2001). Interestingly, students also reported that teachers emphasized performance goals more in middle than in elementary school, suggesting that students' performance goals may increase during middle school.

Researchers have examined how children's achievement-goal orientations relate to the other constructs we have discussed so far. Pintrich and Wolters did early work in this area, looking at relations of task values, self-efficacy, achievement-goal orientations, and self-regulation in middle-school students (Pintrich, Ryan, & Patrick, 1998; Wolters et al., 1996; see Wigfield & Cambria, 2010, for review). This work shows that children's mastery goals, task values, and self-regulation are positively related. Wolters, Fan, and Daugherty (2013) found that 14- to 17-year-olds holding performance approach goals attributed success more to ability and failure less so. Somewhat surprisingly, students holding mastery goals were less likely to explain failure as due to lack of effort. Finally, Conley (2012) found seven clusters of students' goals, values, and competence beliefs. Interestingly, the cost aspect of subjective task value was the variable that differentiated students with positive patterns of goals, values, and competence beliefs from those with less positive patterns. We anticipate more integrative research of this sort will occur.

In studies in both the United States and Europe, there are declines in both mastery and performance goals from about Age 10 to 14 (Meece & Miller, 2001; Shim, Ryan, & Anderson, 2008). These declines appear to stabilize after Age 14 in Finland (Tuominen-Soini, Salmela-Aro, & Niemivirta, 2011). These results run somewhat contrary to the prediction that, due to increasing evaluative pressure in high school, performance goals should take precedence over mastery goals.

The Role of Social and Academic Goals in Achievement

Researchers also have studied other types of goals that might motivate behavior in academic achievement settings (see Wentzel, 2013, for review). This work differs from that of the achievement goal orientation theorists in that it focuses on the *content* of children's goals to guide and

direct behavior, rather than the criteria they use to define success or failure (i.e., mastery versus performance). In this sense, these goals are like the goals and self-schema that relate to attainment value hierarchies in the Eccles-Parsons et al. (1983) expectancy value model. Wentzel (2002, 2013) often has focused on both academic and social goals in her work.

Research on children's social goals (e.g., Urdan & Maehr, 1995; Wentzel, 2002) shows that both social and academic goals relate to adolescents' school performance and behavior. Higher-achieving students have higher levels of both social responsibility and achievement goals than lower-achieving students. A. M. Ryan and Shim (2008) studied 12-year-old students' social development goals, or goals focused on developing social competence, and social demonstration approach and avoid goals (wanting to be popular, or avoid negative judgments from others). They found over the course of a school year that the students with social development goals were better adjusted than those with social demonstration avoid goals. Further, A. M. Ryan and Shin (2011) found that students holding social demonstration avoid goals were less likely to seek academic help when they needed it. More broadly, Rodkin and Ryan (2012) reviewed research showing that, in the United States, adolescents seeking popularity at the expense of academic goals are more likely to engage in risky behaviors and less likely to engage academically. Thus an overly strong focus on social goals appears to have a negative impact on students' engagement and achievement when these goals conflict with academic goals (see also Wentzel, 2005).

In summary, work on achievement goals over the past 10 years has defined these goals with greater precision and identified additional dimensions of them. There is a strong need to examine more closely how children's goal orientations develop over time, and relate to the other motivation constructs we discuss in this chapter. The same is true for the work on children's social and academic goals.

Self-Regulated Learning: What Do I Need to Do to Succeed?

What are some processes that translate motivational beliefs, values, and goals into action? One is self-regulated learning. For instance, higher-achieving U.S. middle adolescents use more self-regulated learning strategies than do average or low achievers. Furthermore, students with higher self-efficacy regulate their behavior more strongly to attain their goals (Zimmerman & Schunk, 2008). Similarly,

children who value their achievement and are intrinsically motivated are more likely to regulate their behavior in order to accomplish what is valuable and interesting to them (R. M. Ryan & Deci, 2009). Children with mastery goals and performance approach goals also engage in more self-regulatory strategies, as discussed earlier. There is also some evidence that the relations between children's motivational beliefs and their self-regulated learning and achievement increase as they get older (Pintrich & Zusho, 2002; Wolters, 2003). How does self-regulated learning develop?

Eccles et al. (1998) reviewed the early work on how young children learn to regulate their impulses and delay gratification (see also McClelland, Geldhof, Cameron, & Wanless, Chapter 14, this *Handbook*, Volume 1; and Thompson, Chapter 6, this *Handbook*, this volume, for discussion of self-regulation).

Turning to self-regulated learning, Zimmerman (2000) proposed a four-step developmental sequence to describe it. First, children learn effective regulatory strategies by observing successful models and focusing on process goals. Second, children imitate the strategies, following what the model did relatively closely. Third, they learn to use the strategies apart from the model; Zimmerman (2000) called this self-controlled learning. Although children do the strategies on their own, they still are dependent on the model. Finally, in the self-regulated learning phase, children begin to both use the strategies in different situations and tailor them to their own purposes. They also focus more on outcome goals.

Knowing when to seek help is one important part of self-regulation (Newman, 2002). There are developmental differences in help seeking; in the United States, younger children are more likely to ask for help than are older children (Marchand & Skinner, 2007); older children are also more likely than younger students to engage in help avoidance (A. M. Ryan, Shim, Lampkins-Uthando, Kiefer, & Thompson, 2009). A. M. Ryan and Shim (2012) found that 11-year-old children's adaptive help seeking from peers decreased as they made the transition to middle school, but that this was moderated by students' perceptions of classroom goal structure. When students perceived teachers emphasizing mastery goals, their adaptive help seeking increased. Thus contextual factors are an important determinant of children's willingness to seek help. It is unfortunate that students who likely need more help are less likely to seek it; research indicates that lower achievers are often less willing to ask for help than high achievers (Newman, 2002).

Engagement in Learning and Other Achievement-Related Activities

Another way that motivation influences achievement is through engagement. The topic of children's engagement has received increasing attention in the past 10 years, with a major handbook on engagement published in 2012 by Christenson, Reschly, and Wylie. There has been a long-standing tradition within sociology of studying how school disengagement predicts dropping out of school (Rumberger & Rotermund, 2012). The models in this area focus on demographic variables such as risky school and family characteristics, risky psychological characteristics and behavior such as self-control difficulties, and low school achievement as predictors of drop out. These scholars argue that these factors lead students to disengage gradually from school, and then ultimately to drop out (see also Wehlage, Rutter, Smith, Lesko, & Fernandez, 1989).

Developmental and educational psychologists have also become interested in the nature of engagement, and its relations to motivation and achievement. In a seminal article, Fredricks et al. (2004) concluded that engagement is a multidimensional construct that includes behavioral, cognitive, and emotional attributes associated with being deeply involved in an activity. They defined behavioral engagement as positive conduct, involvement in academic tasks (as indicated by effort and persistence), and participation in various school activities. Cognitive engagement was defined as the active use of cognitive strategies and other cognitive resources in learning activities; this aspect of engagement relates closely to the self-regulatory processes just discussed. Emotional engagement encompasses the ways in which students react affectively to classroom activities (see Pekrun & Linnenbrink-Garcia, 2012, for a broader discussion of motivation and emotion). Reeve (2012; Reeve & Tseng, 2011) modified Fredricks's typology by adding what they call agentic engagement—"students' constructive contribution into the flow of the instruction they receive" (Reeve & Tseng, p. 258). This interesting construct needs further research before it is considered a component of engagement. Both Reeve and Tseng (2011) and Fredricks et al. (2004) consider engagement to be a metaconstruct, meaning that it is broader than many other constructs (such as motivation) and encompasses a variety of these constructs.

Both Reeve and Tseng (2011) and M. T. Wang, Willett, and Eccles (2011) documented the multidimensional factor structure of these components of engagement and showed that the factor structure is invariant across gender and

race in adolescents within the United States and Taiwan. Further, M. T. Wang and Eccles (2012a) found a decline in all three of these components of engagement from Ages 12 to 16, with both the sense of school belonging (one of the indicators of emotional engagement) and behavioral engagement declining to a greater extent than self-regulated learning (a component of cognitive engagement). Similar declines have been documented in Finnish adolescents (see Upadyaya & Salmela-Aro, 2013). These findings mirror the declines in motivational beliefs and values discussed earlier.

Fredricks et al. (2004) and Upadyaya and Salmela-Aro (2013) reviewed research showing that various forms of engagement relate positively to adolescents' academic achievement and well-being. Similarly, when students attend school regularly, work hard in their class, and become involved in extracurricular activities, they are less likely to drop out (see also Rumberger & Rotermund, 2012). Furthermore, in M. T. Wang et al.'s (2011) study, the rates of decline in both cognitive and behavioral engagement predicted declines in GPA and declines in all three components predicted declines in educational aspirations. In Reeve and Tseng's (2011) study, all four components of engagement mediated the relationship between motivation and academic achievement among adolescents. Using a person-centered approach, M. T. Wang and Peck (2013) identified five engagement prototypes: highly engaged, moderately engaged, and minimally engaged (each of these three prototypes showed consistent levels of engagement across all three types of engagement), emotionally disengaged, and cognitively disengaged. They showed that these groups differ in their educational and psychological functioning with the minimally engaged being most likely to drop out of high school and least likely to go on to college (exactly the opposite pattern was evident for the highly engaged). Similarly, the minimally engaged and the emotionally disengaged showed the highest levels of depressive affect and the highly engaged showed the least. These findings show the importance of maintaining students' engagement in school.

Skinner and her colleagues (see Skinner, Kindermann, Connell, & Wellborn, 2009; Skinner & Pitzer, 2012) presented another model of the development of engagement and its effects on different outcomes. They argued that engagement is the instantiation of motivation. Like Fredricks et al. (2004), Skinner et al. (2009) distinguished behavioral, cognitive, and emotional aspects of engagement and discussed antecedents of engagement. Importantly, like Salmela-Aro and colleagues (see Upadyaya & Salmela-

Aro, 2013), they distinguished between engagement and disaffection; disaffection is the opposite of engagement and consists of a variety of behaviors, emotions, and cognitions. For instance, engagement implies effort and exertion; disaffection implies giving up and withdrawal. Engagement means goal strivings, enthusiasm, and interest; disaffection means boredom, disinterest, and resignation. Skinner and her colleagues (Furer & Skinner, 2003; see Skinner et al., 2009) have documented the predictive role of both engagement and disaffection in predicting the academic achievement of children in middle childhood and early adolescence.

Eccles, Fredricks, and Baay (in press) discussed the relation between EVT and the work on engagement, stressing the processes by which engagement is fostered. Eccles and Wang (2012) discussed how the distal and proximal influences in the Eccles-Parsons et al. (1983) expectancy-value model presented earlier influence engagement. They also pointed to the importance of affect in determining engagement: positive affect stems from success experiences and pleasurable participation in activities heightens engagement, whereas negative affect reduces it. In support of these suggestions, M. T. Wang and Eccles (2012b) showed that social support from parents, teachers, and peers increased several aspects of school engagement, as well as the subjective task value of learning (see Upadyaya & Salmela-Aro and Skinner & Pitzer, 2012, for review of additional kinds of support).

In summary, self-regulation and engagement have to do with translating motivation into effective action. Over the past 10 years, the work on engagement has played a more central role in the motivation field. There are a number of challenging issues with respect to it, however. As Fredricks et al. (2004) initially noted, definitions of engagement are not yet clear, and the different aspects of engagement often are not clearly distinguished conceptually or operationally (see Reschly & Christenson, 2012, and Eccles & Wang, 2012, for further discussion). Along with clearer definitions, Eccles and Wang (2012) note that the different levels of engagement need to be more clearly defined and separated: Individual, classroom, school, and community levels of engagement each have unique characteristics that need to be reflected in definitions and measures. Measurement remains a problem because there are a variety of measures in the literature that do not necessarily operationalize engagement in the same ways. Additionally, Eccles and Wang (2012) discussed the thorny problems of distinguishing between engagement and motivation. Somewhat similarly, there is conceptual overlap between

cognitive engagement and self-regulation; for theoretical clarity researchers should investigate the relations of these constructs. Finally, a clearer understanding is needed of the development of engagement and the different forms that it takes.

GENDER, CULTURAL, AND ETHNIC DIFFERENCES IN ACHIEVEMENT MOTIVATION

There has been considerable interest for at least the past 60 years in group differences in achievement motivation. Wigfield, Eccles, et al. (2006) reviewed the empirical evidence for such differences extensively so we focus here primarily on important work done since then on such differences. But the most important shift on this topic over the past 10–15 years has been the movement from a focus on between-group mean-level differences to a much greater focus on within-group heterogeneity, coupled with an increasing sensitivity to the difficulty of interpreting mean-level group differences in precise, theoretically meaningful, and policy-relevant ways. In addition, there is an increasing sensitivity to potential risks associated with the misuse of information on group-level differences by policymakers and practitioners—misuse that can further the inequities in educational experiences and outcomes for various groups.

There has also been greater attention to the question of whether one should focus on mean-level differences on various constructs or group differences in the nature of the relations among the constructs themselves. It could be that group differences in the outcomes of motivated behavior such as school achievement result from group differences in the mean levels of the various constructs, or in-group differences in the ways in which these various constructs interact with each other, or both. For example, Eccles-Parsons et al.'s (1983) expectancy-value model was originally developed to guide research into gender differences in various fields of study and occupational niches with a particular focus on gender differences in participation in scientific and technological fields (Eccles, 2009). This model focused attention on gender differences in specific aspects of motivation rather than on whether the model fitted equally well for females and males. That is, in this model, Eccles-Parsons et al. assumed that gender differences in achievement-related choices result primarily in gender differences in the various motivational constructs discussed thus far. They assumed that the underlying model would be equally applicable for females and males. With

the availability of structural equation modeling (SEM) techniques, researchers have now begun to test whether models such as those specified in EVT are equally appropriate for different populations or groups. It is not yet clear what will emerge from these types of studies and it is even less clear what the developmental implications of such work are. But, right now there is not strong evidence of any systematic group differences in the applicability of the various models that have been studied. Furthermore, it is also quite likely that the relative importance of these different options in explaining behavior vary over ages and larger social contexts. Given these theoretical and methodological complexities, we will keep our discussion of group differences themselves relatively brief, highlighting some differences in achievement-related outcomes that might be related to the types of motivational processes we have discussed thus far and the nature of the debates currently guiding research efforts on these central topics.

Gender Differences in Motivation and Achievement

As noted above, Eccles-Parsons et al.'s (1983) expectancy-value model was originally designed to guide research on the development of gender differences in achievement-related motivational constructs and achievement-related behaviors. Although there have been major changes in females' participation in a wide range of achievement-related activities including substantial increases in participation in competitive sports, professional music, and all formerly male-dominated college majors and careers, stereotypic gender differences in many fields continue. Females in most countries still dominate in fields such as primary and secondary school-teaching, nursing, and other health-related support fields and remain underrepresented in professional sports in general, the most male-dominated sports more specifically, and college majors in the physical sciences, engineering, computers, and technology, as well as philosophy and economics (Schoon & Eccles, in press; Watt & Eccles, 2008). Furthermore, in most Western industrialized countries, females now outnumber males in secondary and tertiary school completion with males being more likely than females to drop out of school early and to perform more poorly in the course work (DiPrete & Buchmann, 2013). Finally, although there are small and inconsistent gender differences in performance on various standardized tests of academic achievement, particularly with males outperforming females in math and science, these differences have become smaller over the past 50 years and differ across countries, with the differences

favoring boys being largest in countries with the lowest levels of gender equity, the highest levels of implicit gender stereotyping, and the biggest power differentials between social status groups (Hamamura, 2011). There is a long history investigating the motivational influences on these types of gender differences in achievement and occupational choices (Eccles, 1994, 2013). Existing evidence, reviewed next, supports the conclusion that gender-role socialization and internalization are likely to lead to gender differences in each of the broad motivational constructs discussed thus far, which, in turn, contribute to gender differences in both rates of participation and performance in many achievement-oriented occupations and activities (Wigfield, Eccles, et al., 2006).

Gender Differences in Competence-Related Beliefs

Gender differences in competence beliefs, are often reported, particularly in gender-role stereotyped domains and on novel tasks, and these differences are apparent as early as Age 5 or 6, if not before (Wigfield, Eccles, et al., 2006). For instance, girls have more positive competence beliefs in reading and music, and boys in math and sports (Jacobs et al., 2002). However, the size of these differences (which are typically quite small), the ages at which they first emerge, and the consistency across childhood and adolescence depend on the gender-role stereotyping of the activity, the specific activities being considered, the country in which the research is conducted, the subpopulations within each country being studied, and the historical period in which the data were gathered. For example, in studies done in Australia, Europe, and the United States, boys hold higher competence beliefs than girls for math and sports, even after all relevant skill-level differences are controlled; in contrast, girls have higher competence beliefs than boys for reading, English, and music (e.g., Watt, 2004) but the magnitude of these differences varies across country (Jerrim & Schoon, in press). With regard to developmental changes in these patterns, gender differences in math-related competence beliefs of European American students decrease during the secondary school years, but those for English competence remain consistent across the primary and secondary school years (Jacobs et al., 2002). Few researchers have looked at these developmental patterns in various subgroups within any countries. Further, the extent to which children endorse the cultural stereotypes regarding which sex is likely to be most talented in each domain predicts the extent to which girls and boys distort their ability self-concepts and expectations in the gender-stereotypic direction (Eccles & Harold, 1991).

Gender differences in causal attributions, mind-sets, performance anxiety, and susceptibility to stereotype threat have also been studied. Some findings suggest that girls attribute failure more to lack of ability, particularly in gender-stereotyped areas such as math, although these differences are not always found (see Wigfield, Eccles, et al., 2006). Similarly, some studies suggest that girls are more likely to believe that difficulty mastering math reflects deficits in innate abilities (Dweck, 2006a) but again these differences are not consistently found and very little is known about the developmental nature of such gender differences.

Gender differences emerge regularly in studies of performance anxiety with females from a very young age reporting higher levels than males (e.g., Zeidner & Matthews, 2011). However, it has been suggested that boys may be more defensive than girls about admitting anxiety on questionnaires and that anxiety may actually undermine their performance more than girls (Wigfield, Eccles, et al., 2006). In support of this suggestion, Lord, Eccles, and McCarthy (1994) found that test anxiety was a more significant predictor of poor adjustment to junior high school for boys even though the girls reported higher mean levels of anxiety.

Closely related to the anxiety findings, several scholars have documented gender differences in stereotype vulnerability/stereotype threat (see Steele, 2010). In the late 20th century, Steele and his colleagues (e.g., Steele, 1997; Steele & Aronson, 1995) hypothesized that members of social groups (such as females or African Americans) stereotyped as being less competent in a particular subject area (such as math) will become anxious when asked to do difficult problems because they are afraid the stereotype might be true of them. This vulnerability is also likely to make them respond more negatively to failure feedback, lowering their expectations and their confidence in their ability to succeed. Evidence has supported this hypothesis for children as young as 9 or 10 and in many countries (Steele, 2010). Some of the most interesting work in this area was done by Shih and her colleagues (e.g., Shih, Pittinsky, & Ambady, 1999), who showed that prompting Asian identity increased the performance of Asian American females on a math test whereas prompting female identity decreased their performance.

Gender Differences in Achievement Values

As with competence beliefs, researchers have found gender-role stereotypic differences in both children's and adolescents' valuing of sports, social activities, and English that begin quite early in the course of development

(e.g., Eccles et al., 1989; Eccles, Wigfield, Harold, & Blumenfeld, 1993; Spinath & Spinath, 2005; Wigfield et al., 1991). Earlier work showed gender differences in math value favoring boys emerging during adolescence (Eccles, 1984), but other studies show that boys and girls value math equally during adolescence (Jacobs et al., 2002). Although boys and girls now appear to value math equally, girls are less interested in the physical and computer sciences, as well as engineering, than boys, and still enroll much less frequently in these majors in college (see Eccles, 2013; M. Wang, Eccles, & Kenny, 2013, for discussion of the psychological processes that underlie some of these sex differences in children's achievement values). These processes include gender-role socialization, the internalization of gender-role stereotypes, the absence of same-sex role models in various activities and fields, as well as the processes associated with both identity development and disidentification (e.g., Betz & Sekaquaptewa, 2012; Simpkins, Fredricks, & Eccles, in press). Interestingly, gender differences in the valuing of various achievement domains differ across countries (Jerrim & Schoon, in press) and these national differences in math achievement on a standardized test are largest in countries with the greatest social status power differential and the most gender-typed workforce participation (Hamamura, 2011).

Disidentification: The Intersection of Competence Belief and Values

Earlier we discussed the relation between values and competence-related beliefs. Drawing on the writings of William James (1892/1963), we suggest further that children will lower the value they attach to particular activities or subject areas if they lack confidence in these areas in order to maintain their self-esteem (see also Harter, 2012). Spencer, Steele, and Quinn (1999) suggested a similar phenomenon related to stereotype vulnerability. They hypothesized that women disidentify with those subject areas in which females are stereotyped as less competent than males. By disidentifying with these areas, the women not only lower the value they attach to these subject areas, but are also less likely to experience pride and positive affect when they are doing well in these subjects. Consequently, these subjects should become irrelevant to their self-esteem. Interestingly, as noted above, research shows that adolescent girls in many countries say they value math as much as boys do, while still believing they are not as good at math as boys believe about themselves and continue to be less likely to aspire to careers in physical science, computers, and technology (Jerrim & Schoon,

in press). Perhaps the gender differences in the perceived value of knowing math has disappeared but females remain less likely to aspire to such careers because they are less certain they can succeed without more effort than they believe they are willing or capable of exerting.

In summary, gender-stereotypic differences continue to exist in several of the motivational constructs linked to the questions “Can I succeed?” and “Do I want to succeed?” Research is needed on how these gender differences vary across culture. We discuss more about the possible origins of these differences in the sections on families and schools. Ruble et al. (2006) discuss the developmental processes and outcomes linked to gender (see also Hines, Chapter 20, this *Handbook*, this volume).

Culture, Ethnicity, Immigration, and Motivation

As is the case in many areas of psychology (see Graham, 1992), less is known about the motivation of children from different cultural, racial, and ethnic groups than about European Americans. However, work in this area is growing quickly; for instance, researchers are examining motivational characteristics of children in different Asian and European cultures (e.g., Bong, 2009; Nagy et al., 2010; Stanat & Christenson, 2006; Q. Wang & Pomerantz, 2009). Much of the work in the United States has focused on differences and disparities in motivation, engagement, and achievement among African American, Latino American, Asian American, and European American children and adolescents, and look to motivation as an important factor in understanding these differences (see Bingham & Okagaki, 2012; Meece & Kurtz-Costes, 2001; Murdock, 2009). Motivation theorists are increasingly interested in the applicability of their theoretical models to diverse groups of children. For instance, in a volume edited by McInerney and Van Etten (2004), theorists representing many of the theoretical perspectives reviewed in this chapter discussed the role of culture in their theoretical views. There were important similarities in how the principles from each theory applied to different groups, but differences as well. In the United States and in European countries where immigrant populations are growing rapidly, a major challenge for motivation researchers is to understand the motivational influences on both the within- and between-group differences in achievement and motivation among various ethnic, racial, and SES groups of immigrant and nonimmigrant children (Bingham & Okagaki, 2012; Graham & Hudley, 2005; Murdock, 2009; Urdan, 2012; Wigfield, Eccles, et al., 2006; as well as

Marks, Ejesi, McCullough, & García Coll, Chapter 9, this *Handbook*, this volume; and McLoyd, Purtell, & Hardaway, Chapter 10, this *Handbook*, this volume). We noted a number of these issues earlier.

The work on ethnic/racial/immigrant group differences in academic achievement is related more broadly to questions regarding how culture, motivation, and achievement are interconnected. The following tentative conclusions have now received substantial empirical support: (a) culture informs the development of identity, motives and behavioral scripts associated with achievement (e.g., Eccles, 2009; Markus & Kitayama, 2010); (b) culture shapes group members’ construal of the meaning of success and failure before and after achievement experiences (e.g., Grant & Dweck, 2001); (c) culture influences how universal and individual psychological needs are expressed in home and school (e.g., Jang, Reeve, Ryan, & Kim, 2009; Reeve & Assor, 2011); and (d) culture influences the enactment of engagement in the classroom (e.g., Bingham & Okagaki, 2012; Cobb & Hodge, 2011). We focus on the first three of these in this section. It is critical to reiterate that families and children from different cultural groups experience quite different challenges and opportunities in most countries. They live in different types of communities with different resources and dangers, they attend different quality schools, and they have differential access to all types of resources and opportunities. The impact of such inequities begin before birth, continue throughout these individuals’ lives, and have a cumulative impact on children’s motivation and achievement (Duncan & Murnane, 2011). These sources of individual and group differences are discussed more fully in other chapters of this *Handbook* (see Marks, Ejesi, McCullough, & García Coll, Chapter 9, this volume; and McLoyd, Purtell, & Hardaway, Chapter 10, this volume).

Contemporary cultural psychology in relation to education focuses on how variations in identity, due to culture-specific socialization practices, can shape students’ school motivation and achievement (Eccles, 2009; see also Spencer, Swanson, & Harpalani, Chapter 18, this *Handbook*, this volume). A major distinction in this work is made between socialization practices anchored in more individualistic (priority placed on goals and preferences of the self) cultural traditions and those anchored in more collectivist (priority placed on needs and norms of the group) cultural traditions (Triandis & Suh, 2002). Markus and Kitayama (2003) developed the notion of “cultural frame” as a way of describing how cultural socialization practices literally come to inform the self. Cultural frames

are meaning systems comprised of language, tacit social understandings, and scripts for enacting these social understandings in daily life. Individuals' self construals (i.e., the individual's understandings about what it means to be a person in the world) are a critical component of these cultural frames. Markus and Kitayama (1991) outlined two different cultural frames: independence and interdependence. In the independent construal of self, individuals come to see themselves as autonomous, self-contained, unique from others, and assertive in pursuing personal goals and desires; such construals are more prevalent in Western societies. In contrast, in the interdependent self-construal, individuals assign primary significance to others in defining the self, feel a fundamental sense of connectedness to others, and attend, first and foremost, to social roles, in-group norms, and obligations and responsibilities to others; such construals are more prevalent in African and Eastern societies (see Oyserman, Coon, & Kemmelmeier, 2002, for a comprehensive review of different strands of research on these two construals; Killen & Wainryb, 2000, discuss work showing within group variance and complexities of the expression of these construals in different countries, suggesting they are not at all monolithic within a given culture). Self-construals are assumed to be the zero-order beliefs from which more explicit goals and motives, including one's achievement-related goals and motives, arise (a similar argument is inherent in Eccles-Parsons et al.'s, 1983, Expectancy-Value Model of Achievement-Related Behavioral Choices). For instance, some research shows that, in more individualistic countries such as the United States, extrinsic motivation is associated with lower academic achievement (e.g., Deci & Ryan, 2002a) but this is not necessarily so in more collectivistic cultures like Hong Kong, where receiving rewards from others may be seen as more positive (Moneta & Sui, 2002).

Although just beginning, research relating culture to achievement motivation tends to examine how (culturally informed) self-construals influence: (a) the kinds of motivations that are prevalent for members of different cultural groups (the issue of approach and avoidance motivation), (b) the kinds of values and goals that are taken up into the self by members of different cultural groups (the issue of diversity in goal content), and (c) the kinds of meanings that individuals from different cultural groups make both before and after engaging with an achievement task (issues of meaning and appraisal). For example, Elliot, Chirkov, Kim, and Sheldon (2001) hypothesized that individualistic self-construals should promote approach motivation in which goals associated with self-assertion are focal; in

contrast, interdependent self-construals should promote avoidance motivation in which goals associated with the reduction of group discord are focal. They found some support for these hypotheses in a cross-cultural study of college students. Among non-Asian college students, small correlations exist between self-as-independent and approach goals and between self-as-interdependent and avoidance goals. Both Asian American college students and students from more collectivistic societies (Korea and Russia) report higher levels of avoidance motivation than European American college students.

These findings are consistent with studies suggesting that both the level and impact of avoidance motivation on achievement may be greater among individuals from cultural groups that emphasize interdependence and group membership. For instance, Eaton and Dembo (1997) found that the fear of failure (an avoidance motive) best predicted 13-year-old Asian and Asian American students' performance on an intellectual task; in contrast, non-Asian students' performance was best predicted by their beliefs about the incremental nature of intelligence, the importance of effort, and their self-efficacy. The authors interpreted these findings in relation to cultural dimensions of Asian cultures such as collectivism in which avoidance motives serve the function of maintaining group harmony. However, Bong, Hwang, Noh, and Kim's (in press) study of Korean adolescents showed that those who had socially perfectionist tendencies (wanting to be perfect to please others) were more anxious and procrastinated more compared to those who were perfectionists for themselves, perhaps indicating that social perfectionism also involves not wanting to disappoint group members. Bong et al. argued that different kinds of perfectionism are a more meaningful and valid construct than fear of failure when thinking about Korean adolescents' motivation.

Looking more directly at the association between culture and individuals' views of such basic universal needs as autonomy, Jang and colleagues (2009) found that high school students in collectivistically oriented South Korea benefit from classroom experiences of autonomy support and psychological need satisfaction. The extension of this work to examine how such cultural orientations and practices, and their level of internalization with regard to hypothesized needs, affect young people's goals and values in relation to education is still only beginning. Even more important for this chapter, very little research has focused on the developmental ontogeny of cultural variations in motivational constructs and their links to actual achievement. When do children's behaviors begin

to reflect variation in cultural construals, and how does this affect their motivation, and ultimately, achievement? Much work needs to be done to address these issues.

With respect to the specific motivational beliefs and values on which we focus in this chapter, earlier research done in the United States on children's competence beliefs showed that African American students reported slightly higher ability self-concepts and domain-specific self-efficacy beliefs than did European American children. However, the correlation between these competence related beliefs and actual indicators of school achievement were lower among African American students' competence than among European American students (see Graham, 1994, and Graham & Taylor, 2002, for further discussion). Other work in the United States does not find consistent ethnic/race differences in efficacy beliefs (Fuligni, Witkow, & Garcia, 2005; Wigfield, Cambria, & Ho, 2012). There are also mean differences in competence beliefs across other groups; Asian and Asian Americans often are modest in their competence beliefs despite their generally high achievement (Jerrim & Schoon, *in press*).

Perceptions of different racial and ethnic groups in the United States and other countries reflect pervasive stereotypes about these groups' abilities, with some groups (e.g., Asians) viewed as high-achieving and others as low-achieving. More problematic, members of the different groups can incorporate these stereotypes into their own self-representations. These views appear in children's implicit beliefs but not necessarily their explicit statements about different groups' abilities (Murdock, 2009). As discussed above with respect to gender differences, these kinds of group stereotypes can produce stereotype threat in individuals from traditionally low-performing groups, such that when they are told an achievement task reflects on their ability, they do less well than when told it is a problem-solving task (Steele, 2010). Much of this work has been done with African American college students, but it is being extended to other groups and to children (see Murdock, 2009, for review).

Although it is not completely clear how stereotype threat influences individuals' competence beliefs, researchers are learning more about the development of this susceptibility. Two possibilities are an increase in anxiety and a lowering of expectancies for success. According to Ambady, Shih, Kim, and Pittinsky (2001), children's susceptibility to stereotype threat varies over the elementary and middle-school years (Ages 6–14) with the greatest susceptibility to both positive and negative stereotypes occurring among 6- to 8-year-olds and 11- to 14-year-olds.

Interestingly, in Cimpian and Erickson's (2012) study, telling children that either boys or girls are really good at a task led 4- to 7-year-old children to work more slowly and solve fewer problems than either telling them nothing or telling them that a particular boy or girl was good at the task. This was true for both boys and girls. Cimpian and Erickson (2012) concluded that just telling that a particular group of children are good at a task is sufficient to elicit an entity-like belief in competence needed for the task, which then undermines the children's performance regardless of their membership in the group. It seems that this susceptibility would become more differentiated by the gender of the participants as they get older.

How might culture affect individuals' answers to the question, "Do I want to do this task?" There is evidence that European American, Latino American, and African American early adolescents perceive that *other* European American children value school more than do Latino American or African American children, especially Latino American and African American boys (Graham, Taylor, & Hudley, 1998); however, their *own* values do not differ in these ways across groups (Harris, 2006). These different findings need to be disentangled.

One explanation of the findings regarding stereotype threat is that children from some groups come to devalue school as a way to protect their self-worth. This process might start with the devaluing of certain activities, but can end up with students in groups who are stereotyped to do poorly fully disidentifying with school, in order to protect their self-worth; self-worth is enhanced when children value those activities at which they perform well (Eccles-Parsons et al., 1983; Harter, 2012). This process helps explain the finding mentioned earlier that African American children's school competence beliefs relate less highly to their performance. This may occur because many of these children are investing in other activities besides school, and so their sense of competence does not relate to their school performance.

Children's perceptions of the cost of achievement activities likely have an influence as well. Due to stereotype threat, discrimination, and other related issues, some children may decide that it is too costly to continue to try to succeed in school. They then make choices to engage more fully in other activities. Although these choices help them maintain self-worth, if children disengage from school in order to do other activities, their school achievement (if not their self-worth) can suffer.

Murdock (2009) discussed how stereotype threat could influence children's achievement goals. Recall our earlier

discussion of the benefits of mastery goals relative to performance goals for students' self-efficacy and intrinsic motivation. Researchers have suggested that stereotype threat can activate performance goals, especially performance avoid goals, which are deleterious to motivation and achievement (K. E. Ryan & Ryan, 2005). The findings with respect to whether various minority groups adopt different kinds of achievement goals are not entirely consistent, but Murdock suggests that there is evidence that group status moderates the adoption of approach as opposed to avoidance goals. These predictions need to be tested developmentally.

Another impact on children's goals is their possible selves. These beliefs are shaped in part by children's cultural backgrounds. Lower-income youth appear to have higher hoped-for selves than their anticipated selves, with respect to amount of education and resources required to attain the hoped-for selves (see Oyserman & Fryberg, 2006). This discrepancy between hoped-for and anticipated selves may be less apparent in other groups.

We have focused primarily on psychological factors that affect children from different cultural backgrounds' competence perceptions and values. In concluding this section, we turn to broader factors such as the discrimination children from some groups feel. Discrimination occurs in the United States and also in many other countries in the world where there are ethnic minority groups that have not attained full acceptance into their new society; examples are Turkish immigrants in different countries in Europe and Korean immigrants to Japan. When children from these groups receive discriminatory treatment from teachers and peers, they lower the value they attach to school (Wong, Eccles, & Sameroff, 2003). Interestingly, however, in their analysis of the PISA 2003 study of early adolescent immigrants living in 17 countries in Europe and Asia, Stanat and Christensen (2006) found that, in nearly every case, the immigrant adolescents had higher competence beliefs and interest in math than did the native adolescents, even though the immigrant adolescents performed much less well in math. As noted at the beginning of this section, the processes behind these complex patterns, and how they develop, require much new research. We return to the topic of discrimination in the section on school influences on achievement motivation.

On a more positive note with respect to both the influences of discrimination and stereotype threat on children from different groups, a growing body of work indicates that African American adolescents and adolescents from other groups who develop a strong racial or ethnic identity

are more likely to stay engaged in school and achieve well (see Murdock, 2009, for review). The implication is that a strong sense of identity with one's group can buffer effects of discrimination and stereotype threat. Developing a strong sense of racial identity often involves the understanding that one's group is discriminated against in the larger society. Thus racial identity can buffer effects of discrimination on school engagement even though the individual knows that his or her group is likely to experience that discrimination. There is a need for developmental work in this area. We return to the impact of discrimination on motivation below, in the section on school influences on achievement motivation.

In summary, there have been tremendous advances over the last 10 years in the field's understanding of the development of motivation in different groups. To date, much of this work focuses on different ethnic groups in the United States. Extending this work to other countries, and studying the motivation of immigrants in different countries, are important priorities for future research.

THE SOCIALIZATION OF MOTIVATION: FAMILY INFLUENCES

In the previous versions of this chapter, Eccles et al. (1998) and Wigfield, Eccles, et al. (2006) reviewed the existing literatures on family influences on motivation organized around the broad socialization model illustrated in Figure 16.2. Although this specific model was originally proposed and elaborated by Eccles and her colleagues (see, e.g., Eccles, 1993; Eccles-Parsons et al., 1983), similar social-cognitive mediational models of parental behavior and influence continue to be proposed by many family influence researchers and research designed to investigate these types of integrative models has continued to proliferate over the past 10 years (e.g., Bugental & Grusec, 2006; Parke & Buriel, 2006). Given the very limited space for each chapter in this *Handbook*, we focus on this model and highlight research findings directly related to the socialization of motivation. Bornstein (Chapter 3, this *Handbook*, Volume 4) and Golombok and Tasker (Chapter 11, this *Handbook*, this volume) focus on other outcomes of parenting.

Although there is extensive work on some components of this model, it is still the case that very few studies include the several components underlying parenting behaviors outlined in Box E. Much of this literature focuses on the association of the exogenous characteristics (Boxes A

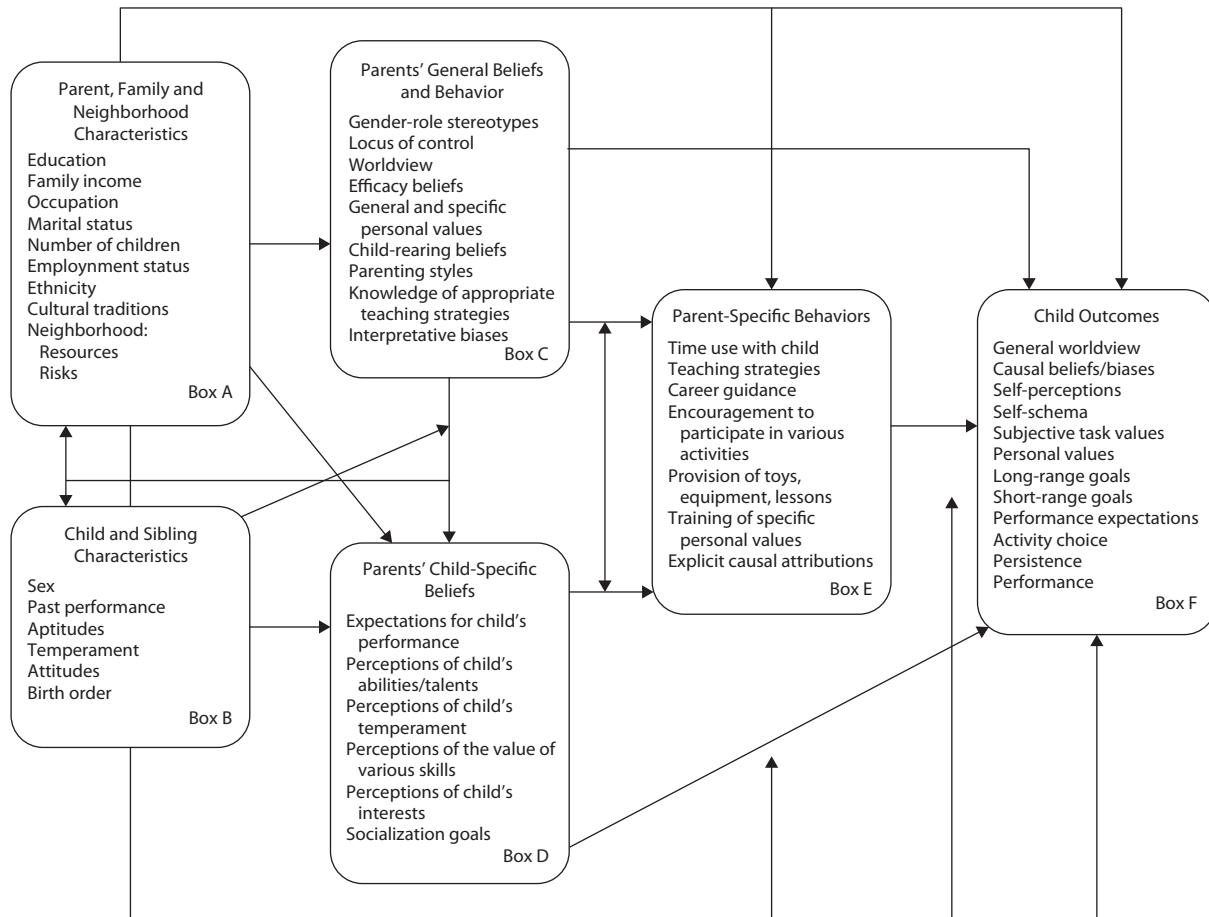

Figure 16.2 Model of parental influences on children's motivation and achievement.

Source: In "Development of Achievement Motivation" (p. 969), by A. Wigfield, J. S. Eccles, U. Schiefele, R. W. Roeser, and P. Davis-Kean, in *Social, Emotional, and Personality Development*, N. Eisenberg (Ed.), 2006, Vol. 3 of the *Handbook of Child Psychology*, W. Damon and R. M. Lerner (Eds.-in-Chief), 6th ed., Hoboken, NJ: Wiley.

and B) with parents' beliefs (Box C) or child outcomes (Box F; e.g., linking family socioeconomic status and/or ethnicity with parents' child-specific beliefs [Box D], specific parenting practices [Box E], and children's academic outcomes [Box F]). Much of the research examining the mediating and moderating hypotheses implied in Figure 16.2 has focused on academic achievement rather than on motivation itself (e.g., Corwyn & Bradley, 2003; Davis-Kean, in press). This work has clearly documented the mediational processes linking the exogenous family and neighborhood or cultural characteristics outlined in Boxes A and B to parenting practices in Box E and then to children's engagement and performance in achievement-related settings in and out of school outlined in Box F (see Bugental & Grusec, 2006; Cabrera & Tamis-LeMonda, in press; Parke & Buriel, 2006; Wigfield, Eccles, et al., 2006, for extensive review). We do not have the space to review these studies here. Instead, we focus on those

studies directly linked to the socialization of motivation as outlined in the previous sections of this chapter.

In general, this research has focused on the role that parent beliefs and behaviors may play in the socialization of achievement motivation in individual children. This research indicates that parents' beliefs and behaviors are critical in setting a climate for children's motivation development by providing various activities or resources in the home environment that may provide stimulation to pursue various activities across time. For example, research on activity involvement suggests that parents play a role in promoting certain types of involvement in academic and sports domains in the early elementary years and that this emphasis translates into greater interest and motivation to continue with these activities over time and to choose course work and extracurricular activities consistent with these activities in adolescence (Simpkins, Fredricks, Davis-Kean, & Eccles, 2006). It is only in the

past few years that this specific research has started to develop and for the most part the research remains quite general; for example, linking family SES and general family socialization styles to general school achievement, achievement motivation, and other general motivational constructs such as mastery orientation, learned helplessness, and school engagement. Very little work looks at these influences for different age groups but it seems quite likely that different parental behaviors will be key at different ages.

Child and Family Demographic Characteristics (Boxes A and B)

Child gender continues to be a widely studied child-level demographic influence on achievement motivation and engagement, particularly in sports and science, technology, engineering, and mathematics (STEM)-related academic fields. Both the early onset and the longitudinal consistency of these gender differences suggest that families are at least one important source of influence (Wigfield, Eccles, et al., 2006). For example, parents rate children's math and sports abilities higher for boys than girls from early on and provide boys and girls with different opportunities to engage in various gender-typed achievement-related activities (Fredricks, Simpkins, & Eccles, 2005; Herbert & Stipek, 2005; Simpkins, Davis-Kean, & Eccles, 2005; Simpkins, Fredricks, & Eccles, *in press*). These differences likely are more pronounced in countries where parents have very rigid gender-typed beliefs; we discuss this issue further below.

The influence of family-level demographic characteristics also continues to be studied, particularly in light of the fact that the demographic landscape of families in many countries has become much more diverse over the last 50 years. Attention has focused on illuminating how such characteristics as family socioeconomic status (SES), ethnicity/race, immigration, and culture shape the values, goals, aspirations, and behaviors of various family members (Benner, Graham, & Mistry, 2008; Van Horn et al., 2009). For example, culturally associated values such as familism have been shown to predict parents' warmth; in contrast, neighborhood characteristics often linked with family SES, such as neighborhood crime, predict parents' behavioral control and family communication patterns (Ceballo et al., 2008). Furthermore, researchers have become aware of the fact that these kinds of family demographically related characteristics often co-occur within families, complicating and magnifying their unique effects. For example, many immigrant families have a

lower SES than their U.S.-born counterparts (Yoshikawa, 2011). Scholars have struggled with how best to investigate these complexities over the past 10 years.

By and large, studies show that children growing up in high-SES families do better academically, evidence higher levels of almost all of the indicators of achievement motivation discussed earlier, and are involved in more organized activities and skill-based informal activities during the after-school hours (e.g., Mahoney, Vandell, Simpkins, & Zarrett, 2009). Why? Family SES could affect children's motivation indirectly through the opportunity structures in the child's surrounding environments as well as parents' beliefs and practices. For children to engage and succeed in a domain, they need to have available opportunities and a family that has the knowledge and ability to take advantage of those opportunities—both of which are often limited in low-SES families (Archer et al., 2012; Simpkins, Delgado, Price, Quach, & Starbuck, 2013). Not only do parents in low-SES families have limited resources to implement whatever strategies they think might be effective, they also have to cope with more external stressors than middle-class families living in stable, resource-rich neighborhoods (Furstenberg, Cook, Eccles, Elder, & Sameroff, 1999; McLoyd, 1990). For example, low-SES parents' jobs are often characterized by long hours, nonstandard shifts, and high physical demands (Updegraff, Crouter, Umaña-Taylor, & Cansler, 2007), which can limit the time and energy parents have to devote to their children (Parra-Cardona, Cordova, Holtrop, Villarruel, & Wieling, 2008; Yoshikawa, 2011). Furthermore, Lareau (2003) and Eccles et al. (1998) suggested that SES differences are not simply a function of resources, but that family norms, goals, and motivational belief systems vary by social class.

Immigration status in the United States and other countries is a second family demographic characteristic that has received a great deal of attention in the last 10 years. In 2011, approximately 40 million people in the United States were immigrants (Pew Hispanic Center, 2013). Furthermore, despite the fact that many first-generation immigrant youth often live in quite poor families, these first-generation youth often fare better than second- or third-generation youth in terms of physical health, academic achievement, and social well-being even after controlling for differences in resources at the family and neighborhood levels (e.g., Suárez-Orozco, Rhodes, & Milburn, 2009). Why? Many families immigrate to provide a better life for their families and more opportunities for their children (Suárez-Orozco et al., 2010). Parents' high valuing of education and children's sense of obligation to the family are two mechanisms that could help explain

the “immigrant paradox” (Fuligni & Fuligni, 2007). However, immigrant families’ efforts to be involved in their children’s lives outside of the home are often impeded by the “linguistic or cultural distance with social institutions” (Glick, 2010, p. 505) in the host country. In their analysis of the PISA 2003 data, Stanat and Christenson (2006) noted that language and culture differences were major factors explaining the achievement gap between immigrant and native adolescents in Europe and Asia. Furthermore, immigrant families often experience more instability in terms of periods of time where the family unit is split between two countries and in terms of mobility within and outside of those countries (Menjívar & Abrego, 2009). Yoshikawa’s (2011) work highlighted the profound implications of parents’ documentation status on children’s early achievement. Parents in the United States who lack documentation have poorer work conditions, receive less pay, and have more stress than similar parents who are citizens. These conditions continue to cascade down and influence the quality and enrichment of the environments in which children develop, including the home environment and childcare settings. It remains to be determined how these same factors influence the ontogeny of children’s motivation for achievement and engagement.

Culture is an even more general characteristic that is likely to influence children’s motivation through its impact on and association with family-level processes and dynamics. In many ways, culture influences which activities and goals (e.g., educational and career choices) are valued and for whom; it also influences general parental childrearing beliefs, theories, and goals (Fuligni & Fuligni, 2007; Rogoff, 2003). For instance, traditional gender-role values and familism are two core aspects of Latino cultures (Knight et al., 2010). Latino daughters in families with highly traditional gender roles are less likely to engage in masculine activities (e.g., sports) and often find it challenging to attend organized after-school activities because they are given less independence and have more family duties than sons (McHale, Updegraff, Kim, & Cansler, 2009; Simpkins et al., in press). Cultural values can also shape the general childrearing environment (Calzada, Tamis-LeMonda, & Yoshikawa, in press). Among Latino families, familism predicts higher parental warmth and lower levels of harsh parenting in the face of neighborhood disadvantage (White, Roosa, & Zeiders, 2012). With respect to education, Asian parents (both in Asia and the United States) are more involved in their children’s education, often believing their children’s educational success is their own responsibility (Pomerantz, Kim,

& Cheung, 2012). Such beliefs and involvement likely affect their children’s motivation and achievement and are quite different from the emphasis on fostering children’s autonomy in many U.S. parents.

In summary, there are many ways for family demographic characteristics to directly or indirectly affect the development of children’s achievement motivation. It is important to note, however, that even though family demographic characteristics have been linked repeatedly to children’s school achievement, their effects are almost always indirect, mediated by their association with parents’ beliefs, practices, and resources (e.g., Benner et al., 2008). In addition, parents’ beliefs and psychological and social resources can override the effects of even the most stressful circumstances (Van Horn et al., 2009).

General Childrearing Climate

Historically, researchers studying parental influence have focused on the impact of the general patterns and philosophy of childrearing on children’s overall orientation toward achievement (Eccles et al., 1998; Wigfield, Eccles, et al., 2006). Researchers have related a set of general behaviors and beliefs to the development of self-esteem, achievement motivation, locus of control, sense of personal efficacy, and so on. The variables investigated have included the general emotional warmth and supportiveness in the home, valuing of achievement, general parental childrearing beliefs and theories, values and goals, as well as sex-typed goals and cultural beliefs. In addition, researchers have examined the influence of parents’ general childrearing style as well as family authority structure, discipline tactics, and general interaction patterns, parental locus of control and personal efficacy, and communicative style and teaching style. Similarly, researchers have documented the benefits of active involvement with, and monitoring of, children’s and adolescents’ schoolwork (e.g., Wigfield, Eccles, et al., 2006).

Several investigators have stressed an integrated view of how these various parenting characteristics work together to produce optimal motivational outcomes. For example, Grolnick et al. (2002) stressed the interplay of three components of general parenting in promoting self-determination in children and adolescents: involvement and interest in the child’s activities, support for autonomous behaviors, and adequate structure. Grolnick et al. (2002) suggest that these parenting behaviors are important in helping children form a sense of autonomy and interest in activities that leads to greater achievement performance and a reduction

in learning problems. For example, autonomy-supportive parents allow children to explore their own environment, to initiate their own behavior, to take an active role in solving their own problems, and to express their points of view (Raftery, Grolnick, & Flamm, 2012). Autonomy support seems to be particularly important for low-achieving children (Ng, Kenney-Benson, & Pomerantz, 2004), especially if mothers stress the importance of effort and learning strategies as they help their children with homework (Pomerantz, Grolnick, & Price, 2005). Such practices may help low-achieving children feel both competent and socially supported.

Similarly, Eccles et al. (1998) stressed the importance of emotional support, role models, and the right balance between structure, control, challenge, and developmentally appropriate levels of support for autonomy. This balance depends on cultural systems, on the specific context in which the family is living, the age of the child, and other individual characteristics. Although the magnitude of effects varies by race/ethnicity, sex, social economic class, and nationality, there is consensus that these general parental practices influence a variety of quite general indicators of children's achievement motivation and motivated achievement behavior (e.g., Benner et al., 2008).

The results are consistent with three general principles: appropriate levels of structure, consistent and supportive parenting, and observational learning. Parents who know enough about their children to provide the right amount of challenge with the right amount of support seem more likely to produce highly competent and motivated children. These parents are also likely to be able to adjust their behavior to meet the changing developmental needs and competencies of their children. Families that provide a positive emotional environment are more likely to produce children who want to internalize the parents' values and goals and therefore want to imitate the behaviors being modeled by their parents. Consequently, children growing up in these homes are likely to develop positive achievement orientation if their parents provide such models and value those specific tasks, goals, and means of achieving one's goals valued by their parents. In contrast, if parents overly control and put excess pressure on their children to succeed at particular activities, this is likely to undermine the children's intrinsic interest in the activity, reduce the children's confidence in their ability to succeed, and lead to negative affective associations with the activity due to classical conditioning (Eccles et al., 1998; Grolnick, 2003). For example, mothers' academic support actually had

negative consequences for youth with whom they did not share warm relationships (Simpkins, Weiss, McCartney, Kreider, & Dearing, 2006).

How Parents Translate Their General Beliefs Into Specific Beliefs and Practices

Parents' general beliefs, such as the valuing of achievement and gender-typed ideologies and goals, are linked to parenting behaviors concerning school achievement (see Wigfield, Eccles, et al., 2006). Two pathways by which general beliefs are translated into specific beliefs by their direct influence on parents' child-specific beliefs (see Boxes C and D in Figure 16.2) and by shaping parents' interpretation of previous performance and aptitude of youth (see the moderating role of Box C on the relation between Boxes B and D).

As outlined in Figure 16.2, parents' general beliefs should directly influence their child-specific beliefs and, therefore, their children's motivation. Some research in the United States focuses on the potential implication of mothers' gender-stereotypical beliefs in mathematics. Mothers with more traditional gender-stereotyped beliefs about math had lower confidence in their daughters' math abilities than mothers with less traditional beliefs (Bleeker & Jacobs, 2004). In addition, such mothers had early elementary school-aged girls who were more susceptible to stereotype threat than mothers with less traditional beliefs (Tomasetto, Alparone, & Cadinu, 2011). In one randomized control trial, Harackiewicz, Rosek, Hulleman, and Hyde (2012) demonstrated that teaching parents about the value of STEM high school courses and careers via computer based materials produces a significant increase in the likelihood that their daughters would take additional course in math and science during their last 2 high school years.

Parents' general beliefs should also influence how children's characteristics (Box B) influence their child-specific beliefs (Box D). In a review, Yamamoto and Holloway (2010) argued that parents' educational expectations would be closely tied to their children's previous achievement only if parents believed ability was innate (rather than malleable or due to hard work), trusted the school and the feedback the school provides, and had high self-efficacy beliefs. Several of these themes are consistent with Dweck's (2006b) ideas linked to growth versus entity mindsets: If parents believe that math aptitude is a stable entity, then they will be likely to interpret their children's successes and failures in math class as indicative of their children's math aptitude,

which in turn should influence how they respond to their children's successes and failures in many ways.

Parents' Child-Specific Beliefs, Values, and Perceptions

According to Figure 16.2, parents can hold many child-specific, domain-specific beliefs, such as the importance of math or sports for their children and how skilled they believe their children are in math or sports. Because these beliefs are domain- and child-specific, parents may believe that their children are much more able in math than in reading and music. Evidence is beginning to emerge showing that such specific beliefs are consistent, powerful predictors of the motivation and achievement of youth (e.g., Simpkins et al., *in press*; Wigfield, Eccles, et al., 2006). Furthermore, such predictive effects hold even when independent estimates of children's actual competence (e.g., teachers' ratings and scores on standardized tests) and demographic characteristics are controlled.

One of the most consistent links is between parents' educational expectations for their children and their children's subsequent academic motivation and performance (e.g., Davis-Kean & Sexton, 2009; W. Fan, Williams, & Wolters, 2012). Parents' beliefs about specific academic subjects, such as science, are even stronger predictors of children's outcomes in these subjects (Archer et al., 2012). Parents' perceptions of children's competence and their valuing of a subject or domain predict children's subsequent self and task beliefs in math, reading, and sports (e.g., Shumow & Lomax, 2002; Simpkins et al., *in press*).

Parental beliefs also predict longer-term outcomes. As noted earlier, the confidence of many youth in their own achievement-related abilities decline from Ages 5 through 17. The confidence parents have in their children's math, reading, and sports abilities while the children are in early elementary school moderate these declines in a positive direction (Fredricks et al., 2005). Both the rate of change and the magnitude of the decline are reduced for children whose parents have higher estimates of their children's abilities. In fact, mothers' prediction of children's success in math-related careers when children were in seventh grade (12 or 13 years old) predicted the beliefs of youth about careers and actual career choices 12 years later (Bleeker & Jacobs, 2004).

Parents as Socializers

Parents socialize children through both direct parent-child interactions and the ways in which they manage and design

their children's environments (Eccles, 1993; Furstenberg et al., 1999; Parke et al., 2003). Researchers have documented the benefits of active involvement with, and monitoring of, schoolwork and time spent by youth on other achievement-related activities such as sports and instrumental music (e.g., Archer et al., 2012; Wigfield, Eccles, et al., 2006). For example, researchers have shown that reading to preschool children predicts children's later reading achievement and motivation (e.g., Davis-Kean & Eccles, 2003; Linver, Brooks-Gunn, & Kohen, 2002). However, it is not essential that parent-child activities focus on skill instruction in order to have an impact. Parents can also support children through games, by being leaders of their organized activities, and by attending community events together. In early elementary school, playing games together that involve math, such as board games with dice, was one of the stronger, consistent family predictors of children's math knowledge and fluency (LeFevre et al., 2009). Such experiences likely influence both children's skill level and interest in doing these activities. Interestingly in W. Fan et al.'s (2012) study, parental advising and parent-school communications had different predictive associations with their children's intrinsic motivation and self-efficacy for different school subjects depending on whether the families were Latino American or Asian American. Other studies have also shown cultural differences in the association of parents' practices at home and with the school with their children's achievement motivational beliefs and behaviors (X. Fan & Chen, 2001). Clearly one needs to think very carefully about the meaning of these behaviors in different cultural contexts.

Parents also structure their children's learning experiences by providing specific toys, materials, and role models in the home environment, as well as by making decisions about the environments children engage in outside of the home (Jacobs, Davis-Kean, Bleeker, Eccles, & Malanchuk, 2005). Many parents try to organize and arrange their children's social environments in order to promote opportunities, to expose their children to particular experiences and value systems, and to restrict dangers and exposure to undesirable influences (Eccles, 1993; Parke et al., 2003). One core aspect of parents' designing of the home environment are the materials provided in the home, such as books, puzzles, and musical instruments. Children who have greater access to activity-related materials in the home have more positive attitudes, spend more time, and have higher achievement in academics, reading, sports, and music than their peers (e.g., McPherson, 2009; Simpkins, Fredricks, & Eccles, 2012).

Summary

The studies reviewed suggest a multivariate model of the relation between antecedent childrearing variables and the development of achievement orientation that depends on the presence of several variables interacting with each other. Specifically, proper timing of achievement demands creates a situation in which children can develop a sense of competence in dealing with their environment. An optimally warm and supportive environment with the minimal necessary control creates a situation in which children will choose their parents as role models and will feel autonomous in that choice. The presence of high yet realistic expectations creates a demand situation in which children perform in accord with the expectancies of the parents. Finally, children's ability levels must be such that attainment of the expected level of performance is within capacity. All these factors are essential for children to develop positive achievement orientations.

Few researchers, however, have adopted such an integrated view of family influences in their work. One promising method is the creation of indexes that include a variety of parental indicators theorized to influence particular outcomes. These indexes often include a heterogeneous set of indicators that may have a low inter-item reliability, but nevertheless, should be combined in a singular construct because they are all theorized to produce the same outcome (Bradley, 2004). Classic examples include research on cumulative risk (Sameroff, Bartko, Baldwin, Baldwin, & Seifer, 1998), the HOME observational scale (Bradley, 2004), and family involvement in children's education (Jeynes, 2007). Researchers have used these frameworks to capture parents' beliefs and behaviors with respect to children's achievement and activities (Fredricks et al., 2005; Simpkins et al., 2012). These studies documented a linear relation between the index of parental beliefs and behaviors and achievement-related outcomes of youth in math, science, sports, and music, suggesting that socialization factors have a cumulative positive impact on motivation. In contrast, when all family predictors were entered into a regression model, parents' expectations for child performance trumped all other potential sources of influence, suggesting that parents' behaviors did not matter. Clearly this was not the case when using an overall index. Researchers should consider the use of indexes, latent variables in SEM (Simpkins et al., 2012), or cluster analysis to provide a more holistic view of parental influences which complement the knowledge gained using traditional regression analysis.

Not only do studies typically have a more narrow focus on family influences, but most studies are limited to a single area of achievement. Simpkins et al. (2012) examined the parental correlates of the beliefs of youth and outcomes in math, reading, sports, and music. Inclusion of all four domains led to some interesting comparisons across domains. For instance, the relations between parenting and youth variables were stronger in the leisure (sports and music) domains than in the academic domains. This may be because sports and music are increasingly occurring outside of the traditional curriculum and are therefore less influenced by school factors than are math and reading. Parents also play a large number of roles in leisure domains, such as driving children to practices and lessons; cheering at games and recitals; paying for equipment, uniforms, and camps; and watching sports and music together. Furthermore, according to Marsh's I/E model (Möller, Pohlmann, Köller, & Marsh, 2009), people's beliefs and behaviors in one domain are likely to affect other domains. For example, parents' strong endorsement of math may have negative consequences for reading. Moving forward, it will be critical for scholars to include multiple domains within a study to allow for cross-domain comparisons and influences.

Further research on parenting and children's motivation needs to address two other important topics. First, researchers should address systematically how the influences discussed in this section vary across children of different ages. It is quite likely that the impact of parents on children changes as children get older; for instance, many parents get less involved in school once their children reach middle school, which likely affects their influence on children's motivation. Second, additional work is needed on culture's impact on parenting practices and the differential relations of these practices to children's motivation and achievement.

SCHOOL INFLUENCES ON ACHIEVEMENT MOTIVATION

In this section, we provide a brief overview of the research on school influences on achievement motivation and engagement. More extended reviews can be found in Eccles and Roeser (2010, 2011), Fredricks (2014), Hattie (2009), and Wigfield, Byrnes, & Eccles (2006), and in this *Handbook* (see Crosnoe & Benner, Chapter 7, Volume 4). Given the limited space, we focus on only four sources of influence: social dimensions (i.e., teacher-student relationships and classroom climate), classroom instruction, racial

and ethnic discrimination, and two aspects of the larger school environment (i.e., curricular tracking and extracurricular activities). We have selected these as examples of the kinds of dimensions of school experiences that are likely to influence individual, group, and developmental differences in achievement motivation in academic settings. Most of the research reviewed is directly related to the assumption that motivation is optimized in learning settings that meet individuals' basic and developmental needs, some of which are universal and some of which are a function of individual differences in aptitudes, temperament, interests, and socialization histories (Eccles & Midgley, 1989; R. Ryan & Deci, 2002). For example, as reviewed earlier, Deci and Ryan (2012; R. Ryan & Deci, 2009) focus on the importance of classroom and schools' impact on three fundamental psychological needs: competence (e.g., experiencing oneself as effective in social interactions), relatedness (e.g., experiencing oneself as connected to other people), and autonomy (e.g., experiencing oneself as a source of action) (R. Ryan & Deci, 2002). Similarly, Eccles and her colleagues (Eccles, 1993; Eccles & Midgley, 1989; Eccles & Roeser, 2010; Wigfield, Byrnes, & Eccles, 2006) focus attention on the various components of school and classroom characteristics that might explain changes in motivation and engagement as students move from elementary school into and then through secondary school. They argued that systematic changes in various classroom and school characteristics can lead to poor person–environment fit, which, in turn, can lead to the average level declines often found in studies of the transition into and through secondary school. They labeled this phenomenon stage–environment fit (see also Juvonen, 2007). Finally, Fredricks (2014) discussed how aspects of teacher-student relations, classroom practices, teacher beliefs, student diversity, and peer relations can impact children's engagement in classrooms in positive and negative ways.

Social Dimensions of Schooling: Teacher–Student Relationships

The quality of students' relationships with their teachers plays a critical role in enhancing motivation and engagement (Eccles & Roeser, 2011; Fredricks, 2014; Wentzel, 2009). Students who believe they share a good relationship with their teacher and feel emotionally supported by their teachers are more motivated and engaged than their peers who believe they do not have good relationships (Hattie, 2009; M. T. Wang & Eccles, 2012b). Teachers

who are trusting, caring, and respectful of students provide the kinds of socioemotional support students need to approach, engage in, and persist with academic learning tasks (Burchinal, Roberts, Zeisel, & Rowley, 2008; Hattie, 2009; NRC/IOM, 2004; Wentzel & Wigfield, 2007). Caring teachers are also attuned to and sensitive to the needs of students in their classroom and adjust their instruction in response to students' need (Pianta, Hamre, & Allen, 2012).

Close, supportive relationships with teachers are particularly important for academically at-risk students (Fredricks, 2014; NRC/IOM, 2004). Unfortunately, students who would benefit most from positive relationships with their teachers are also those that are least likely to get this support (Baker, Grant, & Morlock, 2008). There is also evidence that teachers hold differential expectations for various individuals within the same classroom. Although the effects of negative expectations are fairly weak and short-lived, there are small but fairly consistent negative effects of low teacher expectations on minority children, on children from lower social class family backgrounds, on low achievers, and on girls for math and science (Jussim, Robustelli, & Cain, 2009).

This link between the quality of teacher–student relationships and motivation and engagement is reciprocal over time (Skinner & Pitzer, 2012). High-quality relationships with teachers serve to bolster students' perceptions of their competence, autonomy, and relatedness, which in turn, elicit further teacher support. In contrast, unsupportive interactions between teachers and students make it more likely that students will perceive themselves as unwelcome, incompetent, and pressured. In turn, these negative self-perceptions will lead to further withdrawal of support from the teacher.

Wentzel and colleagues (Wentzel, 2012; Wentzel, Battle, Russell, & Looney, 2010) also have studied the role of perceived social support in classrooms. For example, in sixth through eighth grade middle-school classrooms in the United States (i.e., classes for 10- to 12-year-olds), even though students' perceived social supports differed across age, gender, and teacher, perceived social support predicted both European American and Latino American students' interest in their classroom activities and the Latino American students' grades (Wentzel, Russell, Garza, & Merchant, 2011). Furthermore, the Latino American students perceived more teacher caring and help but less parent help than the European American students had in their earlier studies. In another study of Latino American children, Wentzel, Baker, and Russell (2012) reported that these

students' perceptions of social and academic expectations of their peers predicted their social and academic goals.

Social Processes: Classroom Social Climate

General classroom social climate is also important for motivation and engagement. Researchers interested in SDT, for instance, have investigated the associations between dimensions of the classroom climate to adolescents' motivation, engagement, and socioemotional development (Deci & Ryan, 2002b). These scholars argued that motivation, engagement, learning, and well-being are highest in classrooms and schools in which the climate and culture stress and provide opportunities for the students to feel autonomous, competent, and emotionally supported. Such classrooms and schools would: (a) provide the students with voice in how the classroom is run and what kinds of assignments are made, (b) allow all students to be successful at the required academic and social tasks, and (c) provide emotional support to all students. Both longitudinal correlational and randomized trial intervention studies support these predictions (Zimmer-Gembeck, Chipuer, Hanisch, Creed, & McGregor, 2006).

Over the last decade, several researchers have looked more specifically at the association between classroom climate and students' emotions in the classroom, and in turn students' motivation and learning (Frenzel, Pekrun, & Goetz, 2007; Hattie, 2009). These researchers argue that emotional reactions to experiences in the classroom have a large impact on student engagement and learning; and have separated individual emotional reactions to classroom experiences from shared emotional reactions. Findings suggest that shared emotional reactions across students within the same classroom are influenced by shared perceptions of teachers' enthusiasm and enjoyment (Frenzel et al., 2007). Furthermore, these shared positive and negative emotions are linked to the general level of achievement in the classroom: as a group, students in high-achieving classrooms reported more positive emotions (pride and enjoyment) and less-extreme negative emotions (anxiety, shame, and hopelessness).

Instructional Dimensions

The nature of the academic work students are asked to do can affect not only what students come to know about themselves and their world, but also their capacities to pay attention, their interests and passions, and their morals and

ethics (Eccles & Roeser, 2010, 2011). Two key aspects of academic work are particularly important for adolescents' development: (1) the content of the curriculum in terms of its intellectual substance and its consideration of global social-historical realities (e.g., Noddings, 2005); and (2) the design of instruction to cultivate interest, meaningfulness, and challenge, as well as deep cognitive, emotional, and behavioral engagement with the material (Fredricks et al., 2004). Both of these characteristics vary in terms of their relative match or mismatch with the developmental needs and capacities of students of different ages, cultures, and social background. Cross-sectional and longitudinal correlational evidence support the notion that academic work that is meaningful to the developmental interests and cultural reality of adolescents' experience promotes motivation to learn and helps to "bond" young people to the institution of school (Burchinal et al., 2008; Roeser, Eccles, & Sameroff, 2000). For instance, boredom in school, low interest, and perceived irrelevance of the curriculum predict diminished engagement and learning and withdrawing from school (Finn, 2006; Fredricks, 2014; NRC/IOM, 2004). Minority students in particular report greater interest in courses in which voices, images, role models, and historical experiences of traditionally underrepresented groups are represented (Graham & Taylor, 2002). Nonetheless, providing curricula that address developmentally and culturally meaningful topics to a diverse and large school population is an ongoing challenge in both the United States and many developed nations today and little attempt has been made to evaluate curricular materials in terms of their meaningfulness for students.

The nature of instruction can also influence adolescents' motivation, engagement, and learning (Eccles & Midgley, 1989; Fredricks et al., 2004, Hattie, 2009; Wigfield, Eccles, et al., 2006). Choosing materials that provide an appropriate level of challenge for a given class, designing learning activities that require diverse cognitive operations (e.g., opinion, following routines, memory, comprehension), structuring lessons so they build on each other in a systematic fashion, using multiple representations of a given problem, and explicitly teaching children strategies that assist in learning (e.g., asking oneself if one has understood what was just read) are but a few of the design features that can scaffold learning and promote interest, engagement, and learning. Work on the role of interest in learning, engagement, and intrinsic motivation highlights the important role of the design of academic tasks (Renninger, 2000). Increased interest is associated with

greater engagement in the task and higher levels of mastery of the material (Fredricks et al., 2004; Hattie, 2009; Wigfield, Eccles, et al., 2006). Even more importantly, interesting tasks increase intrinsic motivation to do well (Deci & Ryan, 2002b) and increase the odds that students will develop a strong personal identity as committed school students (Eccles, 2009).

From a developmental perspective, there is evidence that the content and design of academic work may not change over time in ways that reflect the increasing cognitive sophistication, diverse life experiences, and identity-linked motivational needs of children and adolescents as they move from the elementary into the secondary school years (Eccles, 2009; Wigfield, Eccles, et al., 2006). As one indication, middle-school children in the United States report the highest rates of boredom when doing schoolwork, especially passive work (e.g., listening to lectures) and in particular in classes such as social studies, mathematics, and science (Larson, 2000). Academic work becomes less, rather than more, complex in terms of the cognitive demands as children move from elementary to junior high school (Juvonen, 2007). It may be that declines in adolescents' motivation during the transition to secondary school in part reflects academic work that lacks challenge and meaning commensurate with children's cognitive and emotional needs. For instance, Roeser et al. (2000) found that perceived curricular meaningfulness was a positive predictor of longitudinal changes in early adolescents' valuing of and commitment to school from the beginning to the end of middle school.

The level of structure in the classroom is also important. Providing opportunities for autonomy and for loosely structured peer interactions support motivation and engagement but not if the classroom is chaotic and poorly managed (Hattie, 2009; NRC/IOM, 2004). Teachers in well-managed classrooms use behavioral management strategies and organizational strategies that encourage students to do the work and be active participants in classroom activities (Bohn, Roehrig, & Pressley, 2004). In these classrooms, students display less disruptive behavior and higher engagement in learning (Pianta et al., 2012). The optimal balance between structure and autonomy support changes as students grow older and desire more opportunities for autonomy (Eccles, Midgley, et al., 1993). One reason for the decline in achievement motivation over time is that many students do not experience changes in the balance between structure and opportunities for autonomy, self-regulated learning, and cooperative peer interactions as they progress through the school years. The

appropriate balance between structure and autonomy for different-aged students likely varies by culture; little is known about this.

Racial and Ethnic Context

Ethnicity and race are two demographic factors that can influence achievement motivation and school engagement through social processes, including stereotypes, discrimination, and prejudice, as discussed earlier (Eccles & Roeser, 2011; Juvonen, 2006; see also Marks, Ejesi, McCullough, & García Coll, Chapter 9, this *Handbook*, this volume). Here, we focus in more detail on one very critical aspect of race/ethnic related school experiences: discrimination.

Frequent experiences of racial/ethnic discrimination from students and teachers at school are common (Hudley & Irving, 2012) and influence various aspects of students' academic motivation, engagement, and feelings of school belonging (Wong et al., 2003). The major sources of this perceived discrimination in the United States are European American classmates, teachers, and neighbors. However, research suggests that the impact of discrimination varies depending on key elements of the students' own racial/ethnic identities. Wong and colleagues (2003), for example, found that the predictive association between daily experiences of racial discrimination and declines in school engagement, confidence in one's academic competence and the subjective task value of school achievement, and grades was moderated by having a strong and positive African American identity. Similarly, Rodriguez, Umaña-Taylor, Smith, and Johnson (2009) showed that having a strong, positive racial/ethnic identity can help buffer the negative effects of perceived daily racial discrimination on school-related motivation and achievement for ethnic youth.

The racial and ethnic experiences of youth may be dependent on the larger school context. The transition to middle or high school can be particularly challenging for ethnic minority youth, as middle and high schools tend to be larger, more stratified by race and class, and more performance-oriented (Juvonen, 2007; Juvonen, Nishina, & Graham, 2006; Roeser, Urdan, & Stephens, 2009); this is true not only in the United States but in other countries as well (Stanat & Christensen, 2006). African American and Asian American adolescents reported increasing levels of discrimination from adults (and peers in the case of the African Americans) as they moved through high school but Latino American students did not (Greene, Way, &

Pahl, 2006). One factor that may be especially relevant to this transition is the ethnic composition of the school. Benner and Graham (2007) found that African American students who experienced more racial incongruence from middle to high school had a larger decline in feelings of belonging over time. Being in a context with fewer classmates of the same ethnicity may make ethnicity more salient and may increase concerns about being the target of others' prejudice. Researchers need to examine developmentally how ethnic makeup of schools impacts younger children; this research also needs to be extended to countries around the world.

Microsettings Nested Within the Larger School Environment

One aspect of the school context that can affect students' motivation and engagement is curricular tracking (e.g., college track course sequences versus general or vocational education sequences). The strongest justification for tracking practices derives from a person–environment fit perspective. Students will be more motivated to learn if their educational materials and experiences can be adapted to their current competence level. There is some evidence consistent with this perspective for children placed in high-ability classrooms in the United States, high within-class ability groups, and college tracks, although there continues to be debate about these findings (Oakes, 2005). In contrast, the results for students placed in low-ability and noncollege tracks do not confirm this hypothesis. By and large, when long-term effects are found for this group of children, they are usually negative primarily because these children are typically provided with inferior educational experience and support (e.g., Hattie, 2009). Low-track placements have been related to poor attitudes toward school, feelings of incompetence, dropping out of school, and problem behaviors (Oakes, 2005). Thus, the effects of tracking seem to differ by achievement level; however, few strong and definitive answers about the impact of tracking have emerged (Hattie, 2009; Wigfield, Eccles, et al., 2006). Tracking also varies in its timing and scope in different countries; for example, in Germany, children traditionally have been separated into three tracks at Age 10 or 11, and there is little movement across tracks once this occurs. These placements obviously would influence students' ability beliefs and values in different ways.

Social comparison theory leads to a different set of predictions regarding the effect of ability grouping and

curricular tracking on one aspect of development: ability self-concepts. People often compare their own performance with the performances of others to determine how well they are doing (Marsh, Trautwein, Lüdtke, & Brettschneider, 2008). Ability grouping should narrow the range of possible social comparisons in such a way as to lead to declines in the ability self-perceptions of higher-ability individuals and to increases in the ability self-perceptions of lower-ability individuals. Marsh et al. refer to this effect as the Big Fish in a Small Pond Effect. Evidence supports this prediction. For example, as mentioned earlier, there is consistent evidence showing that attending a more academically elite high school leads to reductions in students' academic ability self-concepts that persist over time (Marsh et al., 2007). These results have led Marsh et al. (2008) to conclude that academic tracking comes at a cost of confidence in one's academic abilities for academically able students. Similarly, Frenzel et al. (2007) have found in Germany that individual students experience slightly more negative emotions (anxiety, hopelessness, and shame) and slightly fewer positive emotions (enjoyment and pride) when they are in higher-achieving classrooms.

Another aspect of the school context that can support students' need for belonging is the opportunity to participate in extracurricular activities such as sports, the arts, and school clubs (Eccles, Barber, Stone, & Hunt, 2003; Feldman & Matjasko, 2012). Involvement in extracurricular contexts increases students' connections to teachers, helps them maintain friendships and make new ones at school, and can connect them to a prosocial peer group that is more likely to value academics and plan to attend college (Fredricks & Eccles, 2005; Schaefer, Simpkins, Vest, & Price, 2011). Activity participation may also have benefits because it provides opportunities for interpersonal competence, challenging life goals, and educational success (Mahoney et al., 2009). Indeed, engaging in an activity that is meaningful to one's identity can reverse outcomes for students who otherwise were on the road to academic failure (Crosnoe & Benner, Chapter 7, this *Handbook*, Volume 4; Peck, Roeser, Zarrett, & Eccles, 2008).

By and large, both the correlational-longitudinal and intervention research supports these assumptions about the positive effects of participation in organized and/or social learning activities (Larson & Hansen, 2005). However, the correlational effect sizes are small and the evidence from randomized trial interventions is not consistent across studies. More specifically, participation in school-based extracurricular activities has been linked to increases in such positive developmental outcomes as high school

GPA, strong school engagement, and high educational aspirations (Eccles et al., 2003), as well as to educational resilience among at-risk youth (Peck et al., 2008). Similarly, participation in high school extracurricular activities, particularly service-based volunteer activities, predicts high levels of adult participation in the political process and other types of volunteer activities, continued sports engagement, better physical and mental health, and reduced participation in risky behaviors (Mahoney et al., 2009; NRC/IOM, 2004; see also Killen & Smetana, Chapter 17, this *Handbook*, this volume).

Interventions to Improve Students' Motivation in the School Setting

Here we briefly describe illustrative group and school-based interventions that have been effective in improving motivation and achievement. There is now more research on effective motivation interventions in different areas such as social skills, reading, creating communities of learning, and fostering engagement, with some of the studies using randomized trial designs; Wentzel and Wigfield (2007) and Yaeger and Walton (2011) provide an overview.

Group Interventions Focused on Beliefs About Intelligence

Blackwell, Trzniewski, and Dweck (2007) conducted an eight-session intervention study (using random assignment to group) to teach the experimental group that intelligence is malleable. Compared to the control group, the intervention students had more positive motivation and their grades, although not increasing, did not decline. Aronson, Fried, and Good (2002) showed that African American college students who were taught the malleable view reported greater school enjoyment and value compared to the control group.

Classroom-Based Interventions

Guthrie, Wigfield, and their colleagues (Guthrie, Wigfield, & Klauda, 2012; Guthrie, Wigfield, & Perencevich, 2004) developed and studied Concept Oriented Reading Instruction (CORI), a reading comprehension instruction program that integrated reading strategy instruction with specific motivational practices to foster students' reading engagement, motivation, and achievement. The motivational instruction practices in CORI include developing self-efficacy, fostering interest through hands-on activities and interesting texts, helping children understand the importance and relevance of reading, and providing

many opportunities for collaboration. Guthrie et al. (2004) studied 9-year-olds and Guthrie et al. (2012) studied 12-year-olds; in both studies they found that students experiencing CORI had higher reading comprehension, stronger engagement, and higher motivation in reading. Guthrie, McCrae, and Klauda (2007) provide a meta-analysis of CORI's effects in numerous other studies.

CORI focuses in part on helping students understand the value and relevance of their work. Hulleman and Harackiewicz (2009) and Hulleman, Godes, Hendricks, and Harackiewicz (2010) conducted intervention studies in which high school students in the treatment group were asked every 3 to 4 weeks to write how what they had learned in science that week was relevant to them. The treatment students who initially expected to do poorly in science had higher science grades. Additionally, students' perceived value mediated the effects of the intervention on general interest and performance. These projects show how a focus on students' valuing of a subject can positively affect their performance.

School-Based Interventions

Goal theorists have worked with schools to try to change the overall school goal structure from performance-oriented to mastery-oriented (Maehr & Midgley, 1996; see Wigfield, Eccles, et al., 2006) for review. The researchers worked closely with teachers and school administrators at an elementary/primary school and a middle school. They found it easier to work with the elementary school staff to develop a stronger mastery orientation in the school; the middle school proved more difficult to work with. At both schools there was evidence that students' motivation improved.

We are encouraged that there are an increasing number of interventions that (using rigorous research designs) are showing that students' motivation and performance in different areas can be enhanced. Some of the interventions just presented here, and by Wentzel and Wigfield (2007), are elaborate long-term interventions involving a great deal of time and effort on the researchers', teachers', and students' part. Yaeger and Walton (2011) reviewed a number of brief social psychologically based intervention programs (including Blackwell et al., 2007) that have been effective in improving both children's and college students' motivation and performance. They describe why these programs are effective even though they are brief, but note there is little information about the longevity of their effects. That is an important topic for future research. As we discussed earlier, it is important to connect motivation and

self-regulation; some interesting intervention programs are doing that, including some that are focused on developing mindfulness in children (Roeser, Taylor, & Harrison, 2013).

Summary

Many aspects of schools and classrooms can influence both individual differences in and the ontogeny of motivation and engagement. In this section, we reviewed the findings for a small subset of these aspects. In each case, the extent to which the particular characteristic being discussed provides students with opportunities to feel competent and both academically and emotionally supported predicts higher levels of motivation and engagement. In addition, the extent to which the students are exposed to learning materials and curriculum that they find meaningful and relevant predicts higher motivation and engagement, as shown in a number of intervention studies. We do not have the space to discuss other very important aspects of school and other institutional settings such as peers' influences, types of role models available, violence, cooperative learning opportunities, service learning opportunities, testing and evaluation practices, teacher and instructional quality, quality of counseling, opportunities to be involved in activities that make genuine contributions to the welfare of other members of the school and class community, school transitions, and various district-wide organizational characteristics such as school start and stop time, and links to the labor market and to local colleges. One feature of school organizational structure that we have long been interested in is grade-level configuration (Eccles & Midgley, 1989; Eccles et al., 1998; Wigfield, Byrnes, & Eccles, 2006; Wigfield, Eccles, et al., 2006). Based on our work and that of others, many schools switched from traditional junior high schools to middle schools to better meet students' developmental needs. There is again interest in the impact of how the K-8 configuration influences students' achievement. Kieffer (2013), in a study utilizing the Early Childhood Longitudinal-Kindergarten dataset, found that students in K-8 schools had significantly higher reading achievement scores at the end of Grade 8 than did students in various middle-school arrangements; math scores did not differ. Future studies of school structure also should examine motivational along with achievement outcomes.

With respect to how these school factors influence motivation and engagement, we believe the same basic principles appear to operate across these various influences with respect to how they influence students' motivation and engagement. Interestingly, these are the same basic

principles that explain much of the association of experiences in the family with both individual differences in and the ontogeny of achievement motivation and engagement. Furthermore, these same school, classroom, and family characteristics are also linked to school achievement. Essentially, highly motivated students learn what is being taught. The central issues for educational settings boil down to two points: how best to create a learning context that motivates engagement and then deciding what to teach the students in those contexts.

CONCLUSIONS

Research on the development of children's achievement motivation and engagement remains a vibrant field. Over the past 10 years, developmental researchers have learned a great deal about individual differences in the development of the achievement-related beliefs, values, and goals that impact motivation and achievement. Most importantly, this work has included diverse groups of children in many different countries, particularly in Europe. Although much remains to be done, motivation researchers increasingly include diverse samples in their work, revise their theories to incorporate culture more clearly in their models, and test their theories in diverse groups (see McInerney & Van Etten, 2004). Following Graham's (1994) call, much work has focused on variation *within* different cultural groups, rather than comparisons across groups.

Another important advance is the growing concern for how motivation and engagement constructs in different theories relate to and affect one another. Each of the motivation constructs discussed in this chapter has its own developmental patterns and relations with outcome variables such as performance and choice. There is also substantial overlap among some of the constructs in the various theories and perspectives, both theoretically and methodologically (e.g., Hulleman, Schrager, Bodmann, & Harackiewicz, 2010; Reschly & Christenson, 2012; Schunk & Pajares, 2009; Wigfield & Cambria, 2010; Wigfield & Eccles, 2000). Researchers have begun to investigate these potential overlaps and thus to get a more comprehensive picture of the critical distinction that need to be maintained. Clearly there are potential relations among a variety of these constructs, and these now are being addressed empirically (see Conley, 2012, for a good example of this work).

The need for domain specificity has become even clearer over the past 10 years. Children and adolescents'

achievement-related motivations differ across different activities and school subjects. More attention has been paid in the associations among the developmental trajectories across various domains. With his work on internal versus external frames of reference, Marsh and his colleagues (e.g., Marsh et al., 2008) have documented that doing well in one subject area (such as math) has consequences for one's motivational beliefs and preferences for other subject areas (such as reading). More work is needed on the cross-domain, within-person dynamics over the course of childhood and adolescence, particularly as it relates to identity formation, activity selection, and the role of perceived costs in the relative subjective task value attached to various achievement-related options.

A great deal more also has been learned about social influences on children's achievement motivation and the processes by which they exert influence, particularly with regard to families and schools. Furthermore, although we did not have space to explore the role of peers, siblings, media, and technology on the ontogeny of motivation, the range of socializing influences being studied has also expanded substantially. More work in this area is still needed on diverse groups of parents and children in different countries so that a fuller understanding of the socialization of motivation can be reached. Although some work has been done on the relative influence of different social influences at different ages and in different groups of individuals, much more work is needed that is guided by strong developmental and sociocultural theories about these variations. It is likely, for example, that the relative role of peers versus parents varies at different ages and in different cultural groups. There is some evidence that peers take on more influence on Western individuals' motivation as the individuals move into adolescence (Arnett, 2012) but it is less certain if this is true for adolescents in other parts of the world. There is also speculation that processes linked to brain maturation across the life span, but particularly during the first 30 years of life and particularly related to preferences for risky and sexual behaviors, may lead to different motivational preferences and styles across development.

Lastly, much more has been learned about how children's motivation varies across different contexts, such as in different kinds of families and different school contexts. It has long been known that motivation is not solely a characteristic of the individual, but the new emphasis on "motivation in context" has brought that point out much more clearly. Again, more of this work needs to be done in different countries to learn more about the different

kinds of educational contexts and how they affect different children.

As noted in the Overview, there are two new areas in the field that we know will receive increasing research attention over the next decade. The first is neuroscience and motivation (Reeve & Lee, 2012). Reeve and Lee describe which areas of the brain are associated with basic reward structures having to do with survival and how those become linked to actions, and the importance of the neurotransmitter dopamine in these links. They also discuss frontal lobe structures dealing with decision making, goal setting, and valuing of achievement, to name just a few. The connections between neuroscience and motivation still are emerging in the field and most of the work has been done with adults; we anticipate that developmental work in this area will become much more active over the next decade.

Second is the role of unconscious or implicit motivation and its role in achievement motivation. Early theories of achievement motivation, such as Atkinson's (1957) EVT, emphasized motivation as an unconscious process, as indicated by the use of projective kinds of measures to assess motivation. McClelland, Koesnter, and Weinberger (1989) described two systems of motivation, one implicit and one explicit. One of the reasons for this distinction is the pervasive finding that measures of a construct using unconscious and conscious means do not correlate with one another, which is interpreted to mean that the two systems are independent (Schultheiss, Rosch, Rawolle, Kordik, & Graham, 2010). Schultheiss et al. (2010) discussed how the implicit system is controlled primarily by nonverbal cues and the conscious or explicit one by verbal cues. Despite their independence, Schultheiss et al. discussed the importance of coordination of the two systems with respect to goal pursuit, if the individual is to have a sense of well-being upon completion of the goal. Most of the work addressing these issues has been done by social psychologists studying young adults. To date, very few developmental psychologists have examined these issues. Because of the importance of implicit motives historically in motivation theory and research and also because of the important findings of social psychologists regarding the impact of implicit motives on well-being and other outcomes, we believe it is time to examine them in children. We postulate that very young children are motivated by the implicit system, with the explicit system becoming more important after the child learns to understand and produce language. The relations of the two systems across childhood seem a very important direction for future research. What happens when the two systems are coordinated? Uncoordinated? We believe this

area of research will become more prominent in developmental psychology. Further, it may integrate with the neuroscientific work on motivation. How do changes in the brain throughout childhood and adolescence affect children's motivations, both implicit and explicit?

As noted earlier, there have been important methodological advances that allow study of the development of motivation in increasingly sophisticated ways, with HLM and latent growth-curve modeling being two particular examples. Researchers are also increasingly using person-centered analyses along with more traditional variable-centered measures. Continuing such work will lead to an even better understanding of the *development* of motivation. Coupling such work with investigations into the *processes* involved in motivation's relations to outcomes also will advance the field.
